Figure 3 (Top) Schematic representation of the calculation of central motor conduction time (CMCT). (a) Motor evoked potential (MEP) induced by TMS. (b) MEP after cervical spinal root stimulation. (c) F-waves after ulnar nerve electric stimulation. CMCT is estimated by onset latency of T1 minus onset latency of T2. T1, onset latency of MEP elicited by TMS; T2, onset latency of MEP elicited by the coil placed on the back of cervical spine; M, onset latency of M-wave by electrical ulnar nerve stimulation; F, onset latency of F-wave by electrical ulnar nerve stimulation. (Middle) Example of silent period to TMS. Stimulation of the hand motor cortex of one hemisphere elicits MEPs in the contralateral first dorsal interosseus muscle (FDI) of the hand, which is followed by a suppression of tonic voluntary electromyographic (EMG) activity. Responses are recorded from the FDI, which is kept contracted with 20% of maximal voluntary force pressing on a force transducer. The intensity of TMS is set at 130% of the motor threshold. (Bottom) A paired pulse experiment illustrating the change of MEP sizes obtained by the paired conditioning–test-stimulus paradigm from the FDI muscle. The intensity of conditioning TMS was set to 80% of resting motor threshold. The intensity of test TMS was adjusted to produce a control MEP of an average peak-to-peak amplitude of 1 mV when given alone. Note that the conditioning stimulus inhibited the test MEP at short interstimulus intervals (1–4 ms) but facilitated it at longer intervals (6–20 ms). In the graph, the size of the MEPs is expressed as a percentage of the control, unconditioned MEPs, and plotted against the interstimulus interval. Data are means of eight healthy subjects. Error bars indicate standard errors.

pulse with suprathreshold intensity is applied over the motor cortex representation of that targeted muscle, the electromyographic (EMG) activity of the muscle will be arrested for a few hundred milliseconds following the MEP. This period of EMG suppression is referred to as a 'silent period' (Figure 3, middle), often defined as the time from the end of the MEP to the return of voluntary EMG activity. Silent periods of abnormally short or long duration are observed in patients with various movement disorders such as

Parkinson's disease. Most of this period is believed to be due to cortical inhibitory mechanisms of the motor cortex. The neuronal elements responsible for the silent period are most likely mediated by GABAergic-type receptors.

Finally, the combination of a conditioning stimulus with a test stimulus delivered at various intensities and with variable interstimulus intervals to the same cortical area can provide insight into cortico-cortical interactions and measure short- and long-term inhibition and facilitation. This technique is referred to as 'paired pulse' stimulation (Figure 3, bottom). Here, a subthreshold conditioning stimulus is followed by a suprathreshold test stimulus at different (1–20 ms) interstimulus intervals through the same TMS coil targeting the primary motor cortex. The effects of the conditioning TMS on the size of test MEP depend on the stimulus intensity and the interstimulus interval. When a conditioning stimulus is set at 60–80% of the resting motor threshold, maximum inhibitory effects are found at short interstimulus intervals of 1–4 ms. The maximum amount of this inhibition is usually 20–40% of the test MEP. Facilitatory effects of the conditioning TMS pulse with the same subthreshold intensity onto the test MEP can be observed at intervals of 7–20 ms. The magnitude of this facilitation is quite variable across subjects and can also vary depending on the size of test MEPs. Thus, for a paired pulse TMS study, it is critical to maintain the relaxation of patients and adjust the size of test MEPs across trials and subjects. This paired pulse technique has also been used to examine the effects of central nervous system-active drugs on the human motor cortex. In this context, paired pulse TMS might be useful in selecting the best-suited medication for a given patient by matching the identified abnormality in a given disorder with the effects of different pharmaceutical agents. Such a neurophysiological-based approach to medication selection in epilepsy or psychosis would certainly be desirable, although systematic studies are needed.

These various measures can give rise to clinically relevant applications of TMS by characterizing corticospinal projections and even cortico-cortical or interhemispheric inhibition and facilitation. It is also noteworthy that stimulation is not limited to cortical areas. TMS can also be applied to the cerebellum or at the level of the foramen magnum, a peripheral nerve, or even nerve plexus, thus allowing an investigator the ability to examine the motor system at different levels of the neuroaxis. From a clinical standpoint, these objective and quantifiable measures can help localize the level of a lesion within the nervous system, distinguish between a predominantly demyelinating or axonal lesion in motor tracts, or even predict functional motor outcome. Like other neurophysiological tests, however, the abnormalities revealed by TMS are not always disease specific. It remains to be fully evaluated whether such neurophysiologic findings provide earlier prognostic indicators compared to those that might be obtained from careful, longitudinal neurological exams.

Repetitive TMS

rTMS refers to the application of a train of TMS pulses of the same intensity to a single brain area at a given frequency. In general, the higher the stimulation frequency and intensity, the greater the disruption of cortical function during the applied train of stimulation. However, following these immediate effects, a train of rTMS can also induce a prolonged modulation of cortical excitability, lasting well beyond the duration of the rTMS train. The modulatory effect may also range from inhibition to facilitation, depending on the stimulation parameters used. Lower frequencies (e.g., 1 Hz) applied over the motor cortex can suppress excitability, whereas higher-frequency stimulation trains (e.g., 20 Hz) lead to increases in cortical excitability. It is noteworthy that these effects vary among individuals and that other forms of trains, combining various stimulation frequencies (e.g., 6 Hz-primed 1 Hz stimulation, or theta burst stimulation), may in fact induce a more robust, consistent, and longer lasting neuromodulation.

The mechanisms underlying these 'off-line' modulatory effects lasting beyond the duration of the rTMS train are unclear. Long-term potentiation and long-term depression of cortical synapses or other closely related neuronal mechanisms have been suggested to explain the effect of high- and low-frequency rTMS, respectively. Animal studies suggest that modulation of neurotransmitters and gene induction may also represent contributory factors. Finally, neuronal network effects within the stimulated hemisphere as well as across a cortico-subcortical bihemispheric network may also play a critical role. It is also noteworthy that the lasting modulation of cortical activity by rTMS is not limited to motor cortical areas. Long-lasting effects of rTMS can be induced in other areas associated with measurable behavioral effects, including visual, prefrontal, and parietal cortex as well as the cerebellum.

Mapping Neuronal Networks in Cognitive Science

TMS has also been used extensively in the mapping of other, nonmotor cortical targets in relation to stud-

ies involving memory, attention, language, visual perception, and imagery. A TMS pulse, appropriately delivered in space and time, can temporally disrupt cortical function in a given area. By establishing a causal link between brain activity and behavior, TMS can be used to uncover which parts of an identified network are necessary for performing a behavioral task and thus supplement and refine conclusions drawn from functional neuroimaging studies. For example, when a TMS pulse is delivered at a specific time to the occipital pole, the detection of a presented visual stimulus can be blocked. By varying the timing between the visual stimulus and TMS pulse, the chronometry of visual perception from primary visual cortex to extrastriate visual areas can be ascertained.

In studies of language function, delivering high-frequency rTMS (on the order of 25 Hz) centered over the inferolateral frontal cortex can induce speech arrest in a subject instructed to count aloud or even induce paraphasia-like errors in a subject asked to name words starting with a given letter. Thus, rTMS may prove to be a noninvasive method to determine the language-dominant hemisphere of an individual (e.g., prior to surgical evaluation), and ongoing clinical trials have demonstrated that TMS may have beneficial effects in the rehabilitation of language function in patients with aphasia due to stroke damage.

Numerous studies have used TMS to establish the functional significance of data obtained through neuroimaging. One particularly elegant example has been the use of TMS to probe the function of occipital (visual) cortex in early blind subjects. Using functional neuroimaging, many investigative groups have demonstrated that the occipital visual cortex is active while blind subjects read Braille. However, with the complementary use of TMS, a clear demonstration that this activation is causally related to the task of Braille reading can be demonstrated. Specifically, it has been shown that reversible disruption of occipital cortex using rTMS disrupts Braille reading performance in early blind readers but not in sighted controls, thus establishing a causal relationship between occipital cortex activation and the necessity of this area for performing this skill. Other studies have also used TMS in conjunction with data obtained with functional neuroimaging to establish the role of occipital cortex in other forms of tactile processing, such as tactile form and object recognition, and even in verbal memory skills in the blind.

For such applications, information regarding the actual site of stimulation is of utmost importance. In studies of motor cortex, for example, the site of stimulation can be identified and reasonably ascertained given that stimulation of this cortical site evokes a clear objective measure such as the motor evoked potential. For other cortical areas in which no such objective measure is easily attainable, the use of fiducial landmarks may not be satisfactory to reliably identify the locus of stimulation, especially if one considers the variability in morphology and size of cerebral areas across individual subjects. For this reason, inferring the site of stimulation using a frameless stereotaxic system can provide the precise anatomical resolution required (**Figure 4**).

Therapeutic Applications

Considerable interest has arisen in the use of TMS as a form of therapy in certain neurological disorders and neuropsychiatric conditions. Its therapeutic potential rests on the fact that rTMS can modulate cortical excitability well beyond the actual period of stimulation. For example, studies have demonstrated that rTMS delivered to cortical motor areas can enhance reaction times in certain motor coordination tasks and improve motor function in parkinsonian patients. Applying low-frequency rTMS (1 Hz) to motor cortex and thereby decreasing cortical excitability has been shown to improve symptoms in focal hand dystonia (e.g., 'writer's cramp'). However, not all studies have been able to reproduce these findings, so results must remain preliminary and further carefully controlled studies are needed.

Although the inhibitory and facilitatory effects of rTMS were first documented in studies of corticospinal excitability, it is possible that rTMS applied to other nonmotor areas may exert similar modulatory and potentially therapeutic effects. One avenue being pursued is in the therapy of patients with medication-resistant major depressive disorder (MDD). Neuroimaging data have demonstrated that patients with MDD display decreased levels of activity in left dorsolateral prefrontal cortex (DLPFC). Stimulation of this cortical target using focal rTMS at 20 Hz has been shown to significantly decrease depressive symptoms. Interestingly, low-frequency rTMS delivered to right DLPFC has also been shown to have antidepressant effects. This suggests that establishing a balance in frontal lobe function may have a beneficial effect in this disorder. Studies are under way to investigate stimulation parameters (e.g., the exact site of

Figure 4 Frameless stereotaxic system used for the on-line guidance of coil location over an anatomical MRI of the subject. The positions of small reflective trackers attached to the TMS coil are monitored relative to trackers positioned on the subject's head. The relative position of the trackers is monitored by an optical position sensor (camera). Following a calibration and coregistration procedure, the position and orientation of the coil relative to the subject's structural MRI can be displayed in real time on a computer monitor and followed throughout the experiment. stimulation, intensity, train duration, and number) in the hopes of establishing rTMS as a viable therapeutic adjunct (if not alternative) for electroconvulsive therapy.

Brain Reward Pathways

Animals, including humans, prefer to engage in behaviors that are rewarding (i.e., pleasurable). This reward acts as a positive reinforcement such that the individual engages in behavior to repetitively obtain that reward. Brain circuits that mediate these effects of reward evolved to regulate an individual's responses to natural rewards, such as food, sex, and social interaction. Adaptations in these circuits, in response to the presence or absence of rewards, mediate powerful drives and memories, which serve to promote survival of the species. Drugs of abuse act on this brain reward circuitry with far more power and persistence than seen with natural rewards. Drugs thereby corrupt the reward circuits in ways that cause drug seeking and consumption to gradually take over the individual's life; that is, they induce a state of addiction.

The most important component of the brain's reward circuitry is the mesolimbic dopamine system, which is composed of dopamine neurons in the ventral tegmental area (VTA) of the midbrain, and the several forebrain regions to which these dopamine neurons project, in particular, the nucleus accumbens (NAc) (also known as ventral striatum) and several areas of frontal cortex (e.g., prefrontal, orbitofrontal and anterior cingulate cortex). This brain circuitry is illustrated in Figure 1. Many other brain regions, including the hippocampus, amygdala, and hypothalamus, to name a few, contribute to the reward circuitry, but are not discussed further here due to space limitations.

All rewarding stimuli, both natural as well as drugs of abuse, activate dopaminergic transmission in the mesolimbic dopamine pathway. Some also produce dopamine-like effects in the NAc and frontal cortex via dopamine-independent mechanisms. The mechanism by which dopaminergic transmission mediates 'reward' is unknown, but is the subject of great interest. Activation of dopaminergic transmission may elicit some of the subjective effects of a reward, as well as its positive reinforcing effects. Chronic activation of dopaminergic transmission can cause behavioral plasticity, which shapes behavior over the longer term to promote further consumption of the reward. The use of dopamine to regulate responses to natural rewards is highly conserved from an evolutionary point of view; rudiments of the pathway are seen in worms and flies, which arose over 1 billion years ago.

Drugs of abuse are thought to cause addiction by producing powerful adaptations in the brain's reward circuitry. During a period of drug use, the reward circuitry, due to its strong, repeated activation by drug, tends to be hyposensitive, such that, in the absence of drug, addicts are not satisfied with natural rewards and require drug to feel normal. These changes, which often lead to relapse, can be viewed as tolerance and dependence to the drug's rewarding effects and typically resolve over days and weeks of withdrawal. Repeated drug use also elicits a more long-lasting sensitized state, when cues previously paired with drug, stress, or the drug itself cause a robust activation of the reward circuitry, and can lead to relapse as well. A major focus of the field is to understand the molecular and cellular basis of these types of drug-induced adaptations in brain reward regions.

Increasing evidence supports the view that the brain's reward circuitry is also involved in other psychiatric disorders, in particular, mood disorders such as depression and bipolar disorder. For example, most patients with depression exhibit a reduced ability to experience pleasure (anhedonia), loss of motivation, and abnormalities in several neurovegetative functions, such as sleep, appetite, energy level, and circadian rhythms, all of which are influenced by the mesolimbic dopamine pathway and related reward regions of brain. Similarly, most patients in a manic state exhibit the opposite symptoms. In addition, it has long been known that stress and other aversive emotional stimuli potently regulate the brain's reward circuitry. These observations suggest that a better understanding of the molecular mechanisms that control the long-term activity of brain reward regions will contribute to our knowledge of these disorders as well.

Neural Plasticity in Brain Reward Pathways

The structure and function of neurons, and the patterns of their connections in any neural circuit, including the reward circuitry, are not fixed. An individual neuron changes its myriad of receptors, its response patterns to diverse stimuli, and eventually its output to other neurons in response to environmental stimuli. This phenomenon of neural plasticity, that is, the ability of neural cells and circuits to undergo modifications in structure, connectivity, and function, plays a critical role not only in growth

Figure 1 Brain reward regions. Brown dotted lines indicate limbic afferents to the nucleus accumbens (NAc). Blue represents efferents from the NAc thought to be involved in drug reward. Red indicates dopaminergic projections of the mesolimbic dopamine system thought to be a critical substrate for drug reward. This system originates in the ventral tegmental area (VTA) and projects to the NAc and other limbic structures, including olfactory tubercle (OT), ventral domains of the caudate-putamen (C-P), amygdala (AMG), and prefrontal cortex (PFC). Green indicates opioid peptide-containing neurons, which are involved in opiate, ethanol, and possibly nicotine reward. These opioid peptide systems include the local enkephalinergic circuits (short segments) and the hypothalamic midbrain beta-endorphin circuit (long segment). Yellow solid structures indicate nicotinic acetylcholine receptors hypothesized to be located on dopaminergic and opioid peptidergic systems, among other sites. ARC, arcuate nucleus; Cer, cerebellum; DMT, dorsomedial thalamus; PFC, prefrontal cortex; IC, inferior colliculus; LC, locus coeruleus; LH, lateral hypothalamus; OT, olfactory tubercle; PAG, periaqueductal gray; SC, superior colliculus; SNr, substantia nigra pars reticulata; VP, ventral pallidum. and development, but also throughout adult life. Our ability to learn and remember depends on this plasticity, as does our ability to maladapt to aversive stimuli, such as drugs of abuse and stress.

The development of addiction can thus be viewed as an example of drug-induced neural plasticity. Upon first exposure, a drug of abuse enters the brain, binds to its initial protein target, and perturbs synaptic transmission at particular synapses in the brain, which in turn causes the acute behavioral effects of the drug (high, euphoria, activation, sedation, etc.). However, these acute drug effects do not *per se* explain addiction; rather, addiction develops gradually and progressively as a result of neuroadaptations to repeated drug intake. Drug-induced adaptations occur in many brain regions, depending on the drug, but all drugs of abuse produce a series of common molecular and cellular adaptations in brain reward regions, as would be expected given their common acute effects on this circuitry. Because the behavioral abnormalities associated with addiction are long lived – individuals can remain at increased risk for relapse despite many years of abstinence – a role for gene expression has been proposed as central to the addiction process. According to this scheme, the repeated, powerful perturbation of dopaminergic and other forms of neurotransmission in the VTA, NAc, and other brain reward regions by drugs of abuse causes long-lived changes in gene transcription within these regions, which alters reward mechanisms in such a way as to underlie addiction.

In a similar way, stress and other negative emotional stimuli can cause neuroadaptations in brain reward pathways and several other areas of brain and mediate the long-lived behavioral abnormalities seen in many stress-related disorders. However, it is important to emphasize that addiction, depression, and other stress-related disorders are highly heritable: roughly 50% of the risk for each of these conditions is genetic, although the specific genes that comprise this risk remain mostly unknown. Hence, a critical advance in studies of the molecular control of the brain's reward pathways will ultimately involve understanding how an individual's genes control the ability of a drug of abuse or stress to induce maladaptive changes within these brain regions.

Transcriptional Mechanisms in the Regulation of Brain Reward Pathways

The activation or repression of specific transcriptional patterns is part of a neuron's response to virtually every cellular signal. Accordingly, transcriptional regulation can be viewed as the ultimate target of signal transduction cascades, and is a critical mediator of a wide range of neuroadaptations in neural structure, connectivity, and function, which occur in response to environmental stimuli.

Considering the importance placed on alterations in gene expression in addiction and depression, it is surprising that only a small number of transcription factors have to date been implicated in these disorders. Moreover, even less is known about the target genes that are regulated by these transcription factors to mediate stable behavioral change. This review focuses on those transcription factors which have been shown to regulate the activity of the brain's reward pathways in animal models of drug addiction and depression.

CREB/CREM/ATF Family

The cAMP response element binding protein (CREB) family of transcription factors, in addition to CREB itself, include cAMP response element modulator (CREM) and activators of transcription (ATF). These proteins are BZip transcription factors; BZip refers to the basic domain (B) of the proteins that binds a specific consensus sequence (CRE or cAMP response element) in gene promoter/enhancer regions, and the leucine zipper domain (Zip) which allows homo- or heterodimerization of two BZip transcription factors necessary for transactivation. Although most proteins of this family heterodimerize selectively with other CREB/CREM/ATF transcription factors, some family members (specifically ATF2) can dimerize with BZips of other families and act on distinct response elements. To complicate matters further, there are many splice variants of these transcription factors that can act as potent repressors of transcription due to the absence of activation domains in the proteins.

Most evidence for a role of the CREB/CREM/ATF family in brain reward regions in stress and addiction models has focused on CREB itself. CREB is activated in both the NAc and VTA in response to acute and chronic administration of certain drugs of abuse (cocaine, amphetamine, opiates) or of stress. This has been shown by direct demonstration of increases in the phosphorylation of CREB at ser133, which is required for its transcriptional activation. It also has been demonstrated by use of CRE-LacZ transgenic mice, in which CRE transcriptional activity has been shown to be induced in brain reward regions under these conditions.

There is now a large body of evidence to support the view that CREB activation in the NAc by drugs of abuse mediates a form of tolerance and dependence to drug exposure. Viral-mediated overexpression of CREB in the NAc decreases an animal's sensitivity to the rewarding effects of several drugs of abuse, whereas blockade of CREB function in this region, via overexpression of a dominant negative antagonist of CREB, causes the opposite effect. Studies of bitransgenic mice, in which CREB or its dominant negative is inducibly expressed in the NAc of adult animals, as well as studies of CREB knockdown mice, generally support these conclusions. Interestingly, increased CREB activity in the NAc also reduces an animal's sensitivity to natural rewards as well as to several types of negative emotional (e.g., painful, stressful, or anxiogenic) stimuli. Thus, CREB activation in the NAc by drugs of abuse or stress seems to induce a general state of emotional numbing. CREB activation could therefore mediate some of the negative emotional symptoms seen in many drug addicts during early phases of withdrawal; it could similarly mediate some of the symptoms seen in depression and other stress-related disorders.

CREB activity in the VTA is more complex. Here, CREB can either decrease or increase an animal's sensitivity to a drug of abuse depending on the subregion of the VTA involved. Further work is needed to better understand these actions of CREB, as well as the influence of several other members of the CREB/CREM/ATF family in regulating responses to drugs of abuse and stress. There is preliminary evidence, for example, that drugs of abuse and stress also activate inducible cAMP early repressor (ICER) in the NAc upon initial exposures. ICER is a transcriptional repressor, encoded by the CREM gene. Consequently, ICER activation may serve to dampen the functional consequences of CREB induction during initial drug or stress exposures.

AP-1 Family

Fos and Jun proteins, like CREB proteins, are BZip transcription factors. Fos family members dimerize with Jun family members to form active AP-1 complexes, which then bind to AP-1 sites in gene promoters/enhancers. Genes encoding Fos and Jun proteins are immediate early genes, which means that they are induced very rapidly in response to an acute stimulus. Accordingly, acute administration of virtually any drug of abuse induces many Fos and Jun family members in the NAc. This induction is not only very rapid, it is also very transient, because the Fos and Jun mRNAs and proteins are all highly unstable. ΔFosB is a C-terminal truncated splice variant of the FosB gene. It, too, is induced rapidly in response to acute drug exposures. However, unlike all other Fos and Jun family proteins, ΔFosB is a relatively stable protein. This stability is mediated partly by the loss of the C-terminus – which contains degrons and is conserved in all other Fos family proteins – and by its phosphorylation. As a result, in response to repeated drug administration, levels of ΔFosB accumulate and

Figure 2 Regulation of ΔFosB by drugs of abuse. The figure shows the several waves of induction of Fos family proteins in the NAc after a single exposure to a drug of abuse. These proteins include cFos and several other Fos family proteins (FosB, Fra-1, Fra-2). Unlike all of these Fos family proteins, which are highly unstable, isoforms of ΔFosB are highly stable and therefore persist in brain long after drug exposure. Because of this stability, ΔFosB accumulates uniquely with repeated drug exposures. From Nestler EJ (2001) Molecular basis of long-term plasticity underlying addiction. *Nature Reviews Neuroscience* 2: 119–128, with permission.

eventually become the predominant Fos family protein in these neurons. This pattern of induction is illustrated in Figure 2. Induction of ΔFosB occurs as a common response to many classes of addictive drugs, including cocaine, amphetamine, methamphetamine, opiates, nicotine, PCP, cannabinoids, and alcohol. ΔFosB is also induced in the NAc after repeated consumption of natural rewards, like wheel running or sucrose intake. In addition, induction of ΔFosB in the NAc occurs as a consequence of chronic exposure to several types of stress.

Studies with inducible bitransgenic mice and viral vectors show that induction of ΔFosB in the NAc increases an animal's sensitivity to the rewarding effects of drugs of abuse, and also seems to increase incentive motivation, or drive, for the drugs. In addition, ΔFosB increases an animal's drive for natural rewards, such as wheel running and sucrose. Thus, ΔFosB may function as a sustained molecular switch, which first helps initiate and then maintains a state of addiction for a relatively prolonged period of time. An important area of current research is to characterize the effect of ΔFosB induction in the NAc in animal models of stress, depression, and antidepressant treatment.

There is early evidence that induction of ΔFosB in the NAc may mediate the ability of a drug of abuse to increase the dendritic branching, and the number of spines on distal dendrites, in NAc neurons. Although the precise functional role played by these morphological changes is not known, the changes have been shown to persist for at least several months after the last drug exposure, and are hypothesized to mediate the near-permanent sensitization in drug responsiveness seen in certain animal models of addiction. ΔFosB appears to be one mediator of these drug-induced changes in dendritic structure via its regulation of one particular target gene, cyclin-dependent kinase 5 (Cdk5). Thus, chronic cocaine administration induces Cdk5 in the NAc, an effect mediated via

ΔFosB, and infusion of a Cdk5 inhibitor into the NAc prevents the ability of cocaine to increase dendritic spine density in this region. The implication of these findings is that structural changes caused by repeated cocaine administration may be mediated, in part, via induction of ΔFosB and may persist long after the ΔFosB signal itself dissipates. While ΔFosB is the longest-lasting known molecular change in the brain seen in the context of drug or stress exposure, and perhaps to any other perturbation of the adult brain, it nevertheless undergoes proteolysis at some finite rate: ΔFosB dissipates to normal levels within a month or two of drug withdrawal. This means that ΔFosB cannot *per se* mediate the extremely long-lived changes in brain and behavior associated with addiction and depression. One possibility is that ΔFosB causes other changes in the brain, such as the changes described in dendritic structure, which themselves are more permanent.

Other Transcription Factors that Regulate Brain Reward Pathways

Recent work has shown that several other transcription factors are also regulated in brain reward regions by drugs of abuse or stress, although in general much less is known about the behavioral consequences of their induction compared with CREB and ΔFosB. The transcription factor, nuclear factor kappa B (NF-κB), has been the subject of intense investigation for its widespread involvement in a multitude of disease states and for its inducible pattern of gene expression. Several types of cellular stress (including cytokines, growth factors, viruses, and environmental hazards) induce NF-κB in peripheral cells. Under normal conditions, NF-κB, which is composed of a combination of two subunits, p50, p52, p65, c-Rel, and RelB (most abundantly p50 and p65), remains sequestered in the cytoplasm by inhibitory-κB (I-κB). Upon phosphorylation by I-κkinase (IKK), I-κB releases the inactive NF-κB dimer, which can then be phosphorylated and transported to the nucleus where it undergoes further posttranslational modifications to initiate transcription of a range of genes involved in cell survival. In the brain, NF-κB has received considerably less attention; however, it has been implicated in certain forms of learning-related plasticity. Although the involvement of NF-κB in addiction and depression models is not well studied, NF-κB has been implicated in the neurotoxic effects of amphetamine and amphetamine-like drugs. Furthermore, it has been shown that chronic cocaine administration upregulates the NF-κB subunits p65, p105 (precursor to p50), and I-κBγ and thereby increases NF-κB-dependent transcription in the NAc. Interestingly, cocaine induction of the NF-κB subunits is mediated by ΔFosB, which further broadens the role of this transcription factor in molecular control of the NAc. Studies are underway to better understand the functional consequences of NF-κB upregulation in drug and stress models.

Clock and other members of the basic helix-loop-helix-PAS (PER-ARNT-SIM) transcription factor family are best known for their control of circadian rhythms. The first evidence that this gene family may be involved in reward came from studies of *Drosophila*, where loss of Clock dramatically altered the flies' responses to cocaine. More recent work has demonstrated a role for Clock and other circadian genes in mammalian models of addiction. Thus, mice lacking Clock show dramatically increased activity of VTA dopamine neurons and increased behavioral responses to cocaine. Mice lacking the Clock homolog, NPAS2, or the Clock-NPAS2 target genes, Per (period), also show abnormal responses to the rewarding effects of cocaine. Work is underway to define the target genes through which these circadian genes act to regulate the VTA-NAc pathway, and to study the influence of these genes on stress models as well.

Several drugs of abuse, as well as stress, induce the release of systemic glucocorticoids, which activate glucocorticoid receptors expressed throughout the brain. These receptors, which are members of the nuclear receptor family of transcription factors, are known to be expressed in the VTA and NAc. Glucocorticoids are, therefore, thought to be one important mechanism by which stress regulates the reward pathway. Estrogen and progesterone receptors, members of the nuclear receptor family as well, are also expressed in the VTA-NAc pathway and have been found to regulate drug reward mechanisms. Such effects may contribute to gender differences observed in behavioral responses to drugs of abuse and stress. However, the target genes for glucocorticoid, estrogen, and progesterone receptors in the VTA and NAc, through which steroid hormones regulate reward mechanisms, have not been established.

Regulation of Chromatin Remodeling in Brain Reward Pathways

Binding of transcription factors to their target genes regulates transcription via chromatin remodeling events, which are becoming increasingly well understood. Interest in chromatin remodeling in the context of brain reward comes from two sources. First, studies of chromatin remodeling make it possible to delineate the detailed molecular events by which

drug- and stress-regulated transcription factors activate or repress target genes in the VTA and NAc *in vivo*. Second, such changes in chromatin structure provide a novel mechanism by which exposure to a drug of abuse or stress may cause lasting changes in gene expression that outlive changes in the transcription factors themselves.

The rate of expression of a particular gene is controlled by its location within nucleosomes and by the activity of the cell's transcriptional machinery. A nucleosome is a tightly wound span of DNA that is bound to histones and other nuclear proteins. Transcription of a gene requires the unwinding of a nucleosome, which makes the gene accessible to the basal transcription complex, comprised of RNA polymerase (which transcribes the new RNA strand) and numerous regulatory proteins (which unwind the nucleosomes). Transcription factors act by enhancing (or inhibiting) the activity of the basal transcription complex; this is achieved by altering nucleosomal structure through changes in histone aceylation, effects mediated by histone acetyltransferases (HAT) or histone deacetylases (HDAC). Transcription factors also recruit other regulatory proteins to the complex, which further modify chromatin structure, for example, through other posttranslational modifications of histones (or through methylation of the DNA itself). In addition, chromatin remodeling involves enzymes that reposition nucleosomes, in an ATP-dependent manner, and thereby further make genes accessible for transcription. The best-studied example is the SWI-SNF (mating switching and sucrose nonfermenting) complex.

Recent evidence has demonstrated the relevance of chromatin remodeling to drug-induced neuroadaptations within the brain's reward pathway. This work is made possible by use of chromatin immunoprecipitation (ChIP) assays, in which brain tissue (under control or drug-treated conditions) is fixed in formaldehyde to cross-link DNA to nearby histones and other proteins. The fixed chromatin is then sheared into smaller fragments and immunoprecipitated using an antibody directed against a protein of interest, and the immunoprecipitate is uncross-linked and then individual genes of interest are analyzed by quantitative real-time polymerase chain reaction (PCR). Alternatively, the immunoprecipitated DNA is amplified and analyzed on a promoter chip to obtain a genome-wide assessment of regulated genes. This approach makes it possible to identify changes that occur genome-wide within the brain reward circuit as a consequence of drug exposure.

Using ChIP assays, differential chromatin remodeling events (such as histone acetylation and deacetylation) have been observed at various cocaine-regulated genes. For example, it was found that chronic, but not acute, cocaine administration induces histone acetylation at the Cdk5 gene promoter in the NAc. This is consistent with earlier observations that cocaine induces Cdk5 expression in this brain region, but provides the first direct evidence that this induction is mediated via activation of the Cdk5 gene *per se*. Moreover, after chronic cocaine, ChIP assays revealed increased binding of ΔFosB to the Cdk5 gene promoter. Furthermore, inducible overexpression of ΔFosB in NAc of adult bitransgenic mice, which is sufficient for induction of Cdk5 expression *in vivo*, caused increased binding of ΔFosB with the Cdk5 gene. Chronic cocaine administration, or inducible overexpression of ΔFosB, also causes increased binding of Brg1 (a component of the SWI-SNF complex) to the Cdk5 gene. Together, these results support a scheme whereby the gradual accumulation of ΔFosB, in response to chronic cocaine administration, recruits chromatin remodeling factors, such as specific HATs to induce histone acetylation as well as Brg1-containing chromatin remodeling complexes, to its target genes such as Cdk5 (**Figure 3**).

Importantly, recent work has established the behavioral relevance of histone acetylation in the NAc. First, viral-mediated overexpression of particular HDACs in the NAc dramatically blocked the rewarding effects of cocaine. Conversely, treatment of animals with two structurally distinct HDAC inhibitors caused the opposite effect and increased an animal's sensitivity to the behavioral effects of cocaine. These HDAC inhibitors were also found to interact synergistically with cocaine to induce histone acetylation at responsive gene promoters. These findings demonstrate directly that histone acetylation can modify both biochemical and behavioral responses to cocaine, and implicate chromatin remodeling as a key mechanism underlying the molecular control of the brain's reward regions by drugs of abuse.

Future Research

Progress has been made in identifying transcription factors, for example, CREB, ΔFosB, NF-κB, Clock, and steroid hormone receptors, among others, that mediate the effects of drugs of abuse and stress on the reward pathway of the brain. Future research is needed to better understand how drugs and stress, presumably via regulation of dopamine and other receptors and of downstream intracellular signaling cascades in the reward pathway, lead to the regulation of these transcription factors, and how these factors induce chromatin remodeling events at particular target genes. ChIP assays now make it possible for the first time to identify the precise steps by which

Figure 3 Scheme of proposed chromatin remodeling events at a cocaine-activated gene. Part (a) shows the repressed state of chromatin, where a site-specific repressor (Rep) recruits an HDAC complex, which removes acetyl groups (Ac) from histone N-terminal tails. Gene inactivation may also involve other modifications, such as methylation (Me) of histone tails. Part (b) shows the active state of chromatin around a cocaine-activated gene (e.g., Cdk5), where a cocaine-induced transcriptional activator (e.g., ΔFosB–JunD) recruits a HAT and chromatin remodeling complex (SWI-SNF), which induce acetylation (and perhaps demethylation and other modifications) of histone tails and repositioning of nucleosomes. These actions facilitate the binding of general transcription factors and the basal transcriptional apparatus (e.g., TFIID and RNA polymerase II [PolII]) to the promoter. different transcriptional complexes are formed at each of the genes regulated in addiction and depression models, and ChIP on chip assays will help identify the complex gene regulatory networks affected by these transcription factors to regulate the reward circuitry. This new dimension of molecular research will dramatically expand our understanding of the regulatory control of brain reward regions, and provide fundamentally new paths for the discovery of novel treatments for these and other psychiatric disorders.

Transcription Control and the Circadian Clock

Introduction

Circadian (Latin, *circa diem*, 'about a day') rhythms are common to most organisms, from bacteria to human, and are driven by circadian clocks. These are intrinsic timekeeping systems that regulate various biochemical, physiological, and behavioral processes with a periodicity of about 24 h and enhance the efficiency and survival of organisms by allowing them to anticipate and adapt to changing environmental conditions.

In mammals, circadian rhythms are generated in pacemaker cells within the suprachiasmatic nuclei (SCN) of the hypothalamus. Pacemakers are composed of molecular oscillators responsible for the control of overt circadian rhythms in the animal's physiology and behavior. Circadian oscillators are endogenous, cell-autonomous systems that maintain their rhythm even in the absence of external time cues. Importantly, entrainment of the endogenous clock is achieved by specific cues, such as light. It is now well established that peripheral tissues also contain independent oscillators, the function of which is orchestrated by the central clock within the SCN. The circadian clock is constituted by three conceptual components. The first is the intrinsic pacemaker, dedicated to generating and sustaining endogenous rhythmicity. The second component is the input, which refers to the pathways through which external cues are perceived and act upon the central pacemaker. The third element is constituted by the output pathways, through which the circadian clock machinery affects a large array of metabolic and physiologic responses.

Central and Peripheral Clocks

Anatomically, the mammalian central pacemaker is located in the SCN, which generates, maintains, and controls circadian rhythmicity. Evidence that the SCN is the master circadian pacemaker originates from several studies. First, it was shown that ablation of the SCN by electrolytic or chemical lesions invariably resulted in the permanent loss of most overt circadian rhythms. This was later confirmed by SCN transplantation studies, in which grafted SCNs restored circadian rhythmic activity with a period specific to the genotype of the donor graft. Finally, it has been demonstrated that SCN neurons exhibit self-sustained, autonomous circadian rhythms even when isolated in culture.

In addition to the SCN, circadian oscillators also operate in almost all peripheral cell types. Studies in *Drosophila* and zebra fish have shown that individual tissues and immortalized culture cells generate their own autonomous oscillation. In the case of zebra fish, all cells display the remarkable feature of being light responsive. Mammals also have self-sustained circadian oscillators distributed throughout the body. Although no peripheral photoreception has been shown to occur in mammalian peripheral cells, the peripheral oscillators can respond to other signals. Indeed, SCN-derived signals operate in the synchronization of the peripheral oscillators, although with a somewhat different timing on diverse target peripheral cells.

Studies using transgenic rats have reported that the peripheral clocks can only sustain circadian oscillations for a few days when isolated from SCN. Based on this evidence, it was thought that peripheral clocks would require input stimuli from the SCN in order to maintain their circadian oscillation and that peripheral clock machineries become inactive in the absence of the SCN. Several studies have challenged this view and have recently demonstrated that single peripheral cells can function as independent circadian oscillators, basically similar to those operating in the SCN. Thereby, the current view is that the absence of the central clock leads to a loss in synchronicity among individual cells. The SCN, rather than being the unique pacemaker, acts as an 'orchestra's conductor' implicated in the synchronization of a resonant network, a web of peripheral oscillators.

The impact of food entrainment on peripheral clocks has important physiologic implications. In nocturnal animals, it has been demonstrated that restricting feeding to daytime elicits uncoupling of the circadian oscillators in peripheral tissues from the central SCN pacemaker. The restricted access to food advances the circadian cycles of gene expression in peripheral tissues without affecting the SCN, which remains faithful to its intrinsic timing system. These findings indicate that food restriction can superimpose the normal communications between the central clock and the peripheral oscillators.

Circadian Feedback Loop in Mammals

In mammals, the molecular mechanisms underlying the establishment and maintenance of biological rhythms comprise interconnected transcriptional–translational feedback loops. These loops rely on positive and negative regulatory elements. The basic

sprockets of the molecular wheel that control the mammalian central clock include a group of proteins: Period (PER) 1, PER2, and PER3; cryptochrome (CRY) 1 and CRY2; and CLOCK and BMAL1. CLOCK and BMAL1 heterodimerize to form an active transcriptional complex that binds to E-box elements (CACGTG) present in the promoters of Per and Cry genes. Once PER and CRY proteins have been translated, they form heterodimers that then translocate to the nucleus to repress CLOCK:BMAL1-mediated transcription through direct protein–protein interaction. It is important to note that the same activators, CLOCK:BMAL1, stimulate the transcription of many other clock-controlled genes (CCGs). These genes in turn influence functions external to the core oscillatory mechanism and mediate the 'output' of the clock. This accounts for the circadian expression of at least 10% of all cellular transcripts; this expression then results in the rhythmicity of a variety of physiological processes (see **Figure 1**).

Additional components regulate the robustness of this molecular clockwork circuitry: these include the bZIP transcription factor E4BP4, the PAR proteins (DBP, HLF, and TEF), and orphan nuclear receptors (Rev-ERB-α, ROR, RARα, and RXRα). It was shown that transcripts of the E4BP4 and PAR transcriptional factors display circadian oscillations with opposite phases in the SCN and liver. Moreover, transcription studies have demonstrated that all PAR proteins activate, whereas E4BP4 suppresses, the promoters of Per genes by direct binding to the same consensus sequence on the promoters.

Another important regulatory loop exists. The CLOCK:BMAL1 heterodimer transactivates the expression of the Rev-ERB-α gene whereas the CRY:PER heterodimer represses it. Once translated, the Rev-ERB-α protein represses in turn Bmal1 expression by direct binding to a consensus motif within the Bmal1 promoter. In addition, ROR, which is not under the circadian regulation, was shown to bind

Figure 1 The mammalian circadian feedback loop. The feedback loop consists of positive and negative elements, the positive ones being two basic helix–loop–helix, Per–Arnt–Sim domain-containing transcription factors, CLOCK and BMAL1. These transcription factors heterodimerize and drive the transcription of negative components of the clock mechanism, specifically three *Period* genes (*Per1*, *Per2*, and *Per3*) and two *cryptochrome* genes (*Cry1* and *Cry2*). The products of these clock genes then negatively regulate their own expression, thereby setting up the rhythmic oscillations of gene expression that drive the circadian clock. CLOCK:BMAL1 also regulates clock-controlled genes (CCGs), and hence rhythmic output. The additional components, such as Rev-ERB and ROR, regulate Bmal1 transcription, forming an additional regulatory feedback loop required for the precision of the core oscillator. In this context, the discovery that CLOCK is a histone acetyltransferase and thereby directly modifies chromatin remodeling is of central importance.

to and activate directly the Bmal1 promoter. Thus, Rev-ERB-α and ROR regulate Bmal1 transcription in opposite manner, forming an additional regulatory loop that is important for the precision of the core oscillator.

It has also been reported that the retinoid receptors, RXRá and RARá, directly interact with CLOCK in a hormone-dependent manner, repressing CLOCK: BMAL1-mediated transcription by blocking E-box binding of the CLOCK:BMAL1 heterodimer. Importantly, several lines of evidence suggest that this retinoid receptor-mediated transcriptional inhibition may be the mechanism by which peripheral clocks can be regulated by humoral factors.

These findings strongly indicate that the control of the circadian feedback loop is complex and involves several yet unappreciated features. In addition to transcriptional positive and negative feedback loops, further levels of regulation and complexity operate in order to establish and maintain circadian rhythms. These include posttranscriptional regulation, posttranslational modifications, and chromatin remodeling.

Posttranscriptional Regulation

Posttranscriptional regulation has been found to be an essential element in the regulation of gene expression, especially among early response genes, such as c-*fos*. The 3′-untranslated regions (3′-UTRs) have been implicated in the regulation of mRNA stability, localization, and translational efficiency. Indeed, it has been reported that the 3′-UTRs of mouse Per1 (mPer1) mRNAs play crucial roles for the posttranscriptional mechanism producing the delay between transcriptional and translational products of genes.

A 196-nucleotide (nt) segment of the mPer1 3′-UTR was shown to exert a negative action on the translation of the mPER1 protein. Importantly, this 3′-UTR region does not affect the half-life of the mPer1 mRNA, showing that the degradation of the transcripts is not associated with this posttranscriptional mPer1 regulation. Although the detailed mechanism of the mPer1 3′-UTR-dependent transcriptional inhibition remains to be determined, these observations raise the possibility that putative regulator(s) such as RNA-binding protein(s) may intervene in the control of mPer1 expression by interacting with the 196-nt region. In support of this idea, the expression of several genes encoding RNA-binding proteins is reported to be under the circadian regulation. The case of mouse *Per3* gene is also relevant: it has been reported that the 3′-UTR of mPer3 controls mRNA stability, its presence inducing mRNA decay. Importantly, the 3′-UTR-mediated mRNA decay has been shown to play an essential role in the circadian oscillation of mPer3 transcript.

Posttranslational Regulation of CLOCK and BMAL1

Clock proteins undergo a number of posttranslational modifications that contribute to their physiological function (see Table 1). Both CLOCK and BMAL1 display circadian oscillation in their phosphorylation status and in their intracellular localization in cells from mouse liver as well as in neurons of the SCN. Apparently it is the dimerization of CLOCK:BMAL1 that induces the phosphorylation, facilitates their nuclear localization, and finally leads to degradation of each protein. Moreover, CRYs were shown to increase the nuclear accumulation and the half-life of unphosphorylated CLOCK:BMAL1 complex.

BMAL1 can be phosphorylated *in vitro* by two kinases, casein kinase I (CKI) and the mitogen-activated protein kinase (MAPK) extracellular signal-related kinase (ERK). MAPK/ERK phosphorylates three residues, Ser527, Thr534, and Ser599 (in mouse BMAL1), residues which are all highly conserved among vertebrates. On the other hand, the CKI phospho-acceptor sites of BMAL1 have not been identified to date. Transactivation studies have shown that MAPK/ERK-mediated phosphorylation of Thr534 results in a decrease of CLOCK:BMAL1 transcription activation potential, whereas CKI-induced phosphorylation appears to stimulate it.

In addition to phosphorylation, BMAL1 is also subjected to modification by the small ubiquitin-related modifier protein (SUMO). Interestingly, BMAL1 undergoes rhythmic SUMOylation *in vivo*, with a timing that parallels BMAL1 circadian activation. Moreover, BMAL1 SUMOylation was shown to play an important role in controlling BMAL1 protein half-life, thus directly influencing clock rhythmicity.

CLOCK is also a phosphoprotein, although to date little is known about the signaling pathways leading to its phosphorylation. The Ser-Pro-rich region of CLOCK appears to be a target of the histone H1 kinases, a group of three kinases exhibiting activity that intriguingly fluctuates in a periodic manner in nuclear extracts from SCN neurons.

BMAL1 contains a highly conserved functional nuclear localization signal (NLS) and a nuclear export signal (NES) in its N-terminal and Per-Arnt-Sim (PAS) domains, respectively. These signals were shown to control nucleocytoplasmic shuttling of BMAL1, which is critical for the circadian function of the CLOCK: BMAL1 heterodimer. Similarly, also CLOCK contains the highly conserved putative NES and NLS. How these signals exert their function still needs to be determined, but it should be noted that studies on PER proteins (see later) indicate that interactions with BMAL1 and CRYs, and their phosphorylation,

Table 1 Modifications of clock proteins

Protein	*Modification (site)*	*Inducer*	*Comment*
CLOCK	Phosphorylation (unknown)	BMAL1 and CRYs induce the phosphorylated and unphosphorylated forms of CLOCK, respectively	The phosphorylated form of CLOCK seems to be transcriptionally active The phosphorylated form of CLOCK is localized in the nucleus, thus phosphorylation may regulate its subcellular localization
	Phosphorylation (the Ser-Pro-rich region)	H1 kinase	The function of this phosphorylation is unknown
BMAL1	Phosphorylation (unknown)	CLOCK and CRYs induce the phosphorylated and unphosphorylated forms of BMAL1s, respectively	The phosphorylated form of BMAL1 seems to be transcriptionally active
	Phosphorylation (unknown)	CKIε	This phosphorylation stimulates CLOCK: BMAL1-dependent transcription
	Phosphorylation (Ser527, Thr534, and Ser599 of mouse BMAL1)	MAPK	Thr534 phosphorylation inhibits CLOCK: BMAL1-dependent transcription Function of the Ser527 and Ser599 phosphorylations is unknown
	SUMOylation (Lys259 of mouse BMAL1))	CLOCK induces the SUMOlylation of BMAL1	This modification regulates BMAL1 protein half-life
PER1	Phosphorylation (amino acids 653–663 of mPER1)	CKIε	This phosphorylation is required for nuclear translocation of PER1
	Phosphorylation (amino acids 902–916 of mPER1)	CKIε	This phosphorylation masks PER1 NLS, inducing its cytoplasmic localization
PER2	Phosphorylation (β-TrCP recognition motif)	CKIε	This phosphorylation is required for β-TrCP binding and for subsequent mPER2 degradation
	Phosphorylation (unknown)	GSK-3β	This phosphorylation induces nuclear localization of PER2
PER3	Phosphorylation (amino acids 613–626 of mPER3)	CKIε	This phosphorylation induces mPER3 degradation and nuclear translocation
CRY1	Phosphorylation (unknown)	CKIε	The function of this phosphorylation is unknown PER acts as a scaffold for this phosphorylation, allowing CKIε and CRY interaction
	Phosphorylation (Ser247 of mCRY1)	MAPK	This phosphorylation reduces its transcriptional inhibition activity
CRY2	Phosphorylation (Ser265 of mCRY2)	MAPK	This phosphorylation reduces its transcriptional inhibition activity
	Phosphorylation (Ser557 of mCRY2)	MAPK	The function of this phosphorylation is unknown The amount of the Ser557-phosphorylated mCRY2 displays robust circadian variation, and the Ser557-phosphorylated form of mCRY2 is localized specifically in the nucleus
	Phosphorylation (Ser553 of mCRY2)	GSK-3β	This phosphorylation induces mCRY2 degradation The Ser557 phosphorylation of mCRY2 is required for this phosphorylation

represent regulatory steps that mask or unmask the localization signals, thus affecting the subcellular distribution of these proteins.

Posttranslational Regulation of PER and CRY

There are three PER proteins in mammals: PER1, PER2, and PER3. The combinatorial dimer associations of PER proteins generate distinct effects on their subcellular localization and posttranslational modifications. For example, studies in cultured cells have shown that the mPER1:mPER2 interaction imposes a shift in mPER1 subcellular localization from the nucleus to the cytoplasm. On the other hand, a serum shock induces the heterodimerization of mPER1 or mPER2 with mPER3, which in turn facilitates the nuclear translocation of the dimer. It has been also shown that rhythmic changes in mPER3 subcellular localization and phosphorylation are highly dependent on the presence of mPER1.

The functional relationship between PER and CKI reveals the crucial role played by phosphorylation in mammalian clock function. A major advance has been the identification of the gene responsible for the tau mutation in the Syrian golden hamster. This is a spontaneous mutation which causes an early onset of locomotor activity under light/dark (LD) conditions and a very short 20 h period length. It was revealed that the tau locus encodes for CKIε, the kinase that phosphorylates the mammalian PER proteins. The tau mutation is caused by a point mutation leading to a deficiency in the ability of CKIε to phosphorylate its targets, which then results in the short-period phenotype. Importantly, a deficient phosphorylation of PER by CKIε has also been implicated in human sleep disorders, such as the familial advanced sleep phase syndrome (FASPS) and the delayed sleep phase syndrome (DSPS).

CKIε specifically interacts with PER1, PER2, and PER3, and regulates their half-life and intracellular localization. Indeed, CKIε-mediated phosphorylation induces PER protein degradation via the ubiquitin–proteasome pathway. Specifically, phosphorylation of PER2 by CKIε leads to recognition by the ubiquitin ligase adapter protein, β-transducer repeat-containing protein (β-TrCP). Polyubiquitination follows β-TrCP binding to PER2 and leads to subsequent degradation of the protein by the 26S proteasome.

In addition to determining PER proteins stability, CKIε specifically controls the subcellular distribution of PER1 and PER3 by masking or unmasking their localization sequences. All PERs contain a functional NLS adjacent to the CKIε-binding domain. In addition to the NLSs, PERs have additional localization sequences, such as the NES and a cytoplasmic localization domain (CLD). In the case of mPER1, CKIε is able to direct both nuclear and cytoplasmic distribution by specifically phosphorylating distinct residues.

CKIε also phosphorylates CRYs, although the biological significance of this event remains to be determined. CKIε does not directly bind to CRYs, although it seems that PER proteins act as a scaffold, bringing CKIε and CRY proteins into close proximity and thereby allowing phosphorylation. In addition to CKIε, CRYs are phosphorylated by two of the other kinases, MAPK/ERKs and the glycogen synthase kinase-3β (GSK-3β). ERKs directly interact with and phosphorylate the highly conserved residues Ser247 of mCRY1 and the corresponding residue Ser265 of mCRY2 *in vitro*, inducing a reduction in CRY repressor activity. ERKs also phosphorylate the conserved Ser557 in the C-terminal domain of mCRY2. Phosphorylation of mCRY2 at Ser557 displays robust circadian variation in the liver, with a peak at late night. The Ser557-phosphorylated form of mCRY2 is localized specifically in the nucleus, where it is degraded by the proteasome following a subsequent phosphorylation at Ser553 by GSK-3β.

The intracellular localization of the CRY proteins is a major determinant of their regulatory function. Functional NLSs have been described in both mCRY1 and mCRY2. Mutations introduced in the NLS (aa 265–282) of mCRY1 shift the subcellular localization from the nucleus to the cytoplasm. A CLD (aa 1–125) is also present in mCRY1, which presumably controls cytoplasmic localization. This may be regulated by PER1, which is thought to serve as an export adaptor for CRY1 and CRY2, challenging the view by which PER:CRY dimerization promotes nuclear accumulation of the complex. Yet, the PER:CRY physical association appears to indeed play a role in the nuclear accumulation of both proteins. In fact, mPER1 and mPER2 remain cytoplasmic in liver cells from mCRY-deficient mice, and vice versa for CRYs proteins in mPER-deficient mice. The cooperative nature of PER–CRY interactions is further substantiated by the observation that PER:CRY dimerization stabilizes both proteins by preventing their ubiquitination–proteasome-mediated degradation.

Chromatin Remodeling

Distinct posttranslational modifications, such as acetylation, phosphorylation, and methylation, occur on histone tails. These are primary events contributing to the dynamic process of chromatin remodeling. Specifically, histone acetylation plays an important role in promoting a conformational change that provides to chromatin a transcription-permissive remodeling state associated with activation of gene expression. It was shown that CLOCK:BMAL1-dependent transactivation of CCGs is coupled to circadian changes in histone H3 acetylation at their promoters. A number of transcriptional coactivators, such as CREB-binding protein (CBP), activin receptor (ACTR), and p300, are known to contain histone acetyltransferase (HAT) activity, and they were shown to interact with the CLOCK:BMAL1 heterodimer. Moreover, transcription assays demonstrated that CBP, p300, and ACTR are capable of enhancing CLOCK:BMAL1-dependent transcription. Therefore, it was believed that the CLOCK:BMAL1 transcription mechanism is dependent on the circadian time-specific recruitment of distinct coactivators.

The recent finding that CLOCK has intrinsic HAT activity has opened novel avenues of research and has multiple physiological implications. The primary structure of CLOCK shares homology with ACTR, a member of steroid receptor activator (SRC) family of HATs. Intriguingly, however, the acetyl-coenzyme

A (acetyl-CoA) binding motif essential to HAT function displays sequence similarity to the MYST family of HATs. Although BMAL1 does not possess HAT activity, it enhances HAT activity of CLOCK. Mutations in the acetyl-CoA binding motif of CLOCK reduce its HAT activity, diminishing also CLOCK:BMAL1-dependent transcription. These findings demonstrate that the intrinsic HAT activity of CLOCK is essential for the circadian transcriptional regulation. Importantly, various types of HATs have been shown to associate in a large complex *in vivo* with other coactivators. It is highly likely that CLOCK may associate with other nuclear proteins that could contribute to chromatin remodeling and circadian control. Indeed, the concerted contribution of the HAT function of CLOCK and other coactivators is likely to integrate the complex signaling governing chromatin remodeling and the circadian clock machinery.

Phenotypes of Circadian Clock Mutant Mice

A number of mutant mice for genes involved in circadian clock regulation exist, mostly obtained by targeted homologous recombination. The phenotypes of these mice are summarized in Table 2. Studies from these mutant mice have demonstrated the detailed and distinct roles of core clock proteins in regulation of circadian clock and light signaling pathways. Moreover, they also reveal the direct link between the circadian clock and various aspects of animal physiology.

Circadian Clock Input Pathways

Light has a profound influence on animal circadian behavior in two ways. First, light resets the circadian clock by its phase-shifting properties. Notably, the phase-shifting effects of light only occur during the nighttime period of the circadian cycle. In nocturnal mammals kept in darkness, a light pulse during the subjective night (that is, the time of the day corresponding to the dark period in a normal light–dark cycle) can reset the clock by evoking changes in the SCN-controlled rhythms. If the light pulse is given at an early point in time during the subjective night, it induces a shift to later times (phase delay). In the opposite way, if the light pulse is provided at the end of the subjective night, the SCN-controlled rhythms will be shifted to an earlier position in the circadian cycle (phase advance). Second, light acutely suppresses locomotor activity, also referred to as a 'masking' effect. The mechanism of masking is independent of the circadian clock. It has been recently shown that dopamine D2R receptor-mediated signaling is an essential component of the neuronal pathway involved in the light-induced masking effect.

Photic signals perceived by the retina are conveyed to the SCN through the retinal–hypothalamic tract (RHT). Glutamate has been identified as the major neurotransmitter responsible for transducing the photic information to the SCN along the RHT. Once glutamate is released by the SCN, it binds *N*-methyl-D-aspartate (NMDA) receptors, which in turn leads to Ca^{2+} influx that is finally responsible for the activation of nitric oxide synthase (NOS) and calcium/calmodulin-dependent protein kinase (CaMK).

Evidence suggests that the MAPK/ERK pathway is intimately implicated in the light input system. Mice exposed to light pulses during their subjective night display a rapid ERK upregulation (phosphorylation) in the SCN. Furthermore, disruption of the MAPK pathway has been shown to block light-induced phase shifting of the circadian clock at the behavioral level. This finding suggests that the ERK cascade is integrally involved in photic entrainment of mammalian rhythms.

Downstream events of the light-induced signaling pathway in the SCN lead to the phosphorylation of cAMP response element-binding protein (CREB), which then stimulates expression of genes containing a calcium/cAMP response element (CRE) in their promoters. These genes include the immediate-early genes c-*fos*, *fos-B*, *jun-B*, *egr1*, and, more importantly, the clock components *Per1* and *Per2*. In addition to CRE-dependent transcription, the CLOCK:BMAL1 complex was also shown to be involved in light-induced activation of these genes. Although the exact mechanism by which light induces early gene expression still needs to be elucidated, it has been shown that a simple light pulse engenders chromatin remodeling via phosphorylation of histone H3 at Ser10 (see Figure 2).

Circadian Photoreceptors

Rods and cones provide the visual information within the retina. These cells, however, are not involved in circadian photoreception. Indeed, rodents that lack classical visual responses are still capable of circadian photoentrainment. Retrograde tracing experiments have identified retinal cells projecting to the SCN through the RHT, but not to the visual centers of the brain. These cells constitute a small subset of retinal ganglion cells (RGCs), and they were shown to display intrinsic phototransduction, with photic properties matching those of clock entrainment.

Two main candidates have been proposed to be the circadian photoreceptors, melanopsin and cryptochromes. Melanopsin is an opsin found in the eye and

Table 2 Circadian phenotypes of mutant mice

Name	*Phenotypes*	*Description*	*Name*	*Phenotypes*	*Description*
Clock (c/c) mutant	Lengthens the circadian period by 4 h, followed by a complete loss of circadian rhythmicity in constant dark (DD)	The c/c mutant has A–T nucleotide transversion in a splice donor site of its allele, which causes the skipping of exon 19, resulting in the deletion of 51 amino acids of CLOCK protein	MOP3 (BMAL1) KO	Displays immediate and complete loss of circadian rhythmicity in constant darkness	
	Displays reduced levels and noncycling expression of clock-controlled genes	The mutant protein can form a dimer with BMAL1 and binds to DNA, but has defective transcriptional activity functioning as a dominant negative regulator		Displays altered distribution of activity during light–dark (LD) cycles and reduced total activity level	
	Displays reduced light induction of immediate-early genes in SCN			Shows reduced levels and noncycling expression of clock-controlled genes	
	Shows the normal spontaneous firing rhythms of SCN neurons, indicative that the loss of circadian rhythmicity might be due to an uncoupling of individual oscillators			Physiology: has reduced life spans with various symptoms of premature aging	
	Physiology: attenuates diurnal feeding rhythm and develops obesity and metabolic syndrome			BMAL1-deficient embryonic fibroblast cells are not capable of differentiating into adipocytes, indicative that BMAL1 plays important roles in the regulation of differentiation	
	Develops salivary gland hyperplasia when it becomes aged			Displays reduced levels of B cells in the peripheral blood, spleen, and bone marrow	
Clock KO	Exhibits almost normal circadian patterns of behavior	The data from Clock KO mice support the notion of the role of CLOCK-del.19 as dominant negative regulator	PER2 mutant	Displays a shorter circadian period followed by a loss of circadian rhythmicity in constant dark	Mutant expresses PAS domain-deleted form of mPER2 protein
	Shows altered responses to light, with reduced phase delays and exaggerated phase advances			Exhibits a defect in circadian clock resetting (unable to delay the clock)	
	Displays altered clock-controlled gene expression (The effects of CLOCK deficiency on gene expression are target gene specific: e.g., the circadian oscillation of *Per2* in the SCN and liver of CLOCK-deficient mice is robust, whereas that of DBP is completely impaired)			Physiology is cancer prone and shows increased sensitivity to γ-radiation and tumor development	
				Lack of food anticipation	

Continued

Table 2 Continued

Name	*Phenotypes*	*Description*	*Name*	*Phenotypes*	*Description*
PER1 KO	Displays a shorter circadian period in constant dark		PER3 KO	Has normal circadian patterns of behavior	Per3/Per1 double, Per3/Per2 double, and Per3/Per1/Per2 triple KO mutants have same circadian phenotypes as those from Per1, Per2, Per1/2 double KOs, respectively, demonstrating that the role of mPER3 is limited
	Exhibits a defect in circadian clock resetting (unable to advance the clock)				
PER1 and 2 double KO	Displays a complete loss of circadian rhythmicity in constant darkness		CRY KOs	Mice lacking the *Cry1* or *Cry2* genes exhibit accelerated or delayed free-running periodicity of locomotor activity, respectively CRY1 and CRY2 double KO mice display immediate and complete loss of circadian rhythmicity in constant darkness	
CRY1-2–PER2 double KO	Shows normal circadian behavior in LD condition Loses circadian rhythmicity immediately upon release into DD condition		CRY1–PER2 double KO	Displays normal circadian behavior in both LD and DD conditions	These data show that mCry2 can act as a nonallelic suppressor of mPer2
CRY1, CRY2, and rd triple mutant	Arrhythmic under both LD and DD cycles	The rd mutant has total loss of rods and massive loss of cones, rendering the animal visually blind by 3 months of age	D2R receptor KO	Exhibit normal circadian rhythmicity	The result from D2R KO indicates that D2R-mediated signaling is essential for light-masking of circadian rhythms
	Display reduced c-*fos* light inducibility in the SCN compared with either rd/rd or CRY1 and CRY2 mutant mice	The rd mutant exhibits normal free-running rhythm both in LD and DD cycles		Shows a deficient light-masking response	
Melanopsin KO	Entrains to a LD cycle and displays normal circadian activity rhythms under constant darkness Is defective for phase resetting in response to brief pulses of light Phase-shifts normally after a light pulse	Inconsistent results reported by two studies on melanopsin KO mice regarding the phase resetting	Melanopsin and rd mutant	Exhibits complete loss of pupil reflex, entrainment to light–dark cycles, and masking response to light	The rd mutant lacks functional rod and cone, thus the result demonstrates that the rod–cone and melanopsin systems together provide all of the photic input for these nonvisual functions

Figure 2 Light signaling evoking changes in the SCN-controlled rhythms. Photic signals perceived by the retina are conveyed to the SCN through the retinal–hypothalamic tract (RHT). RHT neurons release glutamate in synapses of the ventrolateral SCN. Glutamate binds and activates NMDA receptors, which then initiates a cascade of events leading ultimately to induction of immediate-early genes (ieg) and clock genes (such as *Per1*) (NOS, nitric oxide synthase; CaMK, calcium/calmodulin-dependent protein kinase). The gene induction is dependent on the activation of MAPK, extracellular signal-regulated kinase (ERK), and the transcription factor cAMP response element-binding protein (CREB).

in other photoreceptive structures in amphibians, and exclusively in the eye in primates and rodents. Although studies using melanopsin-null mice did not provide clear evidence that melanopsin plays a central role in circadian photoentrainment, several features of melanopsin would make it a good candidate for being the circadian photoreceptor. Its distribution is restricted to a subset of RGCs that project to the SCN and mediate entrainment. Moreover, all photoreceptive RGCs contain melanopsin, whereas RGCs lacking light response are devoid of this protein. Melanopsin-deficient mice entrain perfectly well to an LD cycle, whereas phase-shifting effects of light may be altered. Importantly, mice lacking rods, cones, and melanopsin exhibit complete loss of photoentrainment of the circadian oscillator as well as lack of pupillary light responses, photic suppression of melatonin production, and masking. The presence of both rod-cone and melanopsin systems appears to be important to mediate the light input.

Genetic evidence supports the possibility that CRYs have photoreceptive properties in mammals. CRY2-deficient mice present some defects in light-dependent Per gene induction in the SCN. In addition, mice devoid of rods, cones, and CRYs are nearly arrhythmic in light–dark conditions and display a severely blunted c-*fos* gene response to light in the SCN. More evidence supporting involvement of CRYs in photoreception, and excluding the participation of a vitamin A-containing chromophore, comes from work done in vitamin A-deficient mice lacking detectable opsins.

It is clear that none of the mammalian photopigments identified to date (rod and cone opsins, melanopsin, or CRYs) is uniquely essential for circadian phototransduction. It is conceivable that, independently of the classical opsins, CRYs and melanopsin work cooperatively to play a role in circadian photoreception as well as in the other nonvisual tasks.

Circadian Output

Circadian clocks regulate a number of physiological functions, including sleep and wakefulness, food intake, body temperature, cardiovascular and renal activity, hormone production, hepatic metabolism, and immune activity. Indeed, disruption of circadian rhythms has profound effects on human health, leading to insomnia, jet lag, stomach ailments, cancer, and depression.

The SCN master clock regulates behavioral circadian rhythms by diffusible signals, such as transforming growth factor-α (TGF-α) and the protein prokineticin 2 (PK2). These were shown to be rhythmically expressed in the SCN, and *in vivo* data demonstrated that they play a role in inhibiting locomotor activity of mice. While additional humoral signals are likely to exist and still await identification, it is apparent that a finely tuned connection between the SCN and target neurons also seems to be essential for a full transmission of the signal from the central clock to peripheral tissues.

Transcription of clock-controlled genes in peripheral clocks is critical for the regulation of local physiology and hormonal production. A good example is the gene encoding D-element binding protein (DBP), whose expression is directly under CLOCK:BMAL1 transcriptional control in the liver. DBP, in turn, regulates the rhythmic transcription of key enzymes involved in hepatic metabolic processes, which include Cyp7a, a key factor in bile acid production, and Cyp2a4, a protein involved in steroid metabolism.

Several lines of evidence recently have revealed a direct link between circadian rhythm and cancer. An early study indicated that Per2-deficient mice are cancer prone. These mice display a marked increase in spontaneous and γ-irradiation-induced tumor development. Later it was shown that CLOCK:BMAL1 directly regulates cell cycle regulator WEE-1, a kinase that controls the G2-to-M transition, restricting entry of dividing cells into mitosis to certain times of the

day. More recently, it has been reported that a number of clock-regulating proteins, such as CRYs, timeless (TIM) and PERs, interact directly or indirectly with cell-cycle-controlling proteins, including checkpoint proteins CHK1 and CHK2, ATR, and ATM, involved in cellular DNA damage responses. These observations provide essential information toward the development of new strategies for cancer chronotherapy. Indeed, administration of cancer therapy based on circadian timing has shown encouraging results, but still lacks a solid mechanistic foundation. Future studies will fully unravel the molecular links between the circadian clock and its control over central cellular processes such as cell proliferation, apoptosis, and response to genotoxic stress.

Transcription Factors in Synaptic Plasticity and Learning and Memory

C M Alberini, Mount Sinai School of Medicine, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Transcription factors are proteins that bind specific sites or elements in regulatory regions of DNA, known as promoters or enhancers, where they control the transcription or expression of target genes. Transcription factors can be selectively activated or deactivated by other proteins, often as the final step in signal transduction. There are three functional classes of transcription factors: (1) general transcription factors, which are ubiquitous and represent the core machinery of transcription; the most common are abbreviated as TFIIA, TFIIB, TFIID, TFIIE, TFIIF, TFIIH; (2) constitutively expressed factors that in each cell type constitutively stimulate or repress transcription; and (3) inducible transcription factors, which are similar to the constitutively expressed transcription factors but require activation or inhibition. Transcription factors are composed of two essential functional regions: a DNA-binding domain and an activator domain. The DNA-binding domain consists of amino acids that recognize specific DNA bases on the regulatory element.

In the last 15 years, there has been great advances in understanding the nature and function of gene expression in the brain and its regulation underlying behavioral responses and, in particular, cognitive functions. However, a great deal remains to be understood. How does gene expression allow complex cognitive responses? What types of genes mediate such 'evolved' functions and how do they work?

Interestingly, the knowledge of the genome sequences of several species and their comparative analyses have revealed a surprising simplicity in the evolution of the genetic content. It is now clear that the number of genes in the genome of the different species does not account for the evolutionary increase in morphological and behavioral complexity: the genome in *Caenorhabditis elegans* is approximately 20 000 and the number of protein-coding genes in the human genome is only about 30 000. Moreover, this small increase is primarily due to duplication of existing genes, rather than creation of new ones. Where then does evolutionary complexity lie? And, particularly, how does the human genome, which is not very different than that of a worm, account for the complexity of human behavior? It has been proposed that behavioral complexity correlates with the number of 'gene expression patterns' exhibited throughout an animal's life cycle. Accordingly, 5–10% of the total coding capacity of a metazoan genome is made up of transcription factors, and humans contain as many as 3000 transcription factors in their genome. Remarkably, the combinatorial nature of transcription regulation produces a spectacular amplification of the repertoire of gene expression, and the brain is the tissue in which changes in protein and gene expression are most pronounced.

Here we will briefly review the role of some transcription factors in synaptic plasticity and learning and memory.

A number of investigations, in the last 15 years, examined the role of transcription factors in long-term synaptic plasticity and memory formation. The transcription factor families most extensively studied include cyclic AMP (cAMP) response element-binding protein (CREB), CCAAT C/EBP, AP-1, Zif 268, and nuclear factor kappa B (NF-κB).

The first idea that transcription regulation is essential for learning and memory came from studies carried out in the 1960s, when it was shown that inhibitors of transcription, such as actinomycin D, block memory formation. Subsequently, with the discovery of long-term synaptic plasticity responses (such as long-term facilitation (LTF) in the invertebrate *Aplysia californica*, long-term potentiation (LTP), and long-term depression (LTD) in mammals), it was also found that transcription is similarly required for long-term synaptic plasticity, but not for short-term responses. Long-term synaptic plasticity refers to long-lasting changes that occur in the strength of synaptic connections as a consequence of neuronal activation processes, and it has been suggested that these processes underlie learning and memory formation. However, more recent knowledge indicates that LTP and LTD have a broader role and contribute to experience-dependent modifications of brain function in general. Therefore, in light of this updated view, the description of the role of transcription factors in these processes is summarized. Obviously, as described below, similar transcription factors have been found to play a critical role in both LTP/LTD and learning and memory.

CREBs, The Most Studied

In the late 1980s, it was discovered that the activation of the intracellular second messenger cAMP affects gene expression via the activation of transcription factors

that bind to DNA regulatory regions carrying specific consensus sequences (Figure 1). These sequences, which were therefore named cAMP-response element (CRE), are generally represented by the palindromic motif *TGACGTCA* or its half. The transcription factors that bind CRE were named CRE-binding proteins or CREBs. The CREB (or CREB/ATF) family of transcription factors includes three homologous genes: creb, cAMP response element modulator (crem), and activating transcription factor-1 (atf-1), which generate a group of highly homologous proteins that have been named after their prototypes CREB, CREM, and ATF-1, respectively (Figure 2). While both CREBs and ATF-1 are ubiquitously expressed proteins, CREMs are mainly present in the neuroendocrine system. Structurally, the CREB family is characterized by a C-terminal bipartite domain which has been named '*b-zip*' because it juxtaposes a region rich in basic amino acids (basic region) with a region containing heptad repeats of leucine that, through an alpha-helix structure, creates a hydrophobic surface that mediates dimerization by resembling a zipper. The b-zip domain, which mediates both dimerization and binding to DNA, is not specific for the CREB family of transcription factors but is also present in other families, such as C/EBP, Gcn4, c-Jun, and c-Fos. Transcription factors bearing the b-zip domain are known to function as dimers, and they can generate both homo- and heterodimers. Heterodimerization can occur between CREB family members, but also with other b-zip transcription factors such as C/EBPs,

Fos and Jun proteins, thus providing a great expansion of the potential repertoire and diversity in the regulation of the target genes. Moreover, alternative splicing of the CREB and CREM genes also contributes to the vast repertoire of CREB family members, which includes several isoforms that have distinct repressor or activator features.

In addition to the b-zip domain, CREBs, as well as all other transcription factors bearing this motif, contain a transactivation domain that activates the transcription of the target genes. The transactivation domain of CREB is also bipartite and includes a constitutive (Q2) and an inducible domain (the kinase-inducible domain, KID). While the Q2 domain mediates the interaction with a component of the TFIID complex, the KID seems to promote isomerization by recruiting the coactivator factors CREB-binding protein (CBP) and p300 to the promoters. The KID region is active only when phosphorylated at Ser 133, which occurs in response to cAMP and critically mediates the activation of CREB. CBP and p300 are transcription coactivators with intrinsic histone acetyltransferase activity and are crucial for mediating transcription enhancement.

CREB factors have been extensively studied in the nervous system and found to be implicated in many functions including neurogenesis, neuronal survival, development, differentiation, neuroprotection, axonal outgrowth and regeneration, circadian rhythms, addiction, synaptic plasticity, and memory formation.

CREBs and Synaptic Plasticity

The discovery of the fundamental role of CREB transcription factors in long-term synaptic plasticity stemmed from early findings in the invertebrate *A. californica*, indicating that cAMP mediates LTF and memory responses. The subsequent discovery of the necessary role of CREBs in *Aplysia* LTF helped unravel the understanding of the molecular bases of memory formation.

LTF, like long-term memory, requires gene expression and is accompanied by the formation of new synapses. The characterization of LTF in the *Aplysia* sensory and motor neuron co-culture model system provided the first direct evidence of the essential role of CRE-binding proteins in long-term synaptic plasticity. Injection of CRE-binding elements into the sensory neuron blocked LTF induced by repeated pulses of serotonin (5-HT), while it left short-term facilitation (STF) intact. This and several other related findings in *Aplysia* led to the understanding of some of the fundamental mechanisms underlying LTF. In the *Aplysia* sensory–motor neuron co-culture, STF is induced by one pulse of 5-HT, which activates adenylyl cyclase leading to a transient increase of cAMP. This second messenger binds to the regulatory subunit of the cAMP-dependent protein kinase (PKA), which releases its catalytic subunit that, in turn, phosphorylates several substrates including channels involved in membrane repolarization and proteins mediating neurotransmitter release. As a consequence, a transient increase in transmission release, or STF, occurs. When repeated pulses of 5-HT are applied to the co-cultures, the increase in cAMP and the activation of PKA are sustained for a longer period of time. Moreover, mitogen-activated protein kinase (MAPK) is also recruited. The activated kinases translocate to the nucleus where they presumably phosphorylate an activator form of CREB, CREB1, leading to its activation. In parallel, a repressor form of CREB, CREB2, is removed, thus promoting gene transcription. A first wave of gene expression induced by CREB activation includes the upregulation of immediate early genes such as the transcription factor CCAAT enhancer binding protein (ApC/EBP) and ubiquitin hydrolase, which leads to sustained PKA activation. As discussed below, C/EBP controls the expression of additional target genes and, like CREB, is required for LTF.

Many of the signaling steps required for *Aplysia*, LTF also mediate hippocampal LTP and memory formation in mammals. Subsequent to induction, two phases of LTP can be resolved: an early phase that involves posttranslational mechanisms and decays within about an hour under high-frequency stimulation (HFS) and a protein synthesis-dependent phase (late LTP) that begins as early as 15 min after HFS and can persist for several hours. This late phase has been suggested to model the gene expression-dependent period of memory consolidation. The first demonstration that CREBs are required for LTP in mammals was provided by studies carried out in mice, in which the most abundantly expressed CREB isoforms of the brain had been knocked out (CREBα/Δ). These mice had a significantly impaired LTP. This result was followed by many others that, together, strongly supported the conclusion that CREB plays a critical role in mammalian long-term synaptic plasticity.

Later, some controversial findings reported that, in other mice models with conditional disruption of all CREB isoforms restricted to forebrain regions, or in conditional mutants lacking all CREB isoforms throughout the brain, hippocampal LTP and LTD as well as some forms of memory were normal. However, these mutants displayed a significant impairment in some forms of memory, such as conditioned taste aversion. Another conditional mouse line, in which the function of all CREB subfamilies was blocked in CA1

neurons of the dorsal hippocampus, also showed impairment in some forms of late-phase LTP but not others. Together, these controversial findings suggest that mechanisms of protein compensation due to the transgenic expression may overcome the requirement for CREB during long-term synaptic plasticity, and/or that some forms of LTP are CREB independent.

More recent studies, following up behavioral findings described below, investigated the temporal profile of CREB activation during LTP. Interestingly, LTP, like memory, is coupled to a biphasic profile of CREB phosphorylation, as revealed by the results found with nondecremental late LTP (L-LTP) *in vivo*. Tetanic stimulation produces a first peak of CREB phosphorylation evident 30 min later, and a second, longer lasting peak evident 2 h later, which is sustained for at least a day. Similarly, in hippocampal slices, during early and L-LTP, pCREB increases in a biphasic fashion showing a first peak of phosphorylation at 45 min and a second one at 6 h posttetanus, which returns to baseline levels at 8 h after LTP induction. Similar profiles of CREB activation are also found in rat organotypic hippocampal slices, where the induction of LTP in CA1 is accompanied by a local increase in pCREB, which is sustained for at least 4 h, once again supporting the hypothesis that CREB plays an important role in the late gene expression-dependent phase of LTP.

CREBs and Memory

Parallel studies in both the invertebrate the *Drosophila melanogaster* and in mice, proved that CREB plays a critical and evolutionarily conserved role during memory formation. The induction of a dominant negative form of CREB in *Drosophila* blocks long-term memory formation and the CREBα/Δ mutants are significantly impaired in several types of memories, including spatial, contextual, and cued. These mice, as pointed out above, also have impaired LTP. A great number of subsequent studies confirmed the essential role of CREB in memory in numerous additional species, brain regions, and learning systems. Interestingly, it also emerged that the activation of CREB is sufficient to transform a short-term memory into a long-lasting one, as the overexpression of activator forms of CREB enhances and prolongs memory retention. In summary, a large body of evidence indicates that CREB plays an evolutionarily conserved role in the formation of long-term memory.

Obviously, like for any transcription factor, CREB acts in concert with a number of other transcription regulator and other molecules; therefore, the critical role of CREB needs to be seen in the context of the pattern of genes expressed in the brain regions that mediate memory formation. This is also supported by the observation that the genetic background and gene dosage may influence the phenotype of CREBα/Δ mutants.

Subsequent studies focused on determining the anatomical and cellular distribution and requirement of CREBs as well as their temporal expression following learning. It emerged that the expression of activated CREB throughout the brain or its functional requisite overlaps with the anatomical circuits required for the various learning tasks. Most of the tasks characterized thus far are hippocampal-dependent tasks, and, in fact, they are among the best understood at the behavioral, anatomical, and electrophysiological levels. Knockdown approaches based on oligodeoxynucleotide (ODN) antisense injections in restricted areas of the brain demonstrated that CREB-mediated transcription in the rat dorsal hippocampus is necessary for the formation of spatial memories such as water maze. These experiments also revealed the temporal dynamics of the CREB requirement. CREB antisense ODNs injected bilaterally in the hippocampus just prior to training block memory retention, whereas a similar treatment given 1 day after training has no effect, indicating that there is a time-limited CREB-dependent phase in the hippocampus during the consolidation of spatial memories.

The temporal on/off dynamics of the activation of CREB, measured by the phosphorylation of its Ser-133 (pCREB), have been more extensively examined in other forms of memories, which, like spatial memories, engage the hippocampus, but form contextual rather than spatial representations. These are, for example, contextual fear conditioning types of memories and include inhibitory avoidance (IA) and contextual fear conditioning. These types of memories also require an intact amygdala, a region that processes fear and aversive responses. In fact, these memories are created by associations formed between a context or cues that, during training, are presented in temporal sequence with an aversive experience, that is, a foot shock. The formation of these memories, like that of spatial memories, shows a biphasic activation of CREB in the hippocampus: one peak of activation is evident immediately after training and returns to baseline at 30 min, and the second rises between 3 and 6 h posttraining and returns to basal levels several hours later. This trend of pCREB enhancement coincides with hippocampal PKA activity, which argues that the CREB activation necessary for consolidation of the memory is mediated by PKA phosphorylation. Importantly, the biphasic pattern in pCREB activation is not restricted to the hippocampus, but also occurs in other brain regions including parietal cortex and amygdala.

In conclusion, the activation of CREB, which appears to occur with a biphasic profile and is temporally limited, represents an essential and evolutionarily conserved molecular event of memory formation.

C/EBP, The First Immediate Early Gene

C/EBP is a family of transcription factors that comprise six isoforms defined by distinct genes known as C/EBPα, C/EBPβ, C/EBPγ, C/EBPδ, C/EBPε, and C/EBPζ. Like CREB, the C/EBP family belongs to the b-zip superfamily of transcription factors. Similarly to all the other members of this superfamily, while the b-zip domain is highly conserved, the N-terminal activation domain greatly diverges (<20% sequence identity) (Figure 3). Different C/EBPs are able to form homo- and heterodimers with members of the C/EBP or other b-zip transcription factor families, including CREB, Fos, Gcn4, and Myc. C/EBPs also can dimerize with NF-κB. Some isoforms of C/EBP, like C/EBPζ, can act as dominant negative inhibitors.

With the exception of C/EBPζ, all C/EBPs generally interact with the dyad symmetrical repeat *5′-RTTGCGYAAY-3′*, where R represents A or G, and Y represents C or T. However, the binding element may also include several variations, indicating that C/EBPs are pleiotropic DNA binding factors. C/EBPζ represents an exception, and because of its different structure, it does not bind to the canonical C/EBP element.

The gene structure of C/EBPs is very simple: C/EBPα, β, γ, and δ are intronless, while C/EBPε and ζ contain two and four exons, respectively. Each of the six C/EBP genes can generate the expression of several proteins by alternative use of translation initiation codons in the same mRNA molecule, alternative use of promoters, and differential splicing (Figure 4).

Figure 3 Structural model of the C/EBPβ bound to DNA. Two alpha-helix b-zip domains dimerize and form an inverted Y-shaped structure. Each activation domain, from each monomer binds to half of the palindromic DNA binding site. From Ramji DP and Foka P (2002) CCAAT/enhancer-binding proteins: Structure, function and regulation. *The Biochemical Journal* 365: 561–575.

Additionally, posttranslational modifications of C/EBP play an important role in directing their function and stability.

C/EBPs are expressed in various tissues, including central nervous system (CNS), adipose, liver, intestine, lung, adrenal gland, peripheral blood mononuclear cells, and placenta. They play key roles in differentiation, inflammatory response, liver regeneration, metabolism, synaptic plasticity, memory, and a variety of cellular functions, including stress, growth, and apoptosis. C/EBPs, like CREBs, are evolutionarily conserved molecules required for memory formation, and they belong to the group of early genes regulated downstream of CREB activation.

C/EBPs and Synaptic Plasticity

The first demonstration that a transcription factor is necessary for long-term synaptic plasticity came from the finding of the role of ApC/EBP in *Aplysia* LTF. C/EBP was cloned in the *Aplysia* CNS using expression library screening and found to be generally undetectable in *Aplysia* neurons at resting condition, but rapidly induced following the activation of cAMP or 5-HT. The regulation of the expression of ApC/EBP is typical of an immediate early gene and its function is essential for LTF but dispensable for STF. In fact, injection into the sensory neurons of either C/EBP DNA binding sites (ERE), antisense DNA, interfering RNA (RNAi), or antibodies that prevent C/EBP binding to its DNA binding elements, all block LTF but leave STF intact. The requirement for ApC/EBP during LTF in cell culture lasts for a relatively long time (more than 9 h), suggesting that the ApC/EBP-dependent transcriptional phase essential for LTF is temporally restricted but long lasting. Like CREB activation, the induction of ApC/EBP in cultured sensory neurons is sufficient for transforming STF into LTF. In fact, the application of a single pulse of 5-HT on sensory–motor neuron co-cultures overexpressing ApC/EBP produces LTF, instead of STF. Recent studies indicate that the regulation of ApC/EBP can be mediated by LAPS18-like protein (LLP), a nucleolar protein that binds to the CRE sequence present in the promoter of ApC/EBP. LLP, like ApC/EBP, is required for LTF and its overexpression is sufficient to produce LTF in response to a single 5-HT pulse.

In mammals, inhibition of all C/EBP isoforms and ATF-4 through a regulated expression of a dominant-negative C/EBP (EGFP-AZIP) results in an enhanced

Figure 4 Schematic representation of the C/EBP family members. AD, activation domain; RD, negative regulatory domain. Adapted from Ramji DP and Foka P (2002) CCAAT/enhancer-binding proteins: Structure, function and regulation. *The Biochemical Journal* 365: 561–575.

LTP following submaximal single train of HFS, indicating that either some isoforms of C/EBP or ATF-4 exert inhibitory constraints on long-term synaptic plasticity.

C/EBP and Memory

The functional role of C/EBPs in memory has mainly been studied in the rat using hippocampal-dependent tasks. In the rat hippocampus, the endogenous expression of two C/EBP isoforms, C/EBPβ and C/EBPδ, increases following IA learning but in a delayed fashion relative to CREB phosphorylation, which occurs immediately after training. C/EBPβ protein expression remains significantly increased between 9 and 28 h after IA training, while C/EBPδ mRNA increases at 20 h. It appears that the learning-related induction of C/EBPβ and δ is under the regulatory control of CREB, because the expression of both C/EBP isoforms follows CREB phosphorylation in the same subset of hippocampal neurons, and disruption of CREB function prevents C/EBPβ induction. Similar to the findings obtained in *Aplysia* cultures, the regulation of C/EBPβ expression in the hippocampus during the consolidation of mammalian memory is evoked by the activation of Ca^{2+} and the cAMP-dependent intracellular pathways. This and the characteristic temporal sequence of CREB phosphorylation, followed by C/EBPβ and δ induction, further supports the existence of a CREB-C/EBP-mediated gene expression pathway essential for memory consolidation.

Like CREB, C/EBPβ is indispensable for memory consolidation, as bilateral injections into the dorsal hippocampus of antisense ODN specific for C/EBPβ (β-ODN) results in amnesia. This role of C/EBPβ is limited to a temporal window that begins a few hours after training and ends 2 days later. Thus, C/EBPβ represents one of the evolutionarily conserved CREB-target genes essential for long-term memory consolidation.

The learning-induced regulation of C/EBPβ expression, like the phosphorylation of CREB, requires an intact fornix. The fornix is a fiber bundle that connects the hippocampus to the septum and the hypothalamus and provides important modulatory inputs to the hippocampus. Rats with bilateral lesions of the fornix have an intact short-term memory but

impaired long-term memory. These amnesic animals fail to exhibit the characteristic induction and maintenance of pCREB, C/EBPβ, and C/EBPδ responses following learning in their hippocampi. This suggests that inputs originating in the septum, hypothalamus, and brainstem, traveling through the fornix, convey signals into the hippocampus that regulate CREB-C/EBP-mediated gene expression.

C/EBPδ also plays an important role in memory formation, but apparently by acting in an opposite direction compared to that of C/EBPβ. The C/EBPδ mouse knockout shows a selective enhancement of contextual fear conditioning, but has normal water maze memory. Similarly, a memory enhancement is also evident in mice in which the expression of a broad dominant-negative inhibitor of C/EBP (EGFP-AZIP), which preferentially interacts with several inhibiting isoforms of both C/EBP and ATF-4, is selectively expressed in the forebrain. This suggests that relief of C/EBP, C/EBP-like, or ATF-4-mediated inhibitory mechanisms lowers the threshold for hippocampal-dependent long-term memory in mice.

Zif 268, A Marker of Plasticity

The transcription factor zif268 (also known as Krox24, NGF-I-A, Egr-1, TZs8, and Zenk) was first discovered as an immediate early gene regulated by nerve growth factor and in response to serum treatment (Figure 5). The zif268 gene encodes for two polypeptides of 82 and 88 kDa, which have different translational starting sites, and belongs to the structural family known as zinc fingers. In fact, the DNA binding domain of Zif268, like that of all members of its family (Egr family), folds into three zinc finger structures that mediate DNA binding to the element *5′-GCGC/GGGGCG-3′* (Figure 6). The high homology of the finger sequence among all members of the family implies that they may bind to the same sites of at least a subset of the same target genes.

Figure 5 Structural model of Zif268 complex with DNA. Biomolecule Gallery: http://gibk26.bse.kyutech.ac.jp/jouhou/jouhoubank.html.

In the rat brain, Zif268 is constitutively expressed in the neocortex, primary olfactory cortex, entorhynal cortex, amygdaloid nuclei, nucleus accumbens, striatum, cerebellar cortex, and hippocampus. In the hippocampus, zif268 is highly expressed in the CA1 region and less in CA2–CA3, but only minimally present in the dentate gyrus, where, however, it can be induced in response to a variety of stimuli. Stimuli that regulate Zif268 expression in the brain include seizure, kindling, brain injury, neurodegeneration, apoptosis, stress, and drug tolerance and dependence.

The family members of the Erg family show a similar pattern of basal expression, which is predominantly localized in the nucleus, except for Egr2, that has been found to be expressed in both nucleus and cytoplasm.

Zif268 and Synaptic Plasticity

The expression of zif268 mRNA is strongly induced during LTP at dentate gyrus synapses 30–60 min following tetanic stimulation of the perforant path, and this induction requires the function of NMDA receptors. Interestingly, the role of zif268 seems to be associated with the maintenance of synaptic plasticity rather than its induction. In fact, the posttetanic increase of zif268 correlates more with the persistence of LTP rather than its magnitude of induction. In agreement, zif268 mutant mice show a normal induction and early phase of dentate gyrus LTP, but a faster decay of the LTP late phase. Thus, it was initially believed that zif268 represents a marker of plasticity.

In addition to hippocampus, several other brain regions have been found to display an increase of zif268 mRNA following LTP. These include, for example, the visual cortex following stimulation of the thalamocortical tract and in the insular cortex following stimulation of the basolateral amygdala.

Some controversial results have been obtained concerning the regulation of zif268 expression following long-term synaptic plasticity. For example, zif268 does not seem to change in the CA1 region of the hippocampus if LTP is induced *in vivo*, but significantly increases following tetanic stimulation in CA1 slices. However, for zif268 as for all other inducible proteins, it is important to keep in mind that the general patterns of gene expression and their regulation differ in brain slices compared to the intact brain.

Figure 6 Modular structure of the transcription factor Zif268. The Zif268 protein contains an extended transcriptional activation domain on the N-terminus and a DNA-binding domain, consisting of three zinc fingers motifs. Additionally, an inhibitory domain has been mapped between the activation and DNA-binding domains that functions as a binding site for transcriptional co-repressor proteins. Reproduced with permission from Rössler OG, Stefano L, Bauer I, and Thiel G (2006) Stimulus Transcription Coupling in the Nervous System: The Zinc Finger Protein Egr-1. In: Thiel G (ed.) *Transcription Factors in the Nervous System*, pp. 379–391. Weinheim: Wiley-VCH (2006). Copyright Wiley-VCH Verlag GmbH & Co. KGaA.

Other conflicting results concerning the expression of zif268 were reported in both experience-dependent plasticity in the visual cortex and kindling in the amygdala. In both cases, while the acute presentation of the stimulus correlated with the expression of zif268, similar experiments performed on zif268 mutant mice did not reveal any difference compared to wild-type littermates. However, as mentioned above in reference to the CREB and C/EBP studies, a possible explanation for the discrepant results found between acute approaches versus general knockout animal models is that, with the latter, functional compensation may overcome the deficit of the deleted gene. Although zif268 is the member of the Erg family more extensively characterized, other members of the family, that is, Erg 2, have also been found to be regulated following LTP.

Zif268 in Learning and Memory

The expression of Zif268 seems to be regulated in response to a variety of behaviors, including learning and memory. Extensive investigations have revealed that Zif268 is rapidly regulated during associative learning, such as song learning in birds, fear-conditioning and spatial learning in rats, and visual-paired association in monkeys.

In birds, the expression of zenk, the avian homolog of zif268, is regulated in regions that process not only song learning but also song perception. Thus, because zif268 has been generally linked to neuronal plasticity in the mammalian brain, it is now believed that zenk may be linked to molecular and cellular mechanisms that generally underlie the experience-dependent modification of song-responsive circuits.

In rodent, fear-conditioning training correlates with an upregulation of zif268 in the CA1 region of the hippocampus and amygdala. However, because similar increases also occur in matched controls, it seems likely that the change in zif268 is generally associated with the experience of novelty. The characterization of zif268 expression in spatial learning has indicated that, in learning tasks based on multiple trials, the regulation of this transcript seems to be restricted to an initial phase and its upregulation becomes attenuated after repeated trials.

Genetic studies in mice have also demonstrated that Zif268 plays a critical role in memory formation. Zif268 knockout mice have impaired long-term memories but intact short-term retention. The long-term memory deficits have been found in a variety of tasks, including spontaneous alternation, social transmission of food preference, object recognition, spatial learning and conditioned taste aversion. Consistent with these findings, the heterozygous mice have memory deficits that fall midway between the performance levels of the knockout and the wild-type animals. Similarly to CREB mutant mice, if zif268 mutants are exposed to overtraining behavioral protocols, they gain the capability to learn and form memories, suggesting that mechanisms of molecular compensation or use of different learning/memory strategies can compensate for the loss of essential genes. Moreover, it has been debated whether the regulation of zif268 expression also occurs in association with the retrieval of a fear-conditioning memory, a process that has been more closely scrutinized over the last few years. Significant changes in amygdala zif268 levels have been reported only in some cases following the retrieval of contextual fear conditioning, but not in others.

In summary, whether the regulation of zif268 is specifically linked to associative learning following acquisition and/or to the reactivation of the memory, or whether it is rather associated to processes that are prerequisite of learning and memory consolidation remains to be fully established.

AP-1, A Marker of Neuronal Activation

The transcription factor AP-1 is mainly composed of dimers of members of the Jun, Fos, and ATF families. AP-1 mediates transcription regulation in response to a variety of physiological and pathological stimuli, including cytokines, growth factors, stress signals, bacterial infections, viral infections, and oncoproteins. Fos proteins include Fos, Fra1, Fra2, and FosB, while members of the Jun family include Jun, JunB, and JunD. AP-1 is involved in both basal and inducible transcription of several genes that bear the AP-1 consensus site (*5′-TGAG/CTCA-3′*, also known as TPA-responsive element, TRE) in their promoter region. AP-1 can also bind, but with a lower affinity to the CRE element. Like most other transcription factors, variants of the canonical sequences can also be recognized by AP-1 and contribute to the differential function of AP-1 at various regulatory sequences.

A common feature of the proteins that form AP-1 is their structural motif b-zip domain. Fos proteins generally do not homodimerize, whereas both Jun homo- and heterodimers can bind to the AP-1 site (Figure 7).

Gene knockout experiments have shown that Fos and Jun family proteins have mostly overlapping functions, but also some show unique roles that cannot be compensated for by other family members. The functions of Fos and Jun family members are multiple and depend on the specific cell type in which they are expressed. Like for all transcription factors, these functional diversities can also be mediated by several regulatory mechanisms, including posttranslational modifications, selective dimerization between different family members or with other classes of transcription factors (ATF, C/EBP, Maf, and NF-E2), and, finally, interaction with different types of regulatory proteins.

Figure 7 Structural model of AP-1 complex with DNA. Two human c-Fos/c-Jun complex with DNA. Biomolecule Gallery: http://gibk26.bse.kyutech.ac.jp/jouhou/jouhoubank.html.

AP1 and Synaptic Plasticity

The upregulation of c-Jun, the principal component of AP-1, is a particularly common event in the developing, adult and also injured nervous system. A variety of evidence points to a bipotential role of c-jun in mediating neurodegeneration and cell death, as well as plasticity and repair. c-Jun expression is strongly increased in seizure and in some but not all cases of LTP and/or LTD and memory formation. In fact, the role of jun in LTP is evident only with certain technical protocols but not with others. c-fos mRNA has also been found upregulated in response to a variety of neuronal activation protocols including LTP; however, because, in fact, a multitude of stimulations, including sensory, electrical and epileptogenic are associated with an increase in c-fos, it appears that c-fos expression correlates with neuronal activity rather than synaptic plasticity. However, it should also be kept in mind that, often, it is difficult to differentiate these two processes.

AP-1 and Memory

Both correlative and functional studies have provided evidence for the role of AP-1 in the formation of several types of long-term memories. However, conflicting results have also been reported. Antisense ODN-dependent knockdown of c-jun but not jun-B inhibits sequence-specific learning following aversive stimuli in the foot-shock-motivated brightness discrimination. Conversely, complete neural deletion of c-jun has no effect on spatial learning in water maze or fear conditioning paradigms. Contrasting results have been found with the expression of c-fos with spatial tasks. On the other hand, in other types of tasks, the role of c-fos appears to be clear: acquisition of socially transmitted food preference and appetitively motivated spatial learning correlates with an increase of c-Fos as well as pCREB, in the hippocampus and c-Fos expression is necessary for the formation of these memories. Moreover, c-fos also plays a critical role in fear-induced immobility, morphine-induced conditioned place preference, brightness discrimination, conditioned taste aversion, and passive avoidance. In agreement, a correlative increase in c-Fos expression occurs following learning. For example, it is found in the dorsal striatum of rats trained on a variable position reward task in the radial arm maze and in the hippocampus, entorhynal cortex, and primary visual cortex 30 min after spatial learning.

The temporal profiles of c-Fos expression in different neuronal populations have been investigated

using several memory tasks and it appears that c-Fos induction occurs early after training, in the range of minutes and, similarly to that of Zif268, becomes mostly evident during the first few trials, but decays following repeated trials. For example, a study that compared sham-trained mice with mice trained in an appetitive operant-conditioning task showed an increase of c-Fos in CA3, anterior cingulate, occipital and parietal cortex 60 min, but not 120 or 180 min posttraining on day 1. On day 2, c-Fos was increased in CA1, CA3, dentate gyrus, entorhinal cortex, posterior cingulate cortex, and striatum 60 min after training and no differences were found at the later time points. Finally, on day 5, no differences were detected between trained and control groups.

NF-κB, The Distant Traveller

The transcription factor NF-κB, discovered first in lymphocytes, is now known to be a ubiquitously expressed protein. Recently, it has been found that NF-κB is critically involved in synaptic plasticity and learning and memory. NF-κB belongs to the Rel family of transcription factors, which consists of five members: p50, which is a product of the NF-κB1 gene, p52, which is a product of the NF-κB2 gene, p65, also known as RelA, c-Rel, and RelB. Rel family members function as dimers and the five subunits can either homodimerize or heterodimerize. The Rel family members share a Rel homology domain, which contains the DNA binding, dimerization, nuclear localization, and IκB inhibitory interactions regions (Figure 8). The NF-κB typical DNA binding element is *5′-GGGACTTTCC-3′*.

A peculiar feature of NF-κB is that, at resting conditions, dimers are present in an inactive form in the cytoplasm where they bind to IκB inhibitory proteins. Upon stimulation, the IκB kinase complex becomes activated and phosphorylates IκB leading to its ubiquitination and subsequent degradation. This degradation allows NF-κB to translocate to the nucleus and regulate the expression of its target genes.

In: Thiel G (ed.) *Transcription Factors in the Nervous System*, pp. 327–343. Wiley-VCH (2006). Copyright Wiley-VCH Verlag GmbH & Co. KGaA.

A critical role of NF-κB has been found in the immune system, where NF-κB-dependent gene expression is critical for inflammation and host defense. NF-κB is also expressed in neurons and nonneuronal cells such as glia and Schwann cells, and expression of multiple NF-κB family members has been found in different cell types of the CNS. The most common species expressed in neurons are p50–p65 heterodimers and the p50 homodimers (Figure 9). Thus far, only a relative small number of NF-κB target genes in neurons have been discovered and include Ca^{2+}-calmodulin-dependent protein kinase II (CaMKII) δ, brain-derived neurotrophic factor (BDNF), μ-opioid receptors, neural cell adhesion molecule, inducible nitric oxide synthetase, and amyloid precursor protein.

NF-κB in Synaptic Plasticity

NF-κB was initially found to be constitutively active in the hippocampus, cerebral cortex, and cerebellar neurons. Thus, it has been suggested that NF-κB is activated upon excitatory synaptic transmission through the Ca^{2+}-responsive signaling cascade and the recruitment of CaMKII. Interestingly, NF-κB also becomes active in response to dopamine. The latent form of NF-κB can become active following a variety of stimuli, including glutamate, kainate, amyloid β peptide, tumor necrosis factor α, brain injury, oxidative stress, or depolarization.

The role of NF-κB in LTP has been established by several lines of evidence including the following:

1. Studies showing that LTP induced either by low-frequency stimulation (LFS) or HFS in hippocampal slices correlates with an increase in the mRNA of both p50 and p65 and a decrease of IκB mRNA.
2. Pretreatment with NF-κB DNA element decoy interferes with the induction of both LTP and LTD.
3. *In vivo*-induced perforant path LTP in mouse hippocampus is accompanied by an enhancement of the NF-κB binding to its DNA binding elements in the hippocampal nuclear extract.
4. An incremental increase of NF-κB active form is detected in granular and pyramidal cells in the hippocampus following LFS and HFS-LTP, respectively.

Figure 9 Structural model NF-κB p50 homodimer complex with DNA. Biomolecule Gallery: http://gibk26.bse.kyutech.ac.jp/jouhou/jouhoubank.html.

Similar investigations carried out in mice with genetic disruption of NFκB restricted to the forebrain confirm that this transcription factor is critical for synaptic transmission, late phase of LTP induced by theta burst stimulation (TBS), and induction of LTD.

NF-κB in Memory

NF-κB plays a critical role in several types of long-term memory in species ranging from invertebrates to mammals. In the crab *Chasmagnathus*, the habituation of the escape response elicited by a fear stimulus (passage of an opaque figure representing a potential predator) correlates with an increase of the activated form of an NF-κB homolog in brain nuclei and isolated synapses. Furthermore, injection of an IκB kinase complex inhibitor blocks NF-κB activation and disrupts the escape memory, indicating that NF-κB is essential for this memory. Further demonstrations provided evidence that NF-κB is also recruited for the maintenance of the crab escape memory following retrieval, as, in fact, blocking NF-κB following memory recall results in amnesia.

Similar conclusions have been obtained with mammalian memory systems. Mice lacking the p65 subunit of NF-κB and tumor necrosis factor receptor 1 (TNFR), a factor necessary for the survival of the p65 knockout, have impaired spatial radial maze memory. However, like with other transcription factors described above, this impairment is overcome if the animals undergo overtraining protocols. Again, similarly to other transcription factors discussed above, the role of NF-κB is not found in all memories, as, indeed some types of memory, but not others, appear to be more readily disrupted by the NF-κB inactivation. Thus, the same NF-κB knockout mice that show impaired radial maze have normal fear-conditioning memory, and intact memory in general is also found in mice lacking the p50 NF-κB subunit. On the other hand, intra-amygdala administration of NF-κB decoy disrupts fear-potentiated startle, and inhibition of NF-κB with decoy elements or pharmacological inhibitors injected into the hippocampus disrupts IA memory. Additional studies showed that forebrain inhibition of NF-κB function obtained by overexpression of IκB in mice affects spatial memory assessed by water maze. Interestingly, in these mice, both the mRNA of the catalytic subunit of PKA and CREB

phosphorylation are significantly decreased, suggesting that NF-κB affects the activation of the CREB pathway during memory consolidation. Together, all these evidence strongly argue for a role of NF-κB in synaptic transmission, regulated synaptic plasticity, and memory formation.

An intriguing aspect of NF-κB expression in neurons that deserves more understanding is its localization not only in the cytoplasm, but also at the synaptic compartment, where it appears to be mainly present as p50–p65 heterodimers. Whether this localization serves the function of retrograde communication to the nucleus or reflects a novel, nontranscriptional function remains to be understood.

Conclusions

Experiments in fruit flies, snails, and rodents have identified highly conserved molecular pathways involved in synaptic plasticity, learning and memory. A large number of studies have revealed that these molecular pathways are regulated by combinatorial efforts of transcription factors, which include members of the CREB, C/EBP, Egr, Rel, and AP1 families. The general outcome of these studies suggests that the contribution of combinatorial transcription regulation, which mediates the expression of specific gene patterns that change over time, represents the molecular bases of memory consolidation. Identifying the distinctive features of these gene expression patterns is the next challenge of the field.

Transcriptional Networks and the Spinal Cord

S L Pfaff and T Macfarlan, The Salk Institute for Biological Studies, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

One of the challenges facing the developing embryonic nervous system is how to ensure the production of multiple neuronal subtypes at the correct time, place, and number during development. One of the areas of the central nervous system (CNS) where the mechanisms for regulating cell fate have been extensively studied is the spinal cord. The spinal cord is embryologically derived from dividing multipotential neuroepithelial cells comprising the neural tube at early stages of development. Over the past two decades, there has been tremendous progress in our understanding of the signaling pathways and transcription factors that instruct neuroepithelial cells to differentiate into functionally specialized subpopulations of postmitotic neurons and glia. Spinal neuronal differentiation signals are distributed along the dorsoventral (D/V) and rostrocaudal (R/C) axes, leading to the generation of specific cell types at stereotypical positions along these axes.

D/V Patterning of the Spinal Cord

Interneurons that process and relay sensory signals are primarily restricted to the dorsal region of the spinal cord, whereas motor neurons and the interneurons that regulate their activity are concentrated ventrally. A key signaling molecule working to pattern the ventral spinal cord is sonic hedgehog (shh), a factor that is used at multiple sites within the embryo to control cell specification and growth. Shh is a glycoprotein secreted from notochord cells located underneath the neural tube. Later in development, shh is also produced by the floor plate, a glial wedge that forms at the ventral midline of the neural tube. A critical feature of shh's action on neural tube progenitor cells is its ability to function as a morphogen, namely to signal the differentiation of different cell types in a concentration-dependent manner. Within the neural tube, ventrally located progenitor cells closest to the floor plate and notochord encounter high levels of shh whereas cells located more dorsally are exposed to lower levels of the factor (Figures 1(a) and 1(b)). Thus, the position of a cell within the ventral neural tube dictates the level of shh it will encounter. Cells exposed to different concentrations of shh activate distinct differentiation programs, express unique genes, and ultimately acquire different cell fates (Figure 1(a)).

Shh signaling controls cell specification in the ventral spinal cord by establishing molecularly distinct classes of precursor cell populations, also referred to as progenitor cell domains. Each of the separate precursor populations established by shh signaling expresses a unique combination of homeodomain-class transcription factors that control gene expression (Figure 1(b)). This group of so-called progenitor factors can be divided into two classes based on how they are regulated by shh; class I factors are expressed by default and become repressed by shh, whereas expression of class II factors is activated by shh. The ventral spinal cord is divided into five separate progenitor cell domains referred to as p0, p1, p2, pMN, and p3 that serve as the precursor cell populations for V0–V2 interneurons, motor neurons, and V3 cells, respectively (Figure 1(a)). Each of the postmitotic neuronal progeny that form from the progenitor domains exhibit different phenotypic characteristics, including unique cell migration patterns, axon targeting, and in the cases examined distinct physiological properties.

Insight from studies on ventral cell patterning has helped us to understand some of the general principles that operate to control dorsal interneuron specification in the neural tube. The precursors of dorsal sensory classes of interneurons (dI) are similarly divided into progenitor cell domains (dp1–6) that represent the precursors for six early forming (dI1–6) and two late developing (dIL^A and dIL^B) neuronal subtypes (Figure 1(a)). These interneuronal cell types can be broadly divided into two groups based on the signals required for their specification. Class A cells, consisting of dorsal interneurons dI1–3, are dependent on secreted factors from the roof plate. In contrast, class B neurons (dI4–6 and dIL^A and dIL^B) are able to differentiate even in the absence of roof plate-derived signals. The roof plate secretes at least two different types of signaling molecules that contribute to class A cell specification. One group of related proteins are members of the transforming growth factor-β (TGF-β) family and include activin, bone morphogenic protein 4 (BMP4), BMP5, BMP7, dorsalin1, and growth differentiation factor 7 (GDF7). Another family of signaling proteins expressed by roof plate cells are the wingless related factors Wnt1 and Wnt3A. Numerous genetic experiments have clearly implicated TGF-βs in dorsal interneuron specification. For example, overexpression of BMPs in the spinal cord increases the

Figure 1 Progenitor domains give rise to distinct cell types. (a) The ventricular zone is divided into progenitor domains based on the differential expression of specific genes. The ventral spinal cord is divided into five progenitor domains (p0–p3 and pMN) that give rise to distinct classes of mature neurons (V0–V3 and MN) that migrate to stereotypical locations and extend axons along specific pathways. Later in development, pOC domains form that gives rise to oligodendrocytes (OC) that disperse throughout the spinal cord. In the dorsal spinal cord, six progenitor domains (dp1–6) give rise to six early-born (dI1–6) and two late-born (dIL^A and dIL^B) classes of interneurons which migrate laterally to stereotypic positions. Where known, the axonal projections are indicated. RP, roof plate; FP, floor plate. (b) In the ventral spinal cord, gene expression patterns are established by a low dorsal to high ventral concentration of shh. Progenitor transcription factors fall into two classes: class II factors (black bars) that are induced by shh and class I factors (gray bars) that are repressed by shh. The shh gradient thus leads to cells expressing a unique combination of progenitor factors. In addition to the graded responses to shh, progenitor factors exist in cross-repressive pairs that are incompatible with co-expression in the same cell, causing discrete boundaries between progenitor domains to form. In the dorsal spinal cord, progenitor domains are classified into two subtypes, the roof plate-dependent class A (dI1–3) and roof plate-independent class B (dI4–6 and $dIL^{A/B}$) neurons. bHLH factors have prominent roles for patterning the progenitor domains in the dorsal spinal cord, whereas homeodomain factors are more common ventrally. Similar to the ventral spinal cord, cross-repression (between Mash1, Ngn1, and Math1) is an important mechanism delineating progenitor boundaries. Other progenitor factors are also shown.

number of dI1 progenitors and interneurons at the expense of other interneurons, whereas inhibition of BMP signaling by expression of the BMP antagonist noggin or inactivation of both BMPr1a and BMPr1b receptors results in reduced numbers of dI1 and dI2 interneurons. Interestingly, dI3 interneurons are still generated in these BMP receptor, mutants, consistent with recent findings suggesting that activated activin receptors promote dI3 interneuron fate independently of BMP signaling. The wnts appear to have complementary functions to those of the TGF-β family, as *Wnt1*/*Wnt3A* double-mutant mice also exhibit defects in dI1–3 interneuron specification.

Negative Gene Regulation: Cross-Repression and Derepression

One of the key features establishing D/V identity in the neural tube is the proper interpretation of the graded shh signal into decisive differentiation programs for cell fate specification, even under conditions when cells reside at the signaling threshold for two different fates. The strategy used by progenitor cells appears to be based on the genetic interactions that take place between the numerous downstream transcription factors that become expressed in progenitor cells. Transcription factors expressed by adjacent progenitor cell populations have been found to repress one another's expression, a process referred to as cross-repression. Class I factors repressed by shh oppose the expression of class II factors induced by shh in adjacent cells, and similarly class II factors repress adjacent class I factors (Figure 1(b)). Thus, mutations in one factor of a cross-repressive pair leads to an expansion of the opposing factor into an inappropriate cell domain. This alteration results in misspecification of neuronal cell fate from the altered precursor cells in the progenitor domain. The cross-repressive interactions between progenitor cell transcription factors likely help to ensure that cells do not acquire mixed or hybrid characteristics even at the progenitor boundaries.

In the dorsal spinal cord, cross-repressive interactions between basic helix–loop–helix (bHLH) class transcription factors such as Math1, Ngn1, and Mash

1 delineate progenitor domains in a manner that is analogous to the homeodomain factors in the ventral spinal cord (Figure 1(b)). Similarly, studies of mouse mutants and gain-of-function experiments in chick embryos have established key roles for Ngn1, Math1, and Mash1 in the specification of dorsal neuron fate. Additional bHLH and homeodomain transcription factors such as Olig3, Gsh1, and Gsh2 are also expressed by dorsal progenitor cells, but do not appear to participate in cross-repression. Nevertheless, genetic experiments have established a role for Olig3 in dI1–3 cell specification and Gsh2 in dI3 interneuron development (Figure 1(b)).

It is likely that the chromatin modifications directed by the progenitor factors have a central role controlling cell fate specification in the developing spinal cord. The groucho/TLE cofactor physically interacts with many of the progenitor cell transcription factors and is essential for cross-repression. Eight of the 11 known transcription factors expressed by ventrally located progenitor cells have an Engrailed homology (eh1) domain that binds to groucho/TLE corepressors. The recruitment of groucho/TLE proteins to DNA inhibits gene expression by recruiting the histone deacetylase Rpd3/HDAC1. This enzyme catalyzes the removal of acetyl groups on histone tails, creating a chromatin structure that is less favorable for transcription. Thus, it is predicted that progenitor factors cross-repress the expression of neighboring progenitor factors by creating a multiprotein enzymatic complex that limits the accessibility of RNA polymerase and other factors needed for transcription.

The finding that progenitor factors are transcriptional repressors helps to explain how they prevent genes from adjacent cell domains from becoming expressed, but it raises further questions about how cells acquire unique identities using gene silencing as a mechanism. Although there is precedence for bifunctional transcription factors that can activate or repress gene expression based on their context, the cell fate specifying activity of the progenitor factors appears to be mediated entirely through transcriptional repression. Fusion of just the DNA-binding homeodomain of the progenitor factors to the eh1 groucho/TLE interaction domain of Engrailed generates constitutive repressors that are found to mimic the activity of the native progenitor factors. Because progenitor cell fate is regulated by gene silencing, it is thought that 'derepression' is important for proper expression of genes. The derepression model predicts that progenitor factors function by preventing the expression of inappropriate genes for alternative cell fates rather than activating the expression of genes for the development of a specific cell type. For this derepression model to work, however, it is thought that general (noncell type-specific) transcriptional activators are poised to activate genes for spinal neuron differentiation unless prevented from doing so by the recruitment of histone deactylases by progenitor factors. Expression of effector genes for a specific cell identity would thus be determined by the absence of binding sites for a particular progenitor factor.

Cell Specification Factors Downstream of Progenitor Factors

Although molecular differences are apparent in the profile of transcription factors expressed by progenitor cells within the ventricular zone of the spinal cord, the process of cell fate specification is best described as a sequential cascade in which progenitor factors control the expression of a second layer of genes that play active roles in regulating the phenotypic characteristics of the differentiating neuronal subtypes. Thus, many of the progenitor cell transcription factors are only expressed by cells within the ventricular zone and become downregulated as neuronal differentiation proceeds. Many of the downstream factors that become expressed in differentiating neurons represent additional homeodomain transcription factors. For example, V0 cells express Evx1, V1 cells express EN1, V2 cells express Chx10, MN cells express Hb9 and Isl1/2, and V3 cells express Sim1.

Gain- and loss-of-function experiments in mouse and chick embryos have helped to define the role of many of the downstream homeodomain transcription factors involved in specifying the phenotype of cells within the spinal cord. Some factors are essential for establishing the complete identity of particular cells, whereas other factors appear to regulate the expression of a subset of the phenotypic characteristics. In *Evx1* mutant mice, for example, V0 commissural interneurons extend axons ipsilaterally as if they have acquired the identity of V1 cells. Mutations in *En1* cause V1 neuron axon pathfinding defects and a slowing in the activity of the spinal locomotor circuitry involved in rhythmic stepping. The loss of En1 function, however, does not appear to be associated with a wholesale conversion in the identity of V1 cells to that of another cell type in the ventral spinal cord. Mutation of the *Isl1* gene expressed by motor neurons results in a block in motor neuron differentiation. As a consequence, the progeny of pMN cells abruptly apoptose in *Isl1* mutants rather than develop with an alternative cell identity. The loss of Hb9 function from motor neurons, in contrast, has a more subtle phenotype in which motor neurons still develop but they inappropriately express V2 interneuron genes. The hybrid motor neuron/V2 interneuron cells that

form in *Hb9* mutants are unable to extend axons to proper muscle targets in the periphery and as a result the animals exhibit severe locomotor defects.

Neurogenesis

Although progenitor cells exposed to roof plate- and floor plate-derived signals become predisposed to produce specific cell progeny, there is also an ancient evolutionarily conserved regulatory pathway that is superimposed on the process of cell specification which controls whether precursor cells continue to divide or begin their terminal differentiation. Gene expression for this regulatory check point termed neurogenesis is controlled by bHLH transcription factors. This family of proteins is defined by the bHLH signature motif consisting of 60 amino acids. The N-terminal 15 amino acids encompass the basic domain that binds to DNA. The remaining C-terminal domain forms a helix–loop–helix that functions as a dimerization domain that mediates the formation of homo- and heteromeric complexes. bHLH dimers bind to a DNA sequence called the E box (CANNTG) found in many neuronal genes. As noted above, the dorsal spinal cord expresses several bHLH transcription factors within the dI progenitor cells, and these factors exhibit cross-repressive interactions, cell fate-specifying attributes, and drive neurogenesis. Thus, a remaining question is to understand how each of these processes is regulated in a context-dependent manner.

The function of proneural bHLH factors is controlled at both the transcriptional and posttranscriptional level. Id-family proteins bind directly to proneural bHLH factors such as Mash1, Ngns, and NeuroD and generate non-DNA binding heterodimers. This inactivation occurs because Id proteins contain helix–loop–helix domains for dimerization but lack the basic region required for DNA binding. In addition, the transcription of proneural bHLH factors is negatively regulated by the Hes1 transcriptional repressor. Thus, in order for neurogenesis to proceed, Hes and Id must be downregulated and/or inactivated in progenitor cells to allow assembly of functional proneural bHLH complexes.

Once neurogenesis is initiated, the differentiation of neurons appears to involve the sequential activity of several bHLH factors that encompass the period when progenitor cells cease dividing, emerge from the ventricular zone as a postmitotic neuron, and mature into a specialized neuronal subtype. Developmental studies suggest that the proneural bHLH factors expressed transiently just prior to neuronal differentiation, including the Ngn family, Mash1, and Math1, initiate neurogenesis programs, while members of the NeuroD/Nex family are involved in the terminal differentiation and maturation of the cells. For example, Ngn2 overexpression decreases the proportion of proliferating progenitors and induces the expression of cell division kinase (CDK) inhibitors which stop the cell cycle, whereas NeuroD expression is more prominent in postmitotic neurons and coincides with their expression of pan-neuronal genes such as neurofilament.

Precursor cells are found to produce neurons at early stages and later give rise to glial cell derivatives. Thus, the check points that control neurogenesis have an important influence on the differentiation of cells within the spinal cord. Oligodendrocytes are produced from the pMN and dp4–5 progenitor domains, whereas astrocytes are generated from the other progenitor cell populations. The differentiation of oligodendrocytes from the pMN domain is initiated when Ngn2 expression is lost from the Olig2-expressing cells. The mechanistic basis for Ngn2's suppression of glial fate may be based on a process of transcription cofactor 'squelching.' This is predicted from the finding that the related factor, Ngn1, inhibits astrocyte formation by sequestering CREB binding protein (CBP), which is an obligate cofactor whose availability is needed in order to efficiently transcribe astrocyte genes.

LIM Networks in Postmitotic Neurons

Many different types of neurons within the spinal cord express LIM homeodomain (LIM-HD) transcription factors as they emerge from the ventricular zone and begin to differentiate. There are 12 LIM-HD genes in higher vertebrates, most of which are matched with homologs in invertebrates that have been shown to control cell fate specification. The regulation of LIM-HD expression in developing neurons remains poorly understood, but these factors are clearly downstream of the progenitor cell factors. Thus, the prevailing model of the transcriptional networks that operate in the neural tube posits that extrinsic factors such as shh and TGFβs regulate progenitor cell factors which in turn regulate the expression of LIM-HD genes, resulting in a sequential cascade of regulatory factors being expressed as development progresses.

A hallmark of the LIM-HD factors is the zinc-binding LIM domain found in their N-terminus. The LIM motif was first identified as a conserved structure in two *Caenorhabditis elegans* genes, *lin-11* and *mec-3*, and in the insulin enhancer binding protein *Isl1*. The LIM domain mediates protein–protein interactions with the cofactor nuclear LIM interactor (NLI). NLI is present in many cell types and possesses its own self-dimerization domain which allows NLI to drive the formation of complexes containing multiple LIM-HD proteins.

A critical finding regarding the LIM-HD factors was that they function in a combinatorial fashion to control cell fate. Although the expression of a single LIM-HD factor does not segregate with neuronal subtypes, the combinatorial expression of LIM-HD factors has been used to define distinct subtypes of neurons. Thus, individual members of the LIM-HD gene family are typically expressed by several neuronal subtypes within the spinal cord, but each neuronal subtype is often associated with a unique mix of LIM-HD proteins, referred to as the LIM code. During neuronal differentiation, LIM-HD factors appear to control several aspects of cell fate in a sequential manner. For example, as motor neurons develop from pMN progenitors, they express LIM-HD factors Isl1 and Lhx3 which specify a generic motor neuron phenotype. This early motor neuron LIM code is transient, however, and is soon followed by new combinations of LIM-HD factors that drive the further diversification of motor neuron identity leading to the formation of motor columns – a subdivision of motor neurons that corresponds to cells that settle together within the spinal cord and extend axons along common pathways in the periphery (Figures 2(a) and 2(c)).

The advantage of a LIM code is that diversity can be generated by mixing and matching a small number of elements; however, a by-product of a combinatorial code is that the elements are reused repeatedly. For example, Lhx3 alone contributes to V2 interneuron development, but Lhx3 combined with Isl1 triggers motor neuron formation. How do LIM-HD factors function in a combinatorial manner to control gene expression? The solution appears to be based on cell-specific protein–protein interactions mediated by the LIM domains. Within V2 interneurons, an Lhx3:NLI complex forms that regulates distinct target genes from the Lhx3:NLI:Isl1 complex that triggers motor neuron development. This example illustrates that the LIM domain is a critical determinant for controlling how LIM-HD factors regulate different cell fates in a combinatorial manner.

R/C patterning, Hox Genes, and Motor Pools

There are distinct classes of neurons that align along the R/C axis of the spinal cord in approximate coordination with the peripheral targets they innervate, ensuring for example that limb-innervating motor neurons are generated in register with the limbs. Motor columns form one of the basic units of motor neuron organization in the spinal cord, with distinct columnar subtypes innervating specific muscle targets. Lateral motor columns (LMCs), for example, are generated at fore- and hindlimb levels and innervate limb musculature, whereas autonomic motor neurons in the preganglionic motor column (PMC) form at thoracic levels (Figures 2(a) and 2(c)). Within motor columns,

Figure 2 The LIM and Hox codes define columnar and pool identity of motor neurons. (a) Schematic representation of the spinal cord showing the approximate location of the motor columns marked by unique combinations of LIM-HD factors (color coded). (b) An expanded view of the brachial spinal cord showing the relative position of several motor pools. The position of motor pools innervating the pectoralis (Pec) and flexor carpi ulnaris (FCU) muscles are determined by Hox5 (Hoxa5 + Hoxc5) and Hoxc8 expression. (c) Transverse sections of the brachial and thoracic spinal cord are diagramed showing axonal projections to muscle targets. d.m., dermamyotome; d.l.b., dorsal limb bud; v.l.b., ventral limb bud; s.g., sympathetic ganglia; b.w., body wall. (d) Within a motor column (in this case the LMC, red), motor pools emerge that connect to specific muscle targets. The intrasegmental distinction between FCU and Pec cells depends on the status of Hoxc6 in combination with other transcription factors.

motor neurons can be further subdivided into motor pools representing cells that form selective connections with individual muscles (Figures 2(b) and 2(d)). Although the LIM code plays an important role in assigning columnar identity, it is insufficient to account for the entire range of motor neuron subtypes. Hox-class homeodomain transcription factors play a major role in the further subdivision of motor columns into motor pools.

The Hox gene family is organized into four clusters in which the expression of the 3′-most genes is initiated at rostral levels of the CNS while the 5′-positioned genes are progressively expressed at more caudal regions. Exposure to retinoic acid (RA) is required for expression of more 3′ Hox genes, whereas fibroblast growth factors (FGFs) activate the expression of more 5′ genes. Recent studies have demonstrated that Hox protein expression segregates with motor neuron columnar and pool identity and that sequential phases of Hox protein expression are required to properly specify motor neuron subtype identity. The basis for this highly precise segregation in Hox expression is analogous to progenitor factors and is due in part to cross-repressive regulatory interactions among the Hox genes. The restriction of Hox proteins to specific motor pools is critical for establishing pool identity and proper muscle connectivity. Hoxc6, for example, is found in motor pools of the LMC that innervate the pectoralis muscle but not the flexor carpi ulnaris (Figures 2(b) and 2(d)). Consequently, misexpression of Hoxc6 causes a switch in motor pool identity leading to muscle targeting errors.

Large muscles are innervated by large motor pools and small muscles by small pools. An important feature of the Hox network is that the inherent strength of the cross-repression mediated by each Hox factor could potentially determine the size of the motor pool. Small motor pools might therefore be defined by weak repressors, whereas large pools could be generated using strong represses. In this way, the number of cells comprising the motor pool could be more accurately matched with the size of the peripheral muscle target.

Conclusions

One of the largest remaining questions in developmental neurobiology is how neuronal migration, axon guidance, and other crucial aspects of a neuron's phenotype are determined by the early gene regulatory events that occur as the neuron's identity is established. It is clear that there exists a sequential transcriptional cascade involving bHLH, homeodomain, LIM-HD, and Hox factors operating at multiple steps. In the first stage, as the neural plate folds to form the neural tube, progenitor domains within the ventral spinal cord are defined by the expression of homeodomain progenitor factors that are either induced (class II) or repressed (class I) by shh. In the second stage, the profile of the class I and II homeodomain transcription factors leads to the expression of determinants of neuronal subtype identity. In the third phase of the transcriptional hierarchy, neuronal subtype transcription factors including LIM-HD and Hox factors act in conjunction with neurogenic bHLH factors to coordinate pan-neuronal with subtype-specific programs of differentiation. Defining the full repertoire of target genes of these transcriptional networks may provide the link between neuronal cell identity and neuronal phenotype.

Transcriptional Silencing

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

Transcriptional silencing is the process by which regions of the eukaryotic genome, ranging from single genes to entire chromosomes, are made transcriptionally inactive through the reorganization of chromatin structure. Chromatin is the material in the nucleus of a eukaryotic cell comprising the nuclear DNA and all of the proteins associated with it. The bulk of this protein content is histones, basic proteins which package the DNA into nucleosomes, each nucleosome consisting of 146 bp of DNA wrapped around a histone octamer containing two copies each of the four core histones H2A, H2B, H3, and H4 (Figure 1). Linker DNA separates adjacent nucleosomes and is, in many species, associated with histone H1. There are also many other proteins in chromatin, including transcriptional activators and repressors, enzymes that modify DNA and histones, enzymes that cleave and repair DNA, components of the replication and recombination machinery, and proteins involved in higher order packaging. Under the microscope, this packaging is revealed by the presence of two different forms of chromatin – densely staining heterochromatin, which is for the most part transcriptionally inactive, and pale euchromatin, which is generally transcriptionally active. Transcriptional silencing reflects the fact that heterochromatic DNA is largely inaccessible to RNA polymerase and other components of the transcriptional machinery. Silencing differs from general transcriptional repression in that the former can extend over large regions of DNA, up to and including entire chromosomes, whereas the latter is specific to individual genes (or in some cases gene clusters). Silencing is also an epigenetic phenomenon which, once established, can be maintained passively through successive cell divisions, whereas gene-specific repression depends on the active maintenance of DNA–protein interactions within the promoter and other regulatory elements of the target gene. Transcriptional silencing is a natural phenomenon which is used to regulate gene expression during the development of the nervous system and as part of it normal function in adulthood. However, it is also used as a defense mechanism to protect the genome against invasive nucleic acids, such as transposable elements, viruses, and endogenous repeat sequences.

Mechanisms of Transcriptional Silencing

Histone Modification

Transcriptional silencing is generally achieved by the structural reorganization of chromatin, a process known as chromatin remodeling. In the brain, chromatin remodeling brought about by histone modification is fairly well characterized, and although much remains to be learned about the precise mechanisms involved, certain key events are now understood in detail. Histones are subject to various forms of reversible posttranslational modification, including the addition and removal of small chemical groups (acetylation, methylation, phosphorylation), larger chemical adducts (ADP-ribosylation), and small proteins (ubiquitylation, SUMOylation). Histones have a characteristic N-terminal tail which contains lysine and arginine residues and in some cases serine/threonine and glutamate. The lysine and arginine residues may be subject to acetylation and methylation, lysine residues may also be ubiquitylated or SUMOylated (SUMOs are small ubiquitin-like modifier proteins), the serine/threonine residues may undergo phosphorylation, and glutamate residues may undergo ADP-ribosylation. The roles of many of these modifications are unclear and may be context specific, but hyperacetylation usually corresponds to active chromatin whereas hypoacetylation correlates with inactive, silenced chromatin. It is thought that histone modification alters the affinity between histones and DNA, and/or between the histones within the nucleosome core, such that the DNA becomes either more or less accessible to the transcriptional machinery. Histone modification may also result in the specific recruitment of certain transcriptional activators and repressors, or proteins that sequester DNA into higher-order structures. There may well be a histone code, in which specific combinations of modifications contribute to defining a state of activity or inactivity which can persist through multiple rounds of DNA replication.

Histone modification is mediated by specific enzymes, and those controlling acetylation and methylation are the best understood. Histone acetyltransferases (HATs) catalyze the acetylation of lysine and/or arginine residues, and a number of known transcriptional activators have been subsequently identified as HATs. Histone deacetylases (HDACs) catalyze the removal of acetyl groups and associate with transcriptional repressors. The actual state of chromatin in any region of the genome depends to a large extent on the balance of these two opposing enzyme activities. In a similar way, the methylation of lysine or arginine residues is

Figure 1 Nucleosome structure showing 148 bp of DNA wrapped around a histone octamer consisting of two copies each of the four core histones H2A, H2B, H3, and H4. Reproduced from Tsankova N, Renthal W, Kumar A, et al. (2007) Epigenetic regulation in psychiatric disorders. *Nature Reviews Neuroscience* 8: 355–367, with permission from Nature Publishing Group.

promoted by histone methyltransferases (HMTs) and reversed by histone demethylases (HDMs), although the role of methylation in gene silencing is not always so clear-cut, as methylation may be associated with either active or inactive chromatin in different contexts.

DNA Methylation

The structure of eukaryotic DNA is remarkably invariant, but epigenetic regulation by DNA methylation constitutes an important exception. In mammals, DNA is methylated at the 5′ position of cytidine residues in the context of the dinucleotide sequence CpG. The methylation of DNA is catalyzed by DNA methyltransferases (DNMTs), which transfer the methyl group from an *S*-adenosylmethionine (SAM) donor. Generally, CpG dinucleotides are constitutively methylated and tend to mutate to TpG by deamination over evolutionary timescales, resulting in significant underrepresentation in today's mammalian genomes. However, those in promoters and other regulatory regions are relatively undermethylated, and therefore escape the evolutionary pressure to mutate, resulting in clusters of dinucleotides known as CpG islands, which have been used to pinpoint the location of genes in genomic DNA clones. Within such islands, the level of DNA methylation corresponds to the degree of transcriptional silencing.

As might be expected, patterns of DNA methylation correspond to patterns of histone modification that establish inactive chromatin. This is achieved through the presence of methyl-CpG-binding proteins

Figure 2 (a) Active chromatin (euchromatin) consists of loosely packed nucleosomes in which the histones are heavily acetylated (A) but are methylated (M) and phosphorylated (P) at low levels. This enables the basal transcription complex and coactivators (Co-Act) to assemble on the promoter, and transcription to commence. (b) Repressed chromatin (heterochromatin) consists of tightly packed nucleosomes in which histones are heavily methylated but are acetylated at low levels. Further repressor proteins (Rep) are also present. Reproduced from Tsankova N, Renthal W, Kumar A, et al. (2007) Epigenetic regulation in psychiatric disorders. *Nature Reviews Neuroscience* 8: 355–367, with permission from Nature Publishing Group.

(MeCPs) that associate with protein complexes containing HDACs and HMTs. DNA methylation, histone methylation, and histone deacetylation are therefore intrinsically linked in order to facilitate transcriptional silencing, establish epigenetic markers, and allow the silenced state to persist through DNA replication and cell division (Figure 2).

Other Chromatin Remodeling Mechanisms

In addition to histone modification, chromatin remodeling can be brought about by a number of other, less well-characterized mechanisms. One example is the phenomenon of histone replacement. Here, instead of modifying histones *in situ* to alter their affinity for DNA and components of the transcriptional machinery, one set of histones is simply swapped for another with properties that are more suitable. Another example is nucleosome sliding, an ATP-dependent process in which the histone octamer is transiently displaced,

allowing the transcriptional machinery to assemble at the promoter. Such repositioning of nucleosomes has been observed directly *in vitro* and is thought to be mediated by proteins of the SWI/SNF family.

Higher-Order Packaging and Nuclear Organization

A key difference between euchromatic and heterochromatic DNA is that the latter is folded into higher-order chromatin structures that maintain the DNA in an inaccessible state. This higher-order packaging is mediated by proteins that recognize the types of histone modification associated with inactive chromatin. For example, heterochromatin protein 1 (HP1) binds specifically to nucleosomes containing histone H3 methylated on lysine-9. A second mechanism for regulating access to the DNA then becomes evident and this involves the spatial positioning of genes within the nucleus. Interphase DNA in the nucleus does not diffuse about randomly, but is instead organized into discrete areas by attachment to the nuclear matrix. Labeling experiments have shown that chromosomes, and even small chromosome regions, tend to have a specific address, known as a chromosome territory, within the nucleus. Not much is known about the precise way in which the territories are established and occupied.

The nucleus is also organized into zones which are enriched with proteins that favor either transcriptional activity (active zones) or transcriptional silencing (inactive zones). Nuclear zones and territories are not aligned, and it appears that the zones are actually superimposed on the territorial organization so that they can incorporate whole chromosomes (e.g., the inactivated X chromosome in female mammals), contiguous chromosome segments, or even regions of similar transcriptional activity on different chromosomes which come together in the same locality. Thus, regulation of gene expression can occur at many levels involving the local chromatin environment, chromosomal territories, and the nuclear zones (Figure 3).

Recruitment to the different zones is mediated by protein–protein interactions, as illustrated by HP1, which not only interacts with modified histones but also with components of the nuclear envelope, thereby positioning heterochromatin within the inactive zone at the nuclear periphery. Specialized DNA elements known as insulators or boundary elements are thought to separate adjacent chromatin regions and allow them to occupy different zones, perhaps by binding to the nuclear matrix and preventing the propagation of heterochromatin structures from one domain to the next (see later, discussion of position effects).

Figure 3 Nuclear organization: the nucleus contains territories (light gray) and silencing zones (dark gray periphery). Histone acetylation (Ac) is shown over active chromatin, while hypoacetylation is associated with inactive chromatin, such as that found at centromeres (black circle) and telomeres. Small domains within a chromosome can acquire properties similar to those of heterochromatin and form a silencing zone (shaded circle). Silencing factors (green and blue shapes) are involved in chromatin compaction, gene silencing, and tethering to the nuclear periphery. Insulator elements (red triangles) partition chromosomes into transcriptionally related domains and assist in zonal organization. Reproduced from Tsankova N, Renthal W, Kumar A, et al. (2007) Epigenetic regulation in psychiatric disorders. *Nature Reviews Neuroscience* 8: 355–367, with permission from Nature Publishing Group.

Events That Trigger Transcriptional Silencing

Endogenous Signaling Pathways

Transcriptional silencing is widely used during the development of the nervous system to maintain states of determination and differentiation as permanent developmental decisions. It is also becoming apparent that transcriptional silencing is used in mature neurons as a mechanism to implement long-term changes in response to external signals. Most brain disorders are characterized by dysregulation of gene expression, resulting in long-lasting effects on behavior. However, such observations clash with what is known about conventional gene regulation, as well as with evidence from animal models showing that the levels of transcription factors and other regulators return to normal within hours or days of perturbation, yet abnormal behavior persists. The possibility that epigenetic mechanisms such as the imposition or lifting of transcriptional silencing could mediate these long-term changes is therefore an attractive one, and a number of neuronal signaling pathways have been shown to fit with this idea. For example, the transcription factor cyclic AMP response element-binding protein (CREB) is phosphorylated on a serine residue by extracellular signal-regulated kinase (ERK) in response to signals that elicit either cAMP or Ca^{2+} as second messengers. Phosphorylated CREB can then recruit CREB-binding

protein (CBP) into a complex, and the intrinsic HAT activity of CBP acetylates histones, making the target gene transcriptionally active. In hippocampal neurons, increases in intracellular Ca^{2+} lead to the activation of Ca^{2+}/calmodulin-activated protein kinases (CaMKs), which phosphorylate class II HDACs. This phosphorylation triggers the shuttling of the enzyme out of the nucleus and results in increased histone acetylation. In both cases, the epigenetic mark for transcriptional activity would persist until erased by HDAC activity.

It is also interesting to note that certain neuroactive drugs are known to induce rapid changes in histone modification. For example, cocaine induces the acetylation of histone H4 and the phosphoacetylation of histone H3 in the promoter of the immediate-early gene c-*fos*. This occurs specifically in the striatum, which mediates the behavioral effects of cocaine.

DNA Rearrangement and Integration

In addition to being a significant feature of normal gene regulation, transcriptional silencing can also occur due to abnormal or unanticipated events. In chromosome rearrangements such as inversions and translocations, DNA at the breakpoint is often subject to what is known as a position effect, where active genes can undergo transcriptional silencing due to the spreading of inactive chromatin. This occurs because the breakpoint brings active and inactive chromatin into juxtaposition without the normal insulator or boundary element to separate them into distinct nuclear zones. What then occurs is down to chance, reflecting the extent of histone modification activity and the abundance of heterochromatin proteins available in the nuclei of different cells. A well-characterized model is the developing eye of the fruit fly *Drosophila melanogaster*. Under normal circumstances, the *white* gene (which encodes an enzyme involved in pigment synthesis and therefore confers the normal red eye color when active) is located far from any heterochromatin. A rare chromosomal inversion brings the *white* gene much nearer, and removes an insulator which normally keeps the heterochromatin restricted to its own zone. The heterochromatin then spreads along the chromosome depending on the availability of the necessary components and enzymes. In some cells of the developing eye, the heterochromatin fails to reach the relocated *white* gene, which remains active. In others, it spreads through the *white* gene and inactivates it. Since the epigenetic mark is heritable, each cell gives rise to a clone of cells in the adult eye, which becomes either a white or red patch. The overall eye is therefore mottled, or variegated, a phenomenon known as 'position effect variegation.'

Positional silencing can also occur when DNA integrates into a heterochromatic region, although it is necessary to establish whether the absence of gene expression is genuinely because an intact transgene has integrated into inactive chromatin, or whether the integration event has resulted in transgene rearrangement or mutation.

Repetitive DNA

Repetitive DNA sequences (both endogenous sequences and transgenes) are often subject to transcriptional silencing because they act as nucleation centers for heterochromatin formation. This occurs both at tandem repeats, such as those found in the centromeric region of chromosomes, and at dispersed repeats, such as transposable elements and integrated transgenes. In some cases, repeated sequences may trigger heterochromatin formation because they attract sequence-specific DNA-binding proteins which are in turn recognized by HDACs or DNMTs, or proteins such as HP1. In yeast, for example, repetitive DNA sequences found at the telomeres are recognized by the DNA-binding protein Rap1, which interacts with components of the heterochromatin machinery and ensures localization at the nuclear periphery. Since mammalian transposable elements and transgenes are diverse in their sequences, it is unlikely that a sequence-specific mechanism is involved and suggests that the cell possesses some kind of mechanism for sensing repeated DNA sequences and targeting them. Models have been proposed based on the formation of DNA–DNA pairs that act as nucleation sites, as well as models involving the production of aberrant RNA species, invoking the RNA-mediated interference (RNAi) pathway (see later).

Invasive DNA

Transgene silencing can occur even following the integration of a single-copy gene at a euchromatic site, suggesting that cells can under some circumstances recognize integrating DNA sequences as invasive and deal with them by sequestering them into heterochromatin following *de novo* DNA methylation. It is possible that cells possess some form of genome scanning apparatus that looks for sequences with unusual base composition compared to the surrounding genomic context. The same mechanism is probably responsible for the *de novo* methylation of integrating human immunodeficiency virus (HIV) genomes, and vectors based thereon, as well as retroviral vectors used to introduce transgenes into mammalian embryos. Prokaryotic DNA appears to be a strong trigger for *de novo* methylation, since the co-integration of vector backbone sequences (which are

generally of bacterial origin) often leads to silencing, whereas clean DNA sequences (just the promoter, coding region, and polyadenylation site) are more successful. It is also possible that invasive DNA somehow induces the RNAi pathway (e.g., through the expression of aberrant RNA species from integrated transgenes, or through the generation of double-stranded RNA intermediates during viral replication).

RNA Silencing

Small RNA molecules can also silence gene expression, but generally do so posttranscriptionally, either by cleaving homologous mRNA molecules (RNA interference) using short interfering RNAs (siRNAs) or by regulating translation (micro-RNAs). However, the RNA silencing apparatus also has significant interactions with chromatin proteins, including histone-modifying enzymes and DNA methyltransferases. Recent evidence has accumulated that the RNAi machinery can set epigenetic marks in *Drosophila* and mammalian cells. Although the mechanisms involved are complex and yet to be elucidated fully, it appears that repetitive regions of the genome such as tandem repeats and transposons (and perhaps integrated transgenes) can generate long double-stranded RNA molecules, which are processed into siRNA-like structures known as repeat-associated siRNAs (rasiRNAs). These are cleaved by the enzyme Dicer to form complexes known as RNA-induced initiation of transcriptional silencing (RITS); these complexes mediate histone modification and DNA methylation.

Nervous System Transcriptional Silencing

Transcriptional Silencing in Neural Development

Transcriptional silencing is used to establish and maintain cell fates in the developing nervous system and, most importantly, to suppress neuronal fates in nonneuronal cells. Embryonic cells and their derivatives have the potential to differentiate into neural cells if grown in the correct conditions (e.g., mouse P19 embryonal carcinoma cells will differentiate into neurons in the presence of retinoic acid), so it is apparent that this developmental lineage must be suppressed in normal development. There is evidence that this is achieved through chromatin remodeling, since HDAC inhibitors can induce neural differentiation in embryonic cortical cells and suppress the differentiation of oligodendrocytes. A more specific example is the neuron-restrictive silencing factor (NRSF), a transcriptional repressor expressed in glia and other nonneuronal cells. The function of NRSF is to repress neuronal differentiation; NRSF associates with a number of other proteins, including transcriptional repressors and the histone deacetylase HDAC2. In this way, the promoters of neuronal genes are maintained in an inactive state in nonneuronal cells. NRSF is also expressed in some neurons later in development, when its function is to regulate the activity of neuronal genes.

Transcriptional Silencing in Mature Neurons

Transcriptional silencing is also used to control gene expression in mature neurons, and a particularly striking example is the regulation of the *BDNF* gene (encoding brain-derived neurotrophic factor). The organization of this gene is very unusual in that there are at least nine distinct promoters, each paired with a unique noncoding exon. When the gene is expressed, one of these noncoding exons is spliced onto a common coding exon to generate one of at least nine possible mature transcripts. The promoters are independently regulated and have different levels of activity and different expression patterns, allowing BDNF to be expressed in different patterns depending on which promoter is activated by a given external signal. This activation is mediated by chromatin remodeling. For example, acute membrane depolarization in mouse cells releases intracellular Ca^{2+}, which results in the activation of Ca^{2+}/calmodulin-activated protein kinase II, causing the phosphorylation of MeCP2 and favoring transcription from promoters P1 and P4. In rats, electroconvulsive seizures or *in vivo* administration of pilocarpine increase histone H4 acetylation at promoter P2, strongly elevating transcription from this promoter.

Transgenic Models of Neurodegenerative Disease

C Li, Weill Medical College of Cornell University, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

The rapid advances in human genetics have been accompanied by a major increase in transgenic animal research for the purpose of neurodegenerative disease study. It is impossible to cover all the transgenic models, their phenotypical analyses, and their usage in this research field. It is also unnecessary to do so because for any particular neurodegenerative disease of interest, a simple search in PUBMed or websites of pertinent disease research foundations will lead to many excellent review articles that are constantly being published with updated information. Therefore, this article introduces the transgenic approach rather than the particular animal models *per se*, explains the underlying principles of the transgenic approach, and compares different transgenic approaches and their advantages and disadvantages. For this purpose, only a small subset of the animal models are presented here.

The development of transgenic animal models has been closely linked to the revolution in human genetics. Most neurodegenerative diseases have either a genetic inheritance component or are purely genetic. Some examples of the former include Alzheimer's disease (AD), Parkinson's disease (PD), and amyotrophic lateral sclerosis, with approximately 10% of patients carrying genetic mutations. Examples of the latter include Huntington's disease (HD) and spinocerebellar ataxia type 1. For the purely genetic diseases, the reason for establishing and studying genetic animal models is self-explanatory. For diseases that are mostly sporadic and are only 10% genetic, why do we put such a major effort in studying the genetic forms of the diseases? First, although many changes or abnormalities have been found from studying the sporadic forms of diseases, in general it is difficult to determine whether these abnormalities are causal, innocuous, or compensatory. In other words, these abnormalities may be pathologic rather than pathogenic. In genetic forms of the diseases, the 'first pushes' of the disease pathogenesis have been unequivocally established – the mutations in disease genes. Thus, the subsequent research, albeit long and arduous, has a firm foundation in logic. Second, the pathogenic mechanisms of genetic forms of the diseases may shed light on the sporadic forms because the pathogenic pathways may converge at some points.

For the previously mentioned reasons, the study of purely genetic neurodegenerative diseases or the genetic forms of neurodegenerative diseases has been the focus of many researchers. In this line of work, although studies at molecular, cell culture levels are important, genetic animal models are clearly one of the most important tools for research.

The genetic diseases have two subtypes: recessive inheritance, which requires both chromosomes to be mutated, or dominant inheritance, which requires only one mutant allele. The former is usually caused by loss of function of gene products, and the latter is commonly caused by gain of function, hyperfunction, or haploinsufficiency. In neurodegenerative diseases, both types are common. For example, in PD, Park 1 and Park 8 have dominant inheritance due to the mutations in α-synuclein and LRRK2 genes, whereas Park 2, Park5, Park 6, and Park 7 have recessive inheritance due to the loss of function of Parkin, UCHL-1, DJ-1, and PINK 1, respectively.

To model these different types of genetic deficits, a variety of methods have been developed. For genetic loss-of-function mutations, researchers commonly use the gene targeting (i.e., knockout) approach in which the gene of interest is deleted from the genome of experimental animals. For genetic dominant diseases, scientists may choose the transgenic approach in which a mutated gene is introduced into the genome of experimental animals. Since the gene targeting approach is explained elsewhere in this encyclopedia, this article focuses on the transgenic approach. It is worth noting that many organisms have been used to generate transgenic models, including yeast, *Caenorhabditis elegans*, *Drosophila*, mice, rat, and sheep. The majority of work in neurodegenerative disease research, however, is mainly done in mouse because this experimental organism is a mammal with a brain structure similar to that of humans, and it is amenable to many highly sophisticated genetic engineering tools.

The generation of transgenic mice involves construction of DNA vectors carrying the gene of interest and subsequent microinjection of DNA vectors into fertilized mouse eggs. In a certain percentage of injected eggs, DNA vectors will integrate into the mouse genome as a transgene, and therefore transgenic mouse founder lines are obtained. It is important to note that the integration site of transgene is random, rather than targeted to the homologous chromosomal sites, and that the copy number of the transgene is random, ranging from a single copy to 100–200. A direct implication of the transgene random integration sites and variable copy numbers is that the expression of transgenes may vary widely among the founder lines, both in spatial and temporal

patterns and in abundance. The random insertion of transgene into mouse genome may disrupt other genes in some cases. Therefore, studies with transgenic mice usually require multiple transgenic lines to ensure that the phenotypes are authentically caused by the transgenes.

The choice of transgenes deserves some discussion. There are two options: a human gene with human disease mutations or the mouse homologous gene with human mutations. Empirically, the former works better in recapitulating the human disease. For example, in HD mouse models, the one carrying mouse Huntingtin with 111 CAG repeats developed much milder phenotypes than another model with human Huntingtin of similar CAG repeat. In α-synuclein mouse models for PD, human α-synuclein gene in transgenic mouse was able to recapitulate disease pathology, whereas mouse α-synuclein gene failed. Conceptually, the most straightforward explanation is that evolution has accumulated enough divergence that a mutation in human protein may or may not cause the same pathogenic conformational change in a mouse homolog. In fact, the human A53T mutation in α-synuclein caused Park 1, whereas in mice the 53T is a wild-type amino acid sequence. Hence, it seems that human genes are more appropriate for modeling human diseases in transgenic mice.

The methods of generating transgenic mice have evolved and become more powerful and versatile. Among the newer ones are bacterial artificial chromosome (BAC)-mediated transgenesis and inducible transgenic system. The traditional method uses a small plasmid vector with a capacity of less than 20 kb of DNA and with promoters such as prion, CMV, and Thy1. The small capacity precludes the regulatory elements such as enhancers, suppressors, and insulators that are all important for gene regulation. When the transgenes integrate into the mouse genome, they are influenced strongly by the adjacent chromosomal areas due to the positional effects that often cause misexpression of the transgenes.Compared to the traditional method, BAC-mediated transgenesis has several advantages. First, the conventional method accommodates only 10 to 15 kb DNA inserts, whereas the BAC vector accommodates up to 400 kb DNA as transgenes, which are large enough for most of the mammalian genes. Second, the large BAC capacity allows the transgene to be insulated from positional effects of insertion sites on the chromosome and to be regulated by its native promoters, enhancers, and suppressors; intron–exon structures; and 5′ and 3′ untranslated regions. Finally, the BAC method does not require assumptions about the splicing variant to be used as a transgene. BAC transgenesis has been used increasingly more often in neurodegenerative disease research.

Another powerful method is the inducible tet-on/tet-off system that allows inducible expression or suppression of transgenes. An elegant example of this method is provided by Yamamoto et al., who demonstrated the possibility of reversing pathology in HD mice by suppressing the expression of mutant Huntingtin.

It is clear that the transgenic mice are increasingly being used in modeling neurodegenerative disease. A further development is that in addition to mimicking the genotypes of human diseases, researchers are generating and using transgenic mice at a new level of sophistication. In an HD study, for example, mice with specific mutations in Huntingtin were made to test the role of proteolysis in HD pathogenesis, and mice expressing mutant HD in particular brain regions and cell types were used to address important questions of cell-autonomous versus non-cell-autonomous degeneration. Also reported are studies using transgenic mice to test genetic modifiers of HD. As a result of the collective efforts from many researchers, there are many transgenic mouse models for each neurodegenerative disease. The vast number of existing mouse models are powerful tools for researchers in this field.

However, despite the overall successful use of transgenic mice to model neurodegenerative diseases, it is a common problem that mice are much more resilient and often do not exhibit the cardinal phenotype of neuronal cell death. For example, in PD and AD research, mouse models were unable to recapitulate this most important aspect of pathology. To combat this obstacle, the transgenic rat approach may be a worthy alternative to create new opportunities. Although closely related in evolution, rats are different from mice and are closer to humans in many physiological aspects. In many pharmacological studies, rats have much more similar pharmacokinetics to humans. It is well-known that cardiovascular diseases are modeled in rats and are unable to be modeled in mice. In Huntington's disease modeling, rat models recapitulated striatal neuronal death with 57 CAG repeat length similar to human mutation, whereas mouse models needed much stronger insults of more than 150 CAG repeats to elicit mutant phenotypes. In chemical models for PD, rats are much more sensitive to rotenone than mice. In an α-synuclein study, viral expression of α-synuclein in rat substantia nigra resulted in loss of dopaminergic neurons, which was not observed in mouse models. These data indicate that rats may be more sensitive to some pathological insults than mice.

In summary, the transgenic animal approach has provided researchers unprecedented powerful tools

for mechanistic dissection of pathogenesis as well as development of therapeutics. The methodology, techniques, and usage of transgenics continue to improve. There is reason for optimism that deeper understanding of neurodegenerative disease pathogenesis will eventually help us fight these human diseases.

Transient Receptor Potential (TRP) Channels

D E Clapham, Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

What Are Transient Receptor Potential Channels?

Transient receptor potential (TRP) is the abbreviation used for naming the transient receptor potential family of ion channel subunits. The nomenclature originally referred to photoreceptors that exhibited a transient voltage response to continuous light exposure in a blind *Drosophila* mutant. This phenotype resulted from the loss of function of a TRP ion channel subunit in the fly photoreceptor. With the sequencing of many genomes and by sequence homology, TRP channel proteins have been identified in all species to date with the exception of bacteria. However, it is likely that homologs will eventually be found in these cells as well. In mammalian cells, TRPs are widely expressed in all tissue types but tend to be most highly expressed in epithelia and endothelia. The nervous system contains all known TRP channel types.

Mammalian TRP channels are encoded by six loosely related families of ~30 TRP genes. These families are grouped by homology and are named C, V, M, A, P, and ML, for canonical, vanilloid binding, melastatin related, ankyrin repeat, polycystin, and mucolipin, respectively (Figure 1). TRP ion channel subtypes are not named based on an endogenous ligand, function, or selectivity because these aspects are disparate within this family of proteins. With the current lack of knowledge about their functions, their unifying feature is simply homology of their transmembrane domains. Most are subunits of nonselective ion channels, allowing Na^+, K^+, and Ca^{2+} ions to permeate the membrane. Thus, when activated under physiological conditions, TRP channels depolarize cells and increase intracellular Na^+ and Ca^{2+}. Since intracellular Ca^{2+} is low under normal conditions (50–100 nM), the most significant change for the cell is an increase in intracellular Ca^{2+}. As is detailed in the following sections, intracellular Ca^{2+} changes have manifold biological consequences. The data shown in Tables 1–4 summarize the major known physiological, pharmacological, and biophysical properties of TRP channels (these data are also available online at http://clapham.tch.harvard.edu).

TRP Channel Selectivity and Gating

TRP channel subunits are currently presumed to have six-transmembrane (6TM)-spanning segments (S1–S6; Figure 2) and almost certainly assemble as tetramers around a central pore. In analogy to the high-resolution structure of the voltage-dependent K^+ channel Kv1.2, it is assumed that each single 6TM protein subunit is composed of two elements, a pore-lining domain (S5–S6) and a ligand/voltage-sensing domain (S1–S4). All four S5–S6 pore domains, one from each subunit, surround the ion-conducting pathway. Each of the four ligand/voltage-sensing domains is connected to the pore segments by a highly flexible linker that contacts the C-terminal end of the S6 helix. However, few studies have tested the assumption that TRPs have only 6TM domains, and hydropathy plots suggest some TRP channels may have additional transmembrane helices at the N- or C-termini.

The TRP Pore and Selectivity Filter

Based on high-resolution structures of K^+ channels, residues between the S5 and S6 transmembrane segments dip into the membrane and line the pore. For K^+-selective channels, K^+ ions interact with carbonyl oxygen atoms along the backbones of these amino acids. Currently there is no detailed structural information for Na^+, Ca^{2+}, or nonselective ion channels, but the principles are presumably similar. The unifying aspect of ion channel selectivity is binding of the ion in the pore; the ion is an integral part of the conducting pore and affects its conformation.

Three or four negatively charged amino acids – aspartatic (E) or glutamic (D) acid residues, each contributed by a separate domain – regulate selectivity by binding Na^+ or Ca^{2+} in the pore of Na^+ and Ca^{2+} channels. For Ca^{2+}-selective channels, Ca^{2+} binding to the pore is the critical determinant; when Ca^{2+} is removed from a solution, Ca^{2+} channels become nonselective cation channels. Ca^{2+} channels bind Ca^{2+} tightly in order to be highly selective, but this comes at the expense of rates of Ca^{2+} permeation.

In general, TRP channels are nonselective, with $P_{Ca}/P_{Na} \leq 10$, and with reversal potentials in the range from 0 to +20 mV. There are four known exceptions: TRPM4b and TRPM5 are Na^+ selective while TRPV5 and TRPV6 are Ca^{2+} selective (Tables 3 and 4). The pore loops of TRP channels are highly variable, and several are relatively long. The length of the S5–S6 linker may be related to unique adaptations of the 'turret,' the region extending above the plasma membrane in the extracellular space.

TRP Channel Gating

Gating is the conformational change in a protein that opens its ion conduction pathway. These protein conformational changes absorb or release energy.

Figure 1 Mammalian transient receptor potential (TRP) family tree. Evolutionary branch lengths in 'point accepted mutation' (PAM) units, the mean number of substitutions per 100 residues (DAG, diacylglycerol; PLIK, serine/threonine kinase). Adapted from Clapham DE (2003) TRP channels as cellular sensors. *Nature* 426: 517–524, with permission.

The lowest energy a protein can directly detect is the thermal energy limit of ~0.6 kcal/mol (a single photon of visible light per molecule is 60 kcal/mol). Ion channel conformational changes that result in gating require energies >1 kcal/mol, but are typically in the range of 5–50 kcal/mol. Energy changes leading to gating are imparted by voltage changes across the membrane, ligand binding, and temperature changes.

Channel gating is a stochastic process and is described by the Boltzmann equation. This equation describes the distribution of channels in the open and closed states at equilibrium. The fraction of open channels is $[1 + \exp(\Delta G/Nk_BT)]^{-1}$, where ΔG is the free energy of transition between the closed and open state, N is Avogadro's number, and k_B is Boltzmann's constant; $Nk_B = R$, the gas constant, and T is the absolute temperature. The free energy, ΔG, is the difference between the conformational energy change upon gating and the sum of energies transduced to the channel from external forces.

At resting membrane potentials (e.g., $V = -70$ mV), the closed state of voltage-sensitive channels is lower in energy than is the open state, and thus is the favored conformation of the protein complex. The cell is thus a battery that provides the inhibitory voltage that keeps the channel in its closed state. Depolarization (reduction of the transmembrane voltage) allows the channel protein to relax into its open (conducting) structural configuration. Classical voltage-gated ion channels (Ca_V, Na_V, and K_V) have several charged amino acids in their S4 transmembrane helices that sense and move in response to a changing electrical field. For these ion channels, the Boltzmann distribution of closed:open states changes over a narrow range of voltage. Strongly voltage-sensitive channels provide fast, decisive changes in transmembrane ion flow in response to changes in potential. The speed of the primary, regenerative pulse (action potential) of nerves and muscle depends on this sharp voltage dependence.

Ligand binding to a protein also imparts energy to induce conformational changes in channels (K_D values of 1 μM imply ~1–10 kcal/mol). Examples of ligands that open ion channels are extracellular

Genetic model or disease mutation	Mouse TRPA1 −/− No hearing defect Pain defect disputed	Polycystic kidney Disease (ADPKD) Mutations in TRPP1 in humans produce polycystic kidney disease, a progressive increase in cyst formation in the kidney. With an onset usually in middle age, it leads to progressive kidney dysfunction and failure. Also associated with cyst formation in liver and other organs. Mouse PKD2−/−	*krd* mice (P2−/− with other deletions in pax) Targeted DT-mediated disruption in taste cells in mouse	N.D.	Mucolipidosis IV is associated with mutations in TRPML1. For details, see 'Molecular Genetics', and 'Animal Model' in OMIM (Online Mendelian inheritance in man website supported by Johns Hopkins University and the NCBI; +252650)	N.D.	Varitint-waddler mouse (Va) A419P in 5th TM domain. Mice heterozygous for the varitint-waddler mutation are deaf and show varying degrees of circling behavior, head-tossing, and hyperactivity. Their coats are white with patches of normal-colored fur. The pathological changes in heterozygotes affect degeneration of the organ of Corti, stria vascularis, spiral ganglion, saccular macula, cristae ampullares, and vestibular ganglion. Viability of heterozygotes is nearly normal, but fertility is reduced. Mortality is very high in homozygotes, and very few of the survivors are fertile
Known functions	Senses various noxious stimuli: pungent natural compounds, noxious cold temperature, environments irritants, inflammatory peptides, noxious mechanical stimuli	Mouse cardiac, skeletal and renal development; kidney and liver cyst formation With PC2(PKD2) mechano-sensation in cilia (kidney)	Kidney development (mice) Acid sensing in sour taste, and potentially in acid sensing in the spinal cord along the central canal	N.D.	Cell vacuolar defects-probably defect in sorting/ transport in late endocytic pathway	N.D.	Hair cell, stereocilia maturation

Single channel conductance (γ) in pS	98 pS in physiol solns	~40 pS high Ca_0 (Luo et al.), ~50 pS 140K (Gonzalez) 90–115 pS in sym 50 mM Ba	130 pS (100 mM Na or 80 mM Ba) Ca>K~Na	300 pS?	83 (100 mM Na) LaPlante		

I–V shape	 Story et al. 2003	Polycystin 1+P2; Linear (Germino et al. 2000) 	~linear  From Chen et al. *Nature*	N.D.	N.D.	N.D.	N.D.
Tissue distribution	DRG, trigeminal ganglia, nodose ganglia, sensory nerve fibers (C-fibers), nociceptive neurons, inner ear, heart, small intestine, colon, lung, kidney, pancreas, skin	Wide distribution: kidney, pancreas, heart, testis, ovary, intestine, blood	High in fetal tissues including kidney and liver, downregulated in adult. Widely distributed, adult heart, skeletal muscle, brain, spleen, testis, retina	Testis Isoform 2/PKD2L2b is found only in transformed lympho-blasts whereas isoform 3/PKD2L2a widespread	Ubiquitous	Lymphocyte B cells	Hair cells of inner ear
Comments	TRPA1 is activated by covalent modification of intracellular cysteines, activation by bradykinin, may be activated by noxious cold but disputed, mechano-activation still under discussion. TRPA1 is modulated by extra- and intracellular Ca^{2+} decreased in fibroblasts after oncogenic transforma-tion; expression is upregulated by deubiquitina-tion by the tumor suppressor (ubiquitin hydrolase) CYLD	TRPP1 (PKD2) heterozygous and null mice develop polycystic kidney and liver lesions that are like those in humans. A 'two-hit' model was proposed to mimic mutations occurring in type 2 autosomal dominant polycystic kidney human disease. TRPP1−/− mice die *in utero* between E13.5 and birth, with defects in cardiac septation and cyst formation in maturing nephrons and pancreatic ducts. Adult TRPP1+/− for an unstable allele mimic the human development of renal cysts and eventual kidney failure with increased severity with modification of both PKD1 and TRPP1. Intracranial vascular abnormalities occur in TRPP1+/− mice with surgically-induced hypertension. Expression of PKD1 activates the JAK-STAT pathway, which in turn upregulates p21 (waf1) to arrest the cell cycle. Mutations that disrupt PKD1 interactions	No known association with human polycystic kidney disease. TRPP2 (PKD2L1) is deleted in the krd mouse which has defects in structures of kidney, retina, optic disc; however the krd deletion is a 7 cM transgene-induced deletion on chromosome 19 that includes the Pax2 locus	Probably testis-specific function	Role in sorting/transport in late endocytic pathway, defective in mucolipidosis type IV lysosomal storage disease		Mouse early-onset hearing loss, vestibular defects, pigmentation abnormalities

Tissue expression	Heart, brain, lung, liver, lesser expression in spleen, kidney, testis; widely expressed in brain, including CA3 region of hippocampus, and cerebellar Purkinje neurons	Vomeronasal organ in nose, (sensory villi)	Brain, pituitary, heart, lung, DRG	Heart, brain, pancreas, placenta, and kidney; inner granule cell layer of the rat olfactory bulb; hippocampus CA1/3, and dentate gyrus.	Brain, testis, kidney, uterus; hippocampal, cerebellar Purkinje neurons, mitral cells of olfactory bulb; hippocampal CA1/3 and dentate gryus cells	Heart, lung, kidney, muscle, intestine, stomach, pancreas, prostate, bone, brain, testis, ovary, and adrenal	Kidney, intestine, pituitary, brain, heart, lung, and eye
Comments	Most unique of TRPC sequences Complexed with TRPC4 or TRPC5, TRPC1 is activated after stimulation of Gq signaling pathways. Low concentrations of La3+ and Gd3+ enhance TRPC1/4 or C1/5 currents Stretch may activate endogenously	No function in human TRPC2b is major variant on mouse cell membrane (VNO) Putative role in erythropoetin-mediated Ca influx in erythroblasts	Generally accepted role for DAG activation	5-HT mediated release of GABA from thalamic interneurons is greatly reduced in TRPC4−/− mice Overall mouse phenotype not reported. Majority of evidence indicates that TRPC4b is receptor-operated Complexed with TRPC1, TRPC4 is activated after stimulation of Gq signaling pathways. When complexed with TRPC1, a current with a unique *I–V* relation is formed	G-protein-linked receptor operated channel as heteromer. I/V of heteromer is similar to NMDA class of ion channels (negative slope region), but unlike NMDA channels is not dependent on Mg voltage-dependent rectification. Not store-operated	Generally accepted role for DAG activation. Probable a1-adrenoceptor-activated channel in portal vein smooth muscle, as well as other vascular smooth muscle. PLC activation, OAG and thapsigargin stimulate delivery of channels to plasma membrane	Generally accepted role for DAG activation

Tissue expression	Skin; melanocytes and retinal pigmented epithelium	Brain; microglia, cerebellum, cortex, medulla oblongata, hippocampus, striatum, pancreatic B-cells, immune cells, PMNs, thymocytes, vascular endothelium	Kidney, pulmonary endothelium, cultured trigeminal neurons, liver, pancreas, ovary, testis, spinal cord Brain: dentate gyrus, lateral septal nuclei, indusium griseum, tenia tecti, epithelial cells of choroid plexus, human iris, retinal pigmented cells	Stomach, aorta, endothelium, esophagus, pancreas, kidney; glom., PCT, MTAL, DCT, CCD brain: widely expressed smooth muscle cerebral arteries	Tongue, taste tissue stomach intestines uterus testis	Small intestine, kidney	Ubiquitous	DRG, trigem ganglia, testis, prostate, bladder
Comments	Decrease in M1 RNA with melanoma progression. loss of melastatin expression correlates with the thickness of the melanomas	Increased $[Ca^{2+}]_i$ potentiates (EC_{50} 340 nM) Regulated by $[Ca^{2+}]_i$ probably via CaM, sensitizes TRPM2 to activation by ADPR, PARP-1 inhibitors (SB750 139>PJ34> DPQ) decrease activation of TRPM2 by oxidative stress. Catalase, dimethyl thiourea, mannitol inhibit TRPM2 activation by oxidative stress.	Independent of $[Ca^{2+}]_i$ insensitive to 1 μM RuR	Probably ubiquitous Voltage-modulated calcium-activated Decavanadate (2 μM) inhibits V dependence; Human; long variant TRPM4b 1214 AA, AF497623; short variant TRPM4a 1040 AA, first 174 AA lacking, AY046396; short splice variant TRPMc, 537 AA N-terminal lacking, AX443225 mouse: two short splice variants from brain AB112658, AB112657	Voltage-modulated Calcium-activated	Contains a protein kinase on its C terminus as part of the protein (chanzyme) Currently difficult to separate from TRPM7 current measurements	Contains a protein kinase on its C terminus as part of the protein (chanzyme). The kinase activity is not required for channel conduction. Overexpression results in cell death. Deletion also results in cell death in DT40 cells. Kinase domain phosphorylates Annexin 1	Correlated with trkA NGF receptors trp-p8 mRNA also expressed in primary tumors of prostate, breast, colon, lung, and skin. Loss of prostate trp-p8 mRNA e associated with shorter survival. trp-p8 may be androgen-regulated

Figure 2 Transient receptor potential (TRP) channel architecture, with emphasis on the pore and cytoplasmic domains. The permeation pathway (red arrow) is formed by four sets of S5 (blue)–S6 (green) transmembrane segments. Pore loops (not shown) linking S5 and S6 segments dip into the membrane to form the selectivity filter. The S4–S5 linker relays movements in the voltage-sensing S1–S4 ligand domain (gold ellipse) to the S6 gate (green, lower). The major domains in the N- and C-terminal polypeptide chains vary by subfamily. The TRP box contains the amino acids EWKFAR in TRPC, but is less conserved in TRPV and TRPM families. AnkR, ankyrin repeat; CIRB, putative calmodulin and inositol 1,4,5-trisphosphate receptor binding domain; EF hand, Ca^{2+} binding domain; NUDIX, ADP ribose/È-NAD binding domain; PLIK, serine/threonine kinase; PDZ, a domain binding to scaffold proteins. Adapted from Clapham DE (2003) TRP channels as cellular sensors. *Nature* 426: 517–524, with permission.

acetylcholine (nicotinic receptor channel), and intracellular Ca^{2+} (Ca^{2+}-activated K^+ channel). Ambient temperature and pH affect all proteins, and thus all ion channel gating. Remember that by inference from work on K_V channels, each 6TM domain can be broken down into two functional units, a voltage-sensing domain (VSD; S1–S4) and a pore/gating domain (S5–S6). The VSD acts as a ligand that floats in the plasma membrane and is tethered via the S4–S5 linker to the pore domain. This linker transfers force from the movement of the VSD to the pore domain. Our current understanding of channels with this architecture is that the S6 helix is not rigid, but rather has a flexible hinge. Movement of the VSDs pulls the lower halves of the hinged S6 helices, splaying them apart to open the conduction path (Figure 2). So, what moves the VSD? TRP channels contain few charged amino acids in the VSD, and are not gated by voltage changes alone. In general, TRP channels have a few charged residues scattered in S4 and in the S4–S5 linker, and are thus less responsive to voltage changes. Additionally, this weak sensitivity can be significantly shifted within the physiological voltage range. For example, the voltage at which TRPV1 begins to open is shifted by −10 mV for every 1 °C increase in temperature, while TRPM8 activation shifts −7 mV for every 1 °C decrease in temperature. Temperature-sensitive TRP channels have Q_{10} values (the change in current imparted by a 10 °C temperature change) up to 30, which is 10 times larger than is typical for enzymes or other ion channels. Through TRP channels, changes in ambient temperature depolarize neurons and are directly encoded to changes in firing rate. Some TRP channels

are sensitive to unique and characteristic temperature ranges, from cool (<20 °C; TRPM8), to warm (>30 °C; TRPV3, TRPV4), to hot (>40 °C; TRPV1).

Many ligands alter TRP channel gating. Capsaicin, the active ingredient in 'hot' peppers, activates the heat-sensitive TRPV1 channels by direct binding to the VSDs. Capsaicin applied to TRPV1-containing neurons activates TRPV1, depolarizes these neurons, and results in increased firing of action potentials. The brain incorrectly interprets this information as a rise in ambient temperature and initiates signals to cause vasodilation and sweating. Many other lipophilic plant compounds, such as menthol, carvacrol, allicin, and camphor, bind to the VSDs of other TRP channels. Presumably, these compounds have evolved in plant leaves and seeds to evoke sensations in animals, ultimately serving the plant's survival.

An area of interest in TRP channels is the interaction of the S4–S5 linker with a hydrophobic pocket on S6. If likened to a knee joint, the upper leg (voltage-sensing domain) acts through the knee joint (S4–S5 linker/S6 pocket) to lift the lower leg (S6) and open the gate. This 'joint' may be accessible to modulation by intracytoplasmic elements, such as phosphatidylinositol 4,5-bisphosphate (PIP_2). Also, domains adjacent to the C-terminus of S6 are common modulatory binding sites for TRP channels (Figure 2), and may lie in close apposition to the crucial junction between S6 and the S4–S5 linker.

In summary, TRP channel gating is initiated by changes in voltage, temperature, and ligand binding. What differentiates TRP channel gating from classical voltage-gated channels is the rough equivalence of these three influences in mediating the conformational change that opens TRP channels. Thus, TRP channels act as signal integrators that sum the energies imparted by voltage, ligands, pH, and temperature to effect gating. Highly voltage-sensitive channels (Na_V) behave more as transistors, which are simple voltage-dependent switches.

TRP Channel Protein Domains

Outside the core 6TM segments (the N- and C-terminals), there are no common domains shared by all TRPs (Figure 2). The proximal C-terminal 'TRP box' containing the sequence EWKFAR in all TRPC family members is less conserved in TRPV and TRPM subfamilies. The function of this domain is not established, although it may play a role in binding PIP_2. As in many Ca^{2+}-permeant channels, intracellular calmodulin (IQ motifs) and Ca^{2+}-binding motifs (EF hand, aspartate/glutamate motifs) are common. Ankyrin repeats are present in TRPC, TRPV, and TRPA N-termini, and may act as flexible linkers to cytoskeletal elements, or as protein interaction domains to auxiliary subunits. Most unique are the domains in the TRPM class, where TRPM2 contains a Nudix motif (binding β-nicotinamide adenine dinucleotide or adenosine diphosphate ribose), and TRPM6 and TPM7 contain functional serine/threonine kinases within the polypeptide chain. All but the kinase domains affect TRP channel gating, conferring conformational changes on the tetramer upon binding or unbinding. Coiled-coil domains present often in the N-terminus are implicated in tetrameric assembly. Postsynaptic density/disc/zonula occludens-1 (PDZ) domains, present in TRPC1, TRPC4, and TRPC5, may interact with scaffolding proteins that organize large protein complexes.

TRP Channels Are Linked to Phospholipase C

Many, if not all, TRP channels are greatly potentiated by phospholipase C (PLC) activity. In the 1980s, genetic approaches established that PLC was organized in a complex with TRPs in photoreceptors. Photons impinging on a chromophore in a photoreceptor initiate a conformational change in the receptor protein. The receptor in turn catalyzes G-protein nucleotide exchange to form active G_α-guanosine triphosphate and $G_{\beta\gamma}$ subunits. These G-proteins activate phospholipase Cβ (PLCβ) to hydrolyze PIP_2 into soluble (inositol 1,4,5-trisphosphate) and lipophilic (diacylglycerol) messengers (Figure 3). In mammalian cells, the G_α subtype mediating this cascade is usually $G_{\alpha q}$. Similarly, growth factor receptors also potentiate TRP channel activity via a different PLC subtype, PLCγ. In this cascade, a growth factor (e.g., epidermal-derived growth factor) initiates the dimerization, autophosphorylation, and association with adapter proteins linking to PLCγ. Both PLCβ and PLCγ have pleckstrin homology, Ca^{2+}-binding EF hand, and C2 domains; both PLCs translocate from cytoplasm to membrane to become active. PLCs hydrolyze PIP_2 to form diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). These two second messengers are capable of releasing many active signal transduction molecules. Additionally, PIP_2 binds many membrane-associated molecules and its hydrolysis thus changes these activities.

To date, there is no unifying mechanism for TRP (or even TRP subfamily) activation by molecules up- and downstream of PLC. Direct activation of TRPs by PLC has not been extensively tested. However, downstream of PLC, IP_3 does not activate TRP channels by itself, but rather binds the endoplasmic reticular IP_3 receptor and releases the universal

Figure 3 Signal transduction pathways common in transient receptor potential (TRP) channel activation or potentiation. signaling ion, Ca^{2+}, into the cytoplasm. The activities of several TRP channels are enhanced by increases in intracellular Ca^{2+} or Ca^{2+}/calmodulin.

DAG activates protein kinase C (PKC), which affects several TRP channel activities. DAG, a diester of glycerol and two fatty acids, is best known for its anchoring and activation of PKCs, but it also binds and translocates protein kinase D, Ras guanyl nucleotide-releasing proteins (RasGRPs), and DAG kinase γ. DAG-dependent signaling is terminated by its phosphorylation by diacylglycerol kinase (DAGK), to create phosphatidic acid. *Drosophila* TRP channels are activated by DAG, and photoreceptor TRP channels are constitutively active in DAGK-defective mutants. DAG may directly activate mammalian TRPC3, TRPC6, and TRPC7, and heteromers containing these subunits. DAG is also converted into arachidonic acid by DAG lipase. Arachidonic acid, a second messenger, is the source of a large cascade of active molecules. It is oxidatively metabolized by the prostaglandin endoperoxide H synthases to yield the prostaglandins, thromboxane, and prostacyclin, by lipoxygenases (LOXs) to form the leukotrienes, hydroxyeicosatetraenoic acids (HETEs), and lipoxins, and by cytochrome P450 to create epoxygenase-derived eicosanoids (EETs). Several of these lipophilic messengers have also been shown to increase the activities of some TRP channels (Tables 1–4).

Interestingly, growth factor receptors activate both PLCγ and phosphatidylinositol 3-kinase (PI3K). PI3K, a master signaling molecule of cell growth, is a dimer of an 85 kDa regulatory subunit and a 110 kDa catalytic subunit. Tyrosine phosphorylation of growth factor receptors enables docking of p85 on the receptor. The partner of p85 is p110, which is proximal to its phospholipid substrate on the membrane. Thus, growth factor activation activates signals that both hydrolyze and create PIP_2. PI3K is also activated by $G_{\beta\gamma}$ subunits, linking the growth factor and G-protein-coupled receptor pathways. PI3K activation appears to promote insertion of several TRP channels into the plasma membrane, and thus increases the potential net TRP current.

TRP Channel Function

Calcium

While a subset of TRP channels (e.g., TRPML) appears to primarily span intracellular membranes, most TRP channels allow Ca^{2+} to enter cells. They either directly conduct Ca^{2+}, or depolarize cells to activate other Ca^{2+}-permeant channels. Ca^{2+} was adopted during evolution to play an especially important role inside cells. Ca^{2+} precipitates phosphate and is thus tightly regulated within the cell; for a cell at rest, $[Ca^{2+}]$ is ~20 000 fold lower in the cytoplasm than outside the cell. Ca^{2+} is maintained at 50–100 nM concentrations in the cytoplasm by export to the extracellular space, or by import into specialized compartments such as endoplasmic reticulum (ER) and mitochondria. Readily bound by proteins, Ca^{2+} is inherently a localized second messenger. Proteins often bind Ca^{2+} within a cage of approximately six oxygens formed by glutamate and aspartate residues.

Ca^{2+} escapes the grasp of negatively charged domains only for an average of ~50 μS before being bound again. This decreases its effective diffusion coefficient from ~800 $\mu m^2 s^{-1}$ in water to less than ~100 $\mu m^2 s^{-1}$. Thus, Ca^{2+} signals are highly localized.

The Ca^{2+} ion triggers fundamental cellular actions such as contraction, secretion, motility, cell division, and cell death. Ca^{2+} can bind, activate, or initiate the translocation of hundreds of proteins, either by itself or through binding to calmodulin or other adapter proteins. Ca^{2+} apparently gates only the two monovalent mammalian TRP channels, TRPM4b and TRPM5. In contrast, it is likely that it modulates directly or indirectly all TRP channels.

PLIK, the Kinase of TRPM6 and TRPM7

Two ion channels are unique among TRPs, and indeed among all ion channels. TRPM6 and TRPM7 are TRP channels that conduct Ca^{2+} and Mg^{2+} divalents into the cell, and monovalents in the outward direction. But they also contain a functional serine/threonine kinase, the phospholipase-interacting kinase (PLIK) domain, at the end of the C-terminus. PLIK autophosphorylates the channel, but this appears to play no role in gating the channel. The function of this kinase in the life of the cell is still a mystery.

TRP Channel Function in the Nervous System

TRPs in Sensation

Temperature and plant compounds Several TRP channels undergo large changes in gating with small temperature changes, and are present in known pain-and temperature-sensing neurons. TRPV1 is the clearest example of a TRP that gates in response to heat. Moreover, capsaicin and acidic pH shift the temperature-sensing range of TRPV1. Capsaicin activates only a subset of primary afferent neurons, particularly those Cδ and Aδ fibers responsible for pain and warmth perception. TRPV1 is most highly expressed in small- to medium-diameter neurons in dorsal root, trigeminal, and nodose ganglia. TRPV1 knockout mice show impaired responses to heat (>~42 °C) and capsaicin-induced pain, consistent with TRPV1's localization. TRPV1 activity is also potentiated by G_q-coupled receptors and growth factors linked to PLC, perhaps explaining the pain-enhancing effects of bradykinin and nerve growth factor. Within sensory ganglia, TRPV2 is highly expressed in medium- to large-diameter neurons that give rise to Aδ and Aβ fibers, but is also less localized to the nervous system than is TRPV1. TRPV2 is insensitive to capsaicin but is activated by noxious temperatures.

TRPV3 and TRPV4, abundant in skin, mouth, and nasal epithelia, are activated by warmth (roughly above 30 °C). Interestingly, unlike most ion channels, TRPV3 current increases (sensitizes) upon repeated exposure to warmth. TRPV3 is also activated by camphor, carvacrol (oregano), and eugenol (cloves). TRPV4 is activated by hypoosmotic stimuli, endogenous metabolites of arachidonic acid, and phorbol esters. *TRPV4* deletion in mice alters central nervous system (CNS) control of ADH secretion. Both TRPV3 and TRPV4 knockout mice have prolonged withdrawal responses to acute peripheral heating and exhibit decreased thermal hyperalgesia following peripheral inflammation.

Cooling below ~25 °C activates TRPM8. Menthol shifts the activation range of the channel to room temperature, thus explaining the cooling sensation of mint. TRPM8 and TRPV1 are found in non-overlapping populations of small-diameter peripheral sensory neurons, leading to speculation that they mediate responses to mild heat and cooling, respectively. The broad tissue distributions of TRPM8 and TRPV1–TRPV4, and the osmotic sensitivity TRPV4, suggest that these channels may do more than just sense temperature.

TRPA1 is co-localized with TRPV1 in a subset of small- to medium-diameter peripheral sensory neurons. Pungent chemicals (isothiocyanates such as those found in mustard oil, wasabi, and garlic, as well as the smoke irritant, acrolein) activate this channel. Anandamide and tetrahydrocannabinoid (THC; the active ingredient in marijuana) induce current in TRPA1-expressing cells, suggesting they might be ionotropic cannabinoid receptors. TRPA1 was initially reported to sense noxious cold (<15 °C) *in vitro*, but this finding has been contested. Neurons still respond to cold sensitivity in mice lacking TRPA1, suggesting additional sensors for noxious cold.

Mechanical forces Ciliated structures act as levers to amplify mechanical forces. *Nanchung*, a member of the *Drosophila* TRPV family, localizes to the cilia of chordotonal neurons and is activated by pressure. Despite normal chordotonal organ morphology, mutants are deaf. *NompC*, a second member of the *Drosophila* TRP family is required for pressure-induced currents in sensory bristles, and may also be a mechanosensitive channel. Reduction of zebra fish *NompC*-like TRP impairs hair cell signal transduction, producing loss of sound sensation in the fish. TRPA1, like *NompC*, has many ankyrin repeats, suggesting that TRPA1 might be mechanosensitive in mammals. This led to the proposal that TRPA1 was the 'hearing' channel of the hair cell, but subsequent experiments showed that *TRPA1*−/− mice had

normal hearing. *In vitro* experiments have also led to the suggestion that TRPC1 is the stretch-sensitive ion channel commonly observed in oocytes.

Taste TRPM5 expresses at high levels in taste tissue and co-localizes with other known elements of the gustatory signaling pathway, including α-gustducin. The T1R and T2R G-protein-coupled taste receptors initiate a common signaling pathway involving PLCβ2 and TRPM5 to encode sweet, umami (amino acid), and bitter taste sensations. This finding indicates that TRPM5 is a common taste transduction element involved in relaying information from a subset of different taste receptors. Studies focusing exclusively on heterologously expressed TRPM5 indicate that the current is a voltage-modulated, monovalent-selective cation conductance that is activated by micromolar levels of intracellular Ca^{2+}. Receptor stimulation upstream of PLCβ2 (which co-localizes with TRPM5) generates IP_3 and thereby increases intracellular [Ca^{2+}] to a level that triggers ion flux through TRPM5.

TRPP2 is present in sour taste receptor cells of the tongue (circumvallate and foliate papilla), as well as in cells in the spinal cord central canal. This TRP channel of the polycystin family appears to mediate acid sensing in the tongue (sour taste), and potentially in cerebrospinal fluid.

Pheromone sensing Murine TRPC2 is essential for the transmission of pheromone-mediated signals. Male mice that lack TRPC2 do not display stereotypical male–male aggression responses and mate indiscriminately with male or female mice, resulting from a lack of pheromone-evoked neuronal activity in their vomeronasal organs (VNOs). Humans lack a discrete VNO and human *TRPC2* does not transcribe a functional protein (i.e., is a pseudogene), but other pheromone-sensing mechanisms may exist.

TRPs in the Brain

TRPs are widely distributed in the brain, with every TRP subunit being represented in at least one study. With the exception of the aforementioned sensory defects, few phenotypes have yet been described that result from CNS-specific deletion of TRPs.

Axons are guided to their targets in the nervous system by diffusible and cell-bound guidance cues. The neuronal growth cone is a palm-shaped structure at the tips of neurites that modulates the rate and direction of neurite extension in response to attractive and repellent cues. Attractive cues include netrin-1 and brain-derived neurotrophic factor (BDNF); myelin-associated glycoprotein and semaphorin 3A are repellant. Intracellular Ca^{2+} levels affect growth cone morphology and trafficking of membrane precursor vesicles. Thus, activation or block of TRP channels would be expected to have some effect on growth cones. In particular, TRPC1, TRPC3, TRPC4, TRPC5, and TRPC6-containing channels have been shown to affect neurite extension, growth cone morphology, and growth cone guidance in hippocampal, cerebellar granule, or spinal cord neurons. Synaptic vesicles move within individual growth cone filopodia and fuse with the plasma membrane after focal depolarization. Regulation of vesicle transport and fusion therefore represents an intriguing mechanism by which TRP channels can participate in steering growth cones or other chemotactic cells.

TRPCs may also underlie metabotropic glutamate receptor (mGluR)-dependent conductances in rat CA3 pyramidal neurons, midbrain dopaminergic neurons, and cerebellar Purkinje neurons. The mGluR-dependent currents in CA3 pyramidal neurons resemble currents from heterologously expressed TRPC1/TRPC5 heteromultimers. G_q activation also stimulates TRPC1/TRPC5 and this current shows a region of negative slope conductance, similar to the mGluR-dependent current observed in brain slice recordings.

Summary

TRPs are a large family of loosely homologous, broadly distributed ion channel proteins. They form homo- and heterotetrameric ion channels that span the plasma membrane; some also form channels across intracellular vesicular membranes. Despite initial enthusiasm, store-operated Ca^{2+} entry does not appear to be a TRP channel function. On the plasma membrane, TRPs are activated by a variety of mechanisms, including temperature, pH, voltage, chemical ligand binding, and mechanical forces. These surface channels depolarize cells and conduct Na^+, Ca^{2+}, and, in some cases, Mg^{2+} into cells. Many plant compounds activate TRPs, suggesting that plants evolved chemicals to repel or attract animals via these sensory channels. Vesicular TRP channels may serve to exchange cations to provide ionic balance as vesicles are loaded with various charged molecules. Many other mysteries remain, such as how TRP channels are gated, their function in vesicles and cilia, their links to neuronal guidance cues, and their roles in functions as disparate as central temperature regulation, pain sensing, smell, and stroke. TRP channels are intrinsically integrative cellular sensors of their environment.

Introduction

The localization and regulated translation of mRNAs within distinct subcellular compartments serve as an important mechanism for spatially regulating gene expression in asymmetric cells. Regulated translation of localized mRNAs provides a means of rapidly altering the macromolecular composition of a specific compartment in a cell and thereby decentralizes the regulation of gene expression from the nucleus to distinct subcellular compartments. This spatially restricted gene expression is likely to play an especially important role in neurons, where the thousands of synapses made by a single neuron are potentially capable of operating as autonomous compartments. Studies in a number of systems have defined roles for local translation during axon guidance, synapse formation, neuronal injury and regeneration, and synaptic plasticity. In each of these processes, local translation serves to persistently alter the structure and function of synapses in a spatially restricted manner.

Early ultrastructural studies of neurons indicated that polyribosomes were present exclusively in the soma of neurons, and these studies were used as evidence that all proteins were translated in the cell body and subsequently transported to distal compartments. An initial indication that translation might occur at synapses came from electron microscopy studies performed in the 1960s by Bodian, in which he observed clusters of polyribosomes at synaptic sites in monkey spinal cord neurons. Nearly 20 years later, in 1982, Steward and Levy published a report in which they also, using electron microscopy, detected clusters of polyribosomes selectively localized beneath postsynaptic sites on the dendrites of hippocampal granule cell neurons. This classic study captured the attention of the scientific community and focused attention on the possibility that extrasomatic protein synthesis might occur in neurons.

Davis, Steward, and Banker demonstrated in 1987 that RNAs were transported into dendrites of cultured hippocampal neurons, using radioactive uridine precursors to visualize RNAs. Together with the discovery of polyribosomes at spines, these studies provided further support for the idea that proteins might be synthesized in dendrites. A year later, in 1988, Garner, Tucker, and Matus published *in situ* hybridization studies clearly showing that the mRNA encoding microtubule-associated protein 2 (MAP2) was present in dendrites in developing (6-day-old) rat cortex and hippocampus, but that tubulin mRNA was restricted to the cell body. Two years later, in 1990, Paul Kelly and colleagues published striking *in situ* hybridization studies showing that the mRNA encoding the calcium/calmodulin-dependent protein kinase II alpha (CaMKIIα) localized to dendrites of adult rat hippocampus, while the mRNA encoding CaMKIIβ was restricted to cell bodies. Subsequent *in situ* hybridization studies showed that, while most mRNAs in the brain were present exclusively in the cell body, a select population of mRNAs was present in the dendritic compartment of vertebrate neurons. The restricted number of mRNAs present in neuronal processes was itself considered to be an attractive feature: presumably this population of mRNAs consisted of transcripts critical in some way to local synaptic function.

Not only were polyribosomes and mRNAs detected in dendrites, but a number of studies also indicated that many components of the translational machinery, including ribosomal proteins, initiation and elongation factors, as well as organelles (endoplasmic reticulum and Golgi apparatus) involved in the synthesis of membrane proteins, were present in dendrites. Taken together, these studies demonstrated that all the molecules required to synthesize new proteins are present in distal neuronal processes. As a result, the idea that local translation can occur is now widely accepted in the neuroscience community, and the focus of investigation has shifted from asking whether extrasomatic translation occurs in neurons to addressing the following questions: (1) Where does local translation occur – that is, presynaptically and/or postsynaptically? (2) What are the mRNAs that are localized? (3) How are the mRNAs localized? (4) How is their translation regulated? (5) What is the function of local translation?

The Sites of Local Translation in Neurons

Does local translation occur in all subcellular compartments of neurons? In the course of ultrastructural studies of hippocampal neurons growing in dissociated culture, Bartlett and Banker noted that while ribosomes could be detected in axons very early in development, they were restricted to dendrites at later time points. Performing *in situ* hybridization for specific mRNAs in cultured hippocampal neurons, Kleiman, Banker, and Steward also found that while

specific mRNAs were present in axons and dendrites at very early time points in culture, they were restricted to dendrites in more mature cultures. The conclusion from these and a number of subsequent studies was that in vertebrate neurons, presynaptic, axonal protein synthesis occurs during development, and that local translation is restricted to postsynaptic, dendritic compartments in mature neurons.

In the developing nervous system, polyribosomes, translation factors, and specific mRNAs have been detected in axonal growth cones of vertebrate neurons, including retinal ganglion cells and sympathetic, spinal cord, cerebellar, and cortical neurons. These mRNAs encode cytoskeletal elements, for example, β-actin, and signaling proteins that modulate the cytoskeleton, for example, rhoA. Studies using a variety of inhibitors have demonstrated that local translation in the growth cone is required for axon guidance and for synapse formation.

The evidence for local translation in mature axons is less complete, although there are indications that mRNAs may be translated in mature axons of some neuronal cell types. Specifically, translation in mature axons has been defined following an injury such as a sciatic nerve crush, when translation is thought to be involved in axonal regeneration. Ribosomes and/or ribosomal RNA have been detected in the adult rabbit and rat spinal nerve roots and in the axon of the goldfish Mauthner neurons, suggesting that translation can occur in these mature axons as well. Specific mRNAs have been detected in mature axons of particular neuronal cell types; for example, mRNAs encoding neurofilament proteins have been detected in the mature axons of goldfish Mauthner neurons, and mRNAs encoding neuropeptides (e.g., vasopressin) have been detected in adult rodent hypothalamo-hypophysial axons. Together, these studies hold open the possibility that axons of mature vertebrate neurons may retain the capacity to translate proteins.

Messenger RNAs and local translation have also been detected in the mature 'axons' of invertebrate neurons, including in the squid giant axon and in neurons from *Aplysia californica* and *Lymnaea*. Not only have ribosomes, translational machinery, and mRNAs been detected in these invertebrate axons, but metabolic labeling and reporter construct assays have also directly demonstrated that mRNAs can be translated in isolated axonal preparations. It is important to note, however, that the polarity of these axons is not as well defined as in the case of vertebrate neurons. Thus, for example, *Aplysia* neurons elaborate neuronal processes called neurites, which contain pre- and postsynaptic elements within a single process. As such, the existence of axonal translation in mature invertebrate axons may not translate directly to the existence of axonal translation in mature vertebrate axons.

That local translation occurs in postsynaptic dendrites of mature vertebrate neurons is now extremely well established. Many mRNAs have been detected in dendrites of rodent central nervous system (CNS) neurons. Translation initiation and elongation factors are present in dendrites and are activated, for example, by phosphorylation, following neuronal stimulation. Following up on Steward and Levy's 1982 description of polyribosomes at the base of spines in hippocampal granule cells, Harris and colleagues have performed serial section electron microscopic analyses of rodent CA1 hippocampal neurons to quantify the number of polyribosomes that are present at postsynaptic sites. Focusing on spines in CA1 pyramidal neurons in 15-day-old rat, they found that 12% of spines had polyribosome clusters present at the base or within the spine. Remarkably, following induction of long-term potentiation (LTP), the number of spines with associated polyribosomes increased to 39%. Furthermore, the spines with polyribosome clusters had larger postsynaptic densities than did spines lacking polyribosomes, suggesting that active translation served to alter the structure of potentiated synapses. Harris and colleagues have subsequently made similar observations in ultrastructural studies of mature (60- to 70-day-old) rat hippocampus.

What mRNAs Are Localized?

Initially, only a handful of mRNAs were thought to be localized, and these were identified primarily by chance in the course of *in situ* hybridization studies. The most striking result to emerge from such studies was the presence of specific mRNAs encoding cytosolic, cytoskeletal, and integral membrane proteins in dendritic layers of the hippocampus and at postsynaptic densities of hippocampal neurons *in vivo* and *in vitro*. These included mRNAs encoding MAP2, CaMKIIα, brain-derived neurotrophic factor (BDNF), activity-regulated cytoskeleton-associated protein (Arc), tyrosine kinase B (TrkB) receptor, L7 protein (in cerebellum), inositol trisphosphate (IP_3) receptor, the atypical protein kinase Mzeta, the *N*-methyl-D-aspartate receptor (NMDAR) NR1 subunit, and glycine receptor α subunit. Recent high-resolution *in situ* hybridization studies and studies using a variety of reporter constructs have revealed that a number of other mRNAs, including those encoding α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate receptor subunits and the potassium channel Kv1.1, are also present in dendrites of vertebrate CNS neurons.

Unbiased approaches to amplify mRNAs from mechanically or biochemically purified dendritic

and/or synaptic compartments have generated lists of localized mRNAs numbering in the hundreds. These experiments suggest that there is a large but select population of localized mRNAs, although wide acceptance of the dendritic localization of these mRNAs has been delayed by the lack of *in situ* hybridization demonstrating that the mRNAs are indeed present in dendrites. Conclusive identification of the entire population of axonally and/or dendritically localized mRNAs remains challenging both because of the difficulties of obtaining pure preparations of axons or dendrites and because of the difficulty of detecting the small quantities of mRNA that are localized in neuronal processes.

As described previously, the mRNAs that are localized to dendrites depend on the developmental state of the neuron, with mRNAs such as β-actin being present in the axonal and dendritic growth cones of hippocampal neurons, but restricted to the cell body of mature hippocampal neurons. The population of localized mRNAs also appears to be regulated by activity, such that a number of mRNAs have been found to localize to dendrites only following stimulation. These include *arc*, which not only translocates into dendrites but also accumulates specifically at stimulated synaptic sites, as well as *BDNF* and *trkB*. These findings suggest that the complement of mRNAs that is present in axons and dendrites is dynamically regulated by development and by activity.

How Are mRNAs Localized to Axons or Dendrites in Neurons?

Early studies used nucleic acid stains and green fluorescent protein fused to RNA-binding proteins to visualize mRNA translocation in live neurons. These studies showed that localized mRNAs are transported in the form of large granules containing mRNAs, RNA-binding proteins, ribosomes, and translational factors in a rapid (average speed $0.1\,\mu m\,s^{-1}$), bidirectional, and microtubule-dependent manner. As has been found to be the case in nonneuronal cells, mRNA localization in neurons has been shown to depend on *cis*-acting sequences, usually in the 3′ untranslated region (UTR), and on *trans*-acting RNA-binding proteins that bind to these sequences. Several groups have shown that the double-stranded RNA-binding protein Staufen is present in adult neurons and that it participates in the trafficking of mRNAs into dendrites. Staufen is proposed to be a component of RNA-containing granules, serving to mediate the transport of these granules along microtubules into dendrites. Bassell, Singer, and colleagues have identified *cis*-acting sequences, termed the 'zip code,' that mediate the localization of β-actin mRNA by binding to the zip code binding protein (ZBP)-1. ZBP1 is a member of the heterogeneous nuclear ribonucleoprotein (hnRNP) family of proteins that also includes hnRNP A2 and fragile X mental retardation protein (FMRP), both of which have been implicated in dendritic mRNA transport. Richter and colleagues have shown that in addition to its role in translational regulation, the cytoplasmic polyadenylation element-binding protein (CPEB) functions to facilitate mRNA transport to dendrites. Notably, disruption of ZBP1, ZBP2, Staufen, or CPEB impairs localization of targeted mRNAs, demonstrating a critical role for mRNA-binding proteins as molecular adapters between *cis*-acting mRNA localization sequences and microtubule-based transport machinery.

Recent studies have begun to characterize the RNA granules that carry mRNAs into dendrites. In a *tour de force*, Hirokawa and colleagues, using affinity chromatography with a kinesin antibody and proteomics, identified more than 42 proteins that constitute the large RNA-containing granule and showed that a subset of component proteins – hnRNP U, Staufen, purine-rich element-binding protein alpha (PURα), and pyrimidine tract binding protein-associated splicing factor (PSF) – are critical to dendritic RNA transport. Additionally, these investigators implicated the KIF5 isoform of kinesin as a motor involved in the active transport of RNA-containing granules into distal dendrites. Studying the composition of RNP particles that mediate transport of RNA in dendrites of *Drosophila* neurons, Ramaswami, Parker, and colleagues discovered that these 'RNA granules' share many components with RNA processing (P) bodies. Athough P bodies were initially described as sites of mRNA degradation, recent studies of micro-RNA (miRNA)-mediated translational regulation have indicated that P bodies are sites of translational silencing. These results suggest that RNA granules serve not only to transport mRNAs to distal sites in neurons, but also to keep these neurons in a dormant, silenced state.

How Is the Translation of Localized mRNAs Regulated?

The translation of localized mRNAs appears to be regulated by multiple mechanisms. Given the large number of mRNAs that have been identified as being dendritically and/or axonally localized, this is not surprising, since one would expect that distinct stimuli would activate the translation of distinct mRNAs via distinct signaling pathways. Furthermore, as specific mRNAs may contain multiple regulatory elements, the control of translation may place mRNAs in a unique position to act as coincidence detectors,

integrating several stimuli in order to regulate protein synthesis. In some studies, stimulus-induced translation of localized mRNAs has been shown to recruit rapamycin-dependent translational regulation, a mechanism involving regulation of translational initiation via the terminal oligopyrimidine tracts within the 5′UTR regions of specific mRNAs. Interestingly, mRNAs containing these tracts include many of the ribosomal proteins as well as translation initiation and elongation factors. Components of rapamycin-sensitive translation have been detected in dendrites of hippocampal neurons and in *Aplysia* synaptosomes. Stimulus-induced translation of localized mRNAs has also been shown to be mediated by regulation of cytoplasmic polyadenylation. For example, NMDAR stimulation has been shown to lead to phosphorylation and activation of CPEB, resulting in increased length of the polyA tail of CaMKIIα, and increased translation of the message. Edelman and colleagues, working in vertebrate neurons, and Sossin and colleagues, working in invertebrate neurons, have proposed that translation of mRNAs using internal ribosomal entry sites provides an additional mechanism for specifically regulating the translation of several localized mRNAs at synapses. Roles for miRNA-mediated translational regulation of localized mRNAs have also been recently discovered. In one study, Kunes and colleagues found that the mRNA encoding CaMKIIα was present in dendrites of *Drosophila* neurons and noted that the 3′UTR contained two putative miRNA binding sites, indicating that binding of miRNAs might function to repress translation. Consistent with this possibility, the learning-induced translation of CaMKIIα was associated with degradation of components of the miRNA machinery, suggesting that persistent generation of miRNAs was required to repress translation. Greenberg and colleagues identified a miRNA that binds to a localized mRNA, encoding LIM motif-containing protein kinase 1 (LimK1), and showed that modulation of the miRNA concentration altered LimK1 protein concentration, which in turn altered spine structure. In one fascinating study, Sutton, Schuman, and colleagues found that local translation in dendrites was negatively regulated by spontaneous neurotransmission. These results suggest that one function of spontaneous neurotransmission may be to sustain translational repression of localized mRNAs.

What Is the Function of Local Translation?

In this section, we focus on studies elucidating a role for local translation during synaptic plasticity in mature neurons. Local protein synthesis has been found to be essential for long-lasting forms of activity-dependent plasticity of hippocampal synapses. Specifically, Kang and Schuman found that hippocampal LTP produced by application of BDNF showed a rapid dependence on protein synthesis and occurred even after the cell bodies had been severed from the dendrites, indicating that the translation occurred in CA1 dendrites. Huber, Bear, and colleagues found that long-term depression (LTD) of hippocampal synapses induced by application of metabotropic glutamate receptors also showed a rapid dependence on protein synthesis (with no dependence on transcription), and furthermore that this LTD occurred in slices in which the dendrites had been severed from cell bodies. Studies from several groups have used reporter constructs to demonstrate that stimuli that elicit long-lasting forms of plasticity (such as LTP) also elicit translation within dendrites.

A role for local protein synthesis during synaptic plasticity has also been defined in *Aplysia* neurons. Using a cell culture system in which a single sensory neuron with a bifurcated axon makes synaptic contact with two spatially separated motor neurons, Martin, Kandel, and colleagues demonstrated that local application of the modulatory neurotransmitter serotonin to the connections made onto one of the motor neurons produced a branch-specific long-term facilitation of that connection without any change in the strength of the unstimulated connection. This branch-specific plasticity was shown to depend on the translation of mRNAs in the distal sensory neurites. Further investigation of this process indicates that local translation is required for the initial induction of branch-specific plasticity and that it is also required for the stabilization of new synaptic growth. Scherff, Carew, and colleagues have made similar observations studying synaptic plasticity in preparations of intact *Aplysia* ganglia.

The role of local translation during learning and memory in behaving animals has also been addressed in a number of studies. In the first, Miller, Mayford, and colleagues expressed a CaMKIIα transgene lacking the 3′UTR (which contains the *cis*-acting dendritic targeting sequences) in CaMKIIα null mice. Using this strategy, they succeeded in generating a mouse that expressed CaMKIIα but lacked dendritically localized CaMKIIα mRNA, allowing them to specifically assay the function of the dendritically translated enzyme. These mutant mice showed deficits in the late phase of LTP at hippocampal synapses and in long-term memory, demonstrating a role for local translation of CaMKIIα during long-lasting forms of plasticity and memory. Intriguingly, these studies also indicated that most of the CaMKIIα protein present in the postsynaptic density derives from locally synthesized protein, since removal of dendritic mRNA produced a dramatic reduction of CaMKIIα in the postsynaptic

density. Ashraf, Kunes, and colleagues found that CaMKIIα mRNA was present in dendrites of *Drosophila* neurons and that its translation was regulated by olfactory learning. Manipulations that prevented dendritic translation of CaMKIIα also inhibited learning, suggesting that local translation is required for learning.

Studies of mice lacking molecules involved in translational regulation have provided further support for the importance of local translation during learning and memory, although in these studies, translation is altered throughout the neuron. Klann and colleagues have studied mice lacking the eukaryotic translation initiation factor 4E (eIF4E) binding protein 2, which normally functions to inhibit translation by binding, in its unphosphorylated state, to eIF4E. When LTP was assayed in these mice, stimuli that usually produced transient LTP elicited long-lasting LTP, while stimuli that usually produced long-lasting LTP produced decreased LTP, suggesting that the increased basal rate of translation altered the threshold for LTP induction. In behavioral assays, these mice exhibited deficits in spatial learning and in long-term contextual conditioning. Sonenberg and colleagues observed a similar phenotype in mice lacking GCN2, a protein kinase that nhibits translational initiation by phosphorylating eIF2a. Interestingly, experiments by Naegerl, Bonhoeffer, and colleagues, as well as others, have suggested a balance between local synthesis and protein degradation and that perturbation of either process, using translational or proteasome inhibitors, led to deficits in late phase LTP, whereas perturbation of both processes rescued the impairment.

Conclusions

The concept of local translation at synapses in neurons has gained increasing acceptance over the past decades. Recent studies have outlined specific roles for local translation during axon guidance, synapse formation, injury and regeneration, and synaptic plasticity. Novel approaches have been used to identify localized transcripts and to elucidate the mechanisms whereby mRNAs are localized and whereby their translation is regulated by neuronal activity. Together, these investigations indicate that neurons are endowed with a remarkable capacity for rapidly regulating gene expression within spatially restricted subcellular compartments.

Myelin Pathologies That Could Be Targeted by Transplantation

Transplantation of myelin-forming cells is considered a potential treatment for leukodystrophies, multiple sclerosis, and spinal cord injury. Congenital myelin disorders such as leukodystrophies are characterized by genetic abnormalities resulting in a failure of proper myelin sheath formation (hypomyelination) and/or maintenance (dysmyelination). The mutations leading to hypomyelination target the genes encoding either proteins or enzymes involved in the development or maturation of oligodendrocyte precursors. One could therefore speculate that in some of these diseases introduction of genetically normal myelinating cells could correct the genetic deficit in myelination. Dysmyelination results from abnormal accumulation of metabolites due to enzymatic deficiencies. Therefore, transplanted cells may also serve as a vehicles for the delivery of normal enzymes to the endogenous cells, thus improving the functional deficit.

Multiple sclerosis (MS) is an inflammatory central nervous system (CNS) disorder characterized by disseminated demyelination and axonal loss. Although remyelination occurs during the early stages of the disease, it becomes progressively impaired with time, resulting ultimately in lesions consisting of chronically demyelinated axons. Taken into account that axonal loss is the leading cause of neurological disability characterizing MS patients and that normal myelin is required for axonal integrity, remyelination therapies would appear necessary to ensure the restoration of the appropriate axonal function for myelinogenic cell transplantation has been considered as a potential therapeutic approach. In addition to myelin restoration, further benefits of cell therapy for MS have been suggested since transplanted cells may contribute to axonal protection by suppressing ongoing inflammation.

Demyelination is also a feature of spinal cord injury (SCI). Even after severe insults, surviving axons persist in the subpial rim of white matter but exhibit demyelination and consequently dysfunctional conduction properties. Endogenous remyelination following SCI occurs very slowly, and it is not clear whether it ever reaches completion; thus, myelinogenic cell engraftment has been proposed as a means of myelin restoration and protection of denuded axons against subsequent degeneration. Engineering the transplanted cells to deliver growth factors associated with neural protection and regeneration to the lesion sites is being attempted to optimize the functional benefits of cell therapy for SCI.

History of Cell Transplantation for Central Nervous System Myelin Regeneration

Santiago Ramon y Cajal and Francisco Tello were the first to suggest that CNS axons may be myelinated by exogenous cells since they observed that these axons would enter the segments of the peripheral nerve implanted into the brain and subsequently become myelinated by peripheral myelin-forming cells, the Schwann cells (SCs). More than 50 years later, William Blakemore demonstrated that SC remyelination occurred following placement of peripheral nerve fragments over the areas of demyelination in the spinal cord, and a similar phenomenon was later described by Duncan and colleagues following engraftment of cultured SCs. Madeleine Gumpel and co-workers then showed for the first time that CNS fragment implantation could also lead to myelination by oligodendrocytes in myelin mutants, and this work was followed by experiments in which oligodendrocyte (re)myelination was achieved by transplantation of cultured CNS cells. During the 1990s, olfactory ensheathing cells (OECs) as well as neural and embryonic stem (ES) cells were added to the list of cellular candidates for graft-mediated remyelination therapies. Pluripotent stem cells derived from peripheral tissues have also been suggested as promising novel sources of myelin (Figure 1).

Although much of the work reported in this article is focused on exploring the therapeutic benefit of transplanted cells for myelin repair, these studies also stress the power of cell transplantation to unravel the biology of glial cells under developmental and pathological conditions.

Early transplantation experiments established models of dysmyelination/demyelination that were to be used in subsequent studies. However, several issues need to be considered when interpreting these experiments. First, the CNS has an intrinsic myelin regeneration capacity, and therefore a means of clearly identifying transplanted cells needs to be employed. Second, although certain leukodystrophies are reliably represented by animal models, no currently available models of MS mimic entirely the highly complex pathology of the disease. Also, important differences

Figure 1 History of experimental engraftment for myelin repair.

between species exist; therefore, validating the results obtained using rodents and other lower species in primate models will be a fundamental step toward developing clinical applications of engraftment for remyelination.

Experimental Models for Studying Graft-Mediated Myelin Generation

These models include the developing CNS, models of hypomyelination/dysmyelination, and models of induced demyelination in the adult CNS. What these have in common is the fact that a substantial proportion of axons are available for the progeny of transplanted cells to myelinate and therefore serve to assay the biology and repair potential of various cell preparations.

Normal Central Nervous System

Developing central nervous system Many studies have used the developing nervous system as a transplantation site for assessing the myelin-generating potential of introduced cells with cells injected into the CNS of embryonic day 19 embryos or newborn rat and mouse pups. These recipients represent a highly permissive environment for myelination because transplanted cells will be responding to developmental cues and therefore do not reflect a chronic disease situation. When using developing animals as recipients, graft-specific markers are essential to identify myelin formed by the transplanted cells.

Although engraftment into the adult forebrain does not offer the possibility to examine the myelinating potential of the grafted populations, cell injections into germinative sites such as the subventricular zone (SVZ) versus nongerminative areas have been performed in order to study the cell fate in terms of survival, proliferation, migration, and differentiation.

Retina Axons of retinal ganglion cells are not myelinated in cats, mice, and rats but can be myelinated in species such as human, dog, rabbit, and chicken. The nonmyelinating retina has been used as a model for graft-mediated myelination. The use of this model has highlighted the fact that CNS axons retain their capacity to become myelinated throughout life, therefore offering a paradigm to study mechanisms governing or promoting myelination. Nevertheless, it does not represent any of the pathological demyelinating or dysmyelinating conditions.

Animal Models of Hypomyelination/Dysmyelination

This group includes animals characterized by (1) aberrant myelin sheath production or maintenance due to a defect in myelin protein-related genes (myelin mutants) or (2) progressive myelin loss resulting from abnormal accumulation of metabolites due to enzymatic deficiencies (models of Krabbe's disease and metachromatic leukodystrophy).

Myelin mutants Since most myelin mutants are short-lived, transplantation is usually performed in developing animals. In the case of mutants with an extended life span (e.g., canine shaking pup), adult animals have been used as recipients. One of the advantages of these models is that myelin produced by the transplanted cells can be readily recognized

because of its normal composition. Myelin mutants are classified into groups according to the myelin protein-related gene affected.

Myelin basic protein mutants. The shiverer (shi) mouse, the most commonly used mutant for transplantation, and the Long–Evans shaker (les) rat lack myelin basic protein (MBP), which leads to uncompacted myelin sheath formation. The utility of these models lies in the easy identification of MBP-positive myelin sheaths when normal tissue is transplanted into the mutant CNS (Figure 2(a)). Shiverer oligodendrocyte processes associate with axons forming thin and uncompacted myelin, which after a few weeks of age may prevent transplant-mediated remyelination. Therefore, to achieve significant myelination by cell engraftment in mature animals, demyelinating lesions must be induced. Backcrossing of shiverer mice to immunodeficient NOD/SCID mice has been used to study the behavior of transplanted human cells since this procedure

Figure 2 Detection of graft-derived myelin. The utility of myelin mutants as myelinogenic graft recipients is that myelin formed by transplanted wild-type cells can be identified by its normal composition. overcomes the rejection of xenografted tissue. *Les* oligodendrocytes form poor myelin during the first 2 weeks after birth, and this myelin disappears by 4 weeks of age. These animals suffer from seizures causing spinal fractures, which limits their use for transplantation studies.

Proteolipid protein mutants. Some mutants have spontaneous defects in the proteolipid protein (PLP) encoding gene, mimicking those found in Pelizeus–Merzbacher disease (PMD) patients. This pathology is characterized by severe hypomyelination in the absence of significant inflammation. The animals belonging to this group include the jimpy mouse and its variants, the myelin deficient (md) rat and shaking pup. The jimpy mouse has a base pair substitution in the fourth intron of the PLP gene, leading to the death of most oligodendrocytes with few surviving cells synthesizing a small amount of myelin. Its life span is approximately 4 weeks. The *md* rat shows an almost complete absence of myelin sheaths and has a similar life span (23–25 days) as that of the jimpy mouse. However, a longer-lived strain surviving up to 75–80 days has been discovered. The shaking pup can survive up to 1 year with careful nursing, which is usually very expensive. Other PLP mutants modeling PMD are the rumpshaker (rsh) mouse, a paralytic tremor model in rabbit, and a congenital tremor in pig.

Transgenic animals overexpressing PLP have also been used for studying graft-mediated remyelination. Whereas homozygous mice have severe hypomyelination and a short life span similar to jimpy mice, heterozygous mice have a longer life span and may be used as recipients since they are characterized by normal myelination followed by progressive demyelination starting at approximately 3 or 4 months of age.

Mag-fyn knockout mouse. The null mouse for the myelin-associated glycoprotein, MAG, and the non-receptor tyrosine kinase of the Src family, fyn, is also hypomyelinated. The myelin sheath is abnormal and does not contain MAG. These animals have a normal life span and have been used as transplant recipients as either postnatal or adult animals.

The taiep rat. This rat is characterized by a microtubular defect in oligodendrocytes that results in a disruption of the normal myelination process in certain CNS areas and failure of myelin sheath maintenance elsewhere, leading to progressive demyelination. The pathology is reminiscent of the chronic areas of demyelination found in MS patients. Exploring the potential benefits of cell therapy in such a model is therefore of great interest. These animals survive until 17 months of age.

Dysmyelination resulting from metabolic mutations

Galactosylceramidase mutants. The animals with mutations in galactosylceramidase-encoding genes represent good models for Krabbe's disease or Globoid cell leukodystrophy (GLD). The characteristic pathological features of this disease are infiltration of macrophages containing periodic acid–Schiff (PAS)-positive materials ('globoid cells') in the CNS with concomitant demyelination. The animals belonging to this group are the twitcher mouse, a GLD dog, a saposin A-deficient mouse, a H168C mutated mouse, and a rhesus monkey mutant.

Arylsulfatase-A knockout mouse. The arylsulfatase (ASA) null mouse is a murine model of human metachromatic leukodystrophy. These animals display progressive sulfatide storage within the CNS, mild loss of myelin, and develop behavioral deficits in adulthood mimicking late infantile/early adulthood forms of the disease.

Induction of Demyelination in the Adult Central Nervous System

The models of induced demyelination include focal demyelinating lesions and induction of inflammatory pathologies associated with disseminated demyelination of the adult CNS.

Focal demyelination *Lysolecithin and ethidium bromide*. Focal demyelination areas can be induced in adult animals by injection of gliotoxic agents into predetermined white matter areas specifically killing glial cells but preserving the majority of the axons. The most commonly used toxins are lysophosphatidyl choline or lysolecithin (LPC) and ethidium bromide (EB). Lesions induced by LPC and EB show a limited amount of inflammation, usually associated with myelin debris removal, and have been used to answer basic questions regarding the remyelinating potential of different cell preparations. EB is a DNA intercalating agent which kills astrocytes, oligodendrocytes, and oligodendrocyte precursors. LPC is a membrane-solubilizing agent which has a particular toxicity for myelin but spares some oligodendrocytes and possibly some of their precursors. As a result, demyelination in EB lesions is more extensive and the remyelination process is slower than in the LPC model. Toxin-induced lesions do not result in behavioral deficits unless they are targeted to the cervical spinal cord. The advantage of these focal models is that the predetermined location of demyelinating lesions facilitates cell transplantation experiments. Cells can be placed either directly in a lesion to evaluate the remyelinating capacity of the preparation or at a distance from the lesion to examine migration. Xenograft rejection can be

bypassed, inducing focal lesions in immunocompromised animals such as nude mice or rats.

Focal lesions induced in rodents undergo spontaneous remyelination. In order to create a situation in which endogenous remyelination is absent, William Blakemore's laboratory at Cambridge University developed a model in which local X-irradiation (40 Gy) of the spinal cord prior to or soon after EB injection is used to deplete the oligodendrocyte precursors present in the tissue, abolishing endogenous remyelination of the lesion for at least 6 weeks. Use of this nonrepairing lesion model overcomes the need to employ graft-specific markers to evaluate remyelination potential of the engrafted preparation since any remyelination observed can be attributed to transplanted cells (**Figures 2(c) and 2(d)**).

Focal lesions induced in rodents are small compared to demyelinating lesions in humans. In order to obtain a better understanding of human demyelinating conditions, nonhuman primate models of gliotoxin-induced demyelination have been developed in which lesions are targeted to a variety of CNS structures. These models reveal that LPC injection leads to chronic demyelination in the macaque optic nerve but acute demyelination followed by partial remyelination in the spinal cord (**Figure 3**).

Cuprizone. Cuprizone intoxication of C57 black 6 mice results preferentially in demyelination of the corpus callosum. Although restricted to a specific structure in the brain, cuprizone lesions are far more widespread than the previously mentioned focal lesions. The advantage of this model is the possibility to achieve chronic demyelination by extending the treatment. Although appealing, this model has not been used for cell therapy.

Focal models of inflammatory demyelination. Several focal models of inflammatory demyelination are also available. Injections of antibodies into the oligodendocyte/myelin epitope such as galactocerebroside and myelin oligodendrocyte protein, in combination with complement have been used to induce focal demyelination and these are characterized by more extensive inflammation than the toxin models. Lipopolysaccharide injections into rat spinal cord also result in focal lesions of primary demyelination and infiltration of polymorphonuclear cells. Targeting of experimental autoimmune encephalomyelitis (EAE) lesions to the rat spinal cord or cortex has been achieved. Whereas spinal cord focal EAE lesions are characterized by extensive inflammation even at 1 month postinduction and behavioral deficits, cortical lesions show rapid remyelination. Except for the myelin-complement model, these models have seldom been used for transplantation studies.

Diffuse demyelinating lesions Several models of demyelination exist in which lesions are more diffusely distributed throughout the CNS. These include EAE, demyelination induced by intrathecal injections of cholera toxin B subunit conjugated to saporin, and various virus-induced demyelinating diseases. These models are characterized by more complex pathophysiological features compared to gliotoxin-induced models of demyelination, including clinical deficits. Therefore, whereas gliotoxin models are used to

answer basic questions regarding the remyelinating potential of transplanted cell preparations, models of diffuse demyelination offer an environment required to address more complex issues of cell therapy, such as the ability of cells to gain access to lesions dispersed throughout the CNS, their survival within an inflammatory environment characterized by recurrent episodes of demyelination, as well as the ability of transplanted preparations to sustain clinical recovery.

Viral-induced models of demyelination. Viral infection has been consistently associated with clinical exacerbations of MS. The two most commonly used models of demyelinating disease are Theiler's murine encephalomyelitis virus and murine hepatitis virus (MHV). Both of these models are characterized by acute inflammatory encephalitis that is followed by chronic CNS demyelinating disease characterized by demyelinating plaques associated with astrogliosis and axonal damage reminiscent of MS lesions. The pathology of virus-induced demyelination is immune mediated. Only MHV has been used as a model for transplant studies.

Experimental autoimmune encephalomyelitis. Demyelination in this model of CNS autoimmune disease is induced by sensitizing animals to oligodendrocyte- and myelin-related molecules by peripheral injections of CNS homogenate, purified myelin, and myelin proteins. The clinical signs and extent of demyelination vary according to the species/strain and the immunization protocol. EAE models can be either monophasic (acute and passive transfer), showing little demyelination, or remitting (chronic relapsing and antibody-mediated) with demyelinating lesions dispersed throughout the CNS, with a prevalence for the spinal cord. These different EAE pathologies have been suggested as good models of T cell/macrophage or antibody-mediated demyelination patterns found in MS. EAE can be induced in several species including monkeys.

Grafting into rodent EAE models has been used mainly to address migration and recruitment of transplanted cells by inflammatory lesions as well as the effect of the graft on the ongoing inflammation.

Spinal Cord Injury Models

As mentioned previously, remyelination of the axons demyelinated following SCI appears to be fundamental to achieve functional recovery. However, in addition to remyelinating the axons in the lesion, transplanted cell preparations should ideally also support CNS axonal elongation and outgrowth. SCI models reflect various degrees of injury, including partial or complete spinal cord transection or contusion and have been used to assess the benefits of cell transplantation on remyelination, axonal regeneration, and clinical recovery.

Cell Preparations That Could Be Used for Remyelination of Demyelinating Central Nervous System Lesions

Myelin formation can be achieved using a variety of cell preparations. However, when choosing suitable candidates for transplantation as a treatment for CNS myelin diseases, factors other than the ability to generate myelin within dysmyelinated/demyelinated CNS or to give rise to progeny that will do so need to be considered. Therefore, ideally the following conditions should be met:

1. Cells should be readily available for transplantation. Although certain myelinogenic cell types can be obtained in a noninvasive manner from adult tissues, others have been isolated mainly from embryonic and fetal CNS; thus, their use might create ethical controversy. The development of techniques for appropriate isolation and expansion of these cells in culture is therefore of great importance.
2. Immunosuppressive protocols should be avoided when possible since these have been shown to interfere with the process of remyelination. Use of autografting (grafting of cells/tissue from one anatomical site to another in the same individual) would represent a transplantation paradigm that does not require immunosuppression. As mentioned previously, noninvasive isolation of several myelinogenic cell types for autologous grafting is possible. In addition, it should also be taken into account that CNS is characterized by exquisite regulation of immune responses and therefore certain cell types may not be targeted by an immune rejection response even if grafted as haplotype-mismatched preparations.
3. Since leukodystrophies are characterized by large areas of dysmyelination and the hallmark of MS is the dissemination of lesions throughout the CNS, transplanted cells should be able to migrate and become established within the CNS tissue.
4. Because axonal loss is the major cause of disability in MS, achieving axonal protection/regeneration is of great clinical interest. Remyelination may reduce axonal loss since axonal integrity is myelin dependent and remyelinated plaques show only a minor reduction in axonal density compared to inactive demyelinated plaques. In addition, neuroprotection may be enhanced by graft-mediated suppression of an ongoing inflammatory process as well as by transplanting cells genetically modified to overexpress neurotrophic molecules.

The following section reviews the cell preparations that have been used to achieve myelination/remyelination and discusses their advantages and disadvantages compared to other cell types.

Cells of Oligodendrocyte Lineage and Their Precursors

Myelination Graft-mediated repair of CNS demyelinating lesions by rodent oligodendrocyte lineage cells and their precursors (ES cells, neural stem cells, and neural precursors) has been extensively studied. Gumpel and colleagues were the first to achieve myelination in the developing CNS of myelin mutants by transplanting fragments containing oligodendrocyte progenitor cells (OPCs) and neural precursors. Subsequent studies showed that myelination could also be achieved by grafting mixed glial cell preparations, purified preparations of different stages of the oligodendrocyte lineage, oligospheres (spheres of OPCs), neurospheres, ES cell-derived glial progenitors, and cells derived from adult rat CNS. Moreover, cryopreservation does not abolish the capacity of oligodendrocyte preparations to myelinate axons. Neural stem or glial cell line grafting also leads to myelin generation.

In addition, the ability to myelinate the hypomyelinated or demyelinated CNS has been shown for cells derived from canine, pig, cat, and human CNS. Human cell transplantation has resulted in variable outcomes. Whereas solid grafts of fresh and frozen human fetal brain and spinal cord tissue (8–20 weeks) have resulted in successful myelination in the neonatal shiverer brain, transplantation of isolated human neural and embryonic stem cells into newborn and embryonic rodent brains has resulted in the generation of scarce populations of oligodendrocytes. Several strategies are currently used to improve oligodendrocyte generation from human tissue. Successful myelin generation has been reported following transplantation of glial-committed progenitors selected from fetal and adult human brains by A2B5 sorting, OPC-enriched preparations obtained by treating ES cells with a sequence of growth factor cocktails, and human neural stem cells overexpressing neurogenin 2. Another strategy of interest may be the overexpression of oligodendrocyte-specific transcription factors Olig1/2, given that such treatment of mouse neural stem cells promotes oligodendrocyte specification.

Intrinsic and extrinsic factors modulate the (re) myelination potential of the transplanted cells. These include the age of the donor tissue, the degree of cell maturation, and the environment in which cells are grafted. Early studies suggested that the extent of myelin generation by engrafted oligodendrocyte lineage cells is inversely related to the maturity of the tissue from which cells originate since myelination is more extensive following engraftment of fetal versus neonatal or adult cells. However, different results were obtained in a study by Steve Goldman laboratory, which observed that human A2B5-sorted cells derived from the adult tissue formed myelin more rapidly and ensheathed more axons per cell than fetal cells after engraftment into shiverer mice. The cell differentiation status is also important; thus, commitment of neural precursors to the oligodendrocyte lineage *in vitro* is required to achieve significant remyelination upon engraftment in an X-EB lesion, and transplantation of multipotential neural precursors results in the generation of astrocytes and sometimes neurons, or nonneural cells in the case of pluripotent ES cell engraftment. However, OPCs are more efficient at myelin formation than preoligodendrocytes and mature oligodendrocytes, suggesting that postmitotic cells have a limited capacity to perform myelin repair.

Myelination by transplanted cells is also dependent on the environment in which they are introduced. Therefore, it is favored in newborn recipients undergoing gliogenesis and even more so when myelination by host cells is defective, as occurs in myelin mutants. In the adult CNS, acute rather than chronic lesions are more likely to be remyelinated by the transplanted populations. Inflammation may play a critical role in this process since inducing inflammation in the noninflammatory environment of the retina or in the dysmyelinated spinal cord of the taiep rat promotes remyelination by transplanted OPCs. In addition, transplantation of CNS precursors into macroglial-free areas of X-EB lesions favors their differentiation into myelin-forming SCs rather than oligodendrocytes, which appears to be due to the presence of bone morphogenetic proteins in the absence of Noggin within these lesions.

Migration The extent of grafted cell migration is dependent on the degree of cell maturation, the host environment, and the site of implantation. Immature cells migrate more extensively through the CNS tissue than the more differentiated cells; thus, when transplanted into developing brain OPCs migrate more extensively than preoligodendrocytes but less than polysialylated neural cell adhesion molecule (PSA-NCAM)-positive pre-OPCs. Transplantation studies also highlight the different migration potential of embryonic, neonatal, and adult tissue-derived cells. Therefore, the human fetal OPCs colonize the neonatal mouse brain more efficiently than the adult OPCs. In addition, whereas rodent and human embryo-derived cells migrate extensively within the adult CNS tissue,

neonatal OPCs do not. Migration is also strongly influenced by the host environment. Generally, it has been observed that the migration in myelin mutants is more extensive than that observed in normal neonatal animals. Also, OPC-depletion of the adult rat spinal cord by X-irradiation renders it permissive for migration of transplanted OPCs. Whether the OPCs grafted away from the areas of demyelination reach the lesions by migrating through the CNS tissue remains a matter of debate.

The site of implantation and the mode of delivery of the transplanted cells appear to be important determinants of their migration. When transplanted into the neonatal shiverer brain parenchyma, OPCs and neural precursors follow the axonal tracts; therefore, multiple injections of OPCs into various sites within the axonal circuitry can lead to massive colonization of the forebrain and spinal cord. Extensive colonization of neonatal and embryonic mouse brains has also been reported after stem cell delivery into the ventricle or the cisterna magna. When grafted into adult forebrain, SVZ-derived neural progenitors migrate along specific routes, such as the rostral migratory stream or the cingulum. Inflammation appears to be a major stimulus of grafted cell migration/recruitment since during EAE, CG4 cells or neonatal neural precursors (NPCs) transplanted into the adult CNS extensively colonize adult recipient tissue, and intravenously injected adult NPCs have been reported to cross the blood–brain barrier. Widespread migration has also been observed following transplantation of glial-committed precursors into the MHV-induced model of demyelinating disease, and although transplanted NPCs did not survive well upon engraftment into the inflammatory environment of the twitcher mouse brain, they extensively migrated toward sites of microglial activation.

Immunomodulation Several studies suggest that the recruitment of transplanted neural precursors into inflammatory EAE lesions attenuates the clinical course of the disease, at least partially due to a reduction of ongoing inflammation. The decreased inflammation has been attributed to an NPC-induced apoptosis of infiltrating immune cells mediated by Fas–Fas ligand interactions as well as to the inhibition of T cell activation in the lymph nodes. However, studies using a viral-induced model of inflammatory demyelination show that glial–precursor engraftment does not modify the inflammatory component of the disease. Although it is possible that the anti-inflammatory effect observed in EAE models is dependent on the maturity of the cell preparation engrafted or on the model itself, further studies are required to confirm these observations.

Rejection As techniques currently employed to isolate oligodendrocyte lineage cells are incompatible with autografting, graft rejection represents a major issue relevant to the applications of oligodendrocyte lineage cell therapy. The exact haplotype matching of the host–donor tissue is extremely difficult due to the polymorphisms of human genes, which means that oligodendrocyte lineage cell grafting would most probably imply the use of mismatched tissue. Only a few studies have examined the persistence of myelination by genetically mismatched oligodendrocytes. Whereas transplantation of allogeneic glial cells into neonatal MD rats resulted in rejection, transplant-mediated myelination (without donor–host tissue matching) in a shaking pup model persisted for 28 weeks in the absence of immunosuppression. In addition, fully mismatched preparations enriched for OPCs and transplanted into a toxin-induced rat spinal cord demyelinating lesion successfully remyelinated the demyelinated axons without eliciting an immune response for at least 2 months postengraftment. Although these results, in addition to low major histocompatibility expression by OPCs, suggest that these cells may be of low immunogenicity, long-term survival and remyelination by allogenic cells in inflammatory models of demyelination must be examined.

Schwann Cells

As mentioned previously, experiments examining SC myelination of CNS axons pioneered the area of transplantation for CNS myelination/remyelination. The fact that peripheral myelin is mostly unaffected in MS suggests that the use of SCs for remyelination of demyelinating MS lesions may result in resistance of newly formed myelin to future immune-mediated damage.

Remyelination by grafted SCs has been achieved in a variety of CNS structures, such as the spinal cord, cerebellar white matter, cortex, and optic disk, and in a number of species, such as mice, rats, cats, and monkeys. Myelin formed by SCs transplanted into the demyelinated spinal cord results in improved conduction of demyelinated axons. The extent of remyelination by SC preparations corresponds to the number of SCs introduced and their purity. A major advantage of SCs compared to OPCs as candidates for transplantation in CNS myelin lesions is that it is possible to obtain substantial numbers of these cells from the adult human and monkey peripheral nerve biopsies. After showing that cryopreservation and *in vitro* expansion of primate SCs do not interfere with the ability of these cells to myelinate demyelinated rodent spinal cord, successful autograft-mediated

remyelination of the LPC-induced lesions in adult monkey spinal cord was demonstrated, suggesting the feasibility of such therapy for human disease. In addition, the ability of SCs to sustain axonal regrowth within the CNS has been widely documented, for they have been considered as important candidates for treatment of SCI.

However, whereas migration of SCs transplanted into the CNS can occur along the meninges and blood vessels, it does not occur in the normal white matter, and this may be at least in part due to the inability of these cells to enter the astrocyte-containing environment. Strategies to overcome this difficulty are under investigation and are designed to target specific molecular interactions that impair SC entry into astrocyte-containing areas and/or migration. Thus, it has been reported that reducing levels of chondroitin sulfate proteoglycans within SC/astrocyte confrontation cultures allows SCs to penetrate deeply into the astrocyte territory and that suppressing the expression of N-cadherin, a molecule mediating the adhesion of SCs to astrocytes, results in increased migration of SCs over the astrocyte layers *in vitro*. In addition, genetic modification of SCs to express PSA-NCAM, an important molecular regulator of CNS precursor cell migration, also results in enhanced migration without affecting the myelinating potential when these cells are placed over postnatal brain slice cultures. Although it is imperative to test these results in models of demyelination, they appear encouraging for the development of strategies aiming to enhance SC migration within the CNS.

Olfactory Ensheathing Cells

Another cell type that has been considered for remyelinating cell therapies in addition to the treatment of spinal cord injuries is the OEC. These cells have been isolated from the olfactory nerve, the outer layer of the olfactory bulb of neonatal and adult rats, and lamina propria. OECs have also been obtained from human tissue, including postmortem tissue. Clinical studies have reported no complications after engraftment of autologous OECs into humans with paraplegia for at least 1 year posttransplantation and functional benefits following autografting of cells isolated from the olfactory mucosa in spinal cord injury patients.

Transplantation of OECs into toxin-induced demyelinating spinal cord lesions results in the formation of peripheral-like myelin, which leads to the molecular reconstruction of nodes of Ranvier and restoration of impulse conduction. Transplantation of adult OECs into the primate spinal cord also results in remyelination. Therefore, in addition to SCs, OECs are another candidate cell type for autograft-based remyelination therapies. The main advantage of these cells compared to SCs is that they successfully interact with astrocytes *in vitro* and they also generate less astrocytic response than SCs *in vivo* following implantation into normal white matter.

However, several issues remain unclear regarding the use of OECs for transplantation-based remyelination therapies. For example, engraftment of pure OEC preparations results in less extensive remyelination than if meningeal cell-containing OEC preparations are transplanted, suggesting a need for a combinatorial approach. In addition, some researchers have questioned the ability of OECs to directly participate in remyelination of the demyelinated spinal cord, suggesting that (1) OECs actually provide tunnel-like structures allowing SCs to enter the lesion from the periphery and remyelinate the denuded axons and (2) SC contamination within the OEC cultures may be the crucial factor leading to remyelination. Therefore, further investigation is needed to establish the exact myelination potential of OECs, which will require the development of cell-specific markers allowing the distinction between these cells and the SCs.

Pluripotent Cells from Nonneural Tissues

Transplantation of pluripotent cells from outside the CNS has been attempted in order to achieve remyelination. Encouraging results have been obtained using bone marrow-derived cells; thus, oligodendrocyte generation has been observed following intraparenchymal transplant of CD117-positive cells into neonate mouse and bone marrow-derived hematopoietic precursors into adult brain and spinal cord injury models. However, these results are preliminary and must be considered with caution since several reports have questioned the ability of hematopoietic stem cells to generate neural cells or oligodendrocytes *in vivo*. In addition, although oligodendrocyte differentiation of umbilical cord blood cells has been reported *in vitro*, this has not been reproduced *in vivo*.

It has also been suggested that SCs may be generated from stem cells derived from peripheral tissues. Direct injection of freshly isolated rat bone marrow or purified mouse bone marrow stromal cells into the demyelinated rat spinal cord, as well as the intravenous introduction of acutely isolated bone marrow cell fraction, resulted in SC remyelination of the lesion. However, significantly more cells were required to achieve remyelination following intravenous than direct intraparenchymal injections. Transplantation of skin-derived precursors into dysmyelinated neonatal shiverer brain also resulted in SC-like myelination, and similar differentiation and myelination were

reported after transplantation of transdifferentiated mesenchymal stem cells into the demyelinated peripheral nerve.

Although pluripotent stem cells from outside the CNS might be attractive novel sources of myelin-forming cells, further studies are required to establish their exact behavior after transplantation in acute and chronic models of demyelination.

Contribution of Transplant-Mediated Remyelination to Clinical Recovery

Whether transplantation of myelin-forming cells can correct the functional deficit associated with CNS demyelination is a fundamental question in cell therapy. It has been shown that conduction block of demyelinated axons can be overcome by engrafted oligodendrocytes, SC, and olfactory ensheathing cells-mediated remyelination. For adult primate SCs, the capability to restore conduction is not affected by cryopreservation.

Functional data on behavioral recovery following graft-mediated remyelination are limited. It has been shown that EB-induced demyelination of cervical corticospinal tracts was associated with measurable motor deficits that were ameliorated by spontaneous remyelination. Suppression of endogenous remyelination in this model by X-irradiation resulted in persistent motor deficits that could be overcome by glial cell transplantation given that extensive axonal degeneration had not occurred. Transplantation of primate SCs into an LPC-induced lesion in nude mouse spinal cord was also reported to contribute to functional recovery. In the mildly contused rat thoracic spinal cord, transplanted SCs sustain recovery better than OECs, possibly due to their ability to remyelinate the demyelinated axons more efficiently. Hans Keirstead's laboratory has reported enhanced remyelination and locomotor recovery after SCI following engraftment of human ES-derived OPCs, but such recovery may have resulted from the trophic support to the endogenous cells.

Use of Cells as Vehicles

In addition to remyelinating the demyelinated axons, transplanted cells could also be used as vehicles for delivery of normal enzymes to correct enzymatic deficiencies (storage disorders) or neurotrophic substances to enhance neuroprotection and axonal regeneration (MS and spinal cord injury). Functional improvement following engraftment of stem/progenitor cells overexpressing the normal enzyme has been observed in several models of leukodystrophies. Thus, following engraftment of galactocerebrosidase (GALC)-overexpressing neural stem cells into a twitcher mouse (model of Krabbe's disease), GALC activity was reported within the areas where transplanted cells had migrated. Reduction of sulfatide storage and/or functional improvement have been reported in neonate ASA null mice (model of metachromatic leukodystrophy) following transplantation of normal OPCs and ES cell-derived glial progenitors engineered to overexpress human arylsulfatase A.

Vehicle strategy has also been explored in models of SCI using both neural stem cells and SCs. Enhanced oligodendrocyte differentiation and functional improvement were observed after transplantation of glial-restricted progenitor cells overexpressing D15 multineurotrophin with brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) activities. Nerve growth factor-transduced SCs myelinate spinal cord axons and show enhanced capacity to support axonal growth. In addition, engraftment of BDNF and NT3-transduced primate SCs into a demyelinating lesion induced in mouse spinal cord led to a functional improvement associated with a reduction in astrogliosis, enhancement of overall remyelination of the lesion (graft-mediated and endogenous), and axonal protection.

Conclusions

This article reviewed the current knowledge regarding the therapeutic potential of cell engraftment for demyelinating disease. It is clear that transplantation of myelin-forming cells into animal models of demyelination, including nonhuman primates, indeed restores myelin and, in some instances, contributes to functional recovery, thus representing a promising approach for treatment of human disease. While strategies are being developed to overcome the disadvantages associated with oligodendrocyte lineage and SC grafting, it is becoming clear that once these issues are resolved, the most likely targets for transplantation therapies will probably be the noninflammatory leukodystrophies, such as PMD. Multiple sclerosis represents a far more difficult target due to its heterogeneity and the fact that the exact cause and the sequence of pathogenic events are not entirely understood. However, any strategies designed to overcome the neurologic deficit present in MS patients should necessarily include remyelination therapies, with the most efficient one to date being transplantation of myelin-forming cells. The development of animal models reliably representing the

Table 1 Candidate cell types for engraftment-based remyelination therapies[a]

Cell type	*Main advantage*	*Limiting factor*	*Strategies under investigation*	*Target demyelinating pathologies*
Oligodendrocyte lineage cells and their precursors	Extensive remyelination and integration into host CNS tissue. Migration under permissive conditions (development and pathology)	Noninvasive isolation currently not possible. Difficulties committing human stem cells to oligodendrocyte lineage in culture	Development of reproducible epigenetic-stimulation protocols. Overexpression of transcription factors governing oligodendrocyte specification in neural/embryonic stem cells	Leukodystrophies Multiple sclerosis Spinal cord injury
Schwann cells	Extensive remyelination. Support axonal regeneration. Candidates for autologous grafting	Do not migrate within the CNS. Do not integrate into astrocyte-containing environment	Targeting of molecular interactions that inhibit migration and integration into astrocyte-containing environment	Multiple sclerosis Spinal cord injury
Olfactory ensheathing cells	Candidates for autologous grafting. Better integration into astrocyte-containing environment than Schwann cells	Role in CNS repair (remyelination and axonal regeneration) recently questioned; more data required	Development of reliable markers for distinction between olfactory ensheathing and Schwann cells	Multiple sclerosis Spinal cord injury
Pluripotent cells from nonneural tissues	Potential sources for noninvasive isolation of myelinating cell precursors	Insufficient data, conflicting on myelinating potential *in vivo* (except bone marrow)	Development of protocols for differentiation into myelinating cell phenotypes	Leukodystrophies? Multiple sclerosis? Spinal cord injury?

[a]Although the remyelinating potential of oligodendrocyte lineage and Schwann cells has been firmly established, that of olfactory ensheathing cells is not entirely clear, and insufficient data are available regarding pluripotent cells from nonneural tissues.

size of MS lesions and their chronicity will therefore be fundamental to predicting the outcome of potential cell therapies.

Transport Dependent Damage Signaling

Central versus Peripheral Nervous System Regeneration

While most tissues in the human body, including peripheral nerves, have a remarkable ability to repair themselves after injury, the central nervous system (CNS), comprising the brain and the spinal cord, has a very poor intrinsic capacity for repair. In adults, most parts of the CNS cannot regenerate axons, which explains the devastating condition of paralysis following spinal-cord injury. Axonal damage may also occur in neurodegenerative processes, such as in Alzheimer's, Parkinson's, and Huntington's diseases, whereby axonal pathologies and degeneration often precede death of neuronal cells.

Research over the past 20 years has identified two major obstacles to mature CNS regeneration. The first one is the expression by the surrounding oligodendrocytes and the glial scar of inhibitory molecules such as Nogo, myelin-associated glycoprotein (MAG), oligodendrocyte-myelin glycoprotein (OMgp), and chondroitin sulfate proteoglycans (CSPGs), which can directly inhibit axonal growth. The second obstacle is that axotomized CNS neurons often fail to activate a program of gene expression that is required to sustain regeneration. The outcome of CNS neuron regeneration is thus likely to result from both the intrinsic growth ability of the injured neuron and the strength of the inhibitory environment.

The competence of CNS neurons to regenerate axons in the presence of a permissive environment will depend in part upon their ability to increase their intrinsic growth ability. Identifying the mechanisms activating the intrinsic growth ability of a neuron – that is, its regeneration program – will be a key step toward improving our ability to restore nerve function following damage. One way to obtain insight into why a given neuron fails to regenerate is to study neurons that can regenerate. Adult olfactory and hippocampal dentate gyrus neurons or developing immature CNS neurons might represent one such category, since they show some level of regeneration. However, due to their larger size, neurons within peripheral nerves offer better access to biochemical approaches. Investigating the molecular mechanisms regulating axonal regeneration in peripheral nervous system (PNS) neurons is therefore crucial to our understanding of why most axons fail to regenerate in the CNS after injury.

Injured PNS neurons undergo a typical reaction, required for axonal regeneration, which includes Wallerian degeneration in the distal portion of the nerve, sprouting of processes in the proximal portion of the nerve, and strong morphological changes in the soma, referred to as the cell body reaction. Another characteristic response is the expression of regenerative-associated genes (RAGs). RAGs identified thus far include transcription and translation factors, cytoskeletal proteins, axonal guidance molecules, trophic factor and cytokines (and their receptors), neuropeptides, neurotransmitter-synthesizing enzymes, ion transporters, cell adhesion and cell-signaling molecules, vesicle-trafficking components, metabolic proteins, and membrane transporters. In marked contrast, in CNS neurons, alteration of gene transcription following injury is weaker and transient, or totally absent.

While it is well established that alteration of gene expression is required for the regenerative competence of PNS neurons, very little is known about how information from the site of damage is communicated to the cell body to initiate these changes. This is a challenging problem, since the site of lesion is often distant from the cell body; the axon of larger vertebrates can reach lengths of up to 1 m.

Evidence for Damage Signaling in the PNS: The Conditioning Injury Paradigm

The key role of RAG expression in regeneration has been elegantly demonstrated in dorsal root ganglia (DRG) sensory neurons, which are unique in having both a long CNS axon that ascends the spinal cord and a second axon branch that projects through a peripheral nerve. 'Conditioning' nerve lesion studies have demonstrated that peripheral axotomy of DRG neurons, but not central axotomy, generates an enhanced growth state that allows a certain degree of regeneration within the CNS. This enhanced growth state is likely to rely upon a program of gene expression uniquely induced by peripheral axotomy to support axon extension. These studies underscore the existence of distinct signaling mechanisms in central versus peripheral branches, which culminate in the distinct abilities of DRG neurons to respond to central versus peripheral injury.

One approach to understanding the molecular determinants of axonal regeneration is to further characterize the target genes activated by peripheral injury. Another important approach is to identify the

nature of the signals that inform the cell body that the axon has been injured and that initiate the appropriate transcriptional program.

Damage Signaling: The Hypotheses

Despite a century of research on the reaction of neurons to axotomy, the identities of the signals that inform the cell body that the axon has been injured are incompletely understood. A series of elegant studies in the early 1990s in the mollusk *Aplysia californica* provided evidence for the existence of multiple signals functioning in a temporal sequence.

First, action potentials propagating from the injury site to the cell body activate a signaling cascade in the cell soma. Supporting this idea, a limited number of studies in both *A. californica* neurons and mammalian neurons indicate that membrane depolarization is one of the earliest events detectable after axotomy. A positive role for membrane depolarization in nerve regeneration is also suggested by the observation that depolarization triggers the expression of immediate-early genes and survival of neurons in the absence of trophic support.

Second are the so-called negative injury signals, in which axotomy prevents molecules that are normally transported retrogradely from reaching the cell body. These negative injury signals function in repressing certain transcriptional programs. Support for this mechanism came from studies in which blocking axonal transport led to the expression of certain molecules in the cell body, suggesting that their repression relies on the constitutive retrograde transport of a signal.

Third are the positive injury signals, which are activated at the injury site and then transported retrogradely back to the cell body. Early morphological studies have shown that the more distal the injury, the longer it takes the neuron to exhibit features of the cell body reaction, which suggests that a signal is traveling from the injury site back to the cell body. More recent studies have confirmed these observations at the molecular level. This positive injury signaling system relies upon a microtubule-based retrograde transport to communicate injury to the distantly located cell body.

Molecular motor proteins such as kinesins and dyneins mediate the intracellular transport of protein complexes, vesicles, and other organelles by translocating along polarized microtubule tracks – the axonal highway system. Kinesins and dynein define a superfamily of motor proteins that use the energy of adenosine triphosphate (ATP) hydrolysis to move cargo along microtubules. Kinesin mediates anterograde axonal transport, while dynein, together with its associated protein complex dynactin, mediates retrograde axonal transport. This microtubule-dependent axonal transport occurs at rates of 1–5 $\mu m\,s^{-1}$. While the notion that microtubule-based transport played a role in conveying information from the injured axon back to the cell body emerged in the early 1970s, the involvement of the molecular motors kinesin and dynein/dynactin has only been recently demonstrated.

Recent Advances toward Identification of Positive Injury Signals

Mitogen-Activated Protein Kinase Signaling Modules

The notion that signaling molecules undergo fast axonal transport has emerged in the past decade. Sciatic nerve ligation experiments have shown that a subset of the signaling components in the mitogen-activated protein kinase (MAPK) pathway, which includes phosphatidylinositol 3-kinase (PI3K), extracellular signal-regulated kinase (ERK-1/2), p38 MAPK, and c-Jun N-terminal kinase (JNK), is transported along axons. The functional role for transporting signaling molecules along the axon remains elusive, but recent observations suggest that they might be part of a damage surveillance system.

JNK signaling plays a positive role in peripheral neuron survival and repair. Following axonal injury, JNK activation and expression of the downstream transcription factor c-Jun in the cell body persist until target reinnervation has occurred. One of the positive damage-signaling molecules leading to JNK activation in the cell body may be JNK itself. Following sciatic nerve injury, JNK is activated locally in the axon at the injury site, where it interacts with the JNK scaffolding protein syd (also known as JIP3 or JSAP1) and the retrograde motor complex dynein/dynactin. The net retrograde transport of a syd/JNK complex observed following injury suggests that mobile axonal syd/JNK complex may generate a transport-dependent axonal damage surveillance system. This study provides one of the earliest pieces of evidence implicating microtubule-dependent transport and molecular motors in damage signaling.

The upstream activating signaling cascade leading to JNK activation may play an important role in the final outcome of the neuron following injury. For example, in a mouse model of type 1 diabetes, activation of JNK along the length of the axon, probably as a result of hyperglycemic stress of the peripheral nerve, may activate retrograde signaling for nerve degeneration. In the case of mechanical damage occurring upon nerve injury, a retrograde signal involving JNK may support nerve survival and regeneration.

Another member of the MAPK family, ERK-1/2, is transported along axons in both directions in rat PNS neurons. However, it only recently became apparent that ERK-1/2 is activated locally in response to sciatic nerve injury, and that it then forms a complex with β-importin, a member of the nuclear import machinery. The ERK/β-importin complex recruits the motor dynein for retrograde transport, suggesting that ERK-1/2 is part of a positive injury signal leading to regeneration of DRG neurons. Other studies have demonstrated that the ERK-1/2 pathway plays a key role in the survival of axotomized mammalian retinal ganglion cells (RGCs) *in vivo*, but that activation of other signaling components is required for axon regeneration in the growth-inhibitory CNS environment.

Another MAP kinase member, the *Aplysia* protein kinase G (ApPKG), is activated at axonal injury sites and retrogradely transported, but the mechanism responsible for injury-induced retrograde transport is still unknown. Further studies of the MAPK signaling cascades activated by injury in peripheral nerves will be necessary to elucidate their role in nerve regeneration.

Retrograde Signaling Dependent upon Nuclear Localization Signals

The targets of positive injury signals in the cell body of an injured neuron are likely to be transcription factors controlling the expression of regeneration-associated genes. Over the past few years, accumulating evidence indicates that the transcription factors can act as positive injury signals. Studies in *A. californica* have shown that nuclear localization signals (NLSs) can target retrograde transport and nuclear uptake of heterologous proteins.

The transcription factor nuclear factor-kappa B (NF-κB) is also retrogradely transported in axons. Different stimulation conditions, including depolarization, result in the redistribution of NF-κB from neurites to nucleus. This retrograde transport is dependent upon an intact NLS sequence and exhibits velocities that are consistent with fast retrograde transport. In adult sensory neurons, blocking endogenous nerve growth factor (NGF), using an anti-NGF antibody, leads to elevated retrograde axonal transport of activating transcription factor 2 (ATF2). This study indicates that lack of neurotrophic support leads to modulation of levels and activation status of a retrogradely transported transcription factor.

Another transcription factor playing a role in injury signaling is the signal transducer and activator of transcription (STAT3). Nerve injury results in STAT3 activation in axons and a wave of activated STAT3 moves along the nerve toward the cell bodies in the DRG. The observation that injury-induced activation of STAT3 occurs in regenerating neurons but not in non-regenerating neurons supports the model that STAT3 is a retrograde signal transcription factor playing a positive role in regeneration. Further support came more recently with the observation that in DRG neurons, peripheral but not central branch injury results in a time-dependent phosphorylation and activation of STAT3. STAT3 activation is thus necessary for increased growth ability of DRG neurons and improved axonal regeneration after a conditioning injury. Activation of STAT3 at the axonal injury site may result from cytokine signaling, such as ciliary neutrophic factor (CNTF) and leukemia inhibitory factor (LIF), which are released at the lesion site and are important for the survival and regeneration of axotomized motoneurons. The proinflammatory cytokine tumor necrosis factor-α (TNF-α) also increases at the injury site and undergoes retrograde axonal transport from the injury site to the DRG and further to the spinal cord.

Much like NLS signaling, sumoylation might serve as a new mechanism to target axonal proteins for retrograde transport following injury. The covalent linking of small ubiquitin-like modifiers (SUMO-1) is biochemically similar to ubiquitination but functionally distinct. Since sumoylation can affect function or subcellular localization, and most SUMO-modified proteins are found in the nucleus, it is therefore tempting to speculate that sumoylation in distal axons might be used in addition to NLS to target axonal proteins to the nucleus for exerting control on transcription.

The nuclear functions of transcription factors and NLS proteins has led to the assumption that their localization within cells should be primarily perinuclear. However, the recent discoveries that transcription factors and proteins participating in nuclear import mechanisms are found along axons opens new lines of investigation on their role in damage signaling.

Axonal Protein Synthesis

While protein synthesis in dendrites is an accepted mechanism involved in synaptic plasticity, whether or not protein synthesis occurs in axons has remained a controversial subject for many years. A small number of studies in the 1960s reported the presence of ribonucleic acid (RNA) and active protein synthesis machinery in invertebrate and vertebrate axons. Work over the past 10 years has now confirmed these earlier findings, and the notion that axons are able to locally synthesize their own proteins is now generally accepted. The functional role for axonal protein synthesis has remained elusive, but recent studies have shown that axonal messenger RNA (mRNA) translation plays a role in axonal growth

during development, allowing developing axons to respond to their complex environment.

Axonal mRNA translation is also used by mature neurons as a mechanism to generate a retrograde damage signal. Following sciatic nerve injury in mice, β-importin protein levels are increased by local translation of axonal mRNA, leading to the formation of an NLS binding complex traveling retrogradely. The intermediate filament protein vimentin is also synthesized from preexisting axonal mRNA following injury and associates with the activated MAP kinase ERK, β-importin, and dynein for retrograde transport.

The list of proteins synthesized in vertebrate axons following injury is increasing, mainly thanks to approaches that include high throughput proteomic methodologies. Ultimately, detailed mechanistic studies will be required to understand the molecular events regulating retrograde transport of these newly synthesized proteins and to identify their downstream target(s) in the cell body.

Protein Degradation

Local axonal protein degradation and synthesis are likely to play an important role in controlling how axons respond to injury. Calcium entry into a damaged axon has been shown to be essential for the formation of a new growth cone in *Aplysia* and mammalian neurons. Proteolytic enzymes such as calpains are activated by calcium, and local degradation of proteins is required for the remodeling of a severed axon into a new growth cone.

Activation of proteolysis may also be required to trigger damage signals. In support of this hypothesis, early studies revealed that inhibition of proteolysis in transected rat sciatic nerves inhibits retrograde axonal transport of organelles from the injury site. More recent studies suggest that the protein degradation by the proteasome system may regulate signaling pathways that control axonal survival and degeneration.

Conclusions and Perspectives

While recent studies in mammals have confirmed the existence of several distinct positive injury signals, the role of negative injury signals and membrane depolarization remains poorly documented. Overall, the emerging picture is that membrane depolarizations along with positive and negative injury signals operate together to different extents in different situations. Coordination between several injury signals might orchestrate the precise program ensuring nerve regeneration or degeneration. Several classes of injury signals may coexist to ensure precise information on the nature of the damage and its distance from the cell body. It is tempting to speculate that the difference in time between the arrival at the cell body of the action potential, the first injury signal, and the later arrival of a positive injury signal might serve as an indicator of the distance of the injury from the cell body. Similarly, the combination of several positive injury signals might serve as an indicator of the extent of damage.

The list of positive injury signals will increase and approaches such as differential proteomics will be of great help in revealing the identity of retrogradely transported molecules after nerve injury. Identifying the molecular mechanisms by which these positive injury signals are transported to the cell body to initiate the cascade of events leading to an enhanced regeneration state will be necessary to improve our ability to restore nerve function following injury.

Ultimately, a direct comparison between injury signaling mechanisms in CNS and PNS neurons might shed light on the poor regenerative capacity of CNS neurons. This will be most important, since, in addition to traumatic axonal damage resulting from spinal cord injury, axonal damage can also occur in neurodegenerative diseases in which axonal pathologies interrupt the cell body/synapse connection.

Successful axonal regeneration may require that the intrinsic growth state of the neuron be activated and that the inhibitory signals from the environment are neutralized. Identification of the pathways that regulate axonal survival and regeneration will provide possible target sites for pharmacological treatments of neurodegenerative diseases and traumatic injury.

Nerve cells communicate with one another primarily by chemical means, and such chemical messages are carried by neurotransmitters released at specialized contacts called synapses. In order to produce fast transmission between neurons, the chemical signal must be rapidly terminated. One way in which the signal can be terminated is by the passive diffusion of the neurotransmitter. However, at most synapses in the brain and peripheral nervous system, the termination of chemical messages is also aided by active processes, either enzymatic degradation or removal of the neurotransmitter from the extracellular space.

At synapses between motor neurons and skeletal muscles, the excitatory neurotransmitter acetylcholine is rapidly degraded by an enzyme located within the synaptic cleft (see Figure 1). This enzyme, acetylcholinesterase, is one of the most avid enzymes described; a single acetylcholinesterase protein is capable of degrading more than 10 000 molecules of acetylcholine each second. Such capacity reduces the time period in which acetylcholine must act, and it also limits the spatial extent over which it signals.

In the brain, fast excitatory synaptic signals are mediated primarily by the excitatory amino acid glutamate. Neurotransmitter clearance at glutamatergic synapses is quite different from the neuromuscular synapse. Here the actions of glutamate are terminated in part by a special class of neurotransmitter transporter, called excitatory amino acid transporters (EAATs), located on the plasma membranes of glial cells and neurons (Figure 1). EAAT proteins are responsible for capturing glutamate from the extracellular space, undergoing a conformational change which transports the glutamate through the plasma membrane, and then releasing it into the cytoplasm.

In general, neurotransmitter transport can serve many purposes. First, it is thought to act as part of a recycling mechanism that allows for the renewal of neurotransmitter pools. Second, it can limit the temporal actions of the neurotransmitter. Third, it can restrict the spatial extent of neurotransmitter action and, in so doing, can sometimes determine which pools of receptors are activated. Fourth, it can help set resting levels of neurotransmitter. This is significant because distinct high-affinity classes of receptors are often found outside synaptic specializations (called extrasynaptic receptors) and such extrasynaptic receptors typically respond to low levels of neurotransmitter. Still other types of receptors desensitize when exposed to very low levels of neurotransmitter, much lower than those required to fully open the receptor. In these ways, even low resting levels of the neurotransmitter can serve as signals of their own or as negative influences on surrounding receptors.

A Family of Excitatory Amino Acid Transporters Responsible for Clearing the Major Excitatory Neurotransmitter Glutamate

Molecular cloning techniques have identified EAATs in a wide variety of species: prokaryotes, insects, amphibians, fish, and mammals. Mammals possess a family of EAATs consisting of five genes. Three of these genes were initially identified in 1992 and named GLAST (glutamate aspartate transporter), GLT1 (glutamate transporter 1), and EAAC1 (excitatory amino acid carrier 1). Soon after, corresponding sequences for these genes were cloned from the human motor cortex and their homologs were named EAAT1 (GLAST), EAAT2 (GLT1), and EAAT3 (EAAC1). Subsequently EAAT4 and EAAT5 were also identified. For the sake of simplicity, we hereafter refer to each subtype by its human (i.e., EAAT) designation.

Molecular Structure of Excitatory Amino Acid Transporters

Our understanding of the molecular structure of EAATs has benefited enormously from the recently determined X-ray crystal structure of a prokaryotic EAAT homolog. This protein, found in the thermophilic archaebacterium *Pyrococcus horikoshii*, has approximately 35% sequence homology to its mammalian counterparts. Figure 2 summarizes the key features of the structure. The transporter exists as a homotrimer with three wedge-shaped subunits forming the sides a large bowl that dips into the membrane and faces the extracellular space (Figure 2(b)). Each subunit exhibits a complicated transmembrane topology (Figure 2(a)), with eight complete membrane-spanning segments and two reentrant loops. The reentrant loops are situated at the bottom of the bowl, where the tips of the three wedges contributed by each subunit come together. This is a key functional region of the transporter protein; the reentrant loops had been identified in prior studies as the likely spot at which glutamate binds. Indeed, the crystal structure shows electron densities characteristic of single glutamate molecules bound to each subunit at the base of the bowl, suggesting that three glutamate molecules bind at these locations before being

Figure 1 Degradative enzymes: (a) in the vertebrate neuromuscular junction synapses; (b) in the extracellular space at most excitatory synapses within the brain. In (a), following release the neurotransmitter acetylcholine (ACh) is degraded rapidly by acetylcholinesterase (ACh esterase), an enzyme situated within the synaptic cleft. In (b), there is no degradative enzyme; rather, high-affinity excitatory amino acid transporters (EAATs) remove glutamate from the extracellular space into intracellular compartments in neurons and glia.

Figure 2 Transmembrane topology of a prokaryotic excitatory amino acid transporter (EAAT) from the archaebacterium *Pyrococcus horikoshii*: (a) structure of the transporter subunits; (b) side-on cross-sectional view of the transporter structure. In (a), each subunit has eight membrane-spanning segments and two reentrant loops, termed hairpin 1 (HP1) and hairpin 2 (HP2). The N- and C-termini are located on the intracellular side of the membrane. In (b), the large bowl-shaped structure formed by three subunits is oriented with the bowl facing extracellularly (top). Glutamate binding and coupled ion binding are believed to occur at the base of the bowl. transported into the cytoplasm. Although it is not certain, these features of the structure suggest that each subunit may transport glutamate independently.

Energetics of Excitatory Amino Acid Transporters

The energy for transport comes from the coupling of the movement of glutamate to the cotransport and the countertransport of sodium, potassium, and hydrogen ions down their respective electrochemical gradients. Flux measurements have established the stoichiometry for a complete cycle of glutamate transport to be three Na^+ and one H^+ cotransported and one K^+ countertransported per glutamate molecule. This elaborate coupling mechanism has a clear benefit; it allows EAATs to accumulate glutamate to a huge concentration gradient. With typical physiological ion gradients, resting potentials, and the coupling stoichiometry just mentioned, glutamate can be taken up and concentrated inside the cell to well more than a millionfold at equilibrium. Given that cytoplasmic glutamate concentrations are thought to be in the millimolar range in some cells (e.g., neurons), these energetics allow for extracellular glutamate levels to be maintained at submicromolar, and possibly even nanomolar, levels. Of course, even at steady state, resting glutamate levels may not be near this theoretical limit. This is because, in addition to the ionic gradients, the amount of glutamate released, the density of EAATs, and the size and shape of the extracellular volume all influence the degree to which transporters can reduce the extracellular glutamate concentration.

Uncoupled Ionic Conductances of Excitatory Amino Acid Transporters

The stoichiometric movement of ions during the glutamate transport cycle provides the energy to accumulate glutamate. Because of the net charge flux of +2 charges moving inward per cycle (one negative glutamate, three positive sodium ions, and one proton in and one positive potassium ion out) transport gives rise to very small transmembrane ionic currents. However, to varying degrees, all five EAATs allow another ionic current to flow. This current is carried by chloride ions under physiological circumstances, and this movement of anions is not coupled energetically to glutamate transport. In simple terms, we might imagine that at a particular point in the cycle of transport the EAAT protein adopts a conformation contains an anion-selective pore across the membrane. The anions flowing through EAATs move according to their own electrochemical gradient, and this anion flux is neither affected by nor affects the cycling of glutamate, sodium, potassium, and hydrogen ions.

The relative size of the anion component of the total current varies characteristically among different EAAT isoforms. EAAT4 has the largest anion current; it dominates the total ionic flux under physiological circumstances. In contrast, EAAT2 has the smallest anion conductance. Several of the EAATs also exhibit a noticeable anion leak under resting conditions (i.e., in the absence of glutamate), and this leak is most prominent in EAAT4. Physiological roles for the uncoupled anion fluxes are not known, but in principle such conductances could allow EAATs to act as ligand-gated inhibitory channels in addition to their glutamate clearance role. In cerebellar Purkinje neurons, in which EAAT4 is expressed at high levels, this does not appear to have a major influence on excitability, but in retinal ON-bipolar cells it has been argued that EAAT-mediated anion currents can couple decreases in photoreceptor glutamate release with the excitation of the ON-bipolar cell.

Cellular Localization of Excitatory Amino Acid Transporters

EAATs are expressed at the highest levels in the nervous system, but are also found in peripheral tissues such as the kidney, enteric nervous system, pancreas, placenta, mammary glands, and possibly bone. The expression of particular EAATs within the brain occurs in overlapping patterns and is largely cell-type specific. Two of the five transporters are found predominantly in the glia, two are found only in certain types of neurons, and one is expressed only in the retina in both neurons and the glia.

The Glial Transporters EAAT1 and EAAT2

EAAT1 is the predominant glial glutamate transporter in cerebellum. It is also expressed at relatively high levels in glial cells of the inner ear and in Müller glial cells of the retina. EAAT1 protein does not appear to be present in oligodendrocytes or in neurons. In cerebellar Bergmann glia, EAAT1 is expressed at extremely high densities ($\sim$4700 m^{-2} of plasma membrane). It is thought to be the dominant transporter in these cells; consistent with this view, animals in which the EAAT1 gene has been disrupted have cerebellar behavioral deficits and exacerbated responses to cerebellar injuries. However, EAAT2 is also expressed at approximately sixfold lower levels in the cerebellar cortex, and thus functional transporters may exist as heteromers.

At a subcellular level, EAAT1 is not found to be distributed uniformly along the plasma membrane of astrocytes. Rather, hot spots of EAAT1 are observed and the highest densities of EAAT1 are seen where astrocytic membranes oppose neuronal membranes (see Figure 3(a)). In the cerebellar cortex, this arrangement could be a mechanism for helping to limit glutamate spillover from active synapse to their neighbors.

Like EAAT1, EAAT2 is also concentrated on fine astrocytic processes that surround excitatory synapses (see Figure 3(b)). Depending on the brain region, these EAAT2-rich astrocytic processes are located at different distances from sites of glutamate release. At one extreme, they can encapsulate pre- and postsynaptic elements (as EAAT1/EAAT2-studded Bergmann glial processes do in the cerebellar cortex). At the other extreme, such as at Schaffer collateral synapses on to CA1 pyramidal neurons of the hippocampus, EAAT2-containing processes are located at some distance from postsynaptic densitities and sites of glutamate release. Finally, in certain brain regions such as the superoptic nucleus of the hypothalamus, the arrangement of astrocytic processes varies according to behavioral state, thereby influencing excitatory synaptic transmission in numerous ways by permitting glutamate to reach or limiting it from reaching specific pools of receptors.

The Neuronal Transporters EAAT3 and EAAT4

An unexpected feature of the localization patterns of the neuronal EAATs is that they are found on dendritic, but not on axon terminal, membranes. EAAT3 is the more widely expressed of the neuronal EAATs, showing localization on excitatory and inhibitory neuronal dendrites in the hippocampus, cerebellum, basal ganglia, cortex, and thalamus. In those neurons that express it, EAAT3 protein is present at relatively high densities on intracellular membranes as well as

Figure 3 Localization of excitatory amino acid transporters (EAATs) at different types of glutamate synapses: (a) parallel fiber to Purkinje neuron synapses in the cerebellar cortex; (b) Schaffer collateral synapse in hippocampus. In (a), the synapses are completely surrounded by astroglial membranes containing the glial isoforms EAAT1 and EAAT2 at average densities of 4700 and 740 molecules μm^{-2}, respectively. The neuronal transporter EAAT4 is concentrated opposite glia-covered parts of the membranes of Purkinje dendrites and is highest in the spines and thinner dendrites. EAAT4 is expressed at varying density in different zones of the cerebellar cortex, but has an average density of 1800 molecules μm^{-2}. EAAT3 is present in Purkinje neurons membrane as well as the cytoplasm, but quantitative data on the precise subcellular distribution are currently unavailable. In (b), the synapses are only contacted, not surrounded, by astroglia. EAAT1 and EAAT2 are present in the astroglial membranes at average densities of 2300 and 8500 molecules μm^{-2}, respectively, with highest concentrations toward the neuropil. Quantitative information is not available for EAAT3, nor is information available for the putative glutamate transporter on the nerve terminal. on the plasma membrane. That said, the density of EAAT3 is believed to be quite low and it is unclear whether it plays a prominent role in clearing glutamate into these neurons.

EAAT4, found almost exclusively in cerebellar Purkine neurons, is present at extremely high densities on dendritic shafts and spines, estimated to be on average ($\sim$1800 m^{-2} of plasma membrane). However, this expression shows a large-scale patchiness, with zones of high expression and low expression occurring at periodic spatial intervals throughout the cerebellar cortex. The resulting zebra-striped pattern matches that of several other gene products (most notably the protein Zebrin). The reasons for this nonuniform expression pattern are not understood, but recent work suggests that in regions of low EAAT4 expression it is easier for certain types of glutamate receptors (GluRs; e.g., metabotropic GluRs (mGluRs)) to be stimulated, whereas in regions with high EAAT4 expression certain GluRs appear to be shielded from released glutamate. Because mGluRs are responsible for initiating particular forms of synaptic plasticity, the variability in EAAT4 may be a mechanism for region specific control of synaptic plasticity.

At the subcellular level, both EAAT3 and EAAT4 have been reported to be excluded from the postsynaptic density but to be concentrated at the edges of these densities, a pattern termed perisynaptic. Such a pattern of localization seems ideally suited to aiding in preventing glutamate escape from synaptic clefts at active synapses (spillover) and in preventing glutamate from gaining access to the postsynaptic densities of inactive synapses (cross-talk). These phenomena are illustrated in Figure 4; physiological evidence suggesting that they occur is discussed in latter sections.

The Retinal Transporter EAAT5

EAAT5 has been reported to be expressed in various neurons (photoreceptors, bipolar cells, and amacrine cells) and Müller glial cells of the retina. Functional evidence suggests that EAAT5 may be a major glutamate transporter on bipolar cell terminals; this work is also notable because it serves as the only direct evidence to date that an EAAT is involved in glutamate uptake into a presynaptic terminal.

Synaptic Functions of Excitatory Amino Acid Transporters

Recycling Glutamate

Constant vesicular release of glutamate from terminals in the brain requires a concurrent replenishment of neurotransmitter stores. It is likely that this happens via an indirect pathway because there is little evidence for the presence of glutamate transporters located on presynaptic terminals. Rather than being directly reabsorbed into the nerve terminal, EAATs in surrounding glia may take up the bulk of glutamate.

Figure 4 Transporters limit (a) spillover of glutamate; and (b) of synaptic cross-talk. In (a), during moderate levels of activity (left), glutamate transporters take up glutamate and limit its escape from the cleft (red crosses). During high levels of activity, the transporters become saturated, so the transmitter spills over (arrow) to activate extrasynaptic receptors. In (b), during high levels of activity (left), transporters are saturated and glutamate escapes the synaptic cleft. Transporters surrounding adjacent synapses take up this glutamate (red cross), limiting cross-talk between synapses. AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor; EAAT, excitatory amino acid transporter; mGluR, metabolic glutamate receptor.

Within glia, glutamate is converted to glutamine by the enzyme glutamine synthetase. Glutamine is an inactive amino acid and thus can be returned to the presynaptic terminal via the extracellular space; once it is back in the presynaptic terminal, it can be made back into glutamate (or γ-aminobutyric acid (GABA)).

There is also indirect evidence that EAATs on inhibitory synaptic terminals take up glutamate to be used for the synthesis of GABA. In these studies, inhibiting glutamate uptake leads to a reduction in GABA release. This result might also explain why many GABAergic neurons express EAAT3 and EAAT4, although, if such proteins are present on the terminals of these neurons, they are, for unknown reasons, immunohistochemically silent.

Maintaining Low Resting Glutamate Concentrations

In order to preserve the sensitivity of postsynaptic receptors, steady-state concentrations of glutamate in the synaptic cleft must remain submicromolar. For example, extrasynaptic receptors such as mGluRs and *N*-methyl-D-aspartate (NMDA) receptors have median effective concentrations (EC_{50}s) in the micromolar range, whereas α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors desensitize to similarly low concentrations of glutamate. Because the rate at which glutamate can leave the synaptic cleft is proportional to its concentration gradient, in order to rapidly terminate the signal a large concentration gradient must be established. Several experiments have demonstrated that EAATs control the resting levels of glutamate. The strongest evidence is based on the measurement of tonic activation of GluR currents, typically NMDA currents. For example, during cortical and cerebellar development many migrating neurons receive tonic nonsynaptic signals mediated by NMDA receptors. Such signals, and the rate of migration of these neurons, can be altered by inhibiting EAATs. In adults, EAATs also appear to play a role in controlling steady-state levels of glutamate. Experiments in cultured hippocampal slices show that large tonic NMDA currents appear within seconds after the inhibition of transporters.

Synaptic signals mediated by AMPA receptors are sometimes altered by inhibiting glutamate uptake, but this seems to depend on the microstructure of the synapse. Three categories of effects are observed when EAATs are inhibited. At some synapses that are not enveloped by glia, as in the hippocampus (schematized in Figure 3(a)), inhibiting glutamate uptake has no detectable effect. This stands in contrast to the slowing of the decay of the excitatory postsynaptic current (EPSC) in response to single stimuli seen at other types of synapses, such as the calyceal synapses or synapses, which are made on postsynaptic spines with extensive glial wrapping as in the cerebellar cortex (schematized in Figure 3(b)). Finally, at several glial-enveloped synapses that are made on dendritic shafts, blocking transport causes a slowing of the decay but only in response to trains of presynaptic stimuli; a good example is the parallel fiber to stellate cell synapse in the cerebellum.

Ensuring Synapse Specificity

In order to ensure independent signaling, glutamate must be prevented from diffusing from one synaptic cleft into neighboring synaptic clefts. The escape of glutamate from the synaptic cleft and the subsequent activation of extrasynaptic AMPA or NMDA receptors have been termed spillover; the breakdown of synaptic independence caused by invading glutamate into an inactive synaptic cleft has been termed cross-talk (see Figure 4). Given the abundant evidence that glutamate escapes the synaptic cleft at significant concentrations and can activate targets at considerable distances, it would seem that these two phenomena are common. Close examination of excitatory transmission at several synapses yields clear evidence for spillover and tantalizing suggestions of cross-talk. Where it has been examined, glutamate uptake plays a pivotal role in minimizing or shaping these unconventional signals.

Limiting cross-talk between synapses An early indication that cross-talk might occur came from a comparison of the relative variabilities of NMDA and AMPA receptor-mediated EPSCs in the hippocampus. Due to the stochastic properties of vesicular release (release probability is not 1.0), EPSCs vary in peak amplitude from trial to trial. Recordings of dual component EPSCs in CA1 pyramidal cells showed that NMDA-mediated EPSCs are consistently less variable than those mediated by AMPA receptors. These results have been interpreted to mean that NMDA receptors detect a larger number of quanta than do AMPA receptors. But where do these extra quanta come from? NMDA receptors have approximately 100-fold higher affinity than AMPA receptors, and it has been hypothesized that this allows NMDA receptors to detect release from neighboring presynaptic terminals not directly apposed to the postsynaptic density in which they reside. A key piece of evidence supporting this idea is that, at higher temperatures, the difference in relative variability between NMDA and AMPA receptors is reduced. Glutamate transport is known to be very temperature sensitive, and consistent with a role for glutamate uptake in this puzzle, inhibitors of glutamate transport erased the effects of increased temperature, making the NMDA EPSCs

relatively more variable than AMPA EPSCs. These results imply that cross-talk to NMDA receptors is occurring at room temperature but that at more physiological temperatures glutamate transporters operate more efficiently and are able to prevent glutamate from indirectly activating the higher-affinity NMDA receptors.

Perhaps the most straightforward evidence of cross-talk has been observed at parallel fiber inputs to stellate cells in the cerebellum, Here, slowly rising AMPA- and NMDA-mediated synaptic responses can be observed under certain conditions in response to trains of presynaptic stimuli. Inhibiting glutamate uptake increases and prolongs such slow responses, indicating that EAATs at least partially limit the indirect access of glutamate to AMPA receptors. Other pharmacological evidence suggests that these indirect responses result at least in part from glutamate entering inactive, neighboring synapses and binding to AMPA or NMDA receptors.

Neuronal EAATs located at the edges of synapses (see Figure 3) seem to be ideally situated to prevent glutamate from entering synaptic clefts from the extracellular space. Is there any evidence that transporters might serve in this capacity? In CA1 pyramidal cells of the hippocampus, experiments suggest that postsynaptic uptake, presumably by EAAT3, can limit the activation of NMDA receptors. Similarly, in cerebellar Purkinje neurons, EAAT4 appears to prevent low concentrations of glutamate from entering inactive synapses.

Limiting spillover of neurotransmitter to extrasynaptic receptors Many potential targets for glutamate are located adjacent to the synapse or completely outside of synaptic clefts – on the same neuron, on presynaptic terminals, or on glial cells. In order for these targets to be activated, glutamate must escape a synapse and diffuse for variable distances in the extracellular space. Recently published data not only demonstrate that glutamate can indeed spill out of the synaptic cleft to activate extrasynaptic receptors but also that EAATs play important roles in ensuring that these receptors are activated only under certain circumstances (e.g., during high levels of activity).

Spillover to receptors on glia In the hippocampus, where glial cell membranes are typically located at some distance from the edges of synaptic clefts, synaptic signals mediated by GluRs or EAATs can be directly recorded in astrocytes. Based on such measurements, it has been proposed that glial membranes outside the synaptic cleft sense glutamate within 1 ms after release, results consistent with expectation maximization (EM) reconstructions of astrocyte membranes and with the localization data for EAAT2 placing the transporters at ~1 μm from synaptic specializations. Likewise, in the cerebellum, AMPA receptor-mediated and EAAT-mediated synaptic currents can be recorded from Bergmann glial cells. These findings suggest that glutamate commonly escapes synaptic clefts at concentrations easily capable of activating most glutamate receptor subtypes.

Spillover to extrasynaptic receptors on neurons In various brain regions, including the hippocampus, retina, hypothalamus, and cerebellum, glutamate escaping synaptic clefts can activate NMDA receptors and these signals are often potently regulated by EAATs. Glutamate escaping synapses can also activate various classes of mGluRs. Some of these are located at the very edges of synapses, surrounding the AMPA and NMDA receptor-rich postsynaptic densities. Both cerebellar parallel fiber synapses and Schaffer collateral synapses have postsynaptic mGluRs (group I) that encircle the postsynaptic densities. At cerebellar synapses, high-frequency trains of presynaptic stimuli are required to elicit mGluR-triggered EPSCs and intracellular calcium signals. In both the hippocampus and cerebellum, the activation of these perisynaptic G-protein-coupled receptor subtypes appears to be limited by EAATs (see Fig ure 4). Postsynaptic neuronal EAATs are co-localized with the mGluRs, and in the cerebellum neuronal EAATs seem to be specialized to limit the activation of these perisynaptic mGluRs.

Spillover to receptors on presynaptic terminals Another class of distant glutamate targets include group II mGluRs (mGluR2 and mGluR3), which are located on excitatory presynaptic terminals. In hippocampal cultures, the mGluR-mediated presynaptic inhibition of glutamate and GABA release is enhanced by antagonizing glutamate uptake. In acute hippocampal slices, a presynaptic mGluR-mediated inhibition caused by spillover of glutamate to distant heterosynaptic targets is limited by EAAT activity. Thus, glutamate acting at some distance from release sites on presynaptic mGluRs generates a form of presynaptic autoinhibition, and this autoinhibition is tightly controlled by glutamate uptake. Similar findings are obtained for presynaptic mGluRs on GABA-releasing terminals.

Introduction

The trigeminal (V) motor system includes most of the jaw muscles, plus the brain stem and higher brain centers that control them and several types of sensory afferent neurons that modulate their activity. Most of these muscles are complex and are made up of many anatomical compartments that can be differentially activated, which allows great variability in patterning of movement. The major motor functions of the system include biting, chewing (mastication), swallowing, respiration, and speech, as well as gagging, coughing, and several more simple reflexes. The proper function of the jaw muscles and their effector organs (the teeth) is crucial for efficient ingestive motor behavior, during which the foodstuffs are crushed and ground down to a size appropriate for swallowing. Highly coordinated processes that include efficient sensory feedback are necessary to allow forces to be properly adapted to the texture of foodstuffs in the mouth during chewing and to coordinate the articulation phase of speech. Major dysfunctions of the central nervous system (CNS) (e.g., cerebral palsy and stroke) can have devastating effects on ingestive motor functions and speech, but the most common cause of dysfunction by far is the loss of teeth. This article provides a review of the neural circuits and mechanisms that underlie the function of the V motor system, with a particular focus on the processes in the CNS.

Peripheral Components

The peripheral components of the V motor system in humans and other mammals include the so-called 'jaw-closing' (JC) muscles (masseter, temporalis, medial pterygoid), the jaw-opening (JO) muscles (anterior digastric, mylohyoid), and the lateral pterygoid muscle, the superior and inferior heads of which may contribute differentially to JC, JO, and horizontal jaw movements. The contractile and viscoelastic elements of these muscles, as well as their sensory and motor innervations, are beyond the scope of this article but have recently been reviewed. Their receptors in general show properties analogous to those of their counterparts in muscles supplied by spinal nerves, but it should be noted that there are some significant differences between these features of the jaw muscles and those of the limbs, trunk, and neck. Whereas muscle spindles and Golgi tendon organs are plentiful in most spinally innervated muscles and, especially in the case of the muscle spindles, are viewed as essential elements of motor control, they are virtually nonexistent in the anterior digastric, mylohyoid, and lateral pterygoid muscles. Moreover, primary afferent neurons that innervate the muscle spindles of the JC muscles have their primary afferent cell bodies within the CNS, in the V mesencephalic nucleus (Mes V), and not in the trigeminal equivalent of the spinal dorsal root ganglia. This endows JC muscle spindles, and thus the V motor system, with unique features (see next section). Another unique feature of the peripheral components is that the V motor system can utilize sensory inputs from tissues that occur only in the orofacial region (e.g., tooth pulp, periodontal tissues, cornea). The V motor system thus has a wide range of sensory inputs from muscle (muscle spindles, tendon organs, nociceptors), teeth, cornea, facial skin, oral and nasal mucosa, periosteum, and temporomandibular joint (TMJ) that can initiate or regulate jaw muscle activity. These are considered in more detail in the following sections.

Central Components

Trigeminal Motor Neurons

The V motor neurons are arranged in a musculotopic fashion within the trigeminal motor nucleus (Motor V) in the brain stem. The pools supplying the powerful temporalis, masseter, and medial pterygoid muscles overlap slightly and occupy the rostral two-thirds of the nucleus. Within each pool of these complex JC muscles, motor neurons supplying functionally distinct compartments intermingle. The motor neurons of the weak JO muscles (anterior digastric, mylohyoid) are found in the ventromedial middle third and the caudal portion of Motor V. The muscles are also innervated by a few small cholinergic neurons ventral to the V motor root. The dendrites of JC motor neurons ramify extensively, but do not extend far beyond the boundaries of Motor V, while JO motor neuron have dendrites extending into the adjacent reticular areas, but not into JC motor neuron pools. Spinal motor neurons have recurrent collaterals that contact Renshaw cells, which are responsible for recurrent inhibition, but there is no good evidence for recurrent inhibition in Motor V.

Cajal was the first to note that V motor neurons appear to enter the motor root without giving off collaterals, and this has been confirmed many times in the subsequent century.

Like other types of motor neurons, V motor neurons express several types of voltage-gated Ca^{2+} channels. These are involved in the release of acetylcholine (ACh) at the end plates but also in the control of the electrical properties of the soma and dendrites. As in spinal motor neurons, Ca^{2+} channels are essential for the generation of sustained bursts of activity during movement. The channels associated with *N*-methyl-D-aspartate (NMDA) receptors seem to be particularly important in motor control, and blockage of these receptors suppresses motor neuron activity during rhythmical jaw movements. The activation of NMDA receptors has several effects that allow the motor neurons to oscillate between two relatively stable membrane states: the depolarized state (plateau potential) during which they fire repetitively, and a repolarized silent state.

The neurotransmitters and modulators that have been identified in synaptic terminals on spinal motor neurons have also been found in synapses within Motor V. These include excitatory and inhibitory amino acids, biogenic amines, neuropeptides, and nitric oxide, and the effects of these substances on trigeminal and spinal motor neurons do not differ in any substantial way. However, there are differences in inputs to JC and JO motor neurons. Up to 80% of terminals contacting JC motor neurons contain inhibitory amino acids (γ-aminobutyric acid (GABA), glycine, or both), compared to about 40% of synapses on JO motor neurons. Most of those remaining are glutamatergic; less than 5% contain the other transmitters and modulators. The most studied of the latter is serotonin, which originates in the raphé nuclei. It has little effect on quiescent motor neurons, but does increase motor neuron excitability during suckling and mastication.

As noted earlier, a unique feature of the V motor system is that cell bodies of all the muscle spindle primary afferents (and about half of the mechanoreceptors in the periodontal ligament) are within the CNS, where they form the V mesencephalic nucleus (Mes V). They are large monopolar neurons like mechanoreceptors in the V and dorsal root ganglia, but unlike the latter, they are contacted by synaptic terminals. Inputs to these neurons from neighboring areas are mainly excitatory, even those mediated by GABAA receptors. GABA depolarizes these neurons because their chloride equilibrium potential is above their resting membrane potential due to a lack of a specific chloride transporter.

Like some large-diameter spinal dorsal root afferents, the jaw muscle spindle cell bodies have resonant properties that produce high-frequency oscillations near their resting membrane potential. Synaptic inputs reset the oscillation and increase the amplitude of the fast oscillations for several cycles. This, combined with electrical coupling to other afferents or to the dendrites of multipolar interneurons, may cause sustained and synchronous firing in groups of Mes V neurons. Synchrony may be important during rapid biting and during the mastication of very hard or tough foods.

Synaptic inputs to jaw muscle spindle afferents are not restricted to the soma. As is the case in other classes of sensory afferents, GABAergic synapses also occur on presynaptic terminals where they induce depolarization that is sometimes strong enough to trigger firing of antidromic action potentials. GABAergic axons are also found in close apposition to the main axons of these afferents, and inputs from local interneurons cause GABAA receptor-mediated blockade of the antidromic action potentials. These mechanisms seem to contribute to the patterning of mastication (see the section titled 'Brain stem pattern-generating circuits').

Premotor Interneurons

Many inputs to Motor V are supplied by glutamatergic, GABAergic, and glycinergic neurons within the rostral V spinal nucleus, the dorsomedial V main sensory nucleus (Main V), and a large band of the adjacent parvocellular lateral reticular formation (RF). These nuclei project to both Motor V nuclei and their contralateral counterparts. The RF interneurons form a column that runs caudally from the lateral part of the nucleus pontis oralis, through the Motor V and the reticular zone surrounding it (including the supratrigeminal and intertrigeminal areas). This column continues caudally through the parvocellular lateral RF down to the hypoglossal nucleus. There are very few direct inputs from the medial RF to Motor V.

The premotor neurons are mainly small fusiform or triangular neurons with dendritic trees extending horizontally in two to three directions over less than 500 μm. Most regions project to both JO and JC pools, but there are some distinctions: dorso-medial Main V projects predominantly, if not exclusively, to JC motor neurons, while projections from the rostral V spinal nucleus are mostly directed to JO motor neurons.

On the basis of a limited number of studies, it seems that the electrophysiological properties of these cells are relatively uniform and typical of small interneurons. Many are spontaneously active, but few

fire rhythmically in response to hyperpolarizing or depolarizing current injection. The exception is dorsomedial Main V, where rhythmic bursting appears to be common (see next section).

Many premotor neurons receive very strong monosynaptic inputs from primary afferents and motor cortex, but they are also tightly interconnected. Stimulation of any subdivision of the premotor neuron zone affects all other subdivisions. Most postsynaptic potentials are excitatory (EPSPs), but some are inhibitory (IPSPs) or mixed. Transmission is rapid and robust in this network. Some parts of the network are strongly interconnected with the medial RF.

Brain Stem Pattern-Generating Circuits

As noted previously, the jaw muscles do the major work in chewing and also participate in several other sensorimotor functions that include swallowing and respiration. These three primitive but vital motor patterns can all be carried out by animals (including humans) that have no CNS above the brain stem. All three of these motor patterns depend on hindbrain central pattern generators (CPGs), neural networks that can generate the fundamental patterns of movement in the absence of structured inputs from higher centers or from the periphery. It is clear that the respiratory, masticatory, and swallowing CPGs are separate entities, but we do not know yet whether suckling is controlled by a separate CPG or by the CPG that also controls mastication. Rhythmical sucking begins *in utero*, while mastication makes its appearance with the posnatal eruption of the teeth and with the maturation of key neurons in the evolving masticatory CPG.

The masticatory CPG can be activated by tonic stimulation of oral sensory afferents and of inputs from the sensorimotor cortex and other forebrain and midbrain structures (also see the section titled 'Higher center mechanisms'). Pattern generation is usually studied in paralyzed anesthetized animals in which the motor output is recorded from motor neurons ('fictive mastication'). During fictive mastication, JO motor neurons fire bursts of action potentials at very high frequency (up to 250 Hz) that are superimposed on long rhythmical depolarizing potentials. The membrane potential returns to resting levels during the JC phase. Similar slow potentials depolarize JC motor neurons during their active phase, but these cause only weak firing. Then, JC motor neurons are hyperpolarized during the JO phase by glycine. These important differences in membrane potential and in firing rate between the two motor neuron pools reflect the relative importance of sensory feedback in controlling their outputs (see later).

The essential parts of the masticatory CPG are found between the rostral poles of Motor V and the facial motor nucleus. The left and right sides of the CPG are connected by axons that cross the midline at several levels, but, like the spinal cord locomotor CPG, each side can generate a rhythm if they are surgically separated. The CPG is made up of neurons within the regions of the caudal pons and rostral medulla that contain the V premotor interneurons. These nuclei also project to motor neurons in the facial and hypoglossal nuclei. Many neurons in these regions change their pattern of firing during fictive mastication. Most of these 'masticatory' neurons receive sensory inputs from oral mechanoreceptors or muscle spindles and from the sensorimotor cortex and subcortical areas, as noted later. Some of them fire tonically during fictive mastication, but most generate rhythmical bursts of action potentials in phase with bursts in either the JC or JO motor neurons, but not both. The CPG also causes presynaptic depolarization of the terminals of jaw muscle spindle afferents within the lateral RF and spinal V nuclei during the JC phase, and this causes bursts of antidromic action potentials that appear to enter branches in Motor V and to add to the depolarization of JC motor neurons. However, GABAergic synapses on the axons themselves prevent propagation into Mes V.

The medial RF at the level of Motor V also seems to participate in the control of mastication. Many neurons in its dorsal half fire in either the JO or JC phases, while most ventral neurons fire tonically. These tonic neurons appear to inhibit the lateral subgroups during mastication, while the phasic dorsal neurons have mixed effects.

The way in which the final masticatory pattern is generated is only beginning to be understood. The pattern varies greatly between foods, and also from the start of a chewing sequence to the end. By comparing activity generated in two or more patterns, we now know that the CPG contains subpopulations of neurons, few of which are active during all motor patterns. For instance, about half of the neurons in the lateral RF and V spinal nucleus participate in grinding on the ipsilateral posterior teeth but drop out during grinding on the contralateral side. Those that participate in both patterns initially change their firing pattern. This data show that at least two mechanisms are in play during the genesis of different patterns of mastication: addition and subtraction of neurons from the active pool, and changes in firing frequency of common elements. The extensive interconnections between the various subgroups of interneurons described previously must be important in this reorganization, and evidence from other CPGs

suggests that the network could also participate in generating the masticatory rhythm.

The rhythm of respiration arises from neurons that show repetitive low-frequency oscillations of their membrane potentials even when isolated from all inputs, and a subpopulation of masticatory CPG neurons in dorsal Main V shows this feature under certain conditions. This ability to burst develops postnatally in Main V, in parallel with the emergence of mastication. It depends on a persistent Na^+ current (INap) that appears to be modulated by the extracellular Ca^{2+} concentration.

Reflexes

Two major reflexes can be triggered with the jaw at rest; one that opens the jaw and one that closes it. The jaw-closing reflex (JC reflex) is the myotatic (stretch) reflex of the JC muscles, in which stretch of muscle spindle afferents activates JC motor neurons through monosynaptic and polysynaptic pathways. The JC reflex provides rapid compensation for changes in the resistance of food during mastication. It also modulates JC muscle tension in response to changes in the gravitational load on the mandible during locomotion.

The jaw-opening reflex (JO reflex) is the V equivalent of the flexion-withdrawal reflex of the limbs. It is a disynaptic reflex that can be triggered by two types of orofacial stimuli: tapping on the lips, teeth, and palate or noxious stimulation of the face, intraoral tissues, muscle, and joints. In animals, JO motor neurons are excited and JC motor neurons inhibited by glycinergic interneurons at the same time. In humans, activation of JO motor neurons is almost absent, but the inhibition of JC motor neurons is very strong.

The Importance of Sensory Feedback during Mastication

The previous sections on reflexes and CPG circuits mention the effects of sensory inputs. Here we consider these in further detail. During mastication, several groups of afferents provide feedback to motor neurons, the CPG, and higher centers, and the pattern of activity that emerges from the motor neurons is the result of these interactions. The effects of three groups, muscle spindles, periodontal mechanoreceptors, and nociceptors, have been well characterized.

The muscle spindles in the JC muscles are stretched during the JO phase of mastication, which causes them to fire at high frequency. However, this does not cause the JC motor neurons to fire because they are hyperpolarized by the CPG (see the section titled 'Brain stem pattern-generating circuits'). During the JC phase, the muscle spindles fire strongly when food between the teeth decelerates the mandible. Since JC motor neurons are now depolarized by the CPG, reflex inputs from the spindles increase firing frequency and burst duration.

Periodontal mechanoreceptors around the roots of the teeth respond to loads generated between the upper and lower jaws. Although tapping on the teeth can cause the JO reflex with the jaw at rest (see the section titled 'Reflexes'), the heavy pressures generated during the JC phase of mastication do not inhibit JC muscles. Instead, these mechanoreceptors cause the JC phase to lengthen and JC motor neurons to fire at higher frequency. It appears that the CPG shuts down the inhibitory pathway and opens up an excitatory one during mastication, as happens with Golgi tendon organ pathways during locomotion. The harder the food, the greater the effect of positive feedback from the periodontal receptors and muscle spindles.

The CPG also modulates inputs from other oral mechanoreceptors and particularly from nociceptors. Nociceptors are frequently stimulated by biting the tongue or cheek, or by objects (e.g., bones) in food. When this happens, JC motor neurons are quickly turned off (<10 ms) and the CPG inhibited. Transmission through this short inhibitory pathway is facilitated by the CPG during the JC phase, which increases the protection of soft tissues at the time that they are most vulnerable.

Higher Center Mechanisms

The V brain stem neurons relaying to thalamus or other brain regions such as the cranial nerve motor nuclei are subject to segmental (afferent) modulation and to descending modulation from various cortical and subcortical structures. Because many of these neurons contribute as interneurons to jaw reflexes and other motor behaviors evoked by stimulation of orofacial tissues, these reflex responses can also be regulated by these modulatory influences. The descending modulatory inputs influence several of the brain stem interneuronal pools mentioned previously, and some (e.g., from sensorimotor cerebral cortex) may even have direct input to Motor V in humans.

Subcortical processes One very important set of subcortical influences on the V motor system derives from various components of the basal ganglia and substantia nigra, as exemplified by the jaw motor deficits or abnormal motor behaviors (e.g., oral dyskinesia) that can result from damage to these structures or from alterations in key neurochemical processes (e.g., dopamine, ACh, GABA, NMDA) within them. Other subcortical areas that can modulate the V motor system include the amygdala, subthalamic nucleus,

nucleus accumbens, hypothalamus, anterior pretectal nucleus, red nucleus, periaqueductal gray, raphé nuclei, and cerebellum. In addition to dopamine, ACh, GABA, and NMDA receptor mechanisms mentioned previously, catecholamine, vasopressin, opioid, and serotonergic-based mechanisms in particular contribute to these various subcortical influences on the V motor system. These features emphasize the complexity of the subcortical control circuits and neurochemical mechanisms involved in jaw motor control, as in the spinal motor control systems.

Cortical processes Several cortical areas exert descending influences on brain stem and other subcortical regions. Imaging and transcranial magnetic stimulation studies in humans have reported that jaw movements may be associated with activation of several cortical areas, e.g., the face primary motor cortex (MI), primary somatosensory area (SI), premotor cortex, supplementary motor area, cortical masticatory area (CMA), insula, and anterior cingulate gyrus. This is consistent with studies in monkeys and subprimates which have shown that intracortical microstimulation (ICMS) can evoke orofacial movements from some of these sites and that cold block or ablation especially of face MI or CMA can disrupt the movements.

The ICMS studies have also revealed that each orofacial muscle or movement is represented multiple times within face MI, including elemental movements (e.g., jaw opening) and more complex activities such as mastication and swallowing, suggesting that each MI output zone controls one of the many contextual functions in which a jaw muscle participates. Furthermore, the cold block or ablation of face MI or CMA may disrupt chewing and swallowing to varying degrees. This indicates that each may be involved differentially in the production and patterning of chewing and swallowing, including the coordination of the tongue, facial, and jaw movements that are necessary for the proper ingestion and transport of food or liquid, and is consistent with studies showing that many face MI and CMA neurons discharge in relation to chewing or swallowing in monkeys or subprimates. Most MI neurons also discharge in association with more elemental orofacial movements. In addition, many face SI neurons also discharge in relation to these movements, including jaw movements. These findings emphasize the importance of the face SI as well as the face MI in the fine motor control of jaw movements. Furthermore, face MI and SI, and perhaps also the CMA, may use the orofacial afferent inputs that they receive to send corticofugal signals directly or indirectly (e.g., via the CPGs) to the V motor neurons and thereby guide, correct, and control movement by the use of sensory cues prior to movement, and by using sensory information generated during movement. Recent findings also implicate face MI in orofacial motor skill acquisition and adaptation to intraoral alterations.

In summary, the V motor system is involved in many complex motor behaviors as well as in simpler behaviors that are either reflex in nature or repetitive. The simple behaviors are coordinated in the brain stem, whereas the more complex motor patterns may involve cortical as well as subcortical regions. Sensory feedback interacts with the central motor programs at all levels of the CNS.

Trigeminal Neuralgia

S Love and N K Patel, University of Bristol Institute of Clinical Neurosciences, Bristol, UK

Introduction

Trigeminal neuralgia (TN) is a syndrome of intermittent facial pain. Because the pain is so severe that it often induces ticlike grimacing, trigeminal neuralgia is also known as tic douloureux (the term was coined by Nicholas André, in his book, *Observations Pratiques sur les Maladies de l'Urethre et sur Plusieurs Faits*, in 1756). However, it was not until 1773 at the Medical Society of London that John Fothergill gave a full and accurate description, and at times the condition has been named Fothergill's disease. In 1999, Rose credits the earliest written description of trigeminal neuralgia to Aretaeus of Cappadocia, in the second century AD.

Clinical Features

The International Association for the Study of Pain defines TN as "a sudden, usually unilateral, brief stabbing recurrent pain in the distribution of one of the branches of the fifth cranial nerve." The incidence of TN is about 4.5 per 100 000 per annum. It is slightly more common in women. The mean age of onset is about 50 years; however, the incidence curve is skewed to the right and the peak incidence of TN is at the age of 60s and 70s. Young adults and children are occasionally affected. Although familial examples of TN are reported, the large majority of cases occur spontaneously. The attacks are characterized by intense unilateral facial pain, often described as stabbing, and sometimes likened to electric shocks. It is localized to areas of the face within the territory of the trigeminal nerve. The pain most often affects the maxillary and mandibular divisions of the trigeminal nerve and the right side is more often involved than the left. Individual attacks usually last less than a minute but tend to recur in bouts that last weeks or months. During bouts, attacks may be relatively infrequent but can occur as often as every few minutes, remitting only during sleep. The attacks may be spontaneous but in most instances are initiated by mild stimulation of small areas of skin or mucosa within the territory of the affected trigeminal nerve. Typical stimuli include light touching, drafts of wind, eating, drinking, washing, brushing of teeth, shaving, and applying makeup. Very rarely attacks are triggered by loud noises, bright lights, or stimuli affecting cranial nerves other than the trigeminal. Between attacks, patients are normal on neurological examination unless there is associated disease, such as multiple sclerosis (see later). Between bouts, patients experience spontaneous remissions that may last months or years and during which patients are completely free of symptoms. Over the years, however, the attacks often become more frequent and the pain more sustained and less responsive to medication.

Etiology of TN

Compression of the Trigeminal Nerve Root

In 80–90% of patients, TN is caused by compression of the trigeminal nerve root within its proximal few millimeters (the root entry zone) by a loop of artery or vein. This part of the trigeminal nerve root consists of central white matter (i.e., nerve fibers that are myelinated by oligodendrocytes) (Figure 1). Recent studies have shown that the compressed nerve fibers undergo demyelination and tend to be in close juxtaposition (Figures 2 and 3). This arrangement is conducive to both spontaneous impulse activity and ephaptic cross-talk (i.e., nonsynaptic spread of excitation from one axon to another adjacent axon, as a result of the extracellular current flux that is associated with depolarization of the first axon). Ephaptic cross-talk between demyelinated fibers subserving light touch (excited by stimulation of mucocutaneous trigger zones) and those involved in the generation of pain has been suggested to underlie the development of TN in most patients with nerve root demyelination.

Several syndromes involving hyperactivity and abnormal spread of activity within the distribution network of innervation of cranial nerves VII–XII are now known often to be associated with vascular compression of the relevant nerve root. These include hemifacial spasm, glossopharyngeal neuralgia, the rarer syndromes of superior oblique myokymia, vestibular paroxysmia and geniculate neuralgia, and some cases of spasmodic torticollis. In addition, hypertension has been associated with arterial compression of the ventrolateral aspect of the rostral medulla in the region of entry of the left glossopharyngeal and vagus nerve roots. Multiple syndromes of cranial nerve hyperactivity due to vascular compression of nerve roots are sometimes present in combination.

Although a loop of blood vessel is usually to blame, there are other occasional causes of compression-induced TN and other related syndromes of cranial nerve hyperactivity. These include local vascular

Figure 1 Normal trigeminal nerve root. Note that the proximal part of the root (arrow) consists of central nervous system white matter and extends several millimeters away from the pons (to the right).

malformations, cysts, neoplasms (particularly cholesteatomas, meningiomas, and schwannomas of the eighth nerve), and deformities of the skull base.

Primary Demyelination of the Trigeminal Nerve Root

After vascular compression of the trigeminal nerve root, the next most frequent cause of TN is multiple sclerosis. This accounts for about 2.5% of patients with trigeminal neuralgia, and a relatively higher proportion of those at 30–40 years of age. Conversely, the prevalence of TN among patients with multiple sclerosis is of the order of 2–4%. Bilateral TN is most often caused by multiple sclerosis. The TN in multiple sclerosis is usually associated with demyelination in the proximal part of the trigeminal nerve root or the immediately adjacent part of the pons. Histology has revealed the presence of clusters of juxtaposed axons without intervening glial processes (as also occurs in patients whose TN is due to vascular compression of the trigeminal nerve root). Rarely, patients with peripheral nerve demyelination due to Charcot–Marie–Tooth disease develop trigeminal neuralgia.

Other Causes of TN

TN is very occasionally a manifestation of neoplastic infiltration of the trigeminal nerve root, gasserian ganglion or nerve, or deposition of amyloid within these structures. A few patients have nondemyelinating lesions of the pons – ischemic, hamartomatous, or neoplastic. Rarely, TN has affected several members of the same family.

Idiopathic TN

In about 5–15% of patients the anatomical or pathological substrate of TN remains unclear, even after extensive investigation that includes direct endoscopic inspection of the nerve root.

Figure 2 Focal demyelination of the trigeminal nerve root in a patient with TN due to vascular compression. In this case, the compressing blood vessel could not safely be mobilized. A partial rhizotomy was therefore performed, during which a small wedge of tissue was excised from the caudal part of the nerve root. The tissue was fixed in glutaraldehyde for resin histology and electron microscopy. (a) Semithin resin section through the region of compression, which was within the proximal (central nervous system) part of the nerve root but close to its junction with the peripheral nervous system. The section includes a wedge-shaped region of demyelination, to the left of which are many thinly remyelinated central nervous system nerve fibers. To the right of the section are some normally myelinated nerve fibers that are within the distal (peripheral nervous system) part of the nerve root. (b) Electron photomicrograph of an ultrathin section through the junction between the demyelinated central nervous system (to the left) and normally myelinated peripheral nervous system (to the right) parts of the nerve root. (c) Electron photomicrograph showing many of the axons within the region of demyelination to be in direct apposition (arrows point to some). The section includes a single oligodendrocyte nucleus.

Figure 3 Schematic illustration of the pathological findings in trigeminal neuralgia due to vascular compression.

Investigation

A diagnosis of TN can usually be made solely on the basis of a typical clinical history and an absence of neurological abnormalities on physical examination. Magnetic resonance imaging (MRI) of the brain is helpful in excluding associated disease such as multiple sclerosis, and is advisable in patients who present before 55 years of age or with atypical features, or who fail to respond to conventional medical treatment (see later). With advances in MRI, it is now often possible to demonstrate neurovascular compression preoperatively; oblique sagittal images are often helpful. The compressive vessel can be detected using routine MRI sequences and magnetic resonance angiography (MRA) with gadolinium enhancement (Figure 4).

Treatment

Most patients respond very well to carbamazepine. The starting dose of carbamazepine is 100 mg once or twice daily, and this is often effective, at least initially; however, the daily dose may need to be increased by up to 1.2 g, to control the acute bouts of TN. Over a period of several years, patients often become less responsive to carbamazepine and require further drugs, often in combination. The principal second-line treatments are the muscle relaxant baclofen and the anticonvulsant drugs gabapentin, lamotrigine, and phenytoin.

Several types of physical intervention have been used in patients who become refractory to medical

Figure 4 Demonstration of a compressing arterial loop by magnetic resonance angiography. (a) Fast field echo imaging of the posterior fossa in the axial plane shows an arterial loop (arrows) medially compressing the right trigeminal nerve in the root entry zone. (b) A reconstructed magnetic resonance angiogram shows the arterial loop (arrow) responsible for right trigeminal nerve root compression.

treatment. In many centers, microvascular decompression is regarded as the treatment of choice for medically intractable trigeminal neuralgia. This procedure is performed under general anesthesia and involves a retromastoid craniotomy, through which the trigeminal nerve root is exposed. Any compressing blood vessel is mobilized and is either separated from the root by Teflon felt or displaced and fixed to the dura by Teflon slings (Figure 4). This relieves pain in 80–90% of patients, although about 20% will need some continuing medication. Over a 10-year period approximately 10–15% will experience recurrent TN and may need further microvascular decompression or some other therapeutic procedure (see later). The mortality is generally under 0.5% but morbidity, predominantly from cerebrospinal fluid leakage and infection, ranges from 1% to 5%. Facial numbness or paresthesias are rare after microvascular decompression.

Figure 5 Microvascular decompression of the trigeminal nerve root. (a) Posterolateral exposure reveals a loop of artery that is pressing (arrow) against the anterior aspect of the nerve root. (b) The artery has been mobilized, transposed, and fixed to the dura with Teflon slings (toward the top right of the image) and fibrin glue. Intraoperative photographs courtesy of Professor Hugh Coakham, Department of Neurosurgery, Institute of Clinical Neurosciences, Frenchay Hospital.

The other types of physical intervention for TN are various forms of ablative procedure. These are suitable for the treatment of patients with medically intractable TN in whom (1) no compressing blood vessel is demonstrable, (2) symptoms persist despite adequate microvascular decompression, (3) a compressing blood vessel is present but not technically amenable to safe repositioning, (4) there are medical contraindications to surgery under general anesthesia, (5) life expectancy is less than 10–15 years, and (6) appropriate surgical expertise is not available for microvascular decompression.

Numerous types of ablative procedures have been used in the past. The ablative techniques most commonly used nowadays can be subdivided into the percutaneous procedures (percutaneous radiofrequency thermocoagulation, injection of glycerol, or balloon compression), stereotactic radiosurgery, and partial rhizotomy. The percutaneous procedures have an initial effectiveness of over 90% but carry a high risk of facial numbness and paresthesias. In most series, the recurrence rate has been considerably higher than that after microvascular decompression. Radiosurgery is used increasingly . Its initial effectiveness of more than 90% is consistent with that of other ablative procedures, but there is still a paucity of good follow-up data; the available information suggests that up to 50% of patients will experience some relapse of symptoms but that in about two-thirds of cases the degree of pain relief is nonetheless sufficient to avoid the need for continuing medical treatment. The risk of facial numbness or paresthesias is about 10%. Partial rhizotomy carries the same general anesthetic and neurosurgical risks as does microvascular decompression (Figure 5) and produces facial numbness in a relatively high proportion of patients. However, it is successful in relieving the neuralgia in the majority of patients and is often used when intraoperative inspection of the trigeminal nerve root either fails to reveal a compressing blood vessel or shows one to be present but not technically amenable to safe repositioning.

Triplicate Repeats: Huntington's disease

J-H J Cha and K B Kegel, MassGeneral Institute for Neurodegenerative Disease, Charlestown, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In 1872, the physician George Huntington described the neurologic disorder that has come to bear his name. This disorder was originally called Huntington's chorea, from the Greek word for dance, referring to the dancelike adventitious movements that are the hallmark of the disorder. Since chorea is not a universal feature, especially in the juvenile forms of the disease, the term Huntington's disease (HD) is now used. Huntington's original report noted the familial inheritance, the adult onset, the constellation of emotional, cognitive, and motor symptoms, and the inexorably progressive and ultimately fatal nature of the disease. Since that time, Huntington's disease has been a paradigmatic neurodegenerative disorder, with advances in HD at the forefront of molecular genetics, of ethical issues around genetic testing, as well as of many important concepts in modern neuroscience.

Huntington's Disease Gene

Recombinant DNA techniques became available in the late 1970s, and their power was brought to bear on the search for the Huntington's disease gene. In 1983, using anonymous DNA markers spread over the human genome, David Housman at the Massachusetts Institute of Technology and James Gusella at Massachusetts General Hospital used DNA samples from the many members of a large Venezuelan family to localize the *HD* gene to the long arm of chromosome 4. In 1993, the Huntington's Disease Collaborative Research Group, a consortium of gene hunter laboratories from around the world, isolated a gene originally named *IT15* ('interesting transcript 15'); it was subsequently renamed *HD*.

The defect in *HD* was found to reside in an unstable region of the gene, in that a cytosine–adenine–guanosine (CAG) trinucleotide repeat present in normal alleles was abnormally expanded in the alleles of HD patients. CAG is the codon for glutamine, and this trinucleotide repeat gives rise to a polyglutamine moiety within the huntingtin protein. Normal huntingtin alleles contain from 6 to 35 CAG repeats, giving rise to 6–35 glutamines in the mature protein, and variation occurs in the normal human population. Patients with Huntington's disease invariably have alleles with more than 35 repeats, and greater than 40 repeats invariably gives rise to HD. There is a 'gray area,' between 35 and 39 repeats, where some uncertainty exists. Some patients with up to 39 repeats have lived into their 70s without developing overt signs of HD, although age of onset as late as 80 years has been described.

Age of onset correlates negatively with repeat length, although the correlation is strongest for high CAG repeat numbers. That is, although repeat numbers of greater than 70 invariably produce juvenile onset of HD, more common repeat numbers – for example, in the 40–45 range – produce a varied age of onset. Neuropathologic grade also varies with CAG number, with the most damage seen in brains with the highest CAG repeats. However, CAG repeat length accounts for only about 50% of the variability of age of onset, suggesting that there are other genetic or environmental influences on age of onset.

HD thus belongs to a novel family of neurologic diseases, the trinucleotide repeat disorders. Certain other diseases, such as myotonic dystrophy, fragile X syndrome, and Friedreich's ataxia, are characterized by trinucleotide repeat expansions in noncoding regions of the genes. In contrast, HD belongs to a family of disorders characterized by expansion of a CAG trinucleotide motif within the coding region of the gene. The CAG repeat disorders, or polyglutamine disorders, display common features, including dominant inheritance, adult onset, threshold levels of approximately 37 repeats, and progressive neurodegeneration (Table 1).

Clinical Features

Huntington's disease is typically an adult-onset disorder characterized by insidious onset of both neurologic and psychiatric symptoms. In the United States, approximately 25 000 persons are affected by HD (about 10 per 100 000 population) and approximately 150 000 persons are at 50% risk for the disease by virtue of having an affected parent. Symptoms usually begin in the mid-30s to mid-40s, although disease onset can range from as young as 2 years or as old as 80 years. Initial symptoms include personality change and the gradual appearance of small involuntary movements. Symptoms progress, with chorea becoming more obvious and incapacitating. Over years, motor symptoms worsen such that walking

Table 1 CAG trinucleotide repeat disorders

Disease	*Protein*	*Inheritance*	*Normal repeat number*	*Range of CAG repeats in disease*
Spinobulbar muscular atrophy (Kennedy's disease)	Androgen receptor	X-linked dominant	11–33	40–62
Huntington's disease	Huntingtin	Autosomal dominant	1–39	36–121
Spinocerebellar ataxia, type 1 (SCA1)	Ataxin-1	Autosomal dominant	<29–36	43–60+
Spinocerebellar ataxia, type 2 (SCA2)	Ataxin-2	Autosomal dominant	15–24	35–59
Spinocerebellar ataxia, type 3 (SCA3; Machado–Joseph disease)	Ataxin-3	Autosomal dominant	13–36	62–82
Spinocerebellar ataxia, type 6 (SCA6)	a_{1a} subunit of voltage-dependent calcium channel	Autosomal dominant	4–16	21–27
Spinocerebellar ataxia, type 7 (SCA7)	Ataxin-7	Autosomal dominant	7–17	38–130
Dentatorubral-pallidoluysian atrophy (DRPLA)	Atrophin-1	Autosomal dominant	7–25	49–85
Spinocerebellar ataxia, type 17 (SCA17)	TATA-binding protein (TBP)	Autosomal dominant	<42	≥43

becomes more difficult, as do speaking and eating. Weight loss is common, partially due to the extra energy required for adventitious movements but also due to increased resting basal energy expenditure. Most HD patients eventually succumb to aspiration pneumonia, due to swallowing difficulties.

About 10% of cases start before the age of 20 years. The juvenile form (Westphal variant) is more parkinsonian in nature. Rather than chorea, the prominent features are bradykinesia, rigidity, and tremor. Seizures can be present in juvenile patients. Juvenile-onset HD usually results from paternal genetic transmission. For individuals who develop symptoms before age 10 years, more than 90% have an affected father. This tendency for 'anticipation' – younger age of onset in successive generations – is especially pronounced in cases of paternal transmission. This phenomenon is not completely understood but may be the result of further CAG expansion during spermatogenesis. Interestingly, both the juvenile-onset and adult-onset phenotypes can be present within the same family.

New mutations have been described, usually from a parent carrying an 'intermediate allele.' Homozygotes for the *HD* gene have also been described. The clinical symptomatology manifested by these very few patients appears to be no worse than that manifested by patients carrying only a single *HD* gene. Thus, HD appears to be a truly genetically dominant disease.

Pathology

Neuropathologically, HD is characterized by gross atrophy of the basal ganglia, specifically the striatum (caudate-putamen), although pathologic changes have also been described in cortex, thalamus, and subthalamic nucleus. Atrophy and gliosis of the caudate nucleus and putamen are progressive and marked. In juvenile-onset cases, cell loss tends to be more pronounced, and can also be seen in the cerebellum. Within the striatum, HD differentially affects subpopulations of neurons, with projection neurons preferentially being lost rather than interneurons. The γ-aminobutyric acid (GABA)-containing medium spiny neurons, which are the output projection neurons, comprise approximately 90% of striatal neurons. HD seems to spare the interneurons while devastating the projection neurons. Consistent with a loss of projection neurons was the early finding that GABA levels were markedly reduced in the caudate-putamen of HD patients.

Of the two populations of striatal projection neurons, the neurons of the indirect pathway (i.e., enkephalin/GABA-containing neurons) are affected first, thus providing an anatomical explanation for the increased movement which is the hallmark of HD. Consistent with this observation is the fact that in early-grade HD cases, markers for this population of striatal neurons are decreased, including dopamine D2 receptors, adenosine A_{2a} receptors, and enkephalin. In early HD, thus, the indirect pathway is predominantly disrupted, and basal ganglia circuitry models predict an overall increase in movement, manifested as chorea and ballism (Figure 1). In later stages of adult HD, both populations of striatal projection neurons are affected, with concomitant loss of markers of the direct pathway (i.e., substance P/dynorphin/GABA-containing neurons), including dopamine D1 receptors and substance P. The functional correlate of degeneration of both direct and indirect pathways is a rigid bradykinetic state. In

Figure 1 Basal ganglia circuitry models of early and late Huntington's disease. Glu, glutamate; D1/D2, dopamine D1/D2 receptors; Sub P, substance P; Enk, enkephalin; GABA, γ-aminobutyric acid; DA, dopamine; VA/VL Thal, ventral anterior/ventral lateral thalamic nuclei; STN, subthalamic nucleus.

juvenile HD cases, which resemble Parkinson's disease, degeneration of both direct and indirect pathway striatal neurons is seen concurrently.

The mode by which neurons die in HD is unknown. One theory is that death in neurons occurs through apoptosis – that is, activation of a programmed cell death pathway. DNA fragmentation characteristic of apoptosis has been described in HD brain. However, it is not yet clear whether apoptosis is the primary pathologic event, or merely the final mode of exit for neurons which have been long compromised by some other process.

Theories of HD Pathogenesis: Excitotoxicity and Mitochondrial Dysfunction

Prior to the discovery of the *HD* gene, the leading hypotheses concerning the pathogenesis of HD implicated either excitotoxicity or energetic dysfunction. Evidence for both theories has been demonstrated in both human and animal model studies of HD. Discovery of the *HD* gene in 1993 did not reveal the pathogenetic mechanism of HD. The novel protein huntingtin had no clear relationship to excitatory amino acid neurotransmission, nor to cellular or mitochondrial energetics.

Excitotoxicity is the process in which neuronal cells die as a result of excessive excitatory amino acid neurotransmission. Excitatory amino acids, especially glutamate, have been postulated to play a role in the pathogenesis of HD because intrastriatal injections of excitatory amino acid receptor agonists, particularly agonists acting at the *N*-methyl-D-aspartate subtype of glutamate receptor, reproduce the neuropathological features of HD. Excessive glutamate has been postulated to kill neurons in a number of neurological disorders, including hypoxia–ischemia, head trauma, epilepsy, schizophrenia, and neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis. Postmortem analyses of HD brains demonstrate reduced glutamate receptors that might represent an effort by cells to reduce glutamate receptor activation and subsequent calcium influx, although this decrease in receptors may also reflect generalized neuronal loss.

Mitochondrial dysfunction has also been implicated as a pathologic mechanism in HD, potentially rendering cells vulnerable to normal ambient levels of extracellular glutamate. Positron emission tomography studies have demonstrated reduced striatal glucose metabolism in HD patients. Magnetic resonance imaging (MRI) spectroscopy shows increased levels of striatal glutamate/glutamine and lactate in HD patients, suggesting that glutamatergic function and abnormalities in energy metabolism may combine to produce pathology. Defects in mitochondrial metabolism have been demonstrated in HD brain tissue, especially in complex II–complex III activity. Further, intrastriatal injection of the complex II inhibitor malonate produces lesions reminiscent of HD. Systemic administration of another

complex II inhibitor, 3-nitropropionic acid (3-NP), produces strikingly focal striatal lesions in rodents and primates, also reminiscent of HD striatal pathology. Currently, clinical trials are exploring the effects of coenzyme Q_{10}, a compound that boosts mitochondrial energetics. In addition, creatine, which is important for storage of high-energy phosphate (creatine phosphate) and subsequent production of ATP, has been shown to extend life in transgenic HD mice, and is being explored as a potential therapy for human HD patients.

Huntingtin

HD encodes a novel protein called huntingtin. The huntingtin gene comprises 67 exons, encoding a 3144-amino-acid protein with an expected molecular mass of 348 kDa. Expectations were that the distribution of huntingtin would mirror the characteristic distribution of neuropathological damage. However, huntingtin mRNA is expressed in almost all tissues of the body and homogenously throughout the brain. No difference in expression is seen between HD and control cases. Immunohistochemical studies confirm the widespread neuronal distribution of the huntingtin protein.

Huntingtin plays an important role in early development, since mice with targeted knockout of the huntingtin gene are embryonic lethal. Humans with Wolf–Hirshhorn syndrome, who have a partial deletion of chromosome 4 and as a result have only one copy of the *HD* gene, do not have the a neurologic disease identical to HD. Therefore, having a single copy of a normal *HD* allele does not produce the HD phenotype and is sufficient for normal embryogenesis in humans. The mutation in huntingtin is thought to confer at least one gain of function. Mutant huntingtin possesses at least certain of the functional properties of wild-type huntingtin, in that mutant huntingtin can rescue the embryonic lethal phenotype seen in huntingtin-null knockout mice.

The huntingtin protein contains 'HEAT repeats,' which correspond to tandemly arranged curlicue-like structures that appear to serve as flexible scaffolding on which other components can assemble (the acronym 'HEAT' derives from names of four proteins found to contain the repeats). Huntingtin has been shown to have numerous protein-binding partners, and many of these interactors have differential affinity for the normal and polyglutamine-expanded versions of huntingtin. Numerous cytoskeletal proteins have been identified as huntingtin interactors. In addition, huntingtin binds to a number of transcriptionally active molecules, raising the possibility that mutant huntingtin may perturb the normal transcriptional activities of neurons. In addition to these interactions, nuclear localization and nuclear export domains have been identified within the huntingtin molecule, suggesting that huntingtin may be shuttled in and out of the nucleus.

The normal function of huntingtin is not completely known, although it has been proposed to act as a molecular scaffold at multiple locations within cells. Huntingtin is a soluble protein that associates with membranes. It can be transported by fast axonal transport, and may be involved in endocytosis and membrane recycling. Aside from functioning as a molecular scaffold, a number of other normal functions have been proposed for normal versions of huntingtin. Wild-type (normal) huntingtin has been found to have antiapoptotic properties. In addition, a permissive role in brain-derived neurotrophic factor (BDNF) transcription has been proposed. Wild-type huntingtin has been found to interact with the transcriptional repressor RE1-silencing transcription factor (REST) in the cytoplasm. In the absence of cytoplasmic sequestration of REST by wild-type huntingtin, REST is free to enter the nucleus, where it serves as a negative regulator or BDNF transcription.

The polyglutamine moiety has been shown to assume a β-pleated sheet conformation when the number of residues exceeds 35. Current opinion is that such a 'toxic fold' leads to aberrant binding interactions with other proteins, including with other copies of misfolded huntingtin. Consequently, one area that has been explored is whether chaperone proteins, such as the heat shock proteins, could mitigate toxicity by keeping polyglutamine-expanded huntingtin from assuming a misfolded conformation.

Posttranslational and Proteolytic Modifications of Huntingtin

Several posttranslational modifications of the huntingtin protein have been identified, including phosphorylation, sumoylation, and palmitoylation. Sumoylation (so named for 'small ubiquitin-like modifier' proteins) of the first 17 amino acids of the N-terminal regions of huntingtin can promote nuclear localization of exon 1 huntingtin fragments. Palmitoylation may govern huntingtin's interaction with membranous structures such as the Golgi or synaptic vesicles. It is likely that these posttranslational modifications alter huntingtin's intracellular distribution as well as its stability and degradation.

At least five different proteolytic mechanisms have been identified for huntingtin: cleavage by the apoptotic proteases known as caspases, cleavage by the calcium-dependent protease calpain, degradation by the ubiquitin–proteasome system, cleavage by an aspartyl protease, and autophagic digestion in the lysosome. There has been much focus on proteolytic processing

of huntingtin, since truncated fragments of huntingtin – specifically, those fragments containing the N-terminal portion of the molecule – appear to be especially toxic in a number of experimental paradigms. Compared to full-length versions of huntingtin, N-terminal fragments enter the nucleus more easily, form aggregates more readily, and induce cellular toxicity more readily. Thus, preventing certain cleavage events has been an attractive strategy by which to mitigate the toxic effects of huntingtin fragments.

Polyglutamines and Aggregates

The polyglutamine moiety that is expanded in mutant forms of the huntingtin protein gives rise to the neuropathologic changes observed in HD. A transgenic mouse model expressing only exon 1 of the huntingtin gene (the portion containing the polyglutamine moiety) develops an abnormal neurologic phenotype. The fact that such a striking phenotype could be produced in an animal expressing only exon 1 of the *HD* gene added weight to the early 'toxic fragment' hypothesis. One of the striking findings which emerged out of the findings with transgenic animals is the observation of novel inclusions in neuronal nuclei, although huntingtin normally exists as a predominantly cytoplasmic protein. This remarkable finding prompted reexamination of human biopsy and necropsy material, and abnormal huntingtin- and ubiquitin-positive nuclear and cytoplasmic aggregates were also found. Although abnormal aggregates are a striking feature of human HD and transgenic mouse HD models, recent studies have raised controversy as to the importance of inclusions. In cell culture models, the presence of inclusions was not correlated with neuronal death. Other models have suggested that inclusions may actually serve as a protective function.

Several theories have developed concerning the gain-of-function which emerges when the length of the polyglutamine moiety extends into the pathologic range. One theory proposes that polyglutamine moieties serve as a substrate for the enzyme transglutaminase. Nuclear inclusions in HD are reminiscent of protein deposits that are pathologic hallmarks of other neurodegenerative diseases; an emerging theme is that neurodegenerative diseases may be disorders of altered protein folding. Polyglutamine moieties are found within other proteins, including transcription factors. Many studies suggest that polyglutamine aggregates may serve as sinks to sequester transcription factors or to deplete proteins involved in vesicle movement. Aggregates present in the cytoplasm may also physically block vesicles, preventing transport within axons and dendrites.

Huntingtin aggregates are dynamic. In *in vitro* systems, one can visualize the appearance and growth of aggregates. In a transgenic mouse model that expressed a portion of the huntingtin protein under the control of an inducible promoter, stopping expression of the mutant transgene led to regression of the size of intranuclear aggregates, attesting to the recuperative ability of neurons with aggregates.

Pathogenesis in HD

Transcriptional Dysregulation

Human HD brains show selective downregulation of neurotransmitters and neurotransmitter receptors, a finding that has been recapitulated in transgenic mouse models. Gene expression studies using DNA microarrays have confirmed widespread alteration of mRNA levels of genes involved in neurotransmission, calcium homeostasis, and intracellular signaling. While transcriptional dysregulation has been acknowledged as an important pathogenic feature in HD, the exact mechanisms have not been elucidated.

Normal huntingtin is found predominantly outside the nucleus, whereas mutant versions, especially N-terminal fragments, of huntingtin tend to localize in the nucleus, where they can form visible aggregates. Mutant huntingtin has been shown to bind directly to a number of transcription factors, including Sp1, p53, cAMP response element-binding protein (CREB)-binding protein (CBP), and nuclear corepressor (NCoR), raising the possibility that mutant huntingtin could interfere with the normal function of these factors. Transcriptional dysregulation in HD likely involves histone proteins and chromatin remodeling, as histone deactylase inhibitors, which promote histone acetylation, have been shown to have beneficial effects in a number of animal and cellular models of HD.

Other Theories of Pathogenesis

Numerous other ideas have been advanced to account for HD pathogenesis, including synaptic dysfunction, disruption of axonal transport, apoptosis, inappropriate cell cycling, calcium dysregulation, oxidative stress, proteasome dysfunction, dysfunction of ion channels, endocrine dysregulation, disrupted mitochondrial biogenesis, altered lipid metabolism, loss of BDNF function, and altered intracellular second messenger signaling. A major challenge within the field is to prioritize the most relevant pathologic processes, while accounting for all of the observed abnormalities.

Genetic Testing

Isolation of the *HD* mutation made direct DNA testing available. While HD genetic testing is now

commercially available, testing should be approached judiciously. Genetic testing is performed in two contexts. Symptomatic gene tests are performed when a patient is manifesting symptoms that could be consistent with HD. For persons who are at risk for HD by virtue of having an affected relative, presymptomatic testing can be helpful in planning life events, such as whether to get married or have children. Caution should be exercised, however, as having a positive gene test result can have many unanticipated negative consequences. Persons undergoing presymptomatic testing should undergo detailed counseling with a genetic counselor. Preimplantation gestational testing, which can determine the gene status of a fetus, is available in some centers.

Therapeutics

There are currently no effective therapies for preventing the onset or for slowing the progression of HD. Current therapies are symptomatic, and include the use of neuroleptics to decrease chorea and the use of psychotropic medications to address depression, obsessive–compulsive symptoms, or psychosis. In addition, speech therapy and physical therapy are useful in addressing the swallowing and walking difficulties that many HD patients experience. An important principle in HD treatment is that the brain is constantly degenerating, and thus the response to medications changes over time. Therapy must therefore be flexible, and constant reevaluation is required. In addition, because of altered by neurotransmitter receptors, paradoxical reactions to medications can occur. Careful empiric trials must be performed with each patient. Only one medication should be altered at a time.

Some efforts at neural transplantation have been made. Transplantation of embryonic stem cells as replacement therapy is currently being evaluated, but remains experimental at this time. Other surgical therapies, such as ablative approaches or deep brain stimulation, have not been extensively tried.

The pathologic mechanisms underlying HD are not yet completely understood; effective therapeutics depends on a more clear elucidation of pathogenic pathways. The Huntington Study Group, a multicenter academic consortium of HD clinicians, has conducted numerous clinical trials for therapeutic compounds, and many are currently under way. Further therapies will no doubt arise as the molecular pathogenesis HD is further delineated.

Triune Brain Concept: A Comparative Evolutionary Perspective

A B Butler, George Mason University, Fairfax, VA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In 1990, Paul MacLean published his book on *The Triune Brain in Evolution: Role in Paleocerebral Functions*, based on years of neuroethological and neurobiological studies in his laboratory and copious other sources. His ideas about viewing the brains of extant mammals, including humans, as comprising three main formations that were gained sequentially over a long evolutionary history, have been enthusiastically accepted by a number of scientists, particularly those interested in neuropsychiatry and related areas but, in stark contrast, strongly rejected by most scientists in the field of comparative, evolutionary neurobiology. While scientific disputes are not unheard of, the level of disagreement over the triune brain concept does distinguish it from many other current hypotheses. In discussing the triune brain concept, it is thus both necessary and of some interest to consider not only the concept itself but also the evolutionary, comparative point of view that takes issue with it.

Two reviews of MacLean's book, one by Anton Reiner, and the other by Boyd Campbell, written the same year as its publication, were critical on a number of points. Subsequently, in both editions of *Comparative Vertebrate Neuroanatomy: Evolution and Adaptation* (Butler and Hodos), those criticisms were supported. More recently, others have mounted defenses of the triune brain concept; Jaak Panksepp particularly addressed conflicts engendered by the work of Joseph LeDoux on the amygdala and its relationship to emotion, and Gerald Cory replied to the reviews by Reiner and Campbell, as well as to the comments on the triune brain concept in the first edition of the Butler and Hodos textbook (as also maintained in the second edition).

As someone thus already involved in the continuing dispute, I will endeavor to be as objective and dispassionate as possible in presenting MacLean's triune brain concept and also the objections to it raised by comparative neuroscientists, recognizing that my own background and knowledge of brain evolution unavoidably influence and inform my perspective. Also, since Cory characterized Reiner's criticisms as 'destructive' rather than 'constructive,' in that Reiner did not offer a 'replacement generalization,' I will do so here. It is my hope that the alternative concepts presented here, an objective-terminology model for amniote brain evolution and an evolutionarily accurate model of mammalian brain evolution, will clarify the reasons why most comparative neurobiologists view the triune brain concept as they do. These alternative models allow for neuroanatomical hypotheses that encompass the recently discovered, exceptionally high-level cognitive abilities of birds without detracting from the similarly high-level cognitive abilities of mammals and especially humans.

From an evolutionary, systematic viewpoint, birds are actually reptiles, derived from the thecodont radiation that also gave rise to crocodiles. Since the brains of birds are, in many respect, enlarged and elaborated versions of other reptilian brains, all of which lack the particular cytoarchitectural arrangements that are the hallmark of the mammalian neocortex, the triune brain model does not account for their remarkable cognitive abilities that far exceed the more basic, species-specific behaviors involved in reproduction of the species and in maintaining homeostasis that MacLean accounts for in his model. While it was never the intent of the triune brain model to account for high-level cognition in birds, the fact that a brain with very different cytoarchitecture can generate such abilities definitively demonstrates that neocortex – the 'neomammalian' telencephalic component of the triune brain model – is not uniquely requisite to this function. It also definitively demonstrates that birds, as legitimate representatives of the reptilian lineage, have far more to their telencephalons than merely basal ganglia and far more to their behavioral capabilities than just 'species-typical stereotyped behaviors,' on which the triune brain model is focused.

The various high-level cognitive abilities of birds were not known when MacLean developed his model. The objections that comparative neurobiologists had to the model were, however, based on the then-current data set of known sensory pathways and other connections of forebrain structures in birds and reptiles, as well as those in mammals. These objections are validated by the new findings on avian cognitive abilities. We will thus now review the basic premises of the triune brain model and the objections raised by the comparative, evolutionary community, two of the most salient and important of which focus on (1) the issue of pallial evolution across all amniotes rather than just within the mammalian lineage and (2) the assignment of involvement of various particular neural structures in the generation of a number of behaviors.

Of great importance for those whose research is focused on human behaviors – including social, psychological, and economic as well as pathological conditions such as those of the basal ganglia – is that

the 'replacement generalizations' (see later), the objective-terminology model for amniotes and the evolutionarily-accurate model for mammals, do not contradict or undermine any of their findings or theoretical base. These models simply rectify the conceptual approach with the full range of comparative evolutionary data on brain evolution. In his foreword to the 2002 book, *The Evolutionary Neuroethology of Paul MacLean*, Jaak Panksepp noted that emotions cannot be understood simply as "channel functions" at the level of single cells but must rather be appreciated as "global 'state-functions' reliant on complex organic organization of broadly operating brain systems," for which the triune brain concept, including the limbic system concept, is valuable. Since both single cellular activity and global brain systems are active and ultimately produce emotional feelings (and other aspects of higher order consciousness), both need to be acknowledged and dealt with in any heuristic device. The revised concepts offered in the following discussions are compatible at both levels. What they both lack is the romantic cache of a 'reptilian' image, darkly lurking under the surface, within the deep 'core' of a mammal – an image unfortunately better suited to a Victorian novel than to a scientific hypothesis.

The Triune Brain Hypothesis

As presented by MacLean in his 1990 book, the triune brain of mammals comprises three formations – a 'Reptilian,' or 'R-complex' formation, a 'Paleomammalian' formation, or limbic system, and a 'Neomammalian' formation (Figure 1). These three formations are shown with equivalent color coding for ease of comparison across Figures 1–4. In the figure caption of the original figure in his book (his figure 2-1), MacLean states that "the human forebrain expands along the lines of three basic formations that anatomically and biochemically reflect an ancestral relationship, respectively, to reptiles, early mammals, and late mammals." The 'reptilian' formation includes the basal ganglia within the telencephalon and a number of brain stem structures. The 'paleomammalian' formation is the limbic system, and the 'neomammalian' formation is the mammalian neocortex and its associated brain stem structures. MacLean focuses on the limbic system as "the common denominator in the brains of all mammals" (p. 16). He states that it consists of "three main subdivisions ... [with] the third subdivision, for which there appears to be no rudimentary counterpart in reptiles, ... implicated in parental care, audiovocal communication, and play behavior" (p. 17). By implication, MacLean recognizes that the other two limbic divisions may have counterparts in the reptilian brain, but clearly excludes the third division. The 'neomammalian'

Figure 1 The triune brain model as presented by PD MacLean in his 1990 book. Reproduced from MacLean PD (1990) *The Triune Brain in Evolution: Role in Paleocerebral Functions*, p. 9. New York: Plenum, with kind permission from Springer Science and Business Media.

Figure 2 'Reversal test' of the triune brain concept. Here, the brain stem and basal ganglia are labeled as the 'Mammalian' formation, the limbic system as the 'Paleoreptilian' formation, and the expanded nonlimbic pallial areas as the 'Neoreptilian' formation. This set of labels depicts amniote brain evolution from a sauropsid chauvinist viewpoint; it is just as evolutionarily inaccurate as the mammalian chauvinist triune brain model. The reversal test thus demonstrates the fallacy of the latter. Redrawn and modified from MacLean PD (1990) *The Triune Brain in Evolution: Role in Paleocerebral Functions*. New York: Plenum.

Figure 3 The objective-terminology model, a 'replacement generalization' for the triune brain concept for both mammals (left), and reptiles and birds (sauropsids; right). This model employs labels that are objective and based on actual brain structures. As in MacLean's original drawing, the formations are labeled only at the level of the telencephalon as basal ganglia, limbic system, and nonlimbic pallium, respectively. These labels comfortably and accurately accommodate evolutionary histories of both the sauropsidian and the mammalian lineages. It should be noted that in this model, the mammalian prefrontal cortex is included in the nonlimbic pallium even though it is sometimes thought of as a limbic component. The model easily could be modified, depending upon one's preference, to include prefrontal cortex as a limbic component in mammals, with a comparable adjustment in sauropsids – particularly birds – to similarly include their pallial areas that are possibly homologous to prefrontal cortex and involved in comparable aspects of higher cognitive processing, such as the nidopallium caudolaterale and/or the dorsolateral corticoid area. Redrawn and modified from MacLean PD (1990) *The Triune Brain in Evolution: Role in Paleocerebral Functions*. New York: Plenum.

formation is the "neocortex and the thalamic structures with which it is primarily connected" (p. 17). MacLean states that "In its evolution the neocortex, together with its brainstem and neocerebellar connections, has afforded a progressive capacity for problem solving, learning, and memory of details ... [and has the] capacity to generate verbal communication [in humans]" (p. 17).

In a later chapter (pp. 43ff), MacLean acknowledges that a large part of the reptilian (and avian) telencephalon, the dorsal ventricular ridge (DVR), is a pallial formation rather than a component of the basal ganglia within the subpallium. He also acknowledges that "In recent years several authors seem to have been persuaded that the DVR is the equivalent of the mammalian neocortex" (p. 45), citing the work of Walle Nauta and Harvey Karten on this issue. MacLean felt that "The question of whether or not some other mammalian structure might be the counterpart of the DVR is better deferred until embryological findings have been reviewed" (p. 45). In this pronouncement, he was highly prescient, since it is currently a matter of substantial debate, based to some extent on recent embryological and gene expression data, as to whether the DVR, particularly its anterior part, the anterior dorsal ventricular ridge (ADVR), is homologous to the mammalian neocortex (i.e., at the level of various specific cell populations within both structures, as Karten originally postulated) or to the thalamo-recipient basolateral division of the amygdala.

The better part of MacLean's book covers neuroethological and experimental behavioral observations from his extensive work on various reptiles and squirrel monkeys. Since the observations of reptilian behaviors, and investigations into the contribution of the basal ganglia toward these behaviors, are of paramount importance as the foundation of the triune concept, this part of MacLean's research program will be focused on here. Much of this research was carried out by Neil Greenberg and his co-workers in MacLean's Poolesville (Maryland) research facility. Greenberg and MacLean, from extensive observations of the behaviors of *Anolis* lizards in laboratory vivaria, as well as observations on other species drawn from the literature, categorized them into daily routines and subroutines and component behaviors associated with territorial and reproductive issues, including establishment of homesite and homerange, patrolling territory, ritualistic defense displays, intraspecific fighting, use of

Figure 4 Comparison of drawings of the left hemisphere through the telencephalon of the squirrel monkey (left), and the right hemisphere through the telencephalon of the tegu lizard (center and right), showing the basal ganglia (tan), the limbic pallium (green), and the nonlimbic pallium (blue). The two versions of the tegu hemisphere represent the two current hypotheses as to whether the ADVR is a nonlimbic (center) or limbic (right) component. Regardless of the homology of the latter structure, note that most of the telencephalic areas are pallial rather than subpallial (the basal ganglia) in both mammals and lizards. In birds, the pallial regions are even more expanded and elaborated than in lizards. Not all structures are present in both the mammal and the tegu hemispheres at the levels shown. A, amygdala; ADVR, anterior dorsal ventricular ridge; C, caudate nucleus; Ci, cingulate gyrus; Cl, claustrum; Ctx, cortex; G, globus pallidus; H, hippocampal formation; IC, internal capsule; LFB, lateral forebrain bundle; N, neocortex; P, putamen; S, septum; St-P, striatopallidum.

defecation posts, foraging, hunting, homing, hoarding, social group formation, establishment of social hierarchy, greeting, grooming, courtship displays, mating and breeding, flocking, and migration.

As discussed by Neil Greenberg in his 1988 paper, they regarded the "highly stereotyped, species-typical behavioral patterns, particularly social displays, [as] the most robust data to illuminate neural corollaries of complex behavioral functions." Since MacLean had previously found that the dorsal striatum "is necessary for the performance of a species-typical display in the [squirrel] monkey ... an investigation of the paleostriatum [i.e., dorsal striatum] of a lizard predicated on a close understanding of the units of behavior spontaneously emitted in naturalistic settings" was undertaken. As summarized by MacLean in his 1990 book, Greenberg had previously identified major stereotyped behaviors in the blue spiny lizard *Sceloporus cyanogenys* – signature ('assertive'), challenge ('territorial'), courtship, and submissive ('appeasement,' 'assentive'). Similarly, *Anolis* lizards, under the seminatural vivarium conditions of the laboratory, exhibit social displays that include assertion (a 'general arousal'), challenge (addressed to a conspecific male), and courtship (addressed to a conspecific female).

Of these behaviors, only the challenge display was disrupted by lesions that involved the output pathway (the lateral forebrain bundle region) of the striatum. The species-typical stereotyped behaviors of assertion and courtship were not disrupted by such lesions. Other studies have not contributed any additional definitive indication of striatal involvement in these sorts of functions. While both lesion and stimulation studies are subject to problems of interpretation, the lack of evidence that the basal ganglia generate most of the behaviors observed in reptiles should preclude designating this part of the brain as singularly crucial to them. The broad generalization of assigning most aspects of reptilian behavior to the 'R-complex' in the triune brain model simply is not justified by the experimental data. Other parts of the reptilian brain, particularly the pallium, may well be contributing substantially, in concert with the basal ganglia, to a number of these behaviors, just as in mammals the neocortex and the basal ganglia interact in concert to generate cognitive and affective as well as stereotypical motor behaviors.

Origins of the Triune Brain Hypothesis and the Comparative Neuroanatomical Perspective

Paul MacLean's life and career recently have been reviewed by Kelly Lambert. Having received his medical degree at Yale University School of Medicine and exposure to the field of psychiatry during a World War II assignment to New Zealand and a brief stint in private practice, MacLean had worked in the laboratory of Stanley Cobb at Massachusetts General Hospital and subsequently held a position in the Department of Physiology at Yale Medical School. During this period he developed an interest in the work of James Papez, who was at Cornell, and was able to meet with him to discuss Papez's work in comparative neuroanatomy and the circuitry of the limbic lobe in mammals.

In a paper published in 1952, MacLean coined the term 'limbic system' to refer to the set of structures that include the limbic lobe of Broca plus the related brain stem structures. While this term has been criticized in some circles, as Panksepp has discussed, it has been widely accepted by comparative neuroanatomists, since the main components of this system – such as the hippocampus and its related cortical areas, the septal nuclei, hypothalamus, amygdala, and ventral striatopallidal components – are widely distributed across vertebrates. This issue will thus not be discussed further here, since from the comparative viewpoint, the limbic system concept *per se* is not a point of contention.

In 1957, MacLean joined a newly founded lab section at the National Institutes of Health (NIH), which subsequently was named the Section on Limbic Integration and Behavior, and in 1971 moved to new NIH laboratory quarters near Poolesville, Maryland, where he was able to expand his studies to include reptile behaviors and to begin his efforts to understand the possible contributions of the basal ganglia to these behaviors. During the several years on either side of that point in time, two major breakthroughs in comparative neuroanatomy were occurring, one in regard to the telencephalic pallium of birds and reptiles and the other in regard to similar parts of the brain in sharks.

In sharks, Sven Ebbesson and his colleagues had found that (1) olfactory projections are confined to a small region of the lateral pallium, rather than being widely distributed across it, (2) two major ascending pathways, one via the midbrain roof and thalamus and one directly via the thalamus, to nonlimbic parts of the pallium are present, and (3) the integrity of the pallium is necessary for the sharks to discriminate visual patterns. This new information contradicted the then generally accepted idea that the forebrains of all fishes were dominated by olfactory information – mere 'smell brains' – and that the other sensory systems had 'invaded' the forebrains of terrestrial vertebrates during their evolutionary transition. In regard to the telencephalic pallium of birds, Harvey Karten and his colleagues had confirmed that a large structure in the telencephalon, the DVR (now also referred to in birds as nidopallium and mesopallium) is indeed pallial rather than subpallial and also is in receipt of several ascending sensory pathways – as known at that time, a visual and an auditory pathway, and, as later identified, a somatosensory pathway. These sensory pathways are in addition to the then-known visual pathway to the more caudal part of the avian equivalent of the cortex in reptiles, called the Wulst or hyperpallium, and a subsequently discovered somatosensory pathway to its more rostral part that also gives rise to a pyramidal tract-like efferent motor pathway.

By the mid-1970s, these findings in sharks and birds were published and were augmented by findings of similar ascending sensory pathways in a variety of reptiles. In 1978, MacLean held a conference at his Poolesville laboratory, to which a number of us were invited and at which many of these findings were presented and subsequently published in the resulting book, edited by Neil Greenberg and Paul MacLean, *Behavior and Neurology of Lizards*. A survey of the comparative findings on telencephalic evolution across vertebrates was subsequently published in another volume edited by Sven Ebbesson in 1980, from a conference held in Caracas, Venezuela, *Comparative Neurology of the Telencephalon*, and from the mid-1960s to the present, a massive body of publications on this subject has appeared in the primary literature and other symposium volumes.

In his own summary of his triune brain hypothesis, MacLean acknowledged current findings about brain evolution within amniotes, particularly within the sauropsid radiation of reptiles and birds, but then set them aside in favor of his 'triune model' of brain evolution within the mammalian line. In the caption for his famous figure of the mammalian triune brain (his figure 2-1), he states that the three formations within the brain – the parts of which are labeled at the rostral end of the brain as the 'Reptilian' formation (or 'R-complex'), the 'Paleomammalian' formation (limbic system), and the 'Neomammalian' formation (neocortex and its related thalamic structures) – "reflect an ancestral relationship, respectively, to reptiles, early mammals, and late mammals." The latter statement is contradictory to all data collected and analyzed by comparative studies over the past four decades, as already discussed. A 'reptilian' formation – that is, the basal ganglia – is

common to early and late reptiles, early and late birds, and early and late mammals. A 'paleomammalian' formation, or limbic system, is also common to all of these taxa. While neocortex is indeed a unique feature of mammals, an expanded nonlimbic pallium, part of which comprises the neocortex in mammals, is likewise common to all of these taxa, and this crowning component of the telencephalon is particularly elaborate and is involved in sensory processing and associative functions that reach very high cognitive levels in both mammals and birds.

MacLean notes in his discussion of anatomical and functional comparisons (in chapter 2 of his 1990 book) that a large formation, the DVR is present in sauropsid brains and is clearly pallial. However, he regards it as having been independently evolved and as not being of significant interest in regard to the evolutionary origins of mammalian neocortex. In this view, he is partly correct and partly wrong. As discussed by Anton Reiner, early amniotes most likely had neither neocortex nor a DVR, but rather had a small "proto-DVR" region in the lateral aspect of the pallium and a modest region of cortex medial to it. In the mammalian lineage, which precedes the reptilian lineage in the fossil record by 10 My, the more medial region became expansively elaborated to form part (or possibly all) of the neocortex, and the lateral region likewise became elaborated to form either part of the neocortex and/or the pallial, thalamo-recipient (basolateral) part of the amygdala. In the sauropsid line, the lateral region became elaborated and expanded to form the definitive DVR, and the medial region formed the rudimentary cortex; within the avian lineage, the medial region expanded substantially to form the Wulst, while the DVR expanded further to reach its apogee.

The triune brain hypothesis, by essentially dismissing interest in pallial elaboration within the sauropsid line, errs by instead promoting the scientifically contradicted but still widespread popular view of a scala naturae, a linear ranking of animal taxa, with fish near the bottom, reptiles not much higher, non-human mammals higher and ranked in sequence (such as rat-to-cat-to-monkey), and with humans at the top. The summary figure of the triune brain, now widely published and commonly referred to in some of the psychiatric literature, implies that the core structures of basal ganglia and the more caudal parts of the brain stem represent the 'reptilian brain' that is still present in mammals, including humans. It specifically states that the gain of a limbic system occurred in early mammals. It specifically implies that a large, expanded nonlimbic pallium is unique to mammals.

Applying a 'reversal test' is often a fruitful way to assess particular situations or statements. We can apply this test to the triune brain hypothesis to assess whether it is a reasonable view of brain evolution. Figure 2 shows the view of brain evolution, as seen from the sauropsid point of view. The labeling in this figure is equally incorrect, from the established body of data on brain evolution, as that of MacLean's canonical figure. It identifies the core of the brain as the 'Mammalian' formation, the limbic system as the 'Paleoreptilian' formation, and the nonlimbic pallium as the 'Neoreptilian' formation. As we have noted, in birds the 'Neoreptilian' formation, comprising the Wulst and DVR, is particularly expanded, and the recent findings of highly sophisticated cognition of which at least some birds are capable compel viewing it as a worthy rival of neocortex in terms of its neural processing abilities. To ignore the sauropsid line and to assign some mammalian behaviors as 'reptilian' is to ignore a virtual goldmine of information on how neurons process and assess information and how thoughts and emotions are generated and dealt with. In trying to understand human behaviors, the latter course is as foolish as if one were to ignore all mammalian, including human, research and study only reptiles and birds. Taking the complete picture into account, based on the actual evolutionary events and particularly including the intriguing differences in cytoarchitecture of the pallial formations in sauropsids versus mammals, is the course most likely to yield a correct understanding of pallial function, including the generation of complex human behaviors.

In assessing the triune brain model, one wonders why MacLean did not simply label its components by their correct terms, as shown in Figure 3. In this figure the core of the brain (at the telencephalic level) is labeled 'basal ganglia.' The limbic system is so labeled, and the overlying nonlimbic pallium is likewise labeled as itself. These labels are objective; they have no scala naturae baggage attached to them. All mammals and all reptiles and birds have a core region (in simplistic terms) that includes the basal ganglia within the telencephalon. All mammals and all reptiles and birds have a limbic system. All mammals and all reptiles and birds have an expanded nonlimbic pallium. For that matter, fish and amphibians also have components of the basal ganglia, limbic system, and nonlimbic pallial regions. None of these neural systems is unique even to amniotes, let alone to mammals. This objective-terminology model is a highly reasonable 'replacement generalization' for the triune brain model. It is anatomically accurate, simple, and straightforward, and does not conflict with any phylogenetic data. It is wholly applicable to all of the

clinical and related findings to which the triune brain model has previously been applied.

Another view of the anatomical comparison is shown in Figure 4. In this figure, a drawing of a transverse hemisection through the telencephalon of a squirrel monkey, the species of primate that Paul MacLean studied so extensively, is shown on the left, and two similar drawings of a transverse hemisection through the telencephalon of a tegu lizard (with features essentially the same as that of *Anolis* and other lizards of this DVR type) is shown on the right. The two drawings of the lizard telencephalon represent the two extremes in the current debate about homology of the ADVR: whether it is nonlimbic pallium, as indicated by its blue shading in the first (center) drawing, or whether it is amygdala and thus a limbic component, as indicated by its green shading in the second drawing. Either way, it is clear that the reptilian telencephalon is largely constituted by pallial territory, just as are mammalian and avian brains, and that the structures designated as the 'R-complex' by MacLean (the basal ganglia, shaded in tan) comprise only a minor fraction of the telencephalic tissue.

For those in the clinically related fields who still wish, however, to retain the triune brain concept (or at least some version of it that may be more in line with the data accumulated to date), a view that focuses

Figure 5 The evolutionarily accurate model of brain evolution within the mammalian (synapsid, i.e., with one temporal fenestra in the skull) radiation, which separated from ancestral lineage of anapsid (lacking any bony fenestrae) amniotes 10 My before the sauropsid (diapsid, i.e., with two temporal fenestrae) line of ancestral reptiles appears in the fossil record. In this model, the neural components present in the common, anapsid ancestor ('Common Amniote Formation,' or 'A-complex') include major limbic system components, primary sensory-recipient and motor pallial areas, and a few association pallial areas, in addition to the basal ganglia. Early mammals and therian (marsupial and placental) mammals then gained additional structures and/or modifications to existing structures, as shown for the 'Stem Mammalian Formation' and 'Therian Formation,' respectively. Redrawn and modified from MacLean PD (1990) *The Triune Brain in Evolution: Role in Paleocerebral Functions*. New York: Plenum.

solely on the mammalian lineage but is evolutionarily accurate is shown in Figure 5. This is offered here as an alternative 'replacement generalization.' It suffers from being more cumbersome in terms of the detail put into the labels for the three sets of brain structures, which even so are only a generalization. It is not shaded in colors as was done for the other figures, since the comparison is no longer one-to-one. The 'common amniote formation' (or 'A-complex,' for those who wish to use such a term), shown in light gray, includes much more than the basal ganglia, and so its color shading would necessarily have to include all three colors used before – tan, green, and blue. Both the intermediately positioned area shown in white, designated here as the 'Stem Mammalian Formation,' and the outer area shown in darker gray, the 'Therian Formation,' would have to include both green and blue. While this model does not thus correspond easily to the original triune brain model or to the objective-terminology model, it nonetheless reflects in somewhat more detail the particular evolutionary course that was taken along the mammalian lineage.

When MacLean developed his triune brain model, the extensive and very high-level cognitive abilities of birds, as alluded to several times previously, were not appreciated. One of the most crucial and difficult questions to answer in all of neurobiology is how such complex cognitive abilities and the probably correlated high levels of consciousness are generated by neuronal assemblies. The foundation of behavioral data amassed by MacLean as well as the numerous other studies in the literature can contribute to answering this question when assessed in an evolutionarily accurate perspective. For example, in discussing the 'paleomammalian formation,' as noted earlier, MacLean specifically cited the third division of the limbic system, that is, its thalamocingulate component, as being "implicated in parental care, audiovocal communication, and play behavior." While it is true that only a few reptiles (mostly crocodiles) exhibit even the most rudimentary of these behaviors, birds exhibit all three to an extensive degree. In his 1981 book *Animal Play Behavior*, Robert Fagan documents and discusses many examples of play behavior in birds; the literature that documents the complexity of song learning and production in songbirds is extensive; and the maternal care exhibited by most species of birds is widely known.

In discussing the 'neomammalian formation,' MacLean cites its roles in "problem solving, learning, and memory of details . . . [and its] capacity to generate verbal communication." As reviewed by Butler and Cotterill, the recent spate of studies on avian cognitive abilities has established that various species of birds also can problem-solve, learn, and remember to an extensive degree, and even generate verbal communication. In fact, they exhibit numerous cognitive behaviors of a very high level. They (1) use transitive inference, the use of logical and successive comparisons (a process attributed to the working memory functions of prefrontal cortex in humans and some other mammals) to determine social hierarchies, (2) exhibit a phenomenon called coherence, or multistability, of ambiguous figures, previously considered unique to primates and also involving working memory, in which one interpretation of a visual stimulus (such as a Necker cube) is perceived for a set of trials, followed by a set of the alternate interpretation, rather than just randomly switching back and forth, (3) form conceptual categories, such as distinguishing cubist paintings from impressionist ones, (4) exhibit object constancy to a high level, as delineated by Piaget, (5) manufacture tools for use in food gathering, another ability previously thought unique to primates, (6) culturally transmit the design features of such tools to conspecifics, (7) communicate with humans using the English language to an extensive degree, (8) understand numerical concepts up to about the number 7 and also exhibit a zerolike concept – a particularly challenging feat, (9) exhibit theory of mind in terms of anticipating and taking steps to prevent thievery from food caches by conspecifics and practicing deceptive behaviors to outwit a dominant rival, and (10) exhibit the capacity to remember past events and their relative lengths of time.

These high-level cognitive abilities are all supported, in concert with the thalamus and other structures, by the ADVR and Wulst in birds – the pallial regions of the telencephalon that are homologous to major pallial regions in mammals and to the major pallial regions of reptilian brains as well. One of the strengths of the comparative method is its focus on identifying both the similarities and differences between brains and the correlated functions that they support. The objective-terminology model of amniote brain evolution offered here (Figure 3) facilitates such comparisons and can contribute to illuminating how different cytoarchitectures, including our own, support the generation of high-level cognition and consciousness by neuronal assemblies.

Introduction

Tuberous sclerosis complex (TSC) is a neurocutaneous disorder with a prevalence of about 1 in 6000. It results from a mutation of either of two different genes (*TSC1* or *TSC2*). The protein products of the TSC genes, hamartin and tuberin, are involved in a complicated schema of cell signaling pathways. Disruption of these signaling pathways resulting from mutations in the TSC genes results in alteration in cellular differentiation and proliferation, which may affect many organ systems, including brain, skin, kidneys, eyes, heart, and lungs. The lesions and tumors of TSC are typically benign, but they may cause potentially severe dysfunction in the affected organ, and malignant tumors may occur rarely. Surveillance monitoring for potential complications can minimize the severity of the complications. Knowledge of the molecular pathogenesis of TSC has permitted development of new treatments for certain complications.

Genetics and Molecular Pathogenesis of Tuberous Sclerosis Complex

Tuberous sclerosis complex has long been recognized as a dominantly transmitted genetic disease, but it arises from a spontaneous mutation 60% or more of the time. Since the elucidation of the *TSC2* gene and gene product (chromosome 16p13.3, tuberin) and the *TSC1* gene and gene product (9q34.3, hamartin), incredible strides have been made in the understanding of how mutations in these genes cause TSC.

TSC has virtually complete penetrance, but its expression is highly variable even among individuals with the same mutation. For example, a parent may have so few clinical findings of TSC that his diagnosis goes unrecognized until his infant develops infantile spasms or congestive heart failure due to TSC. Additionally, somatic and gonadal or germ-line mosaicism appears to be relatively common, and in such individuals only certain cells carry the TSC mutation, depending on when the mutation occurred during embryogenesis. Mosaicism may result in a very mild phenotype in a parent, and in the case of pure germ-line mosaicism, the parent has no clinical manifestations of TSC. A TSC mutation will not be found in somatic cells such as leukocytes or buccal cells, yet the parent may have more than one affected child due to the occurrence of the TSC mutation in egg or sperm progenitor cells. Because mosaicism may confound the heritability of TSC, even in apparently sporadic cases, parents should be cautioned of a 1–2% recurrence risk in subsequent children.

More than 1000 different mutations in the two TSC genes have been identified to date. When TSC gene mutations are analyzed in large groups of individuals with TSC, approximately 30% of individuals will have mutations in the *TSC1* gene and 70% will have mutations in the *TSC2* gene. About 10–20% of individuals with definite TSC by clinical criteria will not have an identifiable TSC gene mutation, which may be explained by mosaicism, at least in some cases.

Despite the fact that there are two TSC genes on two different chromosomes that code for two entirely different proteins, the phenotype produced by mutations in each of these genes is virtually indistinguishable. Some reports have suggested that there is a more severe phenotype in individuals with a *TSC2* mutation (for example, mental retardation, autistic behavior, and renal malignancy are reportedly increased); other reports have not confirmed this phenotypic pattern. At this time, with the exception of the *TSC2*/adult polycystic kidney disease contiguous gene syndrome (discussed later), the question of a clear-cut genotype–phenotype relationship is unclear. A large-scale natural history study of individuals with TSC, which will soon be underway, may help us understand whether there is any link between mutations in the different genes – and even specific types of mutations – with specific phenotypes.

TSC1 and *TSC2* are tumor suppressor genes. The TSC gene products, hamartin and tuberin, form a heterodimeric complex in the cell. This protein complex is integrally involved in several different signaling pathways. When either of the TSC gene products is compromised, the tumor suppressor function is diminished. Loss of regulation in the various cell signaling pathways may result in cell proliferation and overgrowth, resulting in the various hamartomatous tumors characteristic of TSC. Biochemical and genetic studies in various types of tumor cells, mammalian models, fruit fly, and yeast systems have helped define the role of the hamartin–tuberin complex in several cell signaling pathways. The most notable of these pathways involves the mammalian target of rapamycin (mTOR). The hamartin–tuberin complex represses mTOR activity in the normal functioning cell. However, when one of the TSC proteins is aberrant, mTOR

repression diminishes, and S6 kinase (S6K) is stimulated, which promotes ribosome assembly and protein translation. This in turn leads to cell proliferation, cell growth, and, ultimately, hamartoma formation. This pathway has become important because rapamycin (sirolimus) inhibits mTOR. Rapamycin is currently available and approved by the United States Food and Drug Administration (FDA) as an immunosuppressant agent, and is now undergoing human trials as a treatment for renal and pulmonary complications of TSC. The hamartin–tuberin complex also affects cellular pathways involving cellular adhesion and migration, and in protein and vesicular trafficking. While a great deal is now known about these cellular signaling pathways, details continue to be refined. As these pathways and the roles of tuberin and hamartin are further clarified, new targets for molecular-based treatments for TSC will surely be developed.

Clinical Features of TSC: General

TSC can involve virtually any tissue or organ system in the human body, but the skin, brain, and kidneys are the most consistently affected organs. Disease presentation is heterogeneous, and presentation even within a family may be extremely variable. Reasons for the variable presentation are not completely understood. However, partial explanations include genotype–phenotype relationships and stochastic developmental processes during embryogenesis. For example, loss of heterozygosity through a 'second-hit' somatic mutation is known to occur in some hamartomas. This mechanism may explain development of some tumors in TSC. An abbreviated discussion of the principal pathologic processes involving nonneurologic systems follows.

Even though genetic testing of TSC has a high rate of identifying TSC gene mutations, the clinical diagnostic criteria (Table 1) are still useful and helpful to establish the diagnosis of TSC. Genetic testing occasionally identifies a patient who has a mutation yet has few clinical findings of TSC, but on the other hand, about 10–20% of individuals with clinically definite TSC will not have a definite gene mutation by current testing methodologies. If, for example, a child with clinically definite TSC has no identifiable gene mutation, it may be helpful to his parents to also be evaluated for the main clinical findings of TSC to determine whether one of them might be a carrier. A brief discussion of the key clinical features follows.

The skin lesions of TSC include facial angiofibromas (Figure 1(a)), hypomelanotic macules and poliosis of the hair (Figure 1(b)), shagreen patches (Figure 1(c)), and other fibromatous skin lesions found on the forehead, scalp, or other body regions, and ungual fibromas. Additionally, pitting and erosions of the dental enamel can occur.

Table 1 Clinical diagnostic criteria for tuberous sclerosis complex[a]

Major features
Facial angiofibromas or forehead plaque
Nontraumatic ungual or periungual fibroma
Hypomelanotic macules (more than three)
Shagreen patch (connective tissue nevus)
Cortical tuber[b]
Subependymal nodule
Subependymal giant cell astrocytoma
Multiple retinal nodular hamartomas
Cardiac rhabdomyoma, single or multiple
Lymphangiomyomatosis[c]
Renal angiomyolipoma[c]
Minor features
Multiple randomly distributed pits in dental enamel
Hamartomatous rectal polyps[d]
Bone cysts[e]
Cerebral white-matter 'migration tracts'[b, e]
Gingival fibromas
Nonrenal hamartoma[d]
Retinal achromic patch
'Confetti' skin lesions
Multiple renal cysts[d]

[a]Definite tuberous sclerosis complex: either two major features or one major feature plus two minor features. Probable tuberous sclerosis complex: either one major feature or two or more minor features. Suspect tuberous sclerosis complex: either one major feature or two or more minor features.
[b]When cerebral cortical dysplasia and cerebral white-matter migration tracts occur together, they should be counted as one rather than two features of tuberous sclerosis complex.
[c]When both lymphangiomyomatosis and renal angiomyolipomas are present, other features of tuberous sclerosis complex should be present before a definite diagnosis is assigned.
[d]Histologic confirmation is suggested.
[e]Radiographic confirmation is sufficient.
Adapted from Roach ES, Gomez MR, and Northrup H (1998) Tuberous sclerosis complex consensus conference: Revised clinical diagnostic criteria. *Journal of Child Neurology* 13: 624–628.

Facial angiofibromas are red to reddish-brown lesions that form on the face in the vicinity of the nose, cheeks, and chin in about 75% of patients with TSC. These lesions, which typically start out as red papules 1–2 mm in diameter, can be seen as early as age 2 years. They can increase in size and number with age. They may become disfiguring, may bleed, and may cause difficulty breathing if close to the nostrils, or difficulty with eyelid closure if close to the eyelid. Various forms of laser treatment may be performed for disfiguring and problematic lesions.

Hypomelanotic macules occur in 90–95% of individuals with TSC. These lesions typically present at birth or in early childhood. In fair-skinned people, they may be difficult to identify without the use of

Figure 1 (a) Multiple facial angiofibromas. (b) Skin hypomelanotic macules and poliosis of the hair. The size of the large hypomelanotic macule and the area of poliosis are atypical. A typical hypomelanotic macule is presented adjacent to the larger one. (c) Shagreen patch. Reprinted from Roach ES and Sparagana SP (2004) Diagnosis of tuberous sclerosis complex. *Journal of Child Neurology* 19: 643–649, with permission.

a Wood's lamp (ultraviolet light). These macules, caused by a normal number of melanocytes with decreased size of melanosomes and melanization, are asymptomatic. Poliosis is much rarer compared to the hypomelanotic macules, and may involve scalp hair and facial hair, such as eyebrows and eyelashes.

The shagreen patch appears in about 30% of individuals with TSC, and tends to appear later in childhood. These 'geographic' patches occur most often in the lumbar and flank regions and appear as raised, pink- to brown-colored skin with a leathery texture. These lesions are benign and do not require treatment.

Ungual fibromas are reddish or flesh-colored nodules arising from the fingernail or toenail beds. These masses can cause disfigurement of the nail, which may be seen as grooves in the nail. These masses are benign. However, they may be easily traumatized and bleed. Surgical resection may be performed, although the fibroma may regrow. Dental pitting and large erosions of tooth enamel are seen in about 90% of adults with TSC. These pits may cause significant problems with dental hygiene.

A variety of ophthalmic and periophthalmic lesions have been reported with TSC. The most significant lesions are nodular astrocytic hamartomas and pigmentary changes (achromic patches). The achromic patches are static and do not cause any harm. While the nodular retinal hamartomas typically do not grow or cause problems, there is potential for growth, and in some cases vision may be compromised. It is recommended that individuals with TSC have at least a baseline evaluation by an ophthalmologist, and those with nodular lesions should have ongoing follow-up.

Cardiac rhabdomyomas occur in half to two-thirds of individuals with TSC but are usually asymptomatic.

When they do cause problems, it is predominantly in infancy. These tumors generally involute over their first two to three years of life. However, large tumors may cause outflow obstruction and result in congestive heart failure. In such cases, surgical intervention is warranted. In some patients, rhabdomyomas may infiltrate the cardiac muscle, and may interrupt electrical conduction pathways in the heart, giving rise to arrhythmias such as Wolff–Parkinson–White syndrome. In such cases, arrhythmias may persist into adulthood and ongoing follow-up by a cardiologist is necessary.

A variety of vascular dysplasias, including coarctation of the aorta, and aortic and cerebral aneurysms, have been described in individuals with TSC. Arterial aneurysms are also common in angiomyolipomas, the most common benign kidney tumor in TSC.

Pulmonary involvement in TSC consists of two primary conditions, multifocal micronodular pneumocyte hyperplasia (MMPH) and lymphangioleiomyomatosis (LAM). MMPH occurs equally in both men and women. MMPH results from hypertrophy of type II pneumocytes, which results in development of small nodules in the lung parenchyma, and these are apparent on high-resolution chest computed tomography (CT) scans. The incidence in TSC is 30–40%, and MMPH has been identified as early as age 10 years. These lesions are benign and cause no pulmonary symptoms.

LAM is seen in about 40% of women with TSC, usually beginning in the third decade. There are rare reports of men with TSC developing LAM. LAM also occurs in some women who do not have TSC, although these women may also have renal angiomyolipomas. LAM results from abnormal proliferation of smooth muscle cells in the lung parenchyma, and results in multiple cysts ranging in size from 15 mm up to several centimeters and can result in severe destruction of normal lung architecture. While LAM cells are benign, there is good evidence showing that these cells may metastasize, with LAM cells having been identified in the kidney and in axial lymph nodes, as well as in lung. The severity and rate of progression of LAM can vary, but LAM can result in severe end-stage cystic lung disease. Symptomatic treatments are commenced as soon as LAM is identified. Antiestrogen agents and progesterone have been used as treatments, although the evidence that they are helpful is slim. For extreme cases, lung transplantation may be necessary. Due to the severity of LAM, it is recommended that adult women with TSC receive a baseline high-resolution CT, with repeat evaluation as needed for pulmonary symptoms.

Kidney involvement in TSC is common, with 80% of individuals showing at least some evidence of renal involvement by age 10 years. Renal disease is also one of the greatest causes of lifelong morbidity in TSC. The most common kidney lesion is a benign tumor called angiomyolipoma (AML). Polycystic kidney disease is rarer, and occurs in about 3–5% of individuals with TSC. Renal cell carcinoma also occurs in TSC with an incidence of less than 1%.

AMLs are present in about 80% of individuals with TSC, and occur equally in males and females. AMLs can occur as early as childhood, and these lesions tend to increase in size and number over time. AMLs are composed of dysplastic blood vessels, which have a tendency to form aneurysms, dysplastic smooth muscle cells, and adipocytes. These tumors are benign; however, there is a greater tendency for them to hemorrhage when they become greater than 4 cm in diameter. The greater the number and size of AMLs, the greater the likelihood there will be complications or loss of kidney function. Embolization is a minimally invasive procedure which has been shown to be very effective in treating AMLs, although this procedure is not typically undertaken until the tumors are about 5 cm in diameter. Rapamycin is currently being investigated as a potential treatment for AMLs.

Polycystic kidney disease (PKD) is another severe renal malady which may be seen in TSC. Many individuals with TSC will develop a few small cysts in the kidneys. However, some individuals develop multiple massive kidney cysts like those seen in adult polycystic kidney disease (APKD). PKD in TSC results from a large mutation bridging both the *TSC2* and *APKD* genes, which are adjacent to one another on chromosome 16, and causes a contiguous gene syndrome with clinical signs and symptoms of both TSC and APKD. The kidney cysts may ultimately replace normal renal parenchyma, resulting in kidney failure and hypertension. Nephrologic management is warranted, and in the extreme, renal transplantation may be necessary.

While uncommon, various renal malignancies have been documented in individuals with TSC, including renal cell carcinoma, oncocytomas, leiomyosarcomas, and others. Renal cell carcinoma appears to be the most common type of malignancy. Lesions may be identified on sonography as being solid and without apparent fat. If fat cannot be clearly identified with sonography or CT imaging, renal biopsy is recommended to determine histological status of the lesion. If a renal neoplasm is identified, surgical resection is warranted as well as a careful investigation for metastasis. Surveillance monitoring of the kidneys with ultrasonography every 1–3 years is recommended to follow the kidney status in individuals with TSC. This approach serves to follow previously identified lesions, and to identify new lesions which might become problematic.

Other organs may also develop benign tumors in individuals with TSC. For example, angiomyolipomas

can develop in the liver of about 25% of individuals with TSC. In contrast to renal AMLs, the hepatic AMLs do not usually enlarge or hemorrhage. Hamartomatous lesions can also develop in the spleen, pancreas, colon, and rectum, and in a variety of endocrine organs. Routine investigation and surveillance monitoring for these tumors is typically not undertaken due to their low morbidity.

Clinical Features of TSC: Neurologic

The brain lesions of TSC result in significant morbidity. Epilepsy, autism, cognitive disability, and a spectrum of psychiatric pathology are all complications of cerebral tubers. Subependymal giant cell astrocytomas (SEGAs) have the potential to cause hydrocephalus, which may result in significant morbidity and even death. Other neurologic lesions have been associated with TSC, although are less likely to cause significant problems.

Cortical and subcortical tubers are the hallmark cerebral lesions of TSC; the tubers (Latin for 'swelling' or 'protuberance') are hard (Greek, 'skleros') on pathological evaluation (**Figures 2(a) and 2(b)**). Tubers are characterized histologically by disruption of the normal cortical lamination pattern, an increase in astrocytes, and disorganization of pyramidal neurons. There are also very large cells, so-called giant cells, which have characteristics of both astrocytes and neurons. Tubers appear to develop during midgestation and have been found as early as 19 weeks of gestation. The exact process by which tubers are formed is not clear. Tubers typically occur in the cerebral cortex but may rarely also be identified in the cerebellum. They may involve cortex, and sometimes extend down into adjacent white matter and other subcortical areas. They may be multiple, and there is a predilection for occurrence in the frontal and parietal lobes. Size of tubers may range from several millimeters to a size which may comprise the bulk of several gyri. On T_2-weighted and fluid-attenuated inversion recovery magnetic resonance imaging (MRI) sequences, they appear as high signal lesions.

Both tuber location and overall tuber burden are responsible for many neurologic complications. Epilepsy occurs in about 80% of individuals with TSC, and is related to some tubers, although there is a question concerning whether seizures arise from the tubers, from the cortex surrounding the tubers, or from both. Seizures may begin in infancy, often as infantile spasms, and epilepsy in TSC may be particularly refractory to medical treatment. In some cases, surgical resection of epileptogenic tubers may be necessary and helpful.

Intellectual and cognitive impairments often occur in TSC. Mental retardation occurs in 40–50% of

Figure 2 (a) A T_2-weighted magnetic resonance image showing multiple cortical and subcortical tubers (arrows) and subependymal nodules lining the lateral ventricles (arrowheads). (b) Gross brain specimen from a deceased patient with TSC demonstrates a tuber involving the frontal cortex. (c) Gross brain specimen of subependymal nodules (arrows). (b, c) Reprinted from Roach ES (1992) Neurocutaneous syndromes. *Pediatric Clinics of North America* 39: 591–620, with permission.

individuals with TSC, although the degree of impairment may be from mild to profound. Estimates of the prevalence of autism in TSC range from 5% to 60%. Neurocognitive disabilities of TSC are related to tuber burden and location, as well as to the degree of seizure control.

Subependymal nodules (SENs) are nodular hamartomatous growths that are primarily found along the walls of the lateral ventricles. They may be found adjacent to or imbedded in the caudate nucleus and also are frequently located adjacent to the foramina of Monro (Figure 2(c)). There are usually multiple SENs, and they may be very numerous (e.g., 15–25). They range in size from 1 to 10 mm, and they may calcify as cells within the nodule die and are replaced with calcium. As a result, calcified SENs appear as high-density lesions on CT scans. SENs appear as low-intensity lesions on T_1- and T_2-weighted MRI sequences. The cellular makeup of SENs includes cells resembling astrocytes, and giant cells with both astrocyte and neuronal lineage, and the ventricular surface is covered by intact ependyma cells. SENs are benign, yet there may be slow growth, and when SENs grow larger than 10 mm, they are referred to as subependymal giant cell astrocytomas (SEGAs).

SEGAs arise from SENs; however, it is not known what causes this transformation. SEGAs occur in about 15% of individuals with TSC and occur primarily during the first two decades of life. SEGAs usually occur in the lateral ventricles, are not malignant, and do not have a tendency to metastasize (Figures 3(a) and 3(b)). Growth may be very slow, in which case excision is not absolutely necessary. However, when SEGAs in the vicinity of the foramina of Monro grow, they may obstruct cerebral spinal fluid flow, resulting in hydrocephalus. If, on serial imaging, there appears to be rapid growth or ventricular enlargement, or if there are signs and symptoms of hydrocephalus, surgical excision of the SEGA is necessary. Surveillance monitoring has resulted in a significant reduction in the morbidity and mortality related to SEGAs.

Other brain lesions occur in individuals with TSC. For example, linear migration lines streaking through the white matter from the ventricular region to the cortex represent the pathways for migration for dysplastic neurons. Other findings occasionally seen include megalencephaly or hemimegalencephaly, transmantle cortical dysplasia (which lesions also have a tendency to calcify), schizencephaly, and intracranial aneurysms.

Work in Progress

The clinical and molecular complexities of TSC have made the disease a mother lode of information, helping us to understand fundamental cellular processes which have bearing on developmental and cancer biology. There have been tremendous strides made in understanding the natural history of TSC and in improving treatments for the many complications of the disease. Basic scientists are continuing their efforts to clarify the roles of tuberin and hamartin in the various cell signaling pathways, and how they

Figure 3 (a) Gadolinium contrast T_1-weighted magnetic resonance image of a moderately sized mass determined to be a subependymal giant cell astrocytoma at surgical resection. (b) Gadolinium contrast T_1-weighted magnetic resonance image of a massive subependymal giant cell astrocytoma, filling much of the lateral ventricle and causing mass effect.

relate to the many clinical manifestations of TSC. A prime example of this is the role of the mTOR inhibitor, rapamycin, in treating renal angiomyolipomas, lymphangioleiomyomatosis, and even SEGAs. Preliminary evidence has demonstrated that treatment with rapamycin results in a significant degree of improvement in these clinical conditions. There are also other major efforts underway to define the natural history of TSC over the human life span, and to evaluate how the clinical findings relate to the genetic variances of TSC. The foremost goal of improving the lives of individuals with TSC is now being achieved through these efforts. The ultimate goal of curing TSC is elusive, yet in some manner, is attainable.

Tumors of the Brain and the Spinal Cord

G Bobustuc and S Baidas, M. D. Anderson Cancer Center Orlando, Orlando, FL, USA

© 2009 Elsevier Ltd. All rights reserved.

Overview

Tumors of the central nervous system (CNS) form a broad spectrum of disease varying from benign to malignant and from primary to metastatic tumors (Table 1). As cancer patients live longer with improved therapy, an increased number of CNS metastatic tumors are being seen. It is estimated that more than 180 000 of the total US cancer patients had CNS involvement by metastatic cancer in 2000.

Primary CNS tumors accounted for 15 new cases per 100 000 persons per year between 1998 and 2002 (45% men, 55% women). Ninety-six percent occur within the cranial cavity and 4% arise in the spine. Brain tumors occur in two peaks: childhood (age 3–12) and later life (age 50–79). An increase in age-adjusted incidence of glial tumors has been noticed since the 1970s. Part of this increase in tumor incidence might be attributed to improvement in imaging technology; further studies are required to look for other causes, especially with the increasing incidence of CNS tumors at younger ages.

CNS tumors represent the second most frequent malignancy in children under the age of 15. The majority of pediatric brain tumors occur below the tentorium. Forty percent are embryonal in type (mainly medulloblastoma), whereas in adults 90% are astrocytomas and occur above the tentorium. Children with brain tumors have a better prognosis than adults, in part because children rarely develop the highly malignant tumors of adults, glioblastomas. Also, low-grade gliomas tend to remain histologically low grade, and, in general, gliomas in children do not demonstrate the same molecular genetic changes identified in adults. Children only rarely develop three common benign tumors of adults: meningiomas, acoustic neuromas, and pituitary tumors.

Spinal cord tumors comprise 4% of CNS tumors. In adults, astrocytomas are less common than ependymomas, comprising only 30–35% of spinal cord gliomas, while in children, astrocytomas and ependymomas comprise 59% and 28%, respectively, of spinal cord tumors.

Tumors of Neuronal and Glial Origin

Brain tumors rarely metastasize outside the CNS with the exception of medulloblastoma and malignant meningioma. In general they have a poor prognosis and a grim outcome. Several clinical and biologic features serve to distinguish primary brain tumors. First, because of their location inside the bony confines of the skull or spinal column, these tumors cause symptoms by direct invasion or compression of normal tissue and by increasing intracranial or intraspinal pressure. The focal organization of brain function, together with poor ability to regenerate and the obvious difficulties of radical surgical excisions, lead to high morbidity and mortality. Of biological interest is the fact that 60% of malignant CNS tumors are of glial origin. Gliomas are prone to infiltrative invasion of normal brain tissue that renders complete surgical excision of such tumors difficult to achieve. These tumors tend to progress from well-differentiated, low-grade to higher grade, poorly differentiated neoplasms with a more aggressive behavior. In addition, compared to the rest of the body, the CNS is a 'privileged' or protected site, largely because the blood–brain barrier blocks access of both natural immune defenses and chemotherapeutic agents. The endothelial cells of the brain vasculature are rich in the multidrug resistance gene (MDR1) contributing to the chemoresistant behavior of CNS tumors.

Other CNS Tumor Types

Aside from tumors of neuronal and glial origin, several other tumor types in the CNS deserve mention. One such tumor, meningioma, of mesodermal origin, comprises 18% of primary intracranial tumors. Meningiomas are mostly benign tumors, the majority of which are surgically curable. Some meningiomas have the tendency to recur or to transform to a higher malignant grade with the capacity to metastasize, behaving like sarcomas. Meningiomas are seen at a higher incidence in women.

Nerve sheath tumors (schwannomas) are mostly benign tumors. They can cause symptoms related to the nerve origin and by compressing the adjacent brain tissues. The most common of these tumors arises from the vestibular part of the eighth cranial nerve and is called acoustic neuroma. Neurofibromatosis consists of two distinct autosomal dominant hereditary disorders.

Neurofibromatosis type one (NF1) is associated with a lesion on chromosome 17q and neurofibromatosis type two (NF2) with a lesion on chromosome 22q. NF1 is characterized by appearance of *café-au-lait* patches and neurofibromas in addition to iris hamartomas (Lisch nodules). NF2 is characterized by bilateral acoustic neuromas and a higher incidence of meningiomas and ependymomas.

Table 1 Tumors of the brain and spinal cord: WHO classification 1993

1. Tumors of neuroepithelial tissue
   - 1.1 Astrocytic tumors
     - 1.1.1 Astrocytoma: variants fibrillary, protoplasmic gemistocytic
     - 1.1.2 Anaplastic astrocytoma
     - 1.1.3 Glioblastoma: variants giant cell glioblastoma, gliosarcoma
     - 1.1.4 Pilocytic astrocytoma
     - 1.1.5 Pleomorphic xanthoastrocytoma
     - 1.1.6 Subependymal giant cell astrocytoma (tuberous sclerosis)
   - 1.2 Oligodendroglial tumors
     - 1.2.1 Oligodendroglioma
     - 1.2.2 Anaplastic oligodendroglioma
   - 1.3 Ependymal tumors
     - 1.3.1 Ependymoma: variants – cellular, papillary clear cell
     - 1.3.2 Anaplastic ependymoma
     - 1.3.3 Myxopapillary ependymoma
     - 1.3.4 Subependymoma
   - 1.4 Mixed gliomas
     - 1.4.1 Oligo-astrocytoma
     - 1.4.2 Anaplastic oligo-astrocytoma
   - 1.5 Choroid plexus tumors
     - 1.5.1 Choroid plexus papilloma
     - 1.5.2 Choroid plexus carcinoma
   - 1.6 Neuroepethelial tumors of uncertain origin
     - 1.6.1 Neuroblastoma
     - 1.6.2 Polar spongioblastoma
     - 1.6.3 Gliomatosis cerebri
   - 1.7 Neuronal and mixed neuronal-glial tumors
     - 1.7.1 Gangliocytoma
     - 1.7.2 Dysplastic gangliocytoma of cerebellum
     - 1.7.3 Dysmoplastic infantile ganglioglioma
     - 1.7.4 Dysembryoplastic neuroepithelial tumor
     - 1.7.5 Ganglioglioma
     - 1.7.6 Anaplastic ganglioglioma
     - 1.7.7 Central neurocytoma
     - 1.7.8 Paraganglioma of the filum terminale
     - 1.7.9 Olfactory neuroblastoma (esthesioneuroblastoma)
   - 1.8 Pineal parenchymal tumors
     - 1.8.1 Pineocytoma
     - 1.8.2 Pineoblastoma
     - 1.8.3 Mixed/transitional pineal tumors
   - 1.9 Embryonal tumors
     - 1.9.1 Medulloepithelioma
     - 1.9.2 Neuroblastoma: variant – ganglioneuroblastoma
     - 1.9.3 Ependymoblastoma
     - 1.9.4 Primitive neuroectodermal tumors (PNETs): medulloblastoma: variants – dysmoplastic medulloblatoma; medullomyoblastoma: variants – dysmoplastic medulloblatoma, medullomyoblastoma, melanotic medullobastoma
2. Tumors of cranial and spinal nerves
   - 2.1 Schwannoma (neurilemmoma, neurinoma) cellular, plexiform, melanotic
   - 2.2 Neurofibroma: circumscribed (solitary), plexiform
   - 2.3 Malignant peripheral nerve sheath tumors (MPNST): neurogenic sarcoma, anaplastic neurofibroma, malignant schwanoma.
3. Tumors of the meninges
   - 3.1 Tumors of meningothelial cells
     - 3.1.1 Meningioma: meningothelial, fibrous, transitional, psamomatous, angiomatous, microcystic, secretory, clear cell, choroid, metaplastic and lymphoplasmacyte-rich
     - 3.1.2 Atypical meningioma
     - 3.1.3 Papillary meningioma
     - 3.1.4 Anaplastic (malignant) meningioma
   - 3.2 Mesenchymal, nonmeningothelial tumors, benign neoplasms: osteocartilaginous tumors, lipoma, fibrous histiocytoma; Malignant neoplasms: hemangiopericytoma, chondrosarcoma, maliganant fibrous histiocytoma, rhabdomyosarcoma, meningeal sarcomatosis
   - 3.3 Primary melanocytic lesions: diffuse melanosis, melanocytoma, malignant melanoma
   - 3.4 Tumors of uncertain histogenesis: hemangioblastoma

Continued

Table 1 Continued

4. Lymphomas and hemopoitic neoplasms
   4.1 Malignant lymphomas
   4.2 Plasmacytoma
   4.3 Granulocytic sarcoma
5. Germ cell tumors: germinoma, embryonal carcinoma, yolk sac tumors, choriocarcinoma, teratoma, mixed germ cell tumors
6. Cysts and tumor-like lesions
7. Tumors of sellar origin: pituitary adenoma, pituitary carcinoma, craniopharyngioma
8. Local extension from regional tumors: paraganglioma, chordoma, chondroma chondrosarcoma, carcinoma
9. Metastatic tumors
10. Unclassified tumors

Pituitary tumors account for about 10% of adult intracranial tumors. They are usually benign tumors but can compress the brain and the optic pathway adjacent to the pituitary at the base of the skull. About one-half of pituitary tumors produce increased amounts of normal pituitary hormones. Increase in prolactin causes amenorrhea/galactorrhea, while increase in growth hormone causes acromegaly and increase in adrenocorticotropic hormone causes Cushing's syndrome.

Pineal region tumors comprise 3–8% of pediatric intracranial tumors (50% under 20 years of age). Most of this group of tumors originate from displaced embryonic tissue remnants or elements of the pineal gland. They include germ cell tumors, pineocytomas, pineoblastomas, and glial-derived tumors. A majority of intracranial germ cell tumors are teratomas that can be treated with radiotherapy alone. Nongerminomatous malignant CNS germ cell tumors have a poor prognosis. Different treatment approaches adding cisplatin-based chemotherapy to conventional surgery and radiation in order to improve survival are being tried with significant survival benefits.

Risk Factors and Molecular Markers

A definite association between environmental or occupational exposure and CNS tumors is lacking. Several reports that did not reach statistical credibility showed increased incidence in CNS tumors with exposure to chemicals, viruses, trauma, magnetic fields, and radiation sources. An increased incidence of primary CNS lymphoma (PCNSL) in immunocompromised individuals has been observed over the last two decades. Most of the PCNSL (more than 90%) are of the large cell, B-cell CD20 positive type. Immunocompromised patients, particularly AIDS patients, have a 17 times higher incidence of PCNSL (0.28 vs. 4.7 in 100 000). Diagnosis relies on imaging and stereotactic biopsy. The mainstay of treatment remains systemic chemotherapy and possibly whole brain radiation.

Tumors occur at a higher rate in individuals with genetic disorders; such syndromes include Li-Fraumeni, Von Hippel Lindau, tuberous sclerosis, Turcot syndrome, and NF1 and NF2.

Recent studies have begun to delineate the genetic abnormalities that underlie CNS tumors, and have implicated two classes of genes: tumor suppressor genes and (proto)oncogenes. P53 on chromosome 17p has been shown to be mutated in low- and high-grade gliomas, while loss of chromosome 9 is an intermediate event and loss of chromosome 10 (site of PTEN, another tumor suppressor gene) is a late event seen mainly in glioblastoma multiforme. Loss of heterozygosity for chromosomes 1p and 19q is often observed in oligodendrogliomas and correlates with an increased sensitivity to chemotherapy and prolonged survival. Meningiomas and schwannomas have shown changes in chromosome 22, especially in females, while medulloblastomas have shown changes in several chromosomes including 1, 7, 8, 17, and 20 together with amplification of c-myc oncogene. Amplification of protooncogenes includes several cytokines and growth factors of which epidermal growth factor receptor (EGF-R) and platelet-derived growth factor receptor (PDGF-R) genes are mainly seen in high-grade gliomas. Increased expression of fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF) plays an important role in neovascularization required for growth of gliomas.

Diagnosis and Treatment

Treatment of most brain tumors requires a tissue diagnosis, making imaging an important tool in surgical planning. The availability of computed tomography, magnetic resonance imaging (MRI), positron emission tomography, and single photon emission computed tomography has added new dimensions in the accurate localization of CNS tumors, diagnosis, and treatment. Combining three-dimensional imaging with functional MRI helps in providing the anatomical

relation between tumors and the different functional areas in the brain, leading to a better surgical planning and outcome. The most important predictors of survival in higher-grade tumor treatment remain the extent of surgical resection, age, and functional status.

Neurosurgical approaches including microsurgery and stereotactic surgery have reduced surgical morbidity, increased survival, and widened the reach of neurosurgeons. Following surgery, radiation is the mainstay of treatment for most brain tumors. New modalities in radiation therapy from hyperfractionation and stereotactic radiosurgery to brachytherapy have become widely available. Moreover, chemoradiation combining external beam intensity modulated radiotherapy with daily temozolamide has been shown to increase survival and quality of life in patients with high-grade gliomas.

Standard chemotherapy for gliomas has been limited to alkylating agents. Nitrosoureas have been used either alone as BCNU (carmustine) or in combination as CCNU (lomustine) together with procarbazine and vincristine as part of the well-known PCV regimen. Temozolamide is a newer generation oral alkylating agent which is currently a first line treatment of gliomas. Exciting new directions in chemotherapy are entering clinical trials. These include protracted use of (combination) chemotherapy in a metronomic fashion, immunotherapy and differentiation therapy, chemotherapy in combination with kinase inhibitors (interfering with protooncogene-driven cytokines and growth factors), and antiangiogenic therapies or gene therapies. Gene therapy approaches assessed in clinical trials include interference with abnormal gene expression, reconstitution of wild-type (normal) gene phenotype, antisense, and antiangiogenesis.

Conclusion

Although new dimensions in the diagnostic and therapeutic modalities have become available, this has not translated into a dramatic increase in survival in patients with CNS tumors, particularly for gliomas. A better understanding of the biology of such tumors together with a better utilization of the available treatment modalities and the continuous search for new agents and for new treatment approaches will be the future challenge.

Two-P-Domain (K_{2P}) Potassium Channels: Leak Conductance Regulators of Excitability

D Thomas and S A N Goldstein, University of Chicago, Chicago, IL, USA

A Potassium Channel Superfamily Dedicated to Membrane Leak

At rest, plasma membranes of excitable cells are selectively permeable to 'leak' of potassium (K^+) ions. Potassium leak pathways exert control over excitability by shaping the duration, frequency, and amplitude of action potentials. Leak currents (also called resting or background conductances) active at rest stabilize cells at hyperpolarized voltages below firing threshold, whereas leak suppression permits depolarization and excitation. Conversely, the majority of voltage-dependent potassium (Kv) channels are silent at rest, permitting excitation because they do not interfere with rise to threshold and open with depolarization to actively promote recovery and rapid refiring. Because membrane potential is fundamental to neuronal activity, regulation of potassium leak is a primary and dynamic mechanism for control of cellular excitability.

As expected for key regulators of excitability, leak channels are under tight control from a plethora of stimuli, including lipids, mechanical stretch, neurotransmitters, oxygen tension, pH, and activators of G-protein-coupled receptors and intracellular second messengers. Leak channels are targets for compounds in clinical use, such as volatile and local anesthetics. Leak channels may also influence long-term regulation of excitability through control of gene expression. Regulation of leak channels alters those attributes that are subject to change in any ion channel: the number of functional pores at a site of operation, open probability, and unitary current.

Assigning Membrane Leak to Open Rectifier K^+ Channels

Although the existence of leak currents was recognized more than 50 years ago by Hodgkin and Huxley, they remained a biophysical curiosity for more than four decades. Despite their significant duties and dynamic regulation, native leak currents defied coherent description; they were readily ignored, easily camouflaged, and even actively removed by 'leak subtraction' during electrophysiological measurements.

During the past 10 years, cloning of the superfamily of *KCNK* genes encoding the K_{2P} channels (with 15 mammalian members) has established unequivocally that leaks are indeed more than dribble through pathways devoted to other functions. Identification of the first molecular correlate of a potassium leak current was preceded by cloning of potassium channels in *Saccharomyces cerevisiae* and *Caenorhabditis elegans* with two pore-forming loops in each subunit and eight or four transmembrane (TM) domains, respectively. Thereafter, the *KCNKØ* (*dORK1*) gene for K_{2P}Ø was isolated by functional expression from neuromuscular tissue of *Drosophila melanogaster* on the basis of its capacity to rescue potassium transport-deficient yeast cells. Electrophysiological characterization revealed K_{2P}Ø to be a potassium-selective channel with the predicted attributes of a background leak conductance – that is, a voltage-independent portal showing Goldman–Hodgkin–Katz, or open, rectification.

Potassium channels that show open rectification pass current more readily in one direction (rectify) due to unequal ion concentration across the membrane. Open rectification refers to a nonlinear current–voltage relationship for ions traveling through an open, ion-selective portal and is distinct from rectification due to voltage-dependent changes in channel activity caused by gating or blockade. Current flows more easily from a side of high permeant ion concentration, which explains why K_{2P} leak channels pass outward current under physiological ionic conditions of high internal and low external potassium and have linear current–voltage relationships when potassium concentrations across the membrane are symmetrical (**Figure 1**). Although the underlying assumptions of electrodiffusion theory are inaccurate here (ions do not move independently of each other through the pore), the theory predicts some observed current–voltage relationships reasonably well.

Of course, any potassium channel open below firing threshold will influence resting potential. Thus, it is not surprising that other potassium channels have been associated with background potassium leak. Inward rectifiers, formed by K_{ir} subunits, stabilize cells near E_K. Some classical voltage-gated potassium channel (K_v) subunits are open at rest if assembled with β subunits, including K_v7.1 (in complex with MiRP1/*KCNE2* in heart or MiRP3/*KCNE4* in intestine) and Kv3.4 (in association with MiRP2/*KCNE3* in skeletal muscle). In the central nervous

Figure 1 K_{2P} channels are potassium-selective leaks. (a) The channels (in this case, K_{2P}Ø) show Goldman–Hodgkin–Katz (open) rectification and allow the passage of large outward currents under physiological conditions of high internal and low external K^+, whereas they pass currents that change in a linear fashion when potassium levels are symmetrical. (b) Raw current traces from K_{2P}Ø studied by two-microelectrode voltage clamp demonstrating attributes of an open, potassium-selective pore as described in (a). The current traces reveal no delay before current starts to flow because the channels are open before the voltage step. Dashed line is 0 mV; Phys and Sym indicate 5 and 100 mM bath potassium, respectively. Reprinted with permission from Goldstein SAN, Price LA, Rosenthal DN, et al. (1996) ORK1, a potassium-selective leak channel with two pore domains cloned from *Drosophila melanogaster* by expression in *Saccharomyces cerevisiae*. *Proceedings of the National Academy of Sciences of the United States of America* 93: 13256–13261. Copyright 1996 National Academy of Sciences, USA.

system, K_v7.X (KCNQ) subunits show a relatively hyperpolarized activation threshold and are implicated in neuronal M-type currents as homomeric K_v7.5 channels and mixed K_v7.2/7.3 complexes.

Potassium Channel Subunits with Two Pore Domains

A striking feature of K_{2P} channels is their subunit body plan: each has two pore (P) loops and four TM domains (Figure 2(a)). As a result, members of this family are referred to as 'two-P-domain,' 'two-pore-domain,' and, formally, 'K_{2P}' channels. This distinct 2P/4TM topology can be found in more than 70 predicted homologs in genome databases. Fifteen mammalian *KCNK* genes encode K_{2P} channels (Table 1 and Figure 2(e)). K_{2P} channels are expressed throughout the body; their distribution in the central nervous system has been particularly well delineated (Table 2).

Classical potassium channel subunits have only one P loop. Because voltage-gated (K_v) and inward rectifier (K_{ir}) channels have six and two TM domains, respectively, they have 1P/6TM and 1P/2TM topology (Figures 2(b) and 2(c)). Two fungal K_{2P} channels have been characterized, and their subunits have 2P/8TM topology (Figure 2(d)). Four P loops aggregate to form a single ion conduction pathway. Thus, K_{2P} channels assemble from two subunits, whereas K_v and K_{ir} channels form with four subunits.

When ion channels are discovered, they are given colloquial names that remain in use until a shared nomenclature is embraced. As a result, identical genes and their subunits carry multiple names (and nonhomologous subunits sometimes share similar root names). A simplified terminology has been instituted by the Human Genome Organization (HUGO) applying the prefix *KCNK* for each gene, and the International Union of Pharmacology classification accords each gene with a K_{2P} ion channel subunit product. These identifiers are presented with some common acronyms for the various isolates in Table 1.

What Is Leak?

From the earliest days of electrophysiological recordings, a fixed conductance called the leak was used to explain the presence of a resting membrane potential from which action potentials emerged and to which they returned. In current parlance, 'leak' is still applied to fixed background currents present at rest and to currents that seem to rise instantly to a new steady level with voltage steps. Leaks can be nonselective (e.g., when a membrane is physically damaged) or result from the movement of specific ions.

Even at rest, the plasma membrane of a living cell is bustling with activity: ions move in and out, and ionic and electrical transmembrane gradients are maintained. The ionic gradient is established by active transport systems (e.g., sodium–potassium pumps). These pumps expend cellular energy (ATP) to keep intracellular levels of sodium low and potassium high. Ion channels dissipate the ionic gradient by opening water-filled pathways across the membrane that allow for free diffusion of selected ions down their electrochemical gradients. An open potassium channel allows potassium ions to flow out of the cell down their concentration gradient. This leaves behind negative counter ions, producing an excess of negative charge inside the cell that limits potassium efflux: net outflow of potassium continues only until

Figure 2 Membrane topology of potassium channels. Subunits are drawn with the extracellular membrane surface facing up. (a) K_{2P} channels have a predicted 2P/4TM subunit topology. (b) Voltage-gated K^+ channel (K_v) subunits have a 1P/6TM domain predicted topology and are noted for their positively charged fourth TM segment (S4) acting as voltage sensor for changes in membrane potential. (c) Inwardly rectifying potassium channel (K_{ir}) subunits have one P domain and two TM segments (1P/2TM topology). (d) TOK1, a fungal K_{2P} channel from *Saccharomyces cerevisiae* with 2P/8TM topology. (e) Phylogenetic tree for human K_{2P} channels. Nucleotide sequence alignment and phylogenetic analysis for the 15 known members of the K_{2P} family were generated using ClustalW software version 1.83 (BLOSUM method) and TreeView. (a–d) Reprinted by permission from Macmillan Publishers Ltd: Goldstein SAN, Bockenhauer D, O'Kelly I, and Zilberberg N (2001) Potassium leak channels and the KCNK family two-P-domain subunits. *Nature Reviews Neuroscience* 2: 175–184, copyright 2001.

the chemical energy favoring efflux is balanced by the electrostatic energy favoring influx. At equilibrium, chemical and electrostatic forces are equal, efflux equals influx, and there is no net movement of potassium ions. The Nernst potential is the membrane voltage that yields equilibrium for a particular ion at a given ionic gradient. For a hypothetical membrane that allows only potassium to cross, the Nernst potential is the same as the equilibrium reversal potential for potassium ions, E_K, and is described in the following equation:

$$E_K = (RT/zF) \times \ln(K_{ex}/K_{in})$$

where R is the gas constant, T is temperature in degrees Kelvin, z is the charge of the ion, F is Faraday's constant, and K_{ex} and K_{in} are the concentrations of potassium ions in the extracellular and intracellular compartments, respectively. For physiological potassium ion concentrations at physiological temperature, RT/zF is $\sim$27 mV and E_K is $\sim$−97 mV. Mammalian cells have resting membrane potentials of −60 to −90 mV because potassium ions are not the only ions that move at rest: for example, leak of sodium and chloride shifts the membrane toward their Nernst potentials (approximately +67 and −93 mV, respectively). Since the concentration gradient of ions across the membrane (which is set by ion pumps) does not change appreciably during an action potential, the membrane potential is highly dependent on the baseline permeability of the cell membrane. The resting membrane potential is often close to E_K because far more potassium channels are open at rest than pathways for other ions. Thus, expression and activation of potassium leak currents is a primary determinant of the resting transmembrane potential.

Excitability depends on the resting membrane potential because action potentials fire when the membrane voltage rises to a threshold level where voltage-gated sodium and/or calcium channels open (and subsequently become inactive). To fire again, these channels must recover from inactivation by returning to a negative potential below threshold (i.e., the resting membrane potential), a shift achieved by outward potassium currents.

Regulation of K_{2P} Channel Surface Expression and Function

Intracellular Trafficking

$K_{2P}3.1$ is expressed throughout the central nervous system. Along with $K_{2P}1.1$, $K_{2P}9.1$, and $K_{2P}10.1$, the

channel is believed to contribute to the potassium standing outward current (I_{KSO}) important in cerebellar granule neurons. Furthermore, the channel is responsive to volatile anesthetics and has been implicated in oxygen sensation in both the brain and the carotid body. K_{2P}3.1 has significant sequence and functional homology to K_{2P}9.1.

Regulated surface expression of plasma membrane receptors is crucial for normal cellular physiology. Yeast two-hybrid analyses and biochemical studies with K_{2P}3.1 and K_{2P}9.1 reveal that successful trafficking of the channels to the plasma membrane is the result of a conflict between two opposing trafficking motifs (and competition for the sites by native binding partners): an N-terminal dibasic retention site and a C-terminal release site. Dibasic retention motifs consist of basic amino-acid residues (R, K) that are often in pairs (but seen singly or in triplets) and serve as recognition sites for coatamer proteins such as β-COP. Vesicles coated with coatamer proteins mediate retrograde transport to the endoplasmic reticulum (ER). Conversely, phosphorylation-dependent binding of the ubiquitous intracellular regulator 14-3-3 to the channel C-terminus promotes escape from the ER via suppression of β-COP binding. This mechanism appears to be used by other membrane proteins as well, including nicotinic acetylcholine receptors and major histocompatibility antigen class II-associated invariant chain. A role for p11, a small annexin II subunit, has been proposed in K_{2P}3.1 forward trafficking. This 97-residue protein implicated in endocytosis, exocytosis, and membrane organization has limited tissue distribution, suggesting that it serves in some locales to modulate 14-3-3/β-COP regulation of K_{2P} channel expression.

In reverse fashion, K_{2P}1.1 in renal proximal tubules appears to have a partner that promotes channel internalization and retrograde trafficking away from the cell surface. A bacterial two-hybrid screen identified EFA6, an exchange factor for the small G-protein

ADP ribosylation factor 6 (ARF6) involved in membrane protein recycling and actin organization, as a protein partner of $K_{2P}1.1$. $K_{2P}1.1$ and EFA6 physically interact in Mabin–Darby canine kidney cells in an ARF6-dependent manner to favor trafficking from the plasma membrane to recycling endosomes. Since ARF6 is a modulator of endocytosis at the apical membrane of epithelial cells, the EFA6/ARF6 system seems to be a strong candidate to contribute to $K_{2P}1.1$ channel trafficking.

Reversible Modification by SUMO Peptide Silences and Activates

Some *KCNK* genes fail to produce currents when expressed in experimental cells (*KCNK1*, *-7*, *-12*, and *-15*). Synthesis of mRNA for the genes in native cells indicates these are not pseudogenes. It was therefore speculated that they might not be targeted correctly to the plasma membrane in experimental systems (which is the case for $K_{2P}7.1$), might have a predominantly intracellular location, might need to assemble with another K_{2P} subtype to operate, or might require an unidentified accessory or regulatory subunit to be activated. The last mechanism has been demonstrated for $K_{2P}1.1$ channels.

$K_{2P}1.1$ is widely expressed with abundant transcript in brain (cerebellum and thalamus), heart, and kidney. Although $K_{2P}1.1$ was first reported to be a weak, inwardly rectifying potassium channel, and hence given the alias TWIK (Table 1), concurrent studies were unable to observe functional expression. $K_{2P}1.1$ has been shown to be inactive, despite residence in the plasma membrane, as long as the protein is covalently modified by a small ubiquitin-related modifier protein, SUMO, at a single C-terminal lysine residue (K274). SUMO was previously associated with the nuclear import/export, activity, and half-life of transcription factors. The posttranslational SUMO modification pathway has since been observed to function in its entirety at the plasma membrane. Desumoylation (removal of covalently bound SUMO) of $K_{2P}1.1$ by the SUMO-specific protease SENP1 relieves chronic silencing, thereby revealing that the protein is a classical K_{2P} open rectifier (Figure 3).

Abundant $K_{2P}1.1$ transcripts in cerebellar granule neurons have suggested a role for the channel in the standing outward potassium leak current, I_{KSO}. Characterization of I_{KSO} suggests that it is composed of four distinct components with attributes similar to those of $K_{2P}3.1$, $K_{2P}9.1$, $K_{2P}10.1$, and a fourth, previously unidentified, subunit now recognized from its biophysical properties to be a good match for $K_{2P}1.1$ channels.

Differential Modulation by Changes in pH

Deviations from normal physiological pH are monitored by multiple sensors *in vivo*. Tissue acidosis is relevant to the pathophysiology of cancer, inflammation, and ischemia, and it contributes to acute pain (e.g., gastroesophageal reflux and peptic ulcer) and inflammatory hyperalgesia, in which afferent nerve fibers are sensitized. Acid sensors in the gut control gastric acid homeostasis, whereas those in the circulatory and central nervous system regulate breathing and arousal. Sensory neurons respond to acidification of their environment via modulation of cellular excitability using at least four acid-sensitive ion channel families: voltage-gated, sodium-selective, acid-sensing ion channels (ASIC1–3); transient receptor potential cation channels (TRPV1 and-V4); ligand-gated, purinoceptor, cation channels ($P2X_{1-5}$ and $P2X_7$); and K_{2P} potassium channels (Table 3).

$K_{2P}3.1$ and $K_{2P}9.1$ are particularly sensitive to extracellular pH variations in the physiological range, displaying pKa values of 7.2 and 6.7, respectively (Figure 4). *In vitro*, these channels can form heterodimers which exhibit intermediate pH sensitivity. A single histidine residue adjacent to the potassium selectivity filter within the first pore-forming loop represents the extracellular proton binding site in both $K_{2P}3.1$ and $K_{2P}9.1$. *In vivo*, decreased brain pH due to hypercapnia induces enhanced respiration

Figure 3 $K_{2P}1.1$ channel activity is regulated by reversible, covalent modification by SUMO. (a) Sumoylation silences $K_{2P}1.1$. Linkage of SUMO to the lysine at position 274 (K274) of $K_{2P}1.1$ by native SUMO conjugation machinery requires the E2 conjugating enzyme Ubc-9 and can be reversed by the desumoylating protease SENP-1. (b) Reversible SUMO modification of $K_{2P}1.1$ and its regulation of channel activity, studied in inside-out patches excised from *Xenopus* oocytes. Active $K_{2P}1.1$ channels in patches excised from cells expressing $K_{2P}1.1$ and the SUMO protease SENP-1 become silent on exposure of the inner channel surface to native Ubc-9 in the interior of a naive cell. Channels return to full activity when the patch is withdrawn and inserted into a cell expressing only SENP-1. Arrows indicate points of patch insertion into each new cell. (b) Reproduced from Rajan S, Plant LD, Rabin ML, Butler MH, and Goldstein SAN (2005) Sumoylation silences the plasma membrane leak K^+ channel K2P1. Cell 121:37–47, copyright 2005, with permission from Elsevier.

(in an effort to reduce pCO_2) and behavioral arousal, serving a protective function, notably during sleep. $K_{2P}3.1$ and $K_{2P}9.1$ currents have been detected in somatic motor neurons, noradrenergic locus coeruleus neurons, and serotoninergic raphe neurons. Since the two latter neuronal types are implicated in central respiratory chemoreception, $K_{2P}3.1$ and $K_{2P}9.1$ have been proposed as molecular mediators of pH-dependent excitability in these cells to regulate breathing and arousal. Indeed, in respiration-related motor neurons, reduction in $K_{2P}3.1$ and $K_{2P}9.1$ currents due to acidification of the surrounding tissue may directly increase excitability.

Other K_{2P} channels alter their activity with intracellular acidosis. Thus, $K_{2P}1.1$, $K_{2P}3.1$, $K_{2P}5.1$, $K_{2P}6.1$, and $K_{2P}18.1$ are inhibited, whereas a mechanosensitive channel, $K_{2P}2.1$, shifts its pressure–activation relationship upon protonation of a C-terminal glutamate. In other channels, the influence of lowered pH may be indirect since residues that mediate the responses have not been identified and methods used to lower pH (i.e., CO_2, dinitrophenol, or NH_4Cl) impact a number of cellular pathways that could act on the channels secondarily.

Phenotypic Flexibility: A Leak That Can Also Operate as a Voltage-Gated Channel

Expressed robustly in the central nervous system, especially in the hippocampus, $K_{2P}2.1$ channels are regulated by a multitude of chemical and physical factors. Single $K_{2P}2.1$ channels show unexpected and dynamic versatility: native hippocampal and cloned $K_{2P}2.1$ channels transform in a regulated and reversible fashion from potassium-selective leak

Figure 4 Cloned $K_{2P}3.1$ channels are inhibited by external protons at physiological pH. $K_{2P}3.1$ channels expressed in *Xenopus* oocytes were studied using two-electrode voltage clamp. (a) A cell exposed to varying pH with 5 mM K^+ bath solution is shown. (b) The plot shows dependence of $K_{2P}3.1$ currents at 0 mV membrane potential on extracellular pH for groups of five cells normalized to pH 8, giving a pKa of 7.24. Reprinted from Lopes CMB, Gallagher PG, Buck ME, Butler MH, and Goldstein SAN (2000) Proton block and voltage gating are potassium-dependent in the cardiac leak channel Kcnk3. *Journal of Biological Chemistry* 275: 16969–16978, with permission.

Figure 5 PKA-mediated downregulation of $K_{2P}2.1$. Inside-out patches were excised from oocytes expressing the channels and studied in symmetric 100 mM KCl. $K_{2P}2.1$ is an open rectifier when the PKA phosphorylation site S348 bears no phosphate (recapitulated here by mutation to alanine), passing inward and outward currents in symmetrical K^+ conditions. When the PKA site is negatively charged via phosphorylation or mutation to aspartate (shown here), the open probability of the channel decreases and both cloned and native hippocampal $K_{2P}2.1$ channels convert from the open rectifier to the voltage-dependent phenotype. Reprinted by permission from Macmillan Publishers Ltd. Bockenhauer D, Zilberberg N, and Goldstein SAN (2001) KCNK2: Reversible conversion of a hippocampal potassium leak into a voltage-dependent channel. *Nature Neuroscience* 4: 486–491, copyright 2001.

conductances to strictly voltage-dependent channels. Thus, $K_{2P}2.1$ is an open rectifier when the single canonical protein kinase A (PKA) consensus site is mutated to alanine or bears no phosphate, passing large currents both inward and outward when potassium levels are symmetrical across the membrane (Figure 5). Conversely, $K_{2P}2.1$ channels altered to aspartate at the site or bearing phosphate pass more outward current even under symmetrical conditions due to voltage-dependent changes in open probability. These channels show a half-maximal activation voltage >0 mV that does not change with the equilibrium reversal potential for potassium (E_K) and therefore behave like classical voltage-gated channels. This phenotypic flexibility is expected to contribute to neuronal plasticity because leak currents inhibit depolarization toward firing threshold, whereas voltage-gated channels activated at supra-threshold potentials do not interfere with rise to threshold but do facilitate recovery and refiring.

Stretch-Gating and Mechanoelectrical Coupling

Mechanosensitive potassium channels are found in central and peripheral neurons, as well as in nonnervous tissues such as the heart and gastrointestinal tract. Native, stretch-activated potassium channels in rat atria, for example, share expression pattern and functional properties with $K_{2P}2.1$, $K_{2P}4.1$, and $K_{2P}10.1$ channels. In experimental cells, mechanical pressure applied to the plasma membrane increases $K_{2P}2.1$, $K_{2P}4.1$, and $K_{2P}10.1$ currents. Convex membrane curving toward the outside of the cell is notably effective in activating the channels. Similar to native stretch-sensitive currents, $K_{2P}2.1$ and $K_{2P}4.1$ channels show pronounced desensitization which is thought to be critical for maintaining dynamic sensitivity and protecting cells from persistent activation. In what may be a related effect, $K_{2P}2.1$ and $K_{2P}4.1$ activities reversibly decrease when osmolarity of the extracellular medium is increased and cell size decreases. Sensitivity to mechanical stretch is enhanced after pharmacological or mechanical disruption of the actin cytoskeleton, suggesting that force may be transmitted directly to the channels through the lipid bilayer, independent of cytoskeletal structures. The relationship between channel activity and pressure is sigmoidal, with a half-maximal activation pressure of approximately −40 and −70 mmHg for $K_{2P}2.1$ and $K_{2P}10.1$, respectively. As noted previously, protonation of $K_{2P}2.1$ shifts the current–pressure relationship to increase activity.

In addition to abundant and overlapping expression of $K_{2P}2.1$, $K_{2P}4.1$, and $K_{2P}10.1$ in brain, human transcripts are found in a variety of tissues routinely exposed to mechanical stretch. $K_{2P}2.1$ is found in heart, stomach, small intestine, colon, bladder, and uterus; $K_{2P}10.1$ gains gastric and uterine expression; and $K_{2P}4.1$ is found in heart. These K_{2P} channels might serve to link stretch and membrane potential, thereby directly transforming mechanical force into altered electrical activity. Such mechanoelectrical coupling might contribute to dysregulation of excitability in the brain and heart caused by ischemia-associated cell swelling (as seen with stroke or myocardial infarction) or abnormal stretch (as associated with altered intracranial pressure or heart failure) leading to seizures or cardiac arrhythmias.

The hypothesis that K_{2P} currents contribute to regulation of contractions in the digestive system, bladder, and uterus is supported by studies of the nematode *Caenorhabditis elegans*, which possesses the largest number of K_{2P} channels cloned to date (~50), two of which have been implicated in muscle contraction. Thus, a mutant of the *C. elegans* K_{2P} channel TWK-18 is associated with a paralysis phenotype, whereas a gain-of-function mutation in TWK-23 results in uncoordinated movements of the worm.

Neurotransmitter Regulation

Slow changes in neuronal excitability (neuromodulation) produced by neurotransmitters are distinct from their rapid actions on ligand-gated ion channels. Inhibition and activation of potassium channels are among primary cellular mechanisms responsible for neuromodulation. Inhibition of background potassium conductances in many areas of the central nervous system (including brain stem aminergic neurons, cerebellar granule neurons, cortex, thalamus, hippocampus, and hypothalamus) is a significant mechanism by which acetylcholine, glutamate, noradrenaline, serotonin, substance P, and thyrotropin-releasing hormone enhance excitability. This mechanism is crucial to the regulation of 'state switching' in the thalamocortical network that is thought to control transitions between sleep and wakefulness. Identified channels that appear to contribute include $K_{2P}3.1$ in native rat hypoglossal motor neurons and cerebellar granule cells, in which it is responsive to norepinephrine, serotonin, substance P, and thyrotropin-releasing hormone, like its cloned counterpart in experimental cells (Figure 6). Regulation of K_{2P} channels by neurotransmitters is not limited to $K_{2P}3.1$ channels alone (Table 4). For example, $K_{2P}2.1$ is inhibited by serotonin via the cAMP–PKA pathway similar to native S-type K^+ currents in the sea slug *Aplysia californica* that are involved in behavioral sensitization. Native potassium leak channels subject to neurotransmitter regulation in other regions of the brain have yet to be identified at the molecular level.

Emerging Roles for K_{2P} Channels in Physiology and Disease

Expression of K_{2P} channels has been studied in detail at the mRNA level (Table 2). Genes encoding six of the K_{2P} channels ($K_{2P}5.1$, $K_{2P}6.1$, $K_{2P}13.1$, $K_{2P}15.1$, $K_{2P}16.1$, and $K_{2P}17.1$) are absent or only weakly expressed in the central nervous system (although $K_{2P}5.1$ and $K_{2P}6.1$ are found in dorsal root ganglia). The remaining genes are differentially distributed throughout the central nervous system and dorsal root ganglia. K_{2P} channel mRNA is also found in other brain cell types, such as choroid plexus ($K_{2P}1.1$), pia mater ($K_{2P}2.1$), and ependymal ventricle-lining cells ($K_{2P}10.1$). To date, there are no selective blockers of K_{2P} channels, so molecular identification of currents in native contexts has relied on comparisons of functional properties of cloned K_{2P} channels and native currents. Outside the nervous system, K_{2P}

Figure 6 $K_{2P}3.1$ channels: correlation with native neuronal currents. (a) *In situ* hybridization of rat brain stem with a ^{33}P-labeled antisense probe to rat $K_{2P}3.1$ cDNA shows a strong signal for message in motor neurons – the nucleus ambiguous (Amb) and the vagal (X) and hypoglossal nuclei (XII). (b) Thyrotropin-releasing hormone (TRH) inhibits $K_{2P}3.1$-like current in hypoglossal motor neurons treated with low pH solution before and after TRH-induced changes in the holding current, demonstrating that the pH-sensitive $K_{2P}3.1$-like current was completely blocked by 1 or 2 μM TRH. (c) TRH inhibits cloned $K_{2P}3.1$ channels in HEK 293 cells when they also express the TRH receptor. Slope conductance from linear fits of ramp currents measured show that channels are fully inhibited by 0.1 μM TRH so that further effect was not observed by reacidification. Reproduced Talley EM, Lei Q, Sirois JE, and Bayliss DA (2000), Task-1, a two pore domain K^+ channel, is modulated by multiple neurotransmitters in motoneurons. *Neuron* 25: 399–410, copyright 2000, with permission from Elsevier.

Table 4 Functional K_{2P} channel regulation by neurotransmitters and signal transduction pathways

Channel[a]	*Activating GPCRs*	*Inhibiting GPCRs*	*Activators*	*Inhibitors*
$K_{2P}1.1$			Phorbol esters	
$K_{2P}2.1$	G_i (mGluR2)	G_q (mGluR1, TRHR1, Orx1R); G_s (5-HT4sR, β-AR)	Nitric oxide, cGMP, PKG, PIP_2	Phorbol esters, DAG, cAMP, PKA, PKC
$K_{2P}3.1$		G_q (mGluR1, Ang II type 1a receptor, ACh M1, TRHR1)	PIP_2	PLC, PKCε
$K_{2P}4.1$			PIP_2	
$K_{2P}5.1$			Phorbol esters	
$K_{2P}6.1$			Phorbol esters	
$K_{2P}9.1$		G_q (mGluR1, TRHR1)	PIP_2	
$K_{2P}10.1$	G_i (mGluR2)	G_q (mGluR1, ACh M3); G_s (5-HT4sR)		DAG, phorbol esters, cAMP, PKA
$K_{2P}18.1$			Ca^{2+} (via calcineurin)	

[a]$K_{2P}13.1$ is functional but not yet studied. $K_{2P}16.1$ and 17.1 are insensitive to activators of PKA and PKC.
ACh M1 and M3, muscarinic acetylcholine receptors; Ang II, angiotensin; β-AR, β-adrenoceptor; DAG, diacylglycerol; GPCR, G-protein-coupled receptor; mGluR1 and R2, metabotropic glutamate receptors; 5-HT4sR, serotonin receptor; Orx1R, orexin receptor; PIP_2, phosphatidylinositol 4,5-bisphosphate; PKA, protein kinase A; PKC, protein kinase C; PKG, protein kinase G; PLC, phospholipase C; TRHR1, thyrotropin-releasing hormone receptor.

channels have been localized in heart and a variety of nonexcitable organs (Table 1). Specific expression patterns and physiological and clinical implications are discussed in the following sections.

Oxygen Sensing and Respiration

Molecular oxygen sensors mediate rapid cardiovascular and metabolic responses to environmental hypoxia, such as increase in respiration rate and vasoconstriction. Located in highly specialized cells, including carotid body cells, pulmonary neuroepithelial body cells, fetal adrenomedullary chromaffin cells, and pulmonary artery smooth muscle cells, these specialized cells share the same general mechanism which transduces decreased oxygen tension into cellular responses. Thus, closing of oxygen-sensitive potassium channels depolarizes oxygen-sensitive cells, leading to increased excitability via opening of voltage-gated Ca^{2+} channels, elevation of intracellular Ca^{2+} level, and cell-type-specific cellular responses.

Among a variety of potassium channels suppressed by hypoxia in peripheral chemoreceptors, there is good evidence that one member of the K_{2P} family, $K_{2P}3.1$, is involved in an oxygen-sensing pathway. Contrary to earlier reports, data from several laboratories suggest that $K_{2P}2.1$ channels are not oxygen sensitive under physiological conditions. The carotid body located above the bifurcation of the common

carotid artery is the major peripheral site for oxygen sensation. $K_{2P}3.1$ channels are expressed in carotid body type 1 cells and a native oxygen-sensitive channel in the cells shares biophysical and pharmacological properties of cloned $K_{2P}3.1$, most notably inhibition by hypoxia. This suggests that the response of these cells to hypoxia is at least partially due to inhibition of $K_{2P}3.1$ leading to membrane depolarization and reflex increase in respiration. Hypoxia-induced closing of native $K_{2P}3.1$-like channels is thought to be mediated by cytosolic second messengers rather than direct oxygen sensing by the channel since channels in excised membrane patches are not subject to regulation by oxygen tension.

$K_{2P}3.1$ channels are also expressed in central respiratory-related neurons, including airway motor neurons and putative chemoreceptor neurons of locus coeruleus. In these central neurons, hypoxia-induced inhibition of $K_{2P}3.1$-like currents increases excitability to enhance respiratory motor neuron output. Thus, modulation of $K_{2P}3.1$ currents appears to contribute at both the central and peripheral levels to the respiratory reflex.

Central Nervous System

Neuromodulation, learning, and memory A classical example of neuromodulation in a behavioral context is the gill withdrawal reflex of the sea slug *Aplysia californica*. Gill withdrawal is a defensive reflex that is potentiated by a noxious stimulus to another part of the body. This form of behavioral plasticity involves inhibition of the *Aplysia* serotonin (S)-type background potassium channel. S-type channels are expressed in slug sensory neurons, in which they are known to contribute to synaptic signal transmission. $K_{2P}2.1$ channels show notable similarities to *Aplysia* S-type channels. Both channels show open rectification and time independence. They are similarly resistant to blockade by barium, cesium, TEA, and 4-AP and sensitive to quinidine. $K_{2P}2.1$ and S-type channels are both activated by volatile anesthetics, arachidonic acid, and membrane stretch and blocked by serotonin via cAMP-dependent phosphorylation. In *Aplysia* and humans, neurotransmitter-mediated inhibition of S channels causes enhanced excitability. In the mollusk *Lymnaea stagnalis*, an S-type channel is responsible for control of presynaptic transmitter release in behavioral sensitization, a simple form of learning and memory. Because $K_{2P}2.1$ is expressed in human cerebral cortex and hippocampus, it is tempting to speculate that the channel may play a role in cognitive processes, perhaps via arachidonic acid and its metabolites acting as retrograde messengers in hippocampal long-term plasticity.

Actions of volatile and local anesthetics Volatile anesthetics induce neuronal hyperpolarization and depression in the central nervous system. Despite their wide clinical use during approximately the past 150 years, relatively little consensus exists on their molecular mechanisms of action. Several ion channels, including $GABA_A$ and glycine receptors, have been implicated in the effects of these drugs. Soon after their discovery, K_{2P} channels were considered prime candidates as targets for anesthetics. The idea was attractive because anesthetics decrease excitability by enhancing leak currents in neuronal tissue and, at the same time, the presence of K_{2P} channels in heart could explain the cardiodepressive side effect of anesthetics.

Volatile anesthetics open background potassium channels and hyperpolarize resting membrane potential in both invertebrates and vertebrates. In *Aplysia*, halothane induces neuronal hyperpolarization via opening of S-type potassium currents. In the mollusk *Lymnaea*, halothane opens the baseline K^+ current, I_{KAn}, which hyperpolarizes pacemaker neurons and reversibly blocks their endogenous firing activity. In rat, halothane activates native $K_{2P}3.1$ currents in hypoglossal and locus coeruleus neurons, which hyperpolarizes the cells, decreasing spike activity. This is thought to contribute to halothane-induced immobilization, analgesia, and hypnotic actions of the drug (**Figures 7(a) and 7(b)**).

Supporting a role for K_{2P} channels as clinically relevant targets for volatile anesthetics during general anesthesia, knockout mice disrupting the gene for $K_{2P}2.1$ show significant reduction in sensitivity to halothane and desflurane, whereas $K_{2P}5.1$ knockout mice do not. *In vitro* studies demonstrate that volatile anesthetics open cloned $K_{2P}2.1$, $K_{2P}3.1$, $K_{2P}5.1$, $K_{2P}9.1$, $K_{2P}10.1$, and $K_{2P}17.1$ channels (**Figure 7(c)**). Interestingly, the yeast K_{2P} channel, TOK1, is also opened by volatile anesthetics, demonstrating evolutionary conservation of this pharmacology. Taking into consideration K_{2P} expression patterns in human brain, anesthetic-induced activation of $K_{2P}2.1$ and $K_{2P}10.1$ in caudate nucleus and putamen, $K_{2P}9.1$ and 10.1 in cerebellum, and $K_{2P}10.1$ in corpus callosum provide a rationale for the cascade of observed pharmacological effects during general anesthesia. Furthermore, activation of $K_{2P}2.1$, $K_{2P}3.1$, and $K_{2P}5.1$ in sensory neurons of dorsal root ganglia could contribute to loss of consciousness through inhibition of sensory neuronal stimuli. Finally, activation of $K_{2P}2.1$ channels in motor neurons may inhibit muscular activity, directly depressing mobility.

Local anesthesia can be achieved pharmacologically by blockade of sodium channels and a variety of potassium currents, including voltage-gated and leak channels, through disruption of action potential

Figure 7 Volatile anesthetics open K_{2P} channels and hyperpolarize resting membrane potential in neurons. (a) *In situ* hybridization of a sagittal rat brain section hybridized with a ^{33}P-labeled specific $K_{2P}3.1$ probe shows a strong signal for message in facial nucleus and locus coeruleus. (b) Halothane (0.3 mM) hyperpolarizes neurons of the rat locus coeruleus and suppresses action potential firing by activating a $K_{2P}3.1$-like current. (Top) Halothane induces a pH-sensitive outward current in a locus coeruleus neuron held at -60 mV. (Bottom) Current clamp recording demonstrating halothane-induced membrane hyperpolarization and spike suppression that is reversed by acidification in the continued presence of halothane. (c) Concentration-dependent activation of single $K_{2P}2.1$ channels in patches excised from COS cells at 0 mV holding potential. Application of 0.2, 0.5, and 1 mM halothane is indicated by horizontal bars. propagation leading to conduction block in peripheral nerves. Whereas volatile anesthetics open K_{2P} channels producing neuronal hyperpolarization, local anesthetics inhibit K_{2P} currents. Diminished potassium flux leads to cellular depolarization and slowed repolarization, producing action potential prolongation and conduction blockade, contributing to peripheral analgesia. The same actions may account for some of the undesirable side effects of local anesthetics, such as central nervous system excitotoxicity and cardiac arrhythmias. Local anesthetics, including lidocaine, bupivacaine, tetracaine, and mepivacaine, block most studied K_{2P} channels (with varying potency) with the notable exceptions of $K_{2P}6.1$ and $K_{2P}10.1$ (studies on $K_{2P}4.1$, $K_{2P}13.1$, and $K_{2P}15.1$ have not been reported).

Cytoskeletal Remodeling and Synaptogenesis

Suggesting a role for $K_{2P}2.1$ in axonal migration and synaptogenesis during neuronal development, $K_{2P}2.1$ (and, to a lesser extent, $K_{2P}10.1$ and $K_{2P}4.1$) expression has been shown to induce formation of filopodia-like structures in dendrites and axons of cultured rat neonatal hippocampal neurons. These protrusions are rich in actin and ezrin and show increased $K_{2P}2.1$ channel density. It is known that this does not depend on channel activity because reducing K^+ flux by elevation of extracellular K^+ or by $K_{2P}2.1$ inhibition with oleylamin did not affect protrusion formation; however, intracellular channel protonation and PKA phosphorylation are required.

Apoptosis

Excitability is critical to neuron survival. Through effects on resting membrane potential, activity of potassium channels has a significant impact on neuronal cell death and survival; this is of particular importance during central nervous system development. Some potassium currents induce apoptotic cell

death, whereas others protect neurons from ischemia and excitotoxicity. Neuronal apoptosis has been linked to K_{2P} channel activity in cerebellar granule neurons (CGNs). CGNs express the standing outward potassium current, I_{KSO}, which shares biophysical, pharmacological, and regulatory characteristics with cloned $K_{2P}1.1$, $K_{2P}3.1$, and $K_{2P}9.1$ channels (and perhaps $K_{2P}10.1$). CGNs undergo apoptosis when exposed to physiological K^+ ion conditions *in vitro*. The apoptosis rate is significantly reduced with depolarizing conditions (high bath K^+ ion), when $K_{2P}1.1$, $K_{2P}3.1$, and $K_{2P}9.1$ channels are blocked by extracellular acidosis or specific inhibitors, or when dominant-negative $K_{2P}3.1$ or $K_{2P}9.1$ mutants are transfected into the cells (Figure 8(a)). Similarly, K^+ ion-induced cell death can be produced in hippocampal neurons that lack I_{KSO} by expression of $K_{2P}3.1$ or $K_{2P}9.1$ channels (Figure 8(b)) or a constitutively active $K_{2P}2.1$ mutant, whereas wild-type $K_{2P}2.1$, displaying little baseline conductance, did not alter cell viability.

Infectious Disease

Human immunodeficiency virus-1 (HIV-1), the causative agent of AIDS, has evolved to invade the complex human immune system. Vpu is a 68-residue HIV-1 membrane protein that enhances the release of progeny virions from infected cells and induces degradation of the HIV receptor on the T lymphocyte CD4. Interestingly, Vpu displays significant homology to the first transmembrane domain of $K_{2P}3.1$, suggesting the viral protein may have evolved through molecular piracy (i.e., evolving from a host gene) in order to foster interaction with host proteins. Vpu and $K_{2P}3.1$ physically interact in experimental cells and lymphoid tissues obtained from AIDS patients. The functional consequence of interaction is bidirectional destruction: in primary $CD4^+$ T lymphocytes infected with HIV, $K_{2P}3.1$ channels are degraded, whereas overexpression of the channel results in the release of fewer viral particles. Due to the ubiquitous expression of $K_{2P}3.1$ in human tissues, this virus–host interaction may influence progression of infection and electrical signaling in host tissues. Indeed, central nervous system infection with HIV-1 can lead to behavioral abnormalities, motor dysfunction, or dementia, and K_{2P} channels may play a role in these pathogenic events.

K_{2P} channels may be linked to prion–protein disorders. Prion diseases (transmissible spongiform encephalopathies) in humans and animals are caused by conformational conversion of a nonpathogenic cellular glycoprotein of largely unknown function (PrP^C) into PrP^{Sc}, an isoform that appears to be infectious in the absence of nucleic acids. PrP^C displays high expression in the peripheral and central nervous systems. $K_{2P}2.1$ has been shown to physically interact with PrP^C protein in a yeast two-hybrid study and experimental cells. Furthermore, $K_{2P}2.1$ and PrP^C colocalize when present in rat cerebellar Purkinje cells.

Figure 8 K_{2P} channels and their potential significance in apoptosis and cancer. (a) $K_{2P}3.1$ and 9.1 channels promote apoptosis in cultured rat cerebellar granule neurons (CGN) expressing the standing outward potassium current, I_{KSO}. Analysis of cell survival under proapoptotic low K^+ conditions was estimated by DAPI nuclear staining. Viral overexpression of $K_{2P}3.1$ or 9.1 in CGN enhances cell death, whereas genetic inactivation of the respective native currents via transfer of nonconducting, dominant-negative mutants protects CGN compared to nonproapoptotic K_{2P} channel ($K_{2P}2.1$) and fluorescence marker (EGFP) controls. (b) Genetic transfer of $K_{2P}3.1$ channels in rat hippocampal neurons lacking I_{KSO} and being insensitive to low K^+ confers potassium-dependent cell death. TUNEL analysis demonstrates a high apoptosis rate in $K_{2P}3.1$-transfected hippocampal neurons in low K^+ (5 mM) that was abolished by elevating the potassium concentration to 25 mM, as predicted. Reprinted from Lauritzen I, Zanzouri M, Honore E, et al. (2003) K^+-dependent cerebellar granule neuron apoptosis. Role of TASK leak K^+ channels. *Journal of Biological Chemistry* 278: 32068–32076, with permission.

The physiological relevance of interaction has not been established.

Evolving Fields of Inquiry

Discoveries suggest additional functional roles for K_{2P} channels. These are potential future fields of significance in physiology and disease.

Neuroprotection and regulation by free fatty acids K_{2P} channels may serve to protect neurons against ischemic and hypoxic insults. Lysophospholipids (LPs) and polyunsaturated fatty acids (PUFAs) activate $K_{2P}2.1$, $K_{2P}4.1$, and $K_{2P}10.1$; this is suspected to result in pre- and postsynaptic hyperpolarization and neuroprotection. In support of these ideas, mice lacking the $K_{2P}2.1$ channel have increased vulnerability to cerebral ischemia and do not show neuroprotective effects of LPs or PUFAs.

Temperature sensation A potassium leak conductance has been implicated in regulation of body temperature. $K_{2P}2.1$, $K_{2P}4.1$, and $K_{2P}10.1$ show changes in activity with temperature in the physiological range of 24–42 °C. K_{2P} temperature responses appear to occur via activity of temperature-sensitive secondary messenger pathways, such as protein kinases that act on the channels.

Tumorigenesis $K_{2P}9.1$ mRNA expression was found to be increased up to 100-fold in breast and lung cancer tissue samples. Moreover, injection of nude mice with tumor cells overexpressing $K_{2P}9.1$ led to tumor formation, whereas the same cells with a $K_{2P}9.1$ mutation that abolishes conduction pore function abrogated oncogenic potential. $K_{2P}9.1$ channels may thus possess paradoxical properties – that is, the capacity to promote cell proliferation, as well as apoptotic cell death in cell-type-dependent manner.

Cardiac channels The cardiac plateau current, I_{KP}, is time independent, potassium selective, and influences the amplitude and duration of the cardiac action potential. On the basis of genetic, biochemical, electrophysiological, and pharmacological evidence, it has been proposed that $K_{2P}2.1$ and $K_{2P}3.1$ channels contribute to I_{KP}. A role in mechanoelectrical feedback and stretch-associated arrhythmogenesis and cardioprotection has been suggested.

Conclusion

A decade since their discovery, the study of K_{2P} channels has revealed that background leakage of potassium ions via dedicated pathways is a highly regulated mechanism to control cellular excitability. K^+ ion leak pathways stabilize the membrane potential below firing threshold and expedite repolarization. K_{2P} channels are easily identified by their unique structure of two pore-forming domains in each subunit. Two-P-domain channels reveal an impressive diversity of mechanisms to control signaling of excitable cells dynamically, and they have been implicated in numerous cellular and body functions, including anesthesia, apoptosis, neuromodulation, and sensing of oxygen tension and mechanical stress. A general operational strategy has emerged: inhibition of K_{2P} channels promotes neuronal activity, whereas enhanced potassium leak stabilizes excitable cells at rest.

Introduction

During the past two decades, two-photon microscopy has become a powerful tool for imaging biological structures with greater depth than confocal microscopy affords. Its high spatial and temporal resolution, down to a micrometer and less than a second, enables imaging of subcellular structures on cell cultures, on tissue slices, and also directly in a living animal. Its potential applications in the neuroscience field have been demonstrated, and intravital studies in the brain have been conducted allowing morphological and physiological observations with a spatial resolution never obtained with methods of neuroimaging such as magnetic resonance imaging or computed tomography.

This article discusses the physical principles behind two-photon microscopy and the methodology for studying structures or phenomena occurring in the brain of living animals. It also describes how the different elements of the nervous system, including neurons, glial cells, and cerebral microvasculature, can be imaged, as well as some applications of two-photon microscopy in neuro-oncology and in research on neurological diseases.

Methods

Instrumentation

Two-photon microscopy belongs to a larger family of techniques that includes nonlinear optics (NLO) and scanning microscopy. NLO phenomena such as multiphoton absorption (mainly two-photon absorption), multiharmonic generation (mainly second harmonic generation (SHG)), and coherent anti-Stokes Raman scattering are now commonly used. NLO phenomena occur at high light intensity during a short time, but biological tissues cannot support excessive heating. These contradictory requirements explain the choice of laser excitation in the pulsed regime, with high instantaneous intensity but low average power and in the near infrared, a spectral window where tissue absorption is minimal. This choice is judicious for other reasons as well: The light scattering by tissue inhomogeneity is minimized; the resulting light emission is in the visible spectral range where sensitive detectors are available; and finally, very stable and robust laser sources, in particular the titanium sapphire femtosecond lasers, are now commercially available at nonprohibitive prices.

Laser scanning technology is derived largely from the confocal microscope: The laser beam is usually scanned by a pair of oscillating mirrors and focused on the sample by an objective with a large optical aperture (Figure 1). The oscillations of the mirrors introduce an x,y scanning of the focused beam in the focal plane. The light resulting from the excitation is usually collected by the same objective and descanned before reaching confocal pinholes in front of detectors. In fact, multiphoton or multiharmonic scanning is simpler since the emitted light comes from only a small region surrounding the focal point and does not have to be descanned and conjugated with a pinhole in front of the detector. For confocal microscopy, the light scattering and the presence of the pinhole are at the origin of photon waste and limit the depth of observation to, for example, $\sim$50 μm in the mouse brain cortex. Near-infrared excitation and non-descanned light collection as close as possible to the microscope objective minimize the photon waste by scattering, and the depth of observation could be increased to 600 μm. An additional advantage of the non-descanned mode is the possibility of having simultaneous trans- and epicollection, as shown in Figure 1.

Like confocal microscopy, multiphoton or multiharmonic microscopy is a three-dimensional (3-D) imaging technique. The z dimension is given by the displacement of the focused laser beam in the z direction by means of a motor driving the microscope objective. 3-D images are made up of stacks of 2-D (x,y) images. The speed of image acquisition is mainly limited by the collected light intensity, itself limited by the laser excitation power, which must not cause excessive tissue damage. In general, one image (512×512 pixels) per second, or a stack of $\sim$60 images per minute, is obtained if the dye is adapted to two-photon microscopy.

NLO phenomena are inefficient for scattered laser photons, and only ballistic laser photons contribute to light emission. So the spatial resolution is the same for scattering and nonscattering tissues. The resolution depends first on the spatial dimensions of the luminescent (or SHG) spot where the laser is focused. The smallness of the spot is governed by the laser beam quality and by the aperture of the microscope objective. For a titanium sapphire laser beam, an objective aperture of 1, and an NLO second-order process (two-photon or SHG), the resolution is about $\sim$3 μm

Figure 1 Basics of multiphoton and multiharmonic microscopy. Top left, energy levels and optical transitions involved in a two-photon process. In red, the simultaneous absorption of two photons, bringing the optical species from ground to excited level; in green, the photon emission from the relaxed excited state. Top right, ray tracing for two-photon excitation (red) and emission (green) in presence of scattering. Scattering reduces the number of focused photons, but the nonscattered (ballistic) photons are still well focused, and the spatial resolution is preserved. A large number of the scattered (and back-scattered) emitted photons can be collected. Bottom, schematic of a multiphoton or multiharmonic microscope with epi and trans light collection and an example of an image of the cortex vasculature. PMT, photomultiplier tube; Ti:Sa, titanium sapphire.

in the z direction and 0.5 μm in the x,y plane. Other causes, such as animal movements (bulk movements or local movements), are at the origin of a lack of spatial resolution. Animal holders are specially designed to limit bulk displacement, and good anesthesia methods should be used to limit excessive local movements.

Two-photon microscopy requires endogenous or exogenous emitting molecules. Unfortunately, while endoluminescence can be used for many tissues, it is rarely sufficient for imaging brain tissues; thus staining is necessary. For intravital brain microscopy, three strategies can be used: local staining by dye injection, staining via the blood circulation after an intravenous injection, and transfection of genes coding for fluorescent proteins. For instance, calcium-sensitive dyes are infused locally to follow neuron activity, and nonpermeant plasmatic dyes are used to image the vascular network. Some dyes can cross the blood–brain barrier (BBB) and stain the adjacent tissues. Additional physicochemical properties have to be considered in the choice of a dye, such as the luminescent and the nonlinear absorption cross section efficiencies, the photochemical stability, and the nontoxicity. The large number of requirements explains why the development of new dyes remains an important area for fundamental research.

Nonlinear optical neuroimaging is used not only for morphological information; quantitative information about brain physiology, such as the local blood volume or the BBB's permeability to specific dyes, can also be extracted. For these purposes the emitted light intensity is treated as a parameter representative of the local volume or the local dye concentration. Image stacks then constitute a 3-D representation of these parameters.

Animal Preparation

Rodents are the main animal models used in neurological two-photon imaging studies. Mice are the most often encountered because of the availability of a wide range of transgenic animals expressing fluorescent proteins. In general, studies on rats are conducted on young animals only (up to 1 month old) whereas on mice, studies can be accomplished during adulthood.

To minimize the movements during image acquisition, the choice of anesthesia is fundamental. A mixture

of xylazine and ketamine is a good candidate, but volatile anesthetics, such as isoflurane (2%) in a mixture of 30% O_2 and 70% N_2O, are generally better. Immobilization of the skull is necessary. During the whole experiment, the temperature of the animal must be monitored and maintained at 37 °C by means of a heating blanket. The next step is to obtain good optical access to the cortex. This surgical procedure can be done in three different ways:

- The bone of the skull is removed, and the objective of the microscope is immersed in physiological saline at the surface of the brain (Figure 2(a)).
- The bone of the skull is replaced by a quartz window, allowing longitudinal studies on the same animal (Figure 2(b)).
- The bone of the skull is just thinned, and observations are made right through it. This method limits the observation depth to the first 200 μm of the cortex due to the high scattering of the photons by the skull (Figures 2(c) and 3).

In adult rats, the dura is removed since its opacity is higher than that of mice.

Imaging the Various Components of the Nervous System

Neurons

The prime function of neurons is to transmit electrical signals in a network that undergoes constant

Figure 2 Schematization of the three surgical approaches for the imaging of the brain cortex *in vivo* with two-photon microscopy. (a) A craniotomy with a diameter in the range of 3–4 mm is carried out above the cortex. The hole is filled with physiological saline and the objective is positioned in immersion. (b) A craniotomy with a diameter in the range of 3–4 mm is carried out above the cortex, the hole is filled with artificial cerebrospinal fluid, and a quartz window is fixed above the craniotomy. This method allows longitudinal studies. (c) The skull is thinned above the cortex and the objective is positioned in immersion on the area of interest. This method is less invasive, but the imaging depth is more limited.

Figure 3 Two-photon microscopy allows repeated imaging of structural details *in vivo* over periods of weeks. The images are from the barrel cortex of a transgenic mouse expressing yellow fluorescent protein in pyramidal neurons of Layer V. (a) Fixed section of barrel cortex, made after intravital two-photon imaging, showing the outlines of the barrels, each of which receives input mainly from one whisker, and a red patch indicating the area imaged *in vivo*. (b) Low magnification intravital image of apical dendrites of pyramidal neurons. (c–f) Repeated imaging, over a period of 2 weeks, of the dendrite boxed in (b). Some dendritic spines were eliminated (arrowheads), and some were formed (large arrows). Filipodia also appeared and disappeared (small arrows). The images were obtained through an area of skull thinned to30–50 μm at a depth of about 150 μm below the pia. Scale bar = 500 μm (a), 10 μm (b), 2 μm (c–f). Reprinted from Macmillan Publishers Ltd: Zuo Y, Yang G, Kwon E, and Gan W-B Long-term sensory deprivation prevents dendritic spine loss in primary somatosensory cortex. *Nature* 436: 261–265. Copyright 2005.

modification as synapses are formed, strengthened, or eliminated. Compared with the traditional techniques of *in vivo* recording of electrical potentials with micropipettes and analysis of ultrastructure on fixed sections of tissue, two-photon microscopy allows very great improvement in the information that can be obtained. What can be achieved depends on the fluorophores that are introduced in the neurons. The most notable imaging to date has been in the upper layers of the mouse cerebral cortex *in vivo*, and on brain slices.

Calcium imaging Electrical activity in neurons is almost always associated with changes in free Ca^{2+} in the cytoplasm. Changes in free Ca^{2+} are readily detected optically because free Ca^{2+} can change by up to a thousandfold and an extensive range of fluorescent Ca^{2+} indicators is available. Ca^{2+} indicators, such as Calcium Green 1 or Fluo 4, can be injected into a single neuron through a fine-tipped micropipette or through a patch pipette. Since only one neuron is labeled, useful information can be obtained with only moderate spatial resolution. To increase the depth of penetration in the tissue, it may be useful to reduce the convergence of the excitation beam by illuminating only the center of the exit pupil of the objective. Calcium signals are generally slow compared with electrical ones (hundreds of milliseconds), so low time resolution allows more photons to be collected from each point in the neuron. Since the injection technique requires an intracellular microelectrode or a patch pipette, the electrical activity in the cell soma can be recorded simultaneously with the Ca^{2+} activity in dendrites, or the cell resting potential can be displaced by injecting current.

Uptake of dye by neurons Many Ca^{2+} indicators are available as esters which cross cell membranes and are de-esterified by endogenous enzymes. When applied to nerve tissue (for example to the surface of the cortex or in the bath of a tissue slice), Ca^{2+} indicators are usually taken up by astrocytes as well as neurons, although some appear to be taken up mainly by neurons (e.g., Oregon Green Bapta-AM). If the astrocytes are simultaneously labeled with sulforhodamine 101, it is possible to distinguish the two types of cell and select recordings from neurons. This simple technique of applying Ca^{2+} indicator to tissue enables large populations of neurons to be labeled so that waves of activity can be observed.

Voltage-sensitive dyes Dye molecules are available with lipophilic moieties that insert in the cell membrane and whose fluorescence varies with membrane potential. So far, the poor signal-to-noise ratio has been a constraint on the use of these dyes in the thick tissues for which two-photon excitation is useful; however, the same intense infrared illumination that produces two-photon excitation of voltage-sensitive dyes also generates a second harmonic (e.g., with excitation at 900 nm, a fraction of the emitted light is at 450 nm). This SHG is more sensitive to changes in membrane potential than is the fluorescence and has been used to detect electrical signals in segments of a single dendrite in a brain slice.

Labeling by expression of fluorescent proteins Mutant mice in which a subpopulation of neurons expresses green fluorescent protein (GFP) have made it possible to image individual features of a neuron through a cranial window or thinned skull over periods of months. Expression of fluorescent label has also been achieved in monkey by injection in the cortex of an adenovirus bearing the gene for enhanced green fluorescent protein. These techniques are extremely productive in studying the development of brain circuits and their plasticity associated with modifications of axon geometry and formation and elimination of dendritic spines (**Figure 3**).

Glial Cells

Glial cells and neurons are the two major cell types encountered in the nervous system. The three main classes of glial cells are astrocytes, oligodendrocytes, and microglial cells. Astrocytes were first described as metabolic supporting cells for neurons as well as having an intimate association with the BBB. However, their potential implication in communication by means of Ca^{2+} signaling was discovered and documented only during the past two decades.

The first studies were conducted on cell cultures and on living slices. Despite the high quality of these preparations, *in vivo* investigations are the only ones that can minimize the preparation artifacts encountered on slices. Further, intravital studies allow the observation of the interactions between neurons and astrocytes with the best physiological state. That is why two-photon microscopy is applied in numerous studies on astroglia. Their staining was reported to be done with specific dyes, such as the sulforhodamine 101 injected in the neocortex. Transgenic animals using fluorescent proteins such as the GFP under the astrocyte-specific glial fibrillary acidic protein promoter are also excellent models for visualizing these cells directly *in vivo* or on living brain slices.

Studies on the Ca^{2+} signaling encountered in astrocytes have been conducted using fluo-4 AM, an indicator whose fluorescence emission is dependent on the intracellular concentration of Ca^{2+}. Such experiments allow the observation of the propagation of

Ca^{2+} waves on brain slices and, more interesting, *in vivo*, where the neuronal/glial interactions can be highlighted. For example, an increased neuronal discharge was associated with increased Ca^{2+} concentration in neighboring astrocytes. Last, the double staining of astrocytes and vasculature using a specific dye and an intravascular fluorescent marker is a novel approach to study the glio-vascular interface *in vivo*.

Other glial cells, such as oligodendrocytes, can be stained using transgenic animals with a fluorescent protein under the control of the proteolipid protein promoter, for example. However, intravital imaging of the white matter remains difficult in rodents due to its depth. Such observations must be considered on living brain slices.

Finally, microglial cell motility has been extensively studied using time-lapse two-photon microscopy. Morphological observations, such as rapid movements of microglial processes and cell migration after a focal injury, were made with a high spatial and temporal resolution. In such experiments, the same laser used for the excitation of fluorescent proteins can be used to generate the injury. Thanks to the two-photon properties, the high power excitation is restricted to the focal point, and as a consequence, the injury is limited on a small volume and induces less damage than a mechanical or chemical one would.

Cerebral Microvasculature

The central nervous system, composed of the brain and the spinal cord, controls the majority of our organs. Cerebral activity is guaranteed by a neuronal network which requires a large and well-regulated supply of energetic substrates. Indeed, the human brain represents about 2% of the total body mass, but it consumes 20% of the respired oxygen. These nutrients, mainly oxygen and glucose, are transported to brain by the blood through a dense and complex vascular system, the cerebral microvasculature. The low diffusivity of the substances transported by the blood makes essential the presence of a large network of capillaries (4–8 μm in diameter) within the whole tissue volume. It is at this scale that exchanges between blood and brain take place.

The cerebral blood perfusion (CBP) is defined as the volume (in milliliters) of blood which irrigates 100 g of brain tissue during 1 min. This parameter is of crucial importance. It has been proved that a strong correlation exists between CBP and cerebral (neuronal) activity. Changes of up to 50% in CBP have been observed in the gray matter in regions activated during a motor task or perception (e.g., taking an object, speaking, visual exercise). In case of brain pathologies, differences in CBP have been described. For instance, some hypoperfused regions were detected in epileptic focal regions (intercritical phase) or in posterior regions of the brain in Alzheimer's disease. Hyper- and hypoperfused zones can be found in high-grade glial tumors. Changes in CBP are often related to alterations in cerebral blood volume. Both parameters can be estimated on clinical imaging systems, such as positron emission tomography or magnetic resonance imaging. However, none of these methods have sufficient resolution to describe the events at a capillary level. Recently, intravital two-photon microscopy has been proposed to investigate local variations of cerebral blood volume in preclinical protocols with very high temporal and spatial resolutions. Indeed, a direct analysis of a 0.16 mm^3 sample can be done in 2 min with submicrometer resolution.

Two-photon microscopy allows observation of the brain microvasculature after the intravenous injection of fluorescent dyes such as fluorescein or rhodamine dextran conjugates (Figure 4). Depending on the age and the animal species, it is possible to image the microvasculature down to 600 μm below the dura with micrometric resolution. Furthermore, 3-D images of the cerebral cortex vasculature can be reconstructed using z-stacks. Using this method, studies on the permeability of the BBB can be conducted *in vivo*. It can be assessed after the intravenous injection of a cocktail of two fluorescent dyes, one with a high molecular weight (e.g., rhodamine dextran 70 kDa) and the second one with a low molecular weight (e.g., FITC dextran 4 kDa). Simultaneous imaging of the distribution of these two dyes in the vascular compartment and in the brain parenchyma is then obtained with two-photon microscopy (Figure 5). The wide availability of fluorescent dyes conjugated with dextran molecules of different molecular weight enables a precise evaluation of the BBB permeability. This method is of particular interest in preclinical studies of new radiotherapeutic or chemotherapeutic approaches. Finally, to study neuronal–glial–vascular interactions, it is possible to use triple staining in a single two-photon microscopy experiment.

Applications to Pathologies

In Vivo Two-Photon and SHG Microscopy for Imaging the Brain Tumor Microenvironment and Therapy Effects

Primary brain tumors, in particular glioblastomas, are among the most therapy-resistant tumors. Until now, no therapy has yet been found to arrest their fast growth. Therefore the development of new therapies on tumor animal models is primordial. In this preclinical research, detailed knowledge of, for example, the different transport barriers for drugs in brain tumors will help since a drug that is injected in the blood

Figure 4 Mouse cerebral microvasculature. The image (a) represents the whole vascular network of the mouse cortex ranged between 0 and 600 μm under the dura. The three smaller vignettes show individual images at different depths in the brain. (b) At the surface (65 μm), large arteries can be detected. They form cortical columns which plunge into the brain and divide into capillaries ((c) and (d), 225 and 475 μm under the dura, respectively). Images were acquired *in vivo* using two-photon microscopy after intravenous injection of fluorescent dye (FITC-dextran 70 kDa). Scale bar = 100 μm.

Figure 5 Visualization of the permeability of the blood–brain barrier (BBB). Simultaneous acquisition of rhodamine dextran 70 kDa (a), FITC dextran 4 kDa (b) and merge of the two pictures (c) at 170 μm below the dura in a healthy mouse. (d) Merge of simultaneous acquisition of rhodamine dextran 70 kDa (red) and FITC dextran 4 kDa (green) at 170 μm below the dura in a mechanically BBB-induced disruption model. Note the 'black holes' (arrows), which are cells not labeled by the extravasated dye. In that case, the FITC dextran 4 kDa crossed the BBB whereas rhodamine dextran 70 kDa did not.

circulation encounters many obstacles before arriving in the tumor cell. These obstacles in the heterogeneous tumor microenvironment include, among others, the tumor vasculature, the more or less leaky vessel walls, the extracellular matrix (ECM), and the cell membrane. *In vivo* two-photon microscopy and SHG imaging allow deep imaging of transport barriers in tumors growing in living animals and may also be useful in monitoring therapy effects.

Imaging the tumor microenvironment In two-photon microscopy, the tumor microvasculature can be observed directly *in vivo* after intravenous injection of fluorescent dyes that stay in the intravascular space. In Figure 6, the neovasculature of the tumor is sprouting from the normal host vasculature (see arrow) at the surface of the tumor and shows abnormalities such as dilatations and numerous bifurcations. These changes have an impact on the blood pressure and perfusion, which often decrease in tumor tissue. If a drug is injected in the blood circulation, then the supply to the tumor may be reduced and become intermittent or even absent in chronic hypoxic areas. These areas often contain viable but radiotherapy- or chemotherapy-resistant tumor cells and are of interest for possible tumor regrowth after treatment. The local blood perfusion rate can be estimated by measuring with two-photon microscopy the linear velocity (in millimeters per second) of single red blood cells in the microvessels. Furthermore, the local vessel permeability determines the transport of drugs across the vessel wall and can be measured in two-photon microscopy using diffusible fluorescent dyes or drugs. But this is not the end of possible transport barriers. Collagen fibers in the ECM, which can be detected by SHG imaging, might influence the intratumoral diffusion. Indeed, the enzymatic breakdown of these fibers has been shown to increase drug diffusion rates in the ECM.

Figure 6 Three-dimensional (3-D) image of the tumor vasculature at the surface of a glioma growing subcutaneously in the hind limb of a living nude mouse. The vasculature is stained after intravenous injection of FITC-dextran (70 kDa). 20× objective, 600 × 600 μm image in 0.9 s. The 3-D image is a *z*-projection of *z*-stack with a depth of 100 μm and a step size of 2 μm. New tumor vessels originating from the muscle vasculature (white arrow) and forming a heterogeneous structure with large bifurcations and dilations are easily seen.

Monitoring therapy In a successful treatment, a marked reduction of the tumor volume or even total ablation of the tumor is observed. But this appears often at weeks or months after the onset of a treatment. Pathophysiological and cellular processes such as the induction of tumor cell death or necrosis and a possible shutdown of the vasculature that precedes volume reduction or tumor ablation can be observed by two-photon microscopy. These two-photon microscopy analyses will help in the fine-tuning and/or modification of a therapy in the early phase if it fails to induce tumor cell death. For these longitudinal *in vivo* two-photon microscopy experiments, scientists need a permanent window in an animal for direct microscopic observations. For grafted brain tumors, two window models exist, namely a dorsal skin fold chamber and a cranial window (see Figure 2(b)). In the first model, a glioma grows on the back of an animal inside a skin fold, which is held upright by two metal plates that include a window. The cranial window approach involves the positioning of a window at the top of the brain cortex after craniotomy of a small area just above the glioma. The latter model is preferred over skin fold chambers because tumor development and physiology strongly depend on the host tissue bed and vasculature.

In summary, two-photon microscopy and SHG imaging are very promising for the *in vivo* microscopic evaluation of the tumor microenvironment and may allow the prediction and monitoring of therapy outcome.

Applications to Nervous System Diseases

The understanding of neurodegenerative diseases such as Alzheimer's disease is an important goal for fundamental and preclinical research. The study of their pathophysiology can be done *in vitro*, but to analyze their mechanisms as a whole, *in vivo* observations are necessary. Two-photon microscopy has the potential to allow such observations. For example, a fluorescent molecule was recently tested which has the ability to cross the BBB and bind specifically to amyloid plaques after an intravenous injection. The intravital staining of these structures, as well as the

validation of the specificity of these molecules, is of particular interest in the development of targeted drugs.

In Alzheimer's disease, there seems to be a correlation between cognitive dysfunctions and a loss of synapses. It has also been shown, using time-lapse two-photon microscopy, that dendrites exhibit spine loss and atrophy in the vicinity of amyloid deposits. Astrocytes and activated microglia that are often found around amyloid plaques have been simultaneously labeled using transgenic constructions to give a better overview of the neuropathology *in vivo*.

Two-photon microscopy is also of particular interest in the study of cerebrovascular diseases such as cerebral ischemia. Short- and long-term effects of stroke can be assessed with time-lapse imaging using cranial window models. Morphological changes of cells and vasculature can be observed in the penumbra (the area surrounding the core lesion, where the blood flow is reduced and where delayed cell death can occur), leading to a better understanding of the injury and the mechanisms of partial recovery. One of the most outstanding two-photon imaging studies of vascular occlusion was photothrombosis of single vessels in the living mouse cortex. Hemodynamics parameters, as well as flow modifications in the neighboring vessels, were studied with great accuracy.

New insights into the pathophysiology of epilepsy have been obtained from the cortex of living animals. It has been shown that antiepileptic drugs such as valproate and gabapentin reduce the ability of astrocytes to transmit Ca^{2+} signals. The potential key role of astrocytes in seizure activity was hypothesized in this study, as well as their possible use in therapeutic targeting.

Two-photon imaging is used in the study of many diseases of the nervous system. The last three examples explain the major breakthroughs in the understanding of neuropathologies. The study of a neuropathology by means of two-photon imaging requires (1) finding the best animal model for the disease, (2) choosing the best way to label the pertinent biological elements (e.g., stain, transgenic animal expressing a fluorescent protein), and (3) determining how the data will be processed, after image acquisition, for quantifying the phenomena.

Conclusions and Perspectives

Two-photon microscopy appears poised to take its place as a key method for neuroscience. It has applications in cell cultures, *ex vivo* tissue slices, and, more interesting, directly in the brains of living animals. Observations can be made to a depth of at least 600 μm below the dura, depending on the species, age, and preparation of the animal model. In mice, nearly all the neocortex is accessible, including layer V. However, deeper structures, such as basal ganglia, thalamus, and hippocampus, cannot be observed with intravital two-photon microscopy.

Research is under way to improve the imaging depth by two different approaches:

- The application of optic fibers that can be directly inserted in cerebral structures using stereotaxic coordinates. First trials have been done in rats, allowing the imaging of the microvasculature in the hippocampus.
- The development of new fluorescent molecules with a higher quantum yield.

In conclusion, two-photon microscopy has opened a new era in the morphological and (patho)physiological studies of the nervous system. Its multidisciplinary approach required strong interactions among biologists, physicists, and chemists to provide a unique imaging tool for a better integrative approach to neuroscience.

Ubiquitin-Proteasome System and Plasticity

A N Hegde, Wake Forest University Health Sciences, Winston-Salem, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

The quest for understanding the mechanisms of synaptic plasticity that underlie learning and memory has revealed a role for posttranslational modifications such as phosphorylation and gene expression in changing synaptic strength. Perhaps most surprising of all was the discovery in recent years of a role in synaptic plasticity for proteolysis by the ubiquitin–proteasome pathway. In this pathway, attachment of ubiquitin, a small protein, serves as a tag for degradation by a proteolytic complex called the proteasome.

Ubiquitin was discovered more than two decades ago. Originally it was thought that ubiquitin marks only abnormal proteins for degradation. Studies on several nonneuronal cells showed that ubiquitin functions to regulate protein degradation under normal physiological conditions. Although ubiquitin was used as a marker for degenerating neurons by neuropathologists, ubiquitin was virtually unknown to broader neuroscience community until recently.

A physiological role for the ubiquitin–proteasome pathway in the nervous system was discovered during investigation on long-term facilitation in the sea slug *Aplysia*. Long-term facilitation underlies a simple form of memory in *Aplysia*, behavioral sensitization of defensive reflexes. Since then, other studies showed a role for this pathway in mammalian long-term memory and formation of synapses at *Drosophila* neuromuscular junction.

The Ubiquitin–Proteasome Pathway

The main function of the ubiquitin–proteasome pathway is to degrade proteins. Proteolysis is highly regulated and specific: only proteins that are marked by attachment of ubiquitin are degraded and only at the right time. The tagging of a protein substrate with ubiquitin is regulated by the action of three enzymes: E1, E2, and E3. First, ubiquitin is activated by E1. Then, the activated ubiquitin is transferred to one of a family of enzymes termed E2s, which associate with E3 ubiquitin ligases. The E3s ligate the ubiquitin to a Lys residue in the protein substrate. A second ubiquitin is covalently attached to the first ubiquitin and thus a polyubiquitin chain is formed. The polyubiquitinated substrate is recognized by the proteasome and is degraded to small peptides and amino acids. The proteasome that degrades polyubiquitinated proteins is called the 26S proteasome based on its sedimentation coefficient. The polyubiquitin chains are not degraded but disassembled by deubiquitinating enzymes (DUBs) (Figure 1).

Ubiquitin Conjugation

The series of enzymatic reactions in the process of attaching a ubiquitin molecule to a substrate is called ubiquitin conjugation or ubiquitination. First reaction in this series is activation of ubiquitin by the enzyme E1. The activation of ubiquitin is ATP dependent. ATP is hydrolyzed to generate AMP, and a high-energy thiol-ester ubiquitin-AMP intermediate is formed. The activated ubiquitin is then transferred to an E2, which is also called a ubiquitin carrier. The ubiquitin molecule is then transferred to an E3 which ligates ubiquitin to an ε amino group of a lysine residue in the substrate protein. A second ubiquitin molecule is then attached to an internal lysine reside in the first ubiquitin and thus a polyubiquitin chain grows.

Ubiquitin-Conjugating Enzymes: E1, E2, and E3

Among the three classes of ubiquitin-conjugating enzymes, E1 is the least physiologically regulated. E2s are more selective and are believed to interact with specific E3s. Substrate specificity of the ubiquitin conjugation reaction is largely determined by E3s.

Originally, E2 enzymes were believed only to carry the activated ubiquitin and transfer it onto the E3s. Recent studies, however, suggest that at least some E2s can directly conjugate ubiquitin to substrates. E2s are structurally and functionally diverse. Simple eukaryotes like yeast (*Saccharomyces cerevisiae*) have 13 genes potentially encoding E2s. The number of E2s in mammals is estimated to be in the range of 25–30. The diversity of E2 generates some degree of specificity in the ubiquitin-conjugating reaction. E2s bind to E3s selectively. Since the diversity of E3s is even greater than that of E2s, the combination of E2s and E3s potentially can generate a high degree of specificity.

E3s are the enzymes that specifically recognize the substrates. E3s can be single proteins or complex of proteins. Single-subunit E3s can accept ubiquitin in a thioester linkage from E2s and ligate ubiquitin to the substrate. When E3 contains multiple subunits, it is generally believed that the enzyme brings the E2 and the substrate together and facilitates the transfer of ubiquitin to substrate. There are two major classes of E3s: HECT (homologous to E6-AP C-terminus) domain E3s and RING (really interesting new gene) finger E3s.

Figure 1 The ubiquitin–proteasome pathway. In this proteolytic pathway, ubiquitin (single ubiquitin molecule is represented by open red circles with straight tails) is selectively and covalently linked to the substrate. The enzymatic process of attaching ubiquitin to substrates is called ubiquitination or ubiquitin conjugation, and depends on the action of three different classes of enzymes: E1, E2, and E3. First, ubiquitin is activated by E1 to form a ubiquitin–AMP intermediate. Activated ubiquitin (closed red circles with straight tails) is passed on to an E2 (ubiquitin carrier enzyme). E2 transfers ubiquitin to an E3 (ubiquitin ligase), which ligates the activated ubiquitin to the substrate. To the ubiquitin attached to the substrate, another ubiquitin is attached, and thus through successive linkages of ubiquitin, a polyubiquitin chain forms. Polyubiquitinated substrates are degraded by a proteolytic complex called the 26S proteasome in an ATP-dependent reaction. Ubiquitin is not degraded but the polyubiquitin chain is disassembled and ubiquitin is recycled by deubiquitinating enzymes (DUBs). Before being committed to be degraded by the proteasome, ubiquitination is reversible. DUBs can disassemble the polyubiquitin chain if a substrate is ubiquitinated erroneously and prevent the degradation of the substrate.

HECT domain E3s The typical example in this class of E3 is the ubiquitin ligase called E6-AP, which ligates ubiquitin to the tumor suppressor protein p53. Viral protein E6 associates with a cellular protein called E6-AP (E6-associated protein). The C-terminal region of E6-AP contains the catalytic domain of the ubiquitin ligase. E6-AP ligase can function with either of the E2s called UbcH5 and UbcH7 (Figure 2). Later studies found that a family of proteins ubiquitin ligases with homology to the catalytic domain of E6-AP exists. These ubiquitin ligases are called HECT domain E3s. In addition to the HECT domain, there is another domain in many E3s called the WW domain. The WW domain-containing E3s also tend to have a C2 domain. The presence of the C2 domain is highly relevant to nervous system function because the C2 domain responds to elevation of intracellular Ca^{2+} and helps in translocation to the plasma membrane. Therefore, presence of this domain in neuronal HECT E3s might be critical in ligating ubiquitin to neurotransmitter receptors or proteins associated with them.

RING finger E3s These E3s are called RING finger E3s because they contain a RING finger domain, which consists of seven cysteine residues and one histidine residue forming a single folded domain binding two zinc ions. During the past few years, several ubiquitin ligases were found to contain the RING finger. RING finger motif in ubiquitin ligases is critical for transfer of ubiquitin to substrates or to RING finger proteins themselves. The RING finger category of E3s can be subdivided into single-subunit RING finger E3s and multi-subunit RING finger E3s (Figure 2).

Single-subunit RING finger E3s contains the RING finger domain and the substrate recognition site in the same protein. One of the well-characterized single-subunit RING finger E3s is Mdm2, which ubiquitinates a postsynaptic density protein PSD-95 in neurons.

Multi-subunit RING finger E3s contain two complexes:

1. *SKP1–cullin–F-Box protein* (*SCF*) *complex*. SCF complex contains at least four proteins: Skp1, Cul1, Roc1/Rbx1/Hrt1, and an F-Box protein. In the center of the SCF complex is the RING finger domain-containing protein Rbx1. The SCF-type ligases have another invariant protein called cullin. The theme appears to be that the cullins interact with linker proteins such as Skp1 to recruit substrate-interacting proteins such as the F-Box proteins. There are at least five different cullins in mammals. There are several F-Box proteins as well. A well-characterized substrate of the SCF complex is IκBα.

2. *Anaphase-promoting complex* (*APC*). Although APC has a subunit with a RING finger domain (APC11), this ubiquitin ligase is distinct from the SCF ligase in overall subunit combination. For example, instead of one adaptor found in SCF ligases (such

Figure 2 Major types of E3s. (a) HECT domain E3. E6-AP ubiquitin ligase in combination with E6 protein and one of the two E2s (UbcH5 or UbcH7) ligates ubiquitin to the p53 tumor suppressor protein. (b1) Single-subunit RING finger E3. Mdm2 ligates ubiquitin to PSD-95 with the help of an E2 enzyme. (b2(i)) Multi-subunit RING finger E3. SCF ligases contain the substrate recognition site on an F-Box protein. Skp1 is an adaptor that joins the F-Box protein to Cul1. Ring finger domain is on Rbx 1. The E2 is Ubc3. Cul1 is modified by Rub1, another ubiquitin-like protein leading to an increase in the activity of the ligase complex. The substrate is phosphorylated (diamonds) IκBα. (b2(ii)) Multi-subunit RING finger E3. APC is a more complex example of multi-subunit RING finger E3s and has a subunit composition distinct from that of SCF. Cdc20 protein in APC has the substrate (cyclin) recognition site. The RING finger domain is on APC11. The E2s Ubc11 or UbcX can function with the APC ligase. In addition, several adaptor proteins, some labeled (Cdc27, Cdc23, APC1, Cdc16) and some unlabeled, interact with Cdc20 and APC11. Diamonds on the adaptor subunits indicate phosphorylation.

as Skp1), APC has multiple subunits that serve as adaptors. Also, unlike SCF ligases, substrate phosphorylation is not an important determinant for specific substrate recognition by the APC ligase. Rather, substrate specificity of APC ligases appears to be modulated by incorporation of 'specificity factors' into the ligase complex. APC acts together with an E2 Ubc11 or Ubc X. One of the most studied substrates of APC is mitotic cyclin.

The Proteasome

The term proteasome is used to describe two kinds of multi-subunit proteolytic complexes, the 26S and 20S, based on their sedimentation coefficient. The 26S proteasome degrades ubiquitinated protein substrates. The 26S complex contains the 20S as a core and regulatory 'caps' on either end like a dumbbell. Each cap of the 26S proteasome is called the 19S regulatory complex (19S RC). The 20S core is a cylindrical structure consisting of the catalytic part of the proteasome.

The catalytic 20S core The 20S catalytic core of the proteasome has two types of subunits, namely, α and β. The subunits are arranged into four stacked rings to form the catalytic cylinder with the two middle rings consisting of β-subunits, which are sandwiched between two rings of α-subunits. In eukaryotes there are seven different α (α1–α7) and β (β1–β7) subunits each. The catalytic core of the proteasome is a threonine protease. The 20S proteasome can exist not only as a core of 26S, but also as a separate population that cannot degrade ubiquitinated proteins. However, the 20S proteasome by itself has chymotrypsin-like, trypsin-like, and postglutamyl peptidase activities which cleave after hydrophobic, basic, and acidic residues, respectively. The peptide-hydrolyzing activity of the 20S proteasome can itself be modulated by an 11S regulatory cap.

19S RC The 19S RC recognizes the polyubiquitinated substrate, and channels the substrate into the catalytic 20S core of the proteasome. It also has the capacity to regulate the activity of the catalytic core and determine the nature of the degradation process. Usually one 19S RC is attached to either end of the catalytic core. Some of the 19S RC subunits are believed to channel the substrate into the catalytic chamber for degradation.

Deubiquitinating Enzymes

Ubiquitination reaction is reversible before the ubiquitinated protein is committed to degradation by the proteasome. Ubiquitin is removed from substrates by enzymes called DUBs. Based on protein sequence and the molecular size, DUBs can be classified into two

general classes: (1) low molecular weight (20–30 K) ubiquitin C-terminal hydrolases (UCHs), and, (2) high molecular weight (around 100 K) ubiquitin-specific proteases (UBPs; also called USPs). Among the DUBs, UBPs belong to a large family containing diverse genes whereas the UCH family has fewer genes. For example, in yeast *S. cerevisiae*, there are 17 UBPs and 1 UCH. In the human genome, there are 63 genes encoding UBPs and 4 genes that code for UCHs. UCHs and UBPs subserve different functions in the eukaryotic cell. Although the current name for these enzymes, that is, DUBs, emphasizes the removal of ubiquitin from substrates, some DUBs, especially UCHs, function to process linearly linked ubiquitin precursors and generate monoubiquitin. DUBs are important for generating free ubiquitin at various steps of the ubiquitin–proteasome pathway. Ubiquitin is encoded by the tandemly linked polyubiquitin gene. In addition to the polyubiquitin gene, ubiquitin is also encoded by fusion to two ribosomal subunits called L40 and S27. These gene products are thought to be processed by UCHs. Cleavage of isopeptide bond in the ubiquitin chains linked through Lys-48 of ubiquitin serves two purposes. One is to recycle ubiquitin after it has been used for marking a substrate for ubiquitination. Another function is to 'edit' the errors made by the ubiquitin-conjugating enzymes and reverse the ubiquitination reaction so that the substrate is no longer degraded. Also, editing function of DUBs probably serves to reverse the monoubiquitin attachment that marks membrane proteins for endocytosis.

Ubiquitin and Endocytosis

Ubiquitin also plays a role in other cellular processes such as endocytosis which regulates the number of receptor proteins in the plasma membrane. In endocytosis, the proteins on the cell surface are internalized in response to a specific signal such as neurotransmitter binding to its receptor. The internalized proteins are either recycled back to the membrane or targeted to the lysosome for degradation. Ubiquitin plays a role in marking the receptor proteins for internalization as well as sorting the endocytosed proteins for degradation in the lysosome. Unlike the polyubiquitin chain that marks substrate for proteasome-mediated degradation, endocytosis appears to be mainly mediated by attachment of single ubiquitins (monoubiquitination). When the receptors are monoubiquitinated, they bind to adaptor proteins called epsins that are part of clathrin-coated pits. Ubiquitinated receptor then undergoes endocytosis and gets incorporated into endosomes which in turn get sequestered into the multivesicular body. The membrane of the multivesicular bodies becomes continuous with lysosomes leading to degradation of the receptor. It has been shown that targeting the internalized receptor to the multivesicular body also requires ubiquitination.

Regulation of the Ubiquitin–Proteasome Pathway

Ubiquitin attachment to proteins is a dynamic process that is highly regulated by intracellular and extracellular signals. Ubiquitination and degradation of ubiquitinated proteins is controlled by modification of the substrate, modulation of ubiquitin ligases, and removal of ubiquitins. Substrates can be made either vulnerable or resistant to ubiquitin conjugation by phosphorylation. Ubiquitin ligase activity is increased or decreased through phosphorylation. Also, a new mode of regulation of ubiquitin ligases by ubiquitin-like proteins has been discovered. Removal of ubiquitins by DUBs serves as a checkpoint before committing a substrate for degradation. In addition, the 26S proteasome itself is subject to regulation. The activity of the 19S RC is regulated by induction or phosphorylation of its subunits as well as by proteins that are loosely associated with it. Also, the proteasome can be regulated by a change in the composition of the intrinsic subunits.

Ubiquitin–Proteasome Pathway and Synaptic Plasticity

The discovery of a physiological role for the ubiquitin–proteasome pathway came from the studies on long-term facilitation in the invertebrate *Aplysia*. It was found that the regulatory (R) subunit of cAMP-dependent protein kinase A (PKA) was a substrate for ubiquitin–proteasome-mediated degradation. Since then, several substrates of the ubiquitin–proteasome pathway have been identified in the nervous systems of other invertebrates as well as vertebrates (Table 1).

Degradation of the R Subunits of PKA

Evidence for a role for the ubiquitin–proteasome pathway in synaptic plasticity came from the investigation on persistent activation of PKA during induction of long-term facilitation. Studies on the biochemical mechanism of long-term facilitation in *Aplysia* indicated that PKA was persistently activated in the absence of elevated cAMP. How was PKA activated in the absence of sustained increase in cAMP? It was found that the R subunits of PKA were decreased without any change in the catalytic (C) subunit during induction of long-term facilitation. Since there was no change in mRNA for either the R subunit or the C subunit, it was concluded that R subunits were diminished perhaps through proteolysis. What is the mechanism of R subunit degradation? A series of

Table 1 Substrates and enzymes of the ubiquitin–proteasome pathway with roles in synaptic plasticity

Protein	*Functional category*	*Description*
Substrates		
GluR1	Neurotransmitter receptor	Ubiquitination of GluR1 in *C. elegans* reduces synaptic strength
PSD-95	Postsynaptic density protein	Degradation of PSD-95 causes endocytosis of AMPA receptors
R subunit	Subunit of cAMP-dependent protein kinase A (PKA)	Ubiquitin–proteasome-mediated degradation of R subunit persistently activates PKA during long-term facilitation (LTF) in *Aplysia*
Ap-C/EBP	Transcription factor	Degradation confines the activity of of Ap-C/EBP to a short time window during induction of LTF in *Aplysia*
Dunc-13	Presynaptic protein	Degrdation of Dunc-13 limits priming of synaptic vesicle release
Enzymes		
Bendless	Ubiquitin-conjugating enzyme (E2)	Bendless controls synapse formation in *Drosophila*
E6-AP	Ubiquitin ligase (E3)	Null mutation of E6-AP impairs synaptic plasticity and contextual memory
APC	Ubiquitin ligase (E3)	Controls synapse size in neurons; regulates abundance of glutamate receptors
SCF	Ubiquitin ligase (E3)	Regulates glutamate receptor number in *C. elegans*
Ap-uch	DUB	Blocking expression or function of Ap-uch inhibits LTF in *Aplysia*
Fatfacets	DUB	Fatfacets controls synapse development in *Drosophila*

biochemical experiments showed that R subunits were substrates for ubiquitination and proteasome-mediated degradation (Figure 3).

Moreover, an enzyme of the ubiquitin–proteasome pathway UCH (Ap-uch) was found to be induced by 5-HT, the neurotransmitter that induced long-term facilitation. Ap-uch was found to be critical for induction of long-term facilitation. The results showed that Ap-uch can increase the activity of the proteasome toward substrates such as the R subunits of PKA (Figure 3). Subsequent experiments found that at sensory–motor neuron synapses, injection of lactacystin, a specific proteasome inhibitor, blocked induction of long-term facilitation. Since R subunits inhibit the activity of C subunits of PKA, the results were interpreted to suggest that the ubiquitin–proteasome pathway operates to remove inhibitory constraints on formation of long-term memory. This has been substantiated by work carried out on the rat hippocampus. Bilateral infusion of lactacystin to the CA1 region of the rat hippocampus causes total retrograde amnesia for a one-trial avoidance learning. Also, total ubiquitination increases in the hippocampus 4 h after the training. These results are consistent with the idea that a decrease in some critical inhibitory proteins during long-term memory formation is mediated by the ubiquitin–proteasome pathway.

Synaptic Role of DUBs

DUBs appear to have a significant role in synaptic plasticity in the adult and in synapse formation during development. Studies on *Aplysia* showed a role in long-term facilitation for neuronal-specific UCH that is the homolog of human UCH-L1. *Aplysia* UCH (Ap-uch) is induced by stimuli that induce long-term facilitation but not stimuli that induce short-term facilitation. Injection of antibodies or antisense oligonucleotides specific to Ap-uch into sensory neurons synapsing onto motor neurons in culture blocked induction of long-term facilitation. Investigation on biochemical functions of Ap-uch indicated that Ap-uch is capable of cleaving small attachments to linearly attached ubiquitin molecules such as Ubiquitin–Ubiquitin–Cysteine but not large attachments like glutathionine-*S*-transferase (GST) in substrates like Ubiquitin-GST. More interestingly, additional biochemical analyses showed that Ap-uch associates with the proteasome. The association of Ap-uch increases the rate of degradation by the proteasome. For example, addition of recombinant Ap-uch to *in vitro* degradation systems showed that there was about twofold increase in degradation of R subunit of PKA. Since persistent activation of PKA has been shown to be critical for induction of long-term facilitation and R subunits of PKA were found to be substrates for the ubiquitin–proteasome pathway, the experiments on Ap-uch provided some molecular explanation for the role of regulated proteolysis in long-term facilitation. How does Ap-uch increase the rate of degradation by the proteasome? Using recombinant ubiquitin with its Lysine-48 mutated to Arg that cannot support multiple monoubiquitin attachments to the protein substrate, it was shown that Ap-uch stimulates the release of ubiquitin from substrates. Therefore, it can be inferred that Ap-uch perhaps cleaves the first ubiquitin in the polyubiquitin chain attached to the substrate.

The evidence for a role of DUBs in synapse formation came from a screen in *Drosophila* designed to identify the genes controlling size and strength of synapses. This screen found that *fatfacets* (*faf*), a gene that encodes a DUB, functions in synapse formation

Figure 3 Role of the ubiquitin–proteasome pathway in long-term facilitation. The figure shows intracellular molecular mechanisms in the sensory neuron in sensory–motor neuron synapses in *Aplysia*. Without 5-HT stimulation (a), PKA and protein kinase C (PKC) are inactive and CREB1b represses transcription by blocking access of the transcription activator CREB1a to CRE or by forming inactive heterodimers with CREB1a. When sensory neurons are stimulated with the neurotransmitter 5-HT (b), which induces long-term facilitation, R subunits of PKA are ubiquitinated and degraded by the proteasome, making the kinase persistently active. The catalytic subunit of PKA (blue circle) translocates to the nucleus and phosphorylates CREB1a, the activator form of CREB. Concomitantly, the transcription repressor CREB1b is degraded by the ubiquitin–proteasome pathway. PKC, which is also activated by 5-HT-mediated signaling, stimulates ubiquitin conjugation to CREB1b and subsequent degradation. Relief of CREB1b-mediated repression and activation of CREB1a by PKA allows CREB-mediated gene induction to occur. One of the genes induced early in the gene expression cascade is Ap-uch, which through enhancement of the proteasome activity stimulates R subunit degradation and hence keeps PKA persistently active. Thus, the ubiquitin–proteasome pathway helps convert the transient stimulation of sensory neuron to long-term synaptic changes that underlie memory storage. 5-HT, serotonin; AC, adenylyl cyclase; PLC, phospholipase.

in the neuromuscular junction. Overexpression of *faf* in the developing *Drosophila* nervous system causes synaptic overgrowth and perturbs synaptic transmission. Another genetic screen for identifying the mutants that enhance the *faf* overexpression phenotype found that a loss-of-function in a gene called *highwire* (*hiw*) causes a significant increase in number of synapses. The *hiw* gene encodes a huge protein with 5233 amino acids. The highwire protein contains a RING finger domain, a characteristic feature of some ubiquitin ligases. Therefore, it is conceivable that highwire and fatfacets promote or inhibit the degradation of the same substrate by ubiquitinating or de-ubiquitinating it, respectively. Recently, highwire has been shown to negatively regulate signaling by bone morphogenetic protein (BMP)/transforming growth factor β (TGFβ), which stimulates presynaptic growth in *Drosophila* neuromuscular junction. Highwire binds to a protein in the BMP/TGFβ signaling pathway called Med. Although there is no direct evidence yet for ubiquitination of Med by highwire, the genetic data suggest that highwire functions to ubiquitinate Med for degradation. Moreover, synaptic overgrowth produced by overexpression of fatfacets is suppressed by disrupting BMP signaling.

Role of the Proteasome in Synaptic Plasticity

The 26S proteasome degrades proteins targeted by polyubiquitination. Initially, it was thought that ubiquitin–proteasome pathway removes constraints on long-term synaptic plasticity by degrading inhibitory proteins such as the regulatory subunits of PKA. This idea has gained additional support with recent results showing that transcription repressors such as a cAMP response element binding (CREB) repressor called CREB1b in *Aplysia* is degraded by the ubiquitin–proteasome pathway during treatments of neurons that induce long-term facilitation (Figure 3). The role of proteolysis is unlikely to be just confined to removal of inhibitory molecules, however. In support of this idea, recent studies show that degradation by the proteasome may also limit the extent of induction of long-term facilitation. Recently, a theory of local protein degradation has been put forward that can explain different, and often opposing, roles of the proteasome in different neuronal compartments. In support of this theory, experiments with *Aplysia* neurons and mouse brain show that proteasome has significantly higher levels of activity in the synaptic

terminals than in the other neuronal compartments such as the nucleus. Also, proteasome in the synaptic terminals and in the nucleus are differentially regulated by protein kinases.

Presynaptic Role of the Ubiquitin–Proteasome Pathway: Degradation of Synaptic Vesicle Proteins

The earlier observations on the role of the ubiquitin–proteasome pathway in synaptic plasticity mainly focused on long-term effects. Recent studies, however, indicate that the ubiquitin–proteasome pathway also functions in regulating short-term synaptic plasticity. For example, a protein Dunc-13, which is critical in priming the synaptic vesicles, is ubiquitinated and degraded by the proteasome in *Drosophila* neuromuscular synapse. Application of proteasome inhibitors and the dominant-negative mutation in a core subunit ($\beta 6$) of the *Drosophila* proteasome both lead to an increase in presynaptic accumulation of Dunc-13 protein. Also, application of the proteasome inhibitors lactacystin and epoxomycin causes an increase in the excitatory junctional current, suggesting that accumulation of Dunc-13 and the resultant increase in the net Dunc-13 quantity leads to enhanced synaptic transmission.

Is it likely that quantity of other synaptic proteins with a key role in neurotransmission is regulated by the ubiquitin–proteasome pathway? If so, regulated proteolysis may have a wider role in controlling short-term synaptic plasticity. As of now, two other synaptic vesicle proteins, synaptophysin and syntaxin, have been shown to be substrates for ubiquitin–proteasome-mediated degradation. Vulnerability of synaptophysin for ubiquitin–proteasome-mediated degradation was discovered indirectly by looking for proteins that bind to synaptophysin in yeast two-hybrid system. Two gene encoding for proteins Siah-1A and Siah-2 were isolated from rat brain two-hybrid cDNA library. These two genes are closely related to each other and are homologs of *Drosophila seven in absentia* gene. Siah proteins are single-subunit RING finger ubiquitin ligases with the RING finger domain in the N-terminal region. It is not clear which ligase (Siah1-A or Siah-2) is responsible for degradation of synaptophysins *in vivo* in neurons. Because the experiments were carried out in non-neuronal cells (Chinese hamster ovary cells) and PC12 cells, the physiological consequences of synaptophysin degradation remain to be determined.

Another presynaptic substrate for the ubiquitin–proteasome pathway is syntaxin 1. The group that isolated the Siah ligases also investigated ubiquitin–proteasome-mediated degradation of syntaxin 1 using the yeast two-hybrid strategy. The ligase that ubiquitinates syntaxin 1 is called staring (syntaxin 1-interacting RING finger protein). Co-expression of staring with syntaxin 1 in HeLa cells increases the degradation of syntaxin 1 which can be inhibited by the proteasome inhibitor MG132. Again, the physiological effect of ubiquitin–proteasome-mediated degradation of syntaxin 1 remains to be determined.

Presynaptic role for a ubiquitin ligase APC has been shown recently in *Drosophila* neuromuscular junction. Mutation in the APC gene leads to an increase in the number of synaptic boutons which can be reversed by targeted expression of the normal allele in neurons.

Postsynaptic Role of the Ubiquitin–Proteasome Pathway: Modulation of Neurotransmitter Receptors, Structural Proteins, and Regulatory Factors

Ubiquitin and proteasome seem to regulate proteins that control synaptic transmission such as neurotransmitter receptors and proteins that are part of the synaptic structure such as postsynaptic density proteins.

Investigations in *Caenorhabditis elegans* revealed a role for ubiquitin in endocytosis of GLR-1 type of glutamate receptor. Recent studies indicate that the multi-subunit ubiquitin ligases APC and SCF both regulate the abundance of GLR-1 in *C. elegans* although the mechanism is still unclear. In *Drosophila* neuromuscular junction, APC regulates the concentration of postsynaptic glutamate receptors. In mammalian hippocampal neurons, treatment with the proteasome inhibitor MG132 blocks agonist-induced endocytosis of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors. Also, AMPA-induced *N*-methyl-D-aspartate (NMDA)-induced internalization is prevented by application of the proteasome inhibitor. The exact mechanism of AMPA receptor endocytosis in mammals is not clear. It is possible that the AMPA receptor itself is not the target of proteasome action but a protein(s) that interacts with AMPA receptor might be the target. Given that both NMDA and AMPA agonists stimulate internalization that is inhibited by the proteasome, it is likely that this is a case of passive internalization and not an instance of regulated AMPA receptor endocytosis. In support of this idea, a postsynaptic density protein PSD-95 is regulated by ubiquitin–proteasome-mediated degradation, and degradation of PSD-95 leads to AMPA receptor internalization. Furthermore, application of the proteasome inhibitor MG132 to hippocampal slices reduces the magnitude of hippocampal long-term depression. A direct role for ubiquitin in regulated endocytotic degradation of AMPA receptors is still an open question, although it is likely that targeting of

AMPA receptors for degradation after internalization depends on ubiquitination.

Endocytosis of other neurotransmitter receptors might be directly or indirectly regulated by ubiquitination. Glycine receptor has been shown to be internalized upon ubiquitination. A protein associated with $GABA_A$ receptors, Plic-1, indirectly controls removal of $GABA_A$ through endocytosis. Interestingly, proteasome inhibitors prevent degradation of internalized $GABA_A$ receptors.

Ubiquitin–proteasome-mediated proteolysis appears to regulate several other proteins in addition to PSD-95 in the postsynaptic density proteins including several structural proteins. For example, Shank, GKAP, and AKAP79/150 are degraded through the ubiquitin–proteasome pathway. Unlike the degradation of PSD-95, physiological relevance of proteolytic removal of Shank, GKAP, and AKAP79/150 is not clear, because the studies were correlative and a direct link between ubiquitin–proteasome-mediated degradation of the PSD proteins and structural remodeling was not established.

There is also evidence that the ubiquitin–proteasome pathway controls a protein that regulates spine shape. Spine-associated Rapgap (SPAR) controls dendritic spine shape by reorganizing the actin cytoskeleton. During activity-dependent remodeling of synapses, SPAR was found to be degraded by the ubiquitin–proteasome pathway. Degradation of SPAR is stimulated by serum inducible kinase (SNK). Activity induces SNK mRNA in the cell body and the induced SNK is targeted to the dendritic spines. Because of the time required for SNK mRNA to travel to the spines, one speculation is that SPAR may function to oppose synaptic remodeling after elevated activity.

Future Perspectives

The research on the role of the ubiquitin–proteasome pathway in synaptic plasticity is in its infancy. Although we now know that proteolysis plays a role in inducing synaptic changes, we are far from elucidation of the mechanisms by which proteolysis contributes to synaptic plasticity. Also, future research has to take the complexity of the ubiquitin–proteasome pathway into consideration. For example, there are myriad components of the pathway such as numerous E3s and several DUBs. The elements of the ubiquitin pathway not only control the level of substrates but also regulate each other's function; for instance, E3s push the substrates in the direction of degradation, and some DUBs pull the substrates back from being committed to destruction. Also, molecules of the ubiquitin–proteasome pathway are known to possess nonproteolytic functions which might be critical for synaptic plasticity.

Synapse-specific plasticity requires local regulation of function. The idea of local function for ubiquitin–proteasome-mediated degradation at the synapse and other compartments of the neuron needs to be pursued in order to fully comprehend the role of proteolysis in synaptic plasticity. Rigorous studies on how proteolysis precisely controls substrates relevant to synaptic plasticity would require development of sophisticated experiments tools. In the coming years, we might expect to see exciting new discoveries on how proteolysis helps alter synapses.

Ultrastructural Analysis of Spine Plasticity

J N Bourne and K M Harris, Medical College of Georgia, Augusta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Dendritic spines are small protrusions that serve as the major site of excitatory synaptic transmission in the brain. The shape and density of spines can be affected by numerous factors, including developmental stage, experimental preparation, temperature, exposure to enriched environments, and neuronal pathology. In addition, physiological models of learning, including long-term potentiation (LTP) and long-term depression (LTD), have indicated that alterations in synaptic ultrastructure may underlie the storage of information in the brain.

Spine Structure and Function

Spine Shape

Dendritic spines can assume striking differences in size, shape, and subcellular composition both within and across brain regions (Figure 1). Most spines are unbranched protrusions that can be classified by their stubby, thin, or mushroom shapes. Branched spines have multiple heads which, in some brain regions, are all innervated by a single axonal bouton (e.g., hippocampal area CA3); in other brain regions the different heads of a branched spine are innervated by different axons (e.g., hippocampal area CA1); and in rare cases some of the heads have no presynaptic partners while other heads are innervated by different axons (e.g., cerebellar Purkinje spiny branchlets).

Localization of Organelles

Smooth endoplasmic reticulum (SER) is an organelle that is likely to be involved in sequestering calcium. Depending on the particular brain regions, few, many, or most of the dendritic spines contain SER (Figure 1). For example, only about 14% of the hippocampal CA1 spines contain SER, and most of it occurs laminated with dense-staining material into a structure known as the spine apparatus (as in Figure 1) in the large, complex spines. In contrast, nearly 100% of the cerebellar Purkinje spines contain SER in a tubular network. Polyribosomes are also present in or near the base of some dendritic spines (Figure 2(d)), suggesting that local protein synthesis of dendritic mRNAs can occur in the spines. In immature neurons, synaptic activity can shift the distribution of polyribosomes from the shaft to spines. Similarly, endosomal compartments including coated pits and vesicles, large vesicles, tubules, and multivesicular bodies are restricted to a subpopulation of dendritic spines that differs from spines that contain SER. Mitochondria rarely occur in dendritic spines and are usually restricted to those that are very large, complex, and highly branched. However, during periods of active synapse formation and remodeling in cultured neurons, mitochondria can localize to smaller dendritic spines.

Postsynaptic Targets

Evaluation of dendritic spine structure readily reveals them to be the major postsynaptic target of excitatory synaptic input (Figure 2(a)). Since all dendritic spines have at least one excitatory synapse on their head, more spines mean more synapses and accordingly more point-to-point connections in a neuronal ensemble involving spiny neurons. The size of the spine head also influences the amount of synaptic input, because larger spines are more sensitive to glutamate, the major excitatory neurotransmitter in the brain. Larger spines have larger postsynaptic densities (PSDs), which can then anchor more glutamate receptors. Thus, one function of spines is the preservation of the individuality of inputs. Occasionally, inhibitory or modulatory axons also form synapses on the heads, necks, or at the bases of dendritic spines. An inhibitory input on spines could act to 'veto' or modify the strength of the excitatory input.

Amplification of Voltage in Spine Head

The constriction in dendritic spine necks poses a small resistive barrier, thereby amplifying the depolarization attained in the immediate vicinity of the synapse, in contrast to that which would be generated if the synapse occurred directly on the wide dendritic shaft (Figure 2(b)). Computer simulations have revealed that most of the spine necks are sufficiently wide and short such that charge transfer to the postsynaptic dendrite is 85–100% complete within 100 ms after the initiation of a synaptic event. The time delay in charge transfer is sufficient, however, to provide a transient amplification of voltage at the spine synapse, which may facilitate opening of voltage-dependent channels in the spine head, such as the calcium channel associated with the *N*-methyl-D-aspartate (NMDA) class of glutamate receptors.

Sharing of Postsynaptic Potential

A long-standing hypothesis has been that the narrow dimensions of the spine neck would attenuate current

Figure 1 Dendritic spine shape. (a) Electron micrograph of a section through dendritic spines in stratum radiatum of hippocampal area CA1. (b) The same micrograph that has been color-coded to identify dendrites (yellow), axons (green), and astroglia (purple). In this fortuitous section, three spines were sectioned parallel to their longitudinal axis revealing spines of the stubby (s), mushroom (m), and thin (t) morphologies. The postsynaptic density (PSD) occurs on the spine head (see t) immediately adjacent and to a presynaptic axonal bouton that is filled with round vesicles (v). This t spine contains a small tube of smooth endoplasmic reticulum (ser) in its neck. In the m spine a spine apparatus (sa) is visible. A perforated PSD (perf PSD) is evident on the head of another mushroom spine. Near to this spine is a large astrocytic process (ast) identified by the glycogen granules and clear cytoplasm. (c) A 3-D reconstruction of a dendrite showing a variety of spine and synapse shapes.

flow between the spine head and the dendrite. Morphological evidence suggests, however, that most spine necks are not thin and long enough to significantly reduce the charge transferred to the parent dendrite. Current electrophysiological evidence from hippocampal CA1 cells suggests that the mean synaptic conductance for a minimal evoked response is 0.21 ± 0.12 ns, such that the current generated by release of 10–20 quanta would likely be fully transmitted to the postsynaptic dendrite. Thus, the constriction in the spine neck is not sufficient to prevent addition of voltage changes among co-activated synapses. Other models endow the spine with active membrane that would further enhance the sharing of postsynaptic potentials among neighboring spines (Figure 2(c)).

Biochemical Compartmentalization

Compartmentalization of calcium has now been demonstrated in the heads of dendritic spines under a variety of conditions. Two features of spines help to achieve localization of this second messenger in spine heads at least for a short time: (1) the spine neck could provide a narrow diffusion path and (2) a rise in spine calcium could cause release from SER, the intracellular calcium stores thereby amplifying the calcium signal. Biochemical compartmentalization in spine heads may also serve an important role in restricting calcium from the postsynaptic dendrite, thereby preventing excitotoxic cell damage such as microtubule breakdown and mitochondrial swelling. Since dendritic spines rarely have microtubules or mitochondria, high calcium concentrations in the spine head

Figure 2 Dendritic spine function. (a) Spines exist as principal sites of excitatory synaptic transmission. Spines exist to (b) amplify electrical potential at the synapse and (c) promote associativity among neighboring synapses. Spine shape and resistance of the spine neck may influence potential (V) generated by synaptic activation. (d) Spines exist as molecular compartments. Smooth endoplasmic reticulum (tubules), calcium, and a myriad of other signaling mechanisms (stippling) are recruited in response to synaptic activation (asterisk). (e) Three-dimensional reconstruction of thin spines emerging from a dendrite. Polyribosomes (black dots) are most frequent at the base of dendritic spines, although they can also occur within them.

are less likely to have these detrimental effects. Not all spine morphologies would be expected to restrict diffusion, and only some spines have internal stores. A recent study that utilized caged glutamate to activate NMDA receptors and a low-affinity Ca^{2+} indicator (to minimize the perturbation of endogenous Ca^{2+} buffering) indicates that small spines with narrow necks exhibit large, isolated increases in $[Ca^{2+}]_i$. However, the necks of larger spines allow for a greater efflux of Ca^{2+} into the dendritic shaft at the base of the spine. Perhaps only a subset of spines, or alternatively all spines, but only at a restricted time during their history, achieve the compartmentalization of calcium, whether in spines or along a short segment of dendrite and its associated spines.

The specific localization of voltage-dependent calcium channels is also an important factor in determining which components of the dendritic arbor will compartmentalize and utilize relatively high concentrations of calcium. Whether spines preferentially sequester other second messengers remains to be determined. Certainly those tethered to the PSD are prevalent in spines, but further work is needed to determine how they are targeted to spines and whether compartmentalization in the spine head is a crucial element in their regulation. Recent evidence suggests that synaptic activity can create a bidirectional barrier to the diffusion of proteins, indicating a synapse-specific mechanism to amplify the biochemical signals necessary for establishing plasticity (Figure 2(d)). In addition, the presence of polyribosomes in some spines could provide the necessary machinery for generating plasticity-related proteins (Figure 2(d)).

Enhanced Connectivity

With the evolution of the brain, the increase in synaptic density had to be accompanied by a significant reorganization of the neuropil. Dendritic spines permit dendrites to synapse with neurons 1–2 μm away, which allows for increased synaptic density in densely packed neuropil (Figure 3(a)). Even some invertebrate neurons exhibit spinelike structures, indicating that dendritic spines appeared well before the evolution of the complex mammalian brain. Consider the simple case of an orthogonal relationship between dendrites and axons (Figure 3(b)). There can only be two

Figure 3 Enhanced connectivity between neurons. (a) Spines increase the packing density of synapses. Schematic illustrates a cross-section through two dendrites (shaded), one without and one with dendritic spines. Convolution and interdigitation of dendrite, axon, and spine membranes support more synapses. (b) The presence of spines also allows for an increase in synaptic density without increasing the overall volume of the brain.

synapses on either side of the dendrite in any given plane without the presence of spines. Dendrites with spines can reach beyond their immediate perimeter to connect with axons in nearby rows, thereby at least doubling the density of possible connections. In addition, the shape of dendritic spines allows efficient interdigitation between neighboring processes, thus achieving the high synapse packing density in the neuropil.

Synaptic Activity and Spine Organization

Spine Stability and Turnover

The stability of spines largely depends on the level of synaptic activity and the developmental stage of the neuron. In immature neurons, spines and filopodia turn over rapidly as connections are formed and stabilized. Only a small amount of glutamate is required to stabilize a spine. Excitotoxicity resulting from too much glutamate can result in the disappearance of spines, while a block of synaptic transmission can result in robust spinogenesis, particularly on mature neurons following traumatic injury or exposure to cold temperatures as occurs during hibernation and some surgical and experimental procedures. The appearance and disappearance of spines may reflect the capacity of mature neurons for recuperative synaptogenesis or a form of synaptic scaling, a homeostatic mechanism that ensures that the output of a postsynaptic cell remains constant despite alterations in synaptic input. In contrast, young neurons do not exhibit spinogenesis with blocked transmission, but rather insert more receptors to maintain synaptic homeostasis.

Brain regions also differ in the amount of synaptic turnover that occurs with the modulation of sensory experience. Recent technological advances have allowed dendritic spines of the somatosensory cortex to be imaged *in vivo* for periods of time ranging from a few hours to a few months. Small spines (thin or filopodial) appear and disappear in an experience-dependent manner associated with synapse formation or elimination, whereas larger spines persist for months. The effect of sensory experience on synapse number depends on the rates of synapse formation and elimination at different developmental stages, and the percentage of stable spines increases with age.

In the visual cortex of adult mice, *in vivo* imaging reveals that the majority of spines (75–90%) are stable under baseline conditions. In another study, rats reared in the dark until postnatal day 30 have a significantly lower spine density compared to light-reared controls and also have shorter, rounder spines. Although an increase in spine head diameter is observed in dark-reared animals that are exposed to light for 10 days, the low spine density is not reversed. Presuming that an increase in the number of receptors present in the PSD accompanies the increase in spine head diameter, the parent dendrite could still preserve the level of synaptic input even in the absence of spinogenesis.

In the neocortex, cerebellum, and hippocampus, localization of different afferent inputs on the same dendritic arbor is dictated by the laminar structure of these brain areas. However, in the lateral nucleus of the amygdala, inputs from the cortex and thalamus are interspersed on the same dendritic branches and afferent specificity is determined by spine morphology. Large spines are contacted by thalamic afferents and exhibit larger Ca^{2+} transients following activation than smaller spines contacted by cortical afferents. The increased Ca^{2+} signaling observed in large spines is mediated by R-type voltage-dependent Ca^{2+} channels that are preferentially localized to thalamic inputs. Thus, in the amygdala, organization of afferent inputs

can be regulated at the level of an individual spine by altering its morphological and molecular properties.

Perisynaptic Astroglia and Spine Structure

Traditionally, astroglia have been thought of as 'support' cells for neurons. However, recent evidence suggests that astroglia may play a much larger role in the maintenance and plasticity of synapses. Release of the cytokine tumor necrosis factor alpha (TNFα) by glial cells enhances excitatory synaptic strength by increasing the surface expression of alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors on dendritic spines while reducing inhibitory synaptic strength by causing the endocytosis of γ-aminobutyric acid ($GABA_A$) receptors. Since astroglial processes can project extensively throughout the neuropil, astroglia are in a position to scale synaptic responses at the level of entire neuronal networks. In addition to affecting the physiological properties of synapses, astroglia can also regulate the structure of dendritic spines in response to synaptic activity. Transient interactions between cell surface molecules such as the ephrinA3 ligand and the EphA4 receptor regulate the structure of excitatory synaptic connections through neuro-glial cross-talk. Activation of EphA4 by ephrin-A3 induces spine retraction, and inhibiting ephrin/EphA4 interactions distort spine shape and organization. In addition to Ephs and ephrins, astrocytic membranes contain other contact-mediated factors that influence synaptic maturation. Astroglial processes tend to be found around larger and presumably more mature synapses, while areas that have undergone recent spinogenesis tend to be devoid of astroglia. Thus in the mature brain, astroglia may be involved in enhancing the stability of spines and preventing the extension of new dendritic protrusions. Interactions between cell surface molecules and the release of various soluble factors by astroglia may be of crucial importance to the turnover and structural alteration of spines observed with synaptic plasticity.

Structural Synaptic Plasticity at Dendritic Spines

Long-Term Potentiation

LTP is a cellular model of learning and memory that has been extensively investigated regarding changes in spine and synapse structure. Two key structural changes would contribute to a potentiated synaptic response: an increase in the number of spines or an increase in the size of synapses with LTP. Several studies in the hippocampus over the last 30 years have attempted to link structural alterations of the synapse to the increase in synaptic strength, but the results remain controversial, particularly in the adult brain. Numerous studies involving *in vivo* induction of LTP in the dentate gyrus of adult rats have led to differing conclusions about the amount of structural plasticity that occurs. Early studies describe an input-specific increase in spine volume and a shortening of spines accompanied by an enlargement of the spine neck. Overall spine density and branched spines in particular are increased 30 min after the *in vivo* induction of LTP in the dentate gyrus, although the increase in branched spines may be due to high-frequency stimulation alone, even in the absence of LTP. While there has been some speculation that branched spines might arise from the splitting of individual potentiated spines, careful three-dimensional (3-D) reconstructions of the neuropil have revealed that branched spines never synapse on the same axonal bouton. In addition, the number of neuronal and dendritic processes that pass between the branches argues against the idea of spine splitting. An alternative hypothesis suggests that branched spines arise from the formation of new protrusions called filopodia which can be initiated by the enhanced synaptic activity, navigate between neighboring processes to find a presynaptic partner, and then become dendritic spines. In any case, the majority of morphological alterations that have been attributed to *in vivo* induction of LTP have included more subtle changes such as increases in the concavity of spine heads and an increase in PSD area, as well as an increase in the ratio of perforated to nonperforated PSDs. Because perforated PSDs tend to occur in mushroom spines, this change could indicate an alteration in spine morphology if potentiation results in a shift from thin spines to mushroom spines.

Uncertainty also exists about the extent of structural plasticity that occurs following the induction of LTP in area CA1 of the adult rat hippocampus. Early studies that analyzed single EM images suggest that there is an increase in shaft and sessile synapses following induction of LTP. However, it was not specified whether these synapses were symmetric (inhibitory) or asymmetric (excitatory). More recent studies specifically aimed at detecting changes in synaptic density failed to detect a reliable increase in synapse number after induction of LTP. Although changes in synaptic density have been difficult to detect, recent evidence suggests that spines can get bigger with LTP. When LTP is induced via stimulation of the Schaffer collaterals, a small fraction of spines transiently expand within minutes of tetanic or theta burst stimulation, but return to their initial size within a few minutes. The percentage of expanding spines varies directly with stimulus strength, presumably

reflecting an increase in number of presynaptic fibers recruited. Even with a stimulation intensity that evokes a maximal field excitatory postsynaptic potential (fEPSP), no more than 10% of spines respond. Thus, the relatively small fraction of expanding spines that synapse with the presynaptic terminals activated by field stimulation reflects the challenges present in detecting plasticity-related changes in the adult brain. Even serial section electron microscopy and 3-D reconstruction of dendrites 2 h post-LTP did not reveal net changes in the density, shape, or size of spines. One possibility is that synaptic proliferation occurs immediately after LTP induction, but with time, competition between recently potentiated spines and their nonpotentiated neighbors results in the elimination of the nonpotentiated spines; thus, the dendrite maintains its optimal number of synaptic connections. Under such a scenario, individual spines could exhibit dramatic plasticity while the overall population number and average size of dendritic spines would appear unchanged.

Although the mature brain presents several challenges to describing the morphological changes that underlie synaptic plasticity, the immature nervous system has provided more consistent results. Dynamic changes in local dendritic segments that were targeted for potentiation-induced changes have been observed in organotypic slice cultures. Significant local outgrowth of filopodia-like dendritic processes is seen 20 min after delivery of a tetanic stimulus, and some of the activity-induced filopodia later turn into spine-like structures. When LTP is induced by pairing postsynaptic depolarizations with single presynaptic stimuli and transmitter release is blocked everywhere but in the small area being imaged, two to nine new spines are formed in the nonblocked region, emphasizing the localized specificity of structural changes associated with LTP. Similarly, stimulation of individual spines with uncaged glutamate induces a localized increase in spine head diameter that is apparent within 1–5 min, and 30% of the stimulated spines remain enlarged 70–100 min after stimulation. The magnitude of potentiation correlates with early or long-lasting spine enlargement, suggesting a high level of fidelity between physiological and morphological changes. Spine and PSD enlargement are also associated with the translocation of polyribosomes into spines following the induction of LTP in acute PN15 hippocampal slices. Given that the maintenance of LTP is dependent on the synthesis of new proteins, the presence of polyribosomes in a subset of spines may provide an indication of which spines underwent potentiation.

Although quite a bit of uncertainty still surrounds the set of structural changes associated with LTP, it appears likely that the effect is selective to potentiated synapses and that changes in a tissue will be correlated with the numbers of stimulated axons and dendrites. Nevertheless, there is evidence that LTP-inducing stimuli can result in increases in spine size and number and may involve the remodeling of the PSD and the translocation of organelles into activated spines. All of these changes could form the basis of long-lasting changes in synaptic strength.

Long-Term Depression

In contrast to LTP, LTD is a long-lasting reduction in synaptic transmission that may also play an integral role in the processing and retention of information. Although the literature concerning structural changes associated with LTD is much less abundant, there does appear to be a correlation between a reduction in synaptic response and a decrease in the number and size of dendritic spines. Low-frequency stimulation (900 pulses at 1 Hz) results in the shrinkage of dendritic spines in acute hippocampal slices and the retraction of spines in organotypic hippocampal slice cultures. While these results indicate a strong link between structural and synaptic plasticity, much work remains to be done to fully elucidate the morphological correlates of LTD.

Ultrastructural Organization of Release Sites in the Calyx of Held

T Kuner, University of Heidelberg, Heidelberg, Germany

Introduction

The calyx of Held is a giant nerve terminal mediating high-frequency excitatory input to principal cells of the medial nucleus of the trapezoid body (MNTB). This synaptic connection is part of the lower auditory pathway and contributes to sound localization. Primary auditory neurons, receiving excitatory input from cochlear hair cells, form giant synapses called endbulbs of Held with neurons located in the cochlear nucleus (e.g., globular bushy cells). The latter extend their axons via the ventral acoustic stria to the contralateral MNTB, where they form the calyx of Held terminal on principal cells (Figure 1(a)). This 1:1 axosomatic synapse forms a highly reliable relay, being capable of transferring presynaptic action potentials to the postsynaptic side (Figure 1(b)) at rates of up to 1 kHz. The principal cell forms inhibitory synaptic connections with neurons located in the medial and lateral superior olivary complex (SOC). The neurons of the SOC also receive ipsilateral excitatory input from neurons of the cochlear nucleus and therefore can function as coincidence detectors. Detection of coincident inhibitory and excitatory signals originating from the contralateral and ipsilateral sides, respectively, is thought to underlie sound localization. Embedded in this physiological framework, the calyx of Held faces a truly remarkable set of functional requirements: the resting frequency of action potentials entering the calyx of Held is approximately 100 Hz, sound stimuli can evoke action potential frequencies of up to 1 kHz, and the precise timing of action potentials is critical for sound localization. A set of highly distinctive morphological specializations provide the calyx of Held with this functionality.

Structural and Functional Maturation

The calyx of Held is not a singular structure–function unit but, rather, shows many different age-dependent faces. During the first three postnatal weeks, the calyx undergoes a series of marked structural and functional changes referred to as the morphogenetic sequence (Figure 2). By postnatal day 2 (P2), a protocalyx with a growth cone-like appearance has formed. Active zones (AZs) are large and contain the typical complement of structures. The first events of synaptic transmission reveal postsynaptic currents of small amplitude. By P5–P7, the calyx has a cuplike shape covering much of the postsynaptic cell. Functionally, they are characterized by action potentials with slow kinetics and limited bandwidth, postsynaptic currents of small amplitude, slow kinetics, and pronounced short-term depression. By P8–P10, the calyx has matured further and forms a single large compartment (Figure 2). Approximately half of the surface of the principal cell is covered by the calyx, giving rise to a large area of membrane apposition. At this still immature stage, action potentials have become faster, postsynaptic currents larger and faster, and synaptic depression somewhat less pronounced. At approximately the same time as the onset of hearing, approximately P12–P16, the calyx acquires a progressively fenestrated morphology: the single compartment is split into several fingerlike processes. Furthermore, the variability of structures encountered during this time frame is large, ranging from immature to mature morphologies. Functionally, action potentials and postsynaptic currents are even faster and synaptic depression is strongly decreased (Figure 2). By P21, structural maturation is almost complete; the calyx now forms many fingers or stalks decorated with protrusions called swellings (Figure 2). The functional state on P21 remains unknown because progressive myelination of the brain stem and the process of morphological differentiation impede paired pre- and postsynaptic patch clamp recordings. The structural maturation is ongoing to at least P28, a postnatal stage at which hearing is fully developed. These examples illustrate that any description of structure and function of the calyx needs to consider the appropriate postnatal maturational stage.

Distribution of Synaptic Contacts

Like other giant nerve terminals, such as the giant terminal of the squid, the calyx contains a large number of synaptic contacts (SCs), specialized sites of neurotransmitter release and postsynaptic signal transduction. An immature P9 calyx contains approximately 600 synaptic contacts distributed at average distances of 590 nm across the entire membrane area of the terminal apposed to the postsynaptic side (Figures 3(a) and 3(b); Table 1). Interspersed between synaptic contacts, approximately twice as many puncta adherentia (PA) – desmosome-like junction complexes – are presumed to provide mechanical stability of the pre- and postsynaptic membranes. Both SCs and PA are not randomly distributed, suggesting that an unknown structural principle governs the distribution of these membrane specializations.

Figure 2 Structural and functional postnatal maturation. Maturation during the first four postnatal weeks (blue time bar), with individual elements arranged according to the postnatal day shown on the left. Morphology as apparent in light microscopy and ultrastructure of synaptic contacts (circles, synaptic vesicles; thick bar, postsynaptic density). Thin lines emanating from the growth cone-like calyx at P2 represent filopodial extensions. The mature calyx at P21 forms fingers covered with numerous swellings. Short-term depression traces reproduced from Taschenberger H and von Gersdorff H (2000) Fine-tuning an auditory synapse for speed and fidelity: Developmental changes in presynaptic waveform, EPSC kinetics, and synaptic plasticity. *Journal of Neuroscience* 20: 9162–9173.

On a functional level, synaptic contacts are arranged in parallel, allowing the calyx terminal to act like several hundred independent small bouton synapses. This functionally parallel arrangement is a major mechanism providing the calyx with the unusual functional properties mentioned previously.

The number of synaptic contacts increases with postnatal maturation (Table 1), and their spatial distribution becomes more distinct. At the onset of hearing on approximately P14, a new structural unit appears, the so-called wrapped donut: within individual swellings, synaptic vesicles are arranged in a donutlike manner, with a cluster of mitochondria in the donut center and active zones predominantly located underneath the synaptic vesicle donut (Figures 3(c) and 3(d)). This structural arrangement develops in synchrony with the fenestration process of the calyx (Figure 3(c)) and is fully expressed on P21. It may optimize the geometries of sites producing ATP and sites using ATP, thereby supporting high-frequency synaptic transmission. Hence, in addition to the number of synaptic contacts, their spatial distribution with progression of maturation needs to be considered when examining structure–function relationships of the calyx.

Ultrastructure of Synaptic Contacts at the P9 Calyx

A synaptic contact (also referred to as synaptic complex) consists of a presynaptic cluster of synaptic vesicles (SVs), an AZ comprising cytomatrix (CAZ) and presynaptic plasma membrane, the synaptic cleft, the postsynaptic plasma membrane, and the postsynaptic density (PSD). This arrangement is similar to terminals of other central synapses containing a single AZ.

Figure 4 shows a typical example taken from a P9 calyx. The SV cluster associated with an SC typically occupies a radial shell of approximately 500 nm and contains approximately 100–300 SVs (Table 1). Because SCs are spaced at distances of approximately 600 nm, these clusters may contain SVs that could be assigned to multiple SCs. Within a more restricted radial shell of 200 nm, all SVs can be considered to be only part of the associated AZ, yielding a cluster size of approximately 63 SVs. In aldehyde-fixed tissue, SVs are densely packed as illustrated in Figure 4, but cryo-fixed tissue often reveals less populated SV clusters. Small electron-dense protrusions, possibly the SV protein synapsin, emanate from SV processes and appear to cross-link SVs.

AZs contain electron-dense material, reflecting the presence of the CAZ (Figure 4, black). The shape of AZs viewed from the top can be disk-like or polygonal. When viewed in cross section, AZs of aldehyde-fixed tissue are often concave, resembling the shape of a boomerang. In contrast, AZs in cryo-fixed material are straight, suggesting that the concave shapes observed after aldehyde fixation are not physiological. The diameter of AZs ranges from 200 to 800 nm, and

The entire structure is approximately 1.5 μm in diameter. (b) Reproduced from Sätzler K, Sohl LF, Bollmann JH, et al. (2002) Three-dimensional reconstruction of a calyx of Held and its postsynaptic principal neuron in the medial nucleus of the trapezoid body. *Journal of Neuroscience* 22(24): 10567–10579. (d) Reproduced from Wimmer VC, Horstmann H, Groh A, and Kuner T (2006) Donut-like topology of synaptic vesicles with a central cluster of mitochondria wrapped into membrane protrusions: A novel structure–function module of the adult calyx of Held. *Journal of Neuroscience* 26(1): 109–116.

the surface area of an AZ is approximately 0.1 μm^2. SVs directly contacting the AZ are commonly referred to as morphologically docked. Often, a less stringent distance criterion for docked SVs of $\leq$10 nm distance yields similar numbers, whereas considering SVs within a distance of 20 nm results in higher counts. Based on the average size of AZs, approximately 50 SVs could theoretically dock at an AZ. However, AZs on P9 have an average of only 2 or 3 docked SVs. Hence, a specific molecular mechanism may exist that represents individual SV docking sites. It remains unclear if such docking sites can always mediate neurotransmitter release and thereby represent functional release sites (Figure 5).

The synaptic cleft is approximately 20–30 nm wide and is partially filled with fuzzy electron-dense material. In aldehyde-fixed tissue, the synaptic cleft is wider than the space between the membranes surrounding the synaptic contacts (Figure 4, arrows designate transition). This feature could be due to the fixation method because cryo-fixed tissue shows similar or even larger spaces surrounding the synaptic contacts.

The PSD is characterized by an accumulation of electron-dense material and contains neurotransmitter receptors and matrix proteins orchestrating postsynaptic signal processing. The PSDs of principal cells of the calyx contain mostly glutamate receptors of the AMPA type consisting of GluR-D_o subunits, the glutamate receptor subunits conferring the fastest activation, desensitization, and deactivation kinetics.

Ultrastructural Changes during Postnatal Maturation

Synaptic contacts of calyces on P5 or P14 exhibit the same basic design previously described for P9 contacts, but there are several differences. At P5 calyces, SVs are clustered around AZs, whereas at P14 they are more distributed within the volume of the calyx. Furthermore, P5 AZs contain six docked SVs and P14 AZs only three SVs, whereas the size of the AZs decreases with maturational age. The number of docked SVs and the size of the AZ are linearly related. Furthermore, the number of docked SVs normalized

AZ, active zone; PA, puncta adherentia; SCs, synaptic contacts; SVs, synaptic vesicles.

to the AZ area remains unchanged between P5 and P14 calyces, as both AZ area and number of SV decrease. Thus, the concentration of a putative docking complex within the AZ and the area of the AZ may define the number of SVs docked at the AZ.

Another obvious difference between P5 and P14 calyces concerns dense core vesicles, which are very prevalent before P5 and decrease in number thereafter. A subset of these dense core vesicles could be piccolo-bassoon transport vesicles, precursors of AZs. An increased number of dense core vesicles during synapse formation between P1 and P4 is consistent with their role as AZ precursors.

In summary, the ultrastructure of synaptic contacts changes within the first two postnatal weeks mostly with regard to the size of the AZs and the number of dense core vesicles, both of which decrease.

Ultrastructural Specializations of the Calyx

The mitochondria-associated adherens complex (MAC) links mitochondria to PA and consists of a mitochondrial plaque, a vesicular chain, and filamentous material. By linking mitochondria to PA, mitochondrial functions such as ATP and glutamate supply as well as Ca^{2+} buffering can be anchored close to AZs. This spatial arrangement could, similar to the wrapped donut geometry, enhance high-frequency synaptic transmission.

Spine-like protrusions of the postsynaptic membrane into the presynaptic compartment are frequently observed. They often contain one or more synaptic contacts, but their functional relevance remains unclear.

Schematized version of the image is shown on the right. Reproduced from Rollenhagen A and Lubke JH (2006) The morphology of excitatory central synapses: From structure to function. *Cell and Tissue Research* 326: 221–237, figure 3a, Copyright 2006. With kind permission of Springer Science and Business Media.

Figure 5 Release sites and active zones. Scheme of an active zone with three release sites. Docked synaptic vesicles are highlighted by gray barrels. Red, active zone; green, synaptic vesicles.

The presynaptic grid, a hexagonal array of electron-dense material with center-to-center distances of 100 nm, has been reported as a specialization of the presynaptic density in other synapses. However, clear evidence for such a regular grid is lacking at the calyx, although structures consistent with the presence of a grid are evident in Figure 4. The presynaptic grid is thought to provide docking slots for SVs. However, its regular gridlike architecture would predict many more docking sites than docked SVs present at any postnatal stage of the calyx. Thus, access to the docking sites might be restricted by some molecular mechanism. Alternatively, the presynaptic grid may not be fully formed at synaptic contacts of the calyx of Held.

Ultrastructure and Function

Number of Releasable SVs

A P9 calyx contains approximately 1200 SVs docked at the AZ. Different physiological methods revealed a readily releasable pool (RRP) size of 800–5000 SVs. This large variability could be due to the different sensitivities of the methods and different definitions of the RRP. Nevertheless, the number of docked SVs roughly corresponds to the size of the RRP, consistent with the idea that morphologically docked SVs constitute the RRP. The low number of docked SVs could be a mechanism to minimize multivesicular release and postsynaptic receptor desensitization.

Release Probability

An action potential releases approximately 200 quanta, suggesting that only 17% of the docked SVs are capable of fusing and releasing glutamate upon local inflow of Ca^{2+}. On the level of AZs, release is initiated in approximately 33% of the AZs. This low probability of release in conjunction with the parallel arrangement of AZs is a mechanism to ascertain reliable synaptic transmission even at high rates because only a fraction of the RRP will be depleted. Release probability could be defined by the composition and state of the molecular complex translating the Ca^{2+} signal into membrane fusion and by the magnitude and temporal profile of the local Ca^{2+} signal.

Figure 6 Geometry of Ca channels and release sites. Scheme of a hypothetical model showing an active zone with three release sites and a cluster of Ca channels (~20). The Ca^{2+} gradient (yellow) reaches only one synaptic vesicle (green), triggering its fusion and neurotransmitter release.

The nonlinear dependency of release on the local concentration of Ca^{2+} implies that the distance between the source of Ca^{2+} inflow, Ca channels, and the location of the sensor for Ca^{2+}, the release site, is a highly sensitive mechanism to control release probability. This could work on the level of a single Ca channel differentially coupled to a release site. Alternatively, Ca channels may form a single cluster within an AZ (Figure 6). Then, release sites positioned at different distances from the Ca channel cluster will experience different Ca^{2+} concentrations and, therefore, different release probabilities. For any given constellation of SV number and distances to the Ca channel cluster, a different release probability will be defined for each SV. A Ca channel cluster freely mobile within the AZ could generate a different set of release probabilities at any given moment in time and could account for the low average release probability. This model has not been experimentally verified, highlighting the need for detailed ultrastructural studies of the distribution of Ca channels and release sites within AZs.

Molecular Composition of the AZ

No information is available on the ultrastructural distribution of presynaptic proteins within the AZ of the calyx of Held. Knowing the exact distribution of presynaptic proteins relative to the components of the AZ will be essential to understand neurotransmitter release and the synaptic vesicle cycle in the context of the functional properties of synaptic transmission mediated by this synapse.

Comparison with Other Synaptic Contacts

The composition of individual synaptic contacts of the calyx is very similar to that in other mammalian

central synapses. For example, AZs have areas of 0.03–0.14 μm^2 in other synapses, comparable to 0.06–0.1 μm^2 for AZs of the calyx. In most mammalian synapses examined to date, including the calyx of Held, the size distribution of the AZs has shown a large coefficient of variation, suggesting that the mechanism defining the size of AZs is quite inaccurate. The number of SVs associated with each calycean synaptic contact is similar to that found in other types of synapses. However, the number of docked SVs is up to five times higher in nerve terminals of the cerebellum, hippocampus, and cortex, which have on average approximately 8–10 docked SVs. AZs with many docked SVs have a higher probability of multivesicular release and postsynaptic receptor saturation. In the calyx, fewer docked SVs minimize this and therefore optimize high-frequency transmission.

Conclusion

The multiple structural and functional states of the calyx provide a unique situation to study the structure and function of this synaptic terminal, ranging from molecular to ultrastructural, morphological, functional, and behavioral levels of complexity. Knowing the molecular composition and exact spatial arrangement of AZ components will be necessary to obtain a better understanding of neurotransmitter release and its modulation at this synapse. Electron tomography and analytical electron microscopy provide new avenues of reaching these goals.

Variant Creutzfeldt–Jakob Disease

D L Ritchie and J W Ironside, University of Edinburgh, Edinburgh, UK

Introduction

Variant Creutzfeldt–Jakob disease (vCJD) is a member of the group of human prion diseases and was first identified in the UK in 1996. Prion diseases in humans are rare, accounting for 1–1.5 deaths per million of the population per annum. Human prion diseases are a unique group of neurodegenerative conditions that occur as idiopathic, familial, and acquired disorders (Table 1). All are fatal, and are associated with the accumulation of an abnormal and disease-specific isoform of a normal cellular protein, the prion protein (PrP), in the brain. According to the prion hypothesis, this abnormal form of the protein, designated PrP^{Sc} ('Sc,' from 'scrapie'), is synonymous with the infectious agent, and its presence within the brain is an important diagnostic feature of these diseases.

vCJD is unique in this group of diseases since it is the only known example of prion disease transmitted to man as a zoonosis (Table 1). Initial epidemiological evidence linked the emergence of vCJD to the epizootic of bovine spongiform encephalopathy (BSE) in the UK, a novel prion disease in cattle first reported in 1987. BSE affected many cattle in the UK, with a peak incidence of around 3500 cases per month in 1992–93. At least 180 000 clinical cases were identified and there is evidence to indicate that the total number of cattle infected with BSE in the UK might be as large as 3 million. Infected bovine tissues (brain and spinal cord) were components of certain meat products that were likely to have been consumed by humans in the UK in the 1980s, and although these tissues were banned from human consumption around 1988, there is evidence to suggest that at least some human exposure to BSE through contaminated food continued up to 1996. The presumed route of human exposure to BSE via high-titer infectivity in the food chain is supported by the findings of a case-control study of risk factors for vCJD, which found an increased consumption of products containing mechanically recovered meat in cases of vCJD (although there was evidence of recall bias in participants).

In view of the potential risk to human health from BSE, surveillance of Creutzfeldt–Jakob disease in the UK was reinstituted in 1990. CJD is not a notifiable disease in the UK and the surveillance system is based on referral of suspected cases to the National CJD Surveillance Unit by clinicians and pathologists. The first cases of vCJD were reported by the National Creutzfeldt–Jakob Disease Surveillance Unit in the UK and linked to BSE after detailed studies to exclude any other possible explanation for this novel human disease. There is now convincing evidence that vCJD is caused by human infection with the BSE agent. vCJD occurs predominantly in the UK, the country with the largest BSE epidemic in cattle. The biochemical profile of PrP^{Sc} in the brain in vCJD is very similar to that of the PrP^{Sc} in the brain in cattle and other animals infected with BSE, and experimental infection of macaques with BSE produces a neuropathological profile closely resembling that of vCJD in humans. Furthermore, experimental transmission studies of BSE and vCJD in wild-type and transgenic mice have revealed that the infectious agent in vCJD had very similar biological properties to the BSE agent.

Clinical Features

vCJD predominantly affects young adults, with a mean age at death of 29 years (range 14–74), in distinction to sporadic CJD (sCJD), which occurs most commonly in the seventh decade of life. Possible explanations for this observation include an increased age-related exposure to BSE and/or age related susceptibility. The duration of the clinical illness in vCJD is also distinct from sCJD, with a mean duration of 14 months, in contrast to only 4 months in sCJD.

Psychiatric symptoms including depression, anxiety, and withdrawal are common at presentation in vCJD, and all patients develop psychiatric symptoms as the illness progresses. A subset of patients develops persistent painful sensory symptoms affecting the trunk, limbs, or face, and the unusual combination of these symptoms with a psychiatric disorder may be an early clue to the diagnosis. All patients develop ataxia, usually around 6 months after the disease onset, which progresses along with evidence of increasing cognitive impairment. Involuntary movements of the limbs are very common as the disease progresses but, in contrast to sCJD, dystonia and chorea occur as frequently as myoclonus. In the later stages of the illness there is an accumulation of multifocal neurological deficits, culminating in severe disability and ultimately akinetic mutism. Death usually occurs as a consequence of intercurrent infection, particularly chest infection.

Diagnostic criteria for vCJD have been established (Table 2). These include a number of preconditions

for diagnosis, a series of clinical features, and the results of both diagnostic tests and neuropathological findings. A definite diagnosis of vCJD requires neuropathological validation, but a probable diagnosis can be made based on a combination of clinical features and either a positive magnetic resonance imaging (MRI) brain scan or a positive tonsil biopsy. The classification as 'probable' has a very high sensitivity and specificity for the diagnosis of vCJD, but the classification of 'possible' vCJD is less precise. For this reason, most reported cases of vCJD include only definite and probable cases. The diagnostic criteria have been recently amended following the publication of a report of two cases of vCJD with an electroencephalogram (EEG) recording typical of sCJD in the late stages of the illness, with periodic sharp wave complexes.

Table 1 Classification of human prion diseases

Classification	*Disease*
Idiopathic	Sporadic Creutzfeldt–Jakob disease
	Sporadic fatal insomnia
Familial	Gerstmann–Straussler–Scheinker disease
	Familial Creuzfeldt–Jakob disease
	Fatal familial insomnia
Acquired	
Bovine source	Variant Creutzfeldt–Jakob disease
Human source	Iatrogenic Creutzfeldt–Jakob disease
	Kuru

Clinical Investigations

The MRI scan can be of great value as a noninvasive diagnostic test in vCJD, and shows a symmetrical region of high signal in the posterior thalamus on T_2 or fluid-attenuated inversion recovery (FLAIR) sequences in over 90% of cases. In the clinical context, these MRI findings are highly suggestive of vCJD, but are not specific, since there is a case report of sCJD with the 'typical' scan appearances of vCJD. In vCJD, high signal on MRI may also be seen in the periaqueductal gray matter and in the caudate nucleus and putamen, but for a scan to be judged diagnostic of vCJD the pulvinar region of the posterior thalamus should have the greatest signal intensity (Figure 1).

Other clinical investigations are of less diagnostic value in the investigation of vCJD. The EEG may show nonspecific slow-wave activity, but many recordings have been normal, including those obtained in individuals with clear evidence of cognitive and neurological impairment. Periodic sharp-wave complexes (which are present in most cases of sCJD) are usually absent, but have been identified in the terminal stages of the illness. The cerebrospinal fluid (CSF) 14-3-3 immunoassay is positive in approximately 50% of vCJD cases (in contrast to sporadic CJD, in which the

Table 2 Diagnostic criteria for variant Creutzfeldt–Jakob disease

Category	*Criteria*
1. Definite	
IA and neuropathological confirmation of variant CJD[a]	IA Progressive neuropsychiatric disorder
	IB Duration of illness >6 months
	IC Routine investigations do not suggest an alternative diagnosis
	ID No history of potential iatrogenic exposure
	IE No evidence of a familial form of transmissible spongiform encephalopthies
2. Probable	
(2.1) I and 4/5 of II and IIIA and IIIB	IIA Early psychiatric symptoms[b]
(2.2) I and IVA[e]	IIB Persistent painful sensory symptoms[c]
	IIC Ataxia
	IID Myoclonus or chorea or dystonia
	IIE Dementia
3. Possible	
I and 4/5 of II and IIIA	IIIA EEG does not show the typical appearance of sporadic CJD[d] in the early stages of illness
	IIIB Bilateral pulvinar high signal on magnetic resonance image scan
	IVA Positive tonsil biopsy[e]

[a]Spongiform change and extensive prion protein deposition, with florid plaques throughout the cerebrum and cerebellum.
[b]Depression, anxiety, apathy, withdrawal, and delusions.
[c]This includes both frank pain and/or dysesthesia.
[d]The typical appearance of the electroencephalogram in sporadic CJD consists of generalized triphasic periodic complexes at approximately one per second. These may occasionally be seen in the late stages of variant CJD.
[e]Tonsil biopsy is not recommended routinely, nor in cases with electroencephalographic appearances typical of variant CJD, but may be useful in suspect cases in which the clinical features are compatible with variant CJD and magnetic resonance imaging does not show bilateral pulvinar high signal.

Table 4 Neuropathological criteria for the diagnosis of variant CJD

1. Cerebral and cerebellar cortices:
   Multiple florid plaques in routine stained sections
   Amorphous and pericapillary prion protein accumulation
   Numerous small cluster plaques in prion protein-stained sections
2. Basal ganglia:
   Severe spongiform change
   Perineurinal and periaxonal prion protein accumulation
   Few amyloid plaques
3. Posterior thalamic nuclei:
   Marked neuronal loss and gliosis
   Patchy spongiform change
   Few amyloid plaques
4. Biochemistry:
   Type 2B PrP^{Sc} on Western blot analysis

figure is over 85%). The CSF in vCJD also contains elevated levels of tau, which may be of potential diagnostic value.

Mutations of the human prion protein gene (*PRNP*) have not been identified in vCJD, but all tested patients belong to methionine homozygosity at the polymorphic codon 129, indicating a genetic risk factor for vCJD. This finding is in marked contrast to the *PRNP* codon 129 genotype frequencies in the normal population and in sporadic CJD in the UK (Table 3). Whether human BSE infection may yet occur, perhaps with longer incubation periods, in the other codon 129 genotypes is uncertain.

Neuropathology

The neuropathological features of vCJD are distinctive and allowed early identification of this new form of human prion disease. The features are relatively uniform, allowing the formulation of diagnostic neuropathological criteria (Table 4). The brain in vCJD in most cases is macroscopically normal, but both cerebral and cerebellar cortical atrophy can be identified in cases with prolonged disease duration (over 2 years). vCJD shows all the histological features of a human prion disease in the brain, with spongiform change, neuronal loss, gliosis, and amyloid plaque formation. Florid plaques are a characteristic feature: these are large fibrillary amyloid plaques surrounded by a corona of spongiform change in an otherwise intact neuropil (Figure 2(a)).These are widespread in the cerebral cortex and are generally most numerous in the occipital cortex. Florid plaques also occur in the cerebellar cortex, particularly the molecular layer, but in the granular layer the typical halo of spongiform change is usually absent. Similar fibrillary plaques without surrounding spongiform change are also found in other gray-matter regions in the brain, including the basal ganglia and thalamus. Florid plaques are not specific for vCJD, as similar lesions have been identified in some cases of iatrogenic CJD associated with dura mater grafts. However, the number and distribution of florid plaques in these cases are not as extensive as in vCJD, where their large numbers and widespread distribution are helpful in establishing a diagnosis (Table 4).

Spongiform change in vCJD is most severe in the basal ganglia, particularly the putamen and caudate nucleus, where confluent vacuolation is common (Figure 2(b)). Neuronal loss is most severe in the posterior thalamic nuclei, particularly the pulvinar, although spongiform change in this region is usually mild and in some cases may be absent. This marked neuronal loss is accompanied by severe astrocytosis;

Figure 2 Neuropathology of variant CJD. (a) A typical florid plaque in the cerebral cortex, showing the fibrillary amyloid core surrounded by a characteristic halo of spongiform change (hematoxylin and eosin stain). (b) Spongiform change within the basal ganglia, with characteristic large confluent irregular vacuoles (hematoxylin and eosin stain). (c) Astrocytosis within the pulvinar nucleus in the thalamus (hematoxylin and eosin stain). (d) Immunohistochemistry for glial fibrillary acidic protein labels the reactive astrocytes within the pulvinar (antiglial fibrillary acidic protein). (e) Prion protein immunohistochemistry in the cerebral cortex, showing pericellular deposits of prion protein and the presence of small cluster plaques (KG9 anti-prion protein antibody). (f) Perineuronal and periaxonal linear deposition of prion protein in the basal ganglia (KG9 anti-prion protein antibody).

the distribution correlates with the areas of hyperintense signal within the pulvinar in MRI scans (particularly in T_2-weighted or FLAIR sequences) in patients during the clinical stage of the illness (Figures 2(c) and 2(d)). In patients who have survived for prolonged periods, neuronal loss and gliosis occur at other sites, including the occipital cortex, the cerebellar cortex, and the midbrain. The areas of gliosis in the midbrain have been associated with hyperintense MRI signal changes in some patients with vCJD.

An additional pathological feature of vCJD, as for all prion diseases, is the deposition of PrP^{Sc} in the brain. Different patterns of PrP^{Sc} accumulation in the brain in human prion diseases have been established using immunohistochemical methods and an ever-expanding number of antibodies raised against the prion protein. In vCJD, immunohistochemistry shows a unique and widespread pattern of PrP^{Sc} accumulation in the brain. In addition to the intense PrP^{Sc} positivity within the florid plaques, there are numerous small plaquelike lesions in the cerebral and cerebellar cortex, which are not evident on routine stains (Figure 2(e)). In addition, pericellular accumulation of PrP^{Sc} in an amorphous or 'feathery' distribution is readily detected around small neurons and astrocytes. Perivascular accumulation of PrP^{Sc} is also noted around small capillaries within the cerebral and cerebellar cortices. There is no evidence of an amyloid angiopathy and the mechanism behind this pattern of accumulation is uncertain. In other brain regions

there is a composite plaquelike and synaptic pattern of PrP^{Sc} accumulation. However, in the basal ganglia, particularly in the putamen, there is a perineuronal and periaxonal pattern of PrP^{Sc} accumulation, often in a linear distribution (Figure 2(f)). Brain biopsy (usually on the frontal cortex) has been performed as an investigative procedure in vCJD, mainly on those cases occurring at or just after the time the disease was identified as a unique entity, but is now seldom employed for diagnosis. The neuropathological features in the brain biopsy are similar to those in the frontal cortex in autopsy cases of vCJD, but the extent and severity of the lesions (including both spongiform change and florid plaques) are less pronounced.

Peripheral Pathology

One of the major unique pathological features of vCJD is the presence of both PrP^{Sc} accumulation and infectivity outside the central nervous system, particularly in the lymphoid tissues and the peripheral nervous system. The sensory and autonomic ganglia show positivity within ganglion cells on immunohistochemistry for PrP^{Sc}, and PrP^{Sc} accumulates in lymphoid tissues within germinal centers, particularly in follicular dendritic cells (Figures 3(a) and 3(b)). PrP^{Sc} positivity in germinal centers has also been found within lymphoid follicles in appendix tissues that were surgically removed because of appendicitis up to 2 years prior to the onset of clinical disease. These findings have suggested the possibility of using lymphoid tissue biopsy (specifically tonsil biopsy) as an aid to premortem diagnosis of vCJD, where PrP^{Sc} accumulation can be detected both biochemically and by immunohistochemistry, in symptomatic patients.

Experimental evidence has shown that peripheral involvement in vCJD can occur early on in the disease, perhaps several years before the onset of clinical symptoms. The risk of spread of vCJD through iatrogenic transmission, particularly through routine surgical procedures from individuals incubating vCJD, remains a concern. Bioassay experiments in wild-type mice from vCJD tonsil and spleen have shown that levels of infectivity within the periphery are lower than in the brain, maintaining the demand for more sensitive and specific methods of PrP^{Sc} detection. One such technique, the paraffin-embedded tissue (PET) blot, has been modified specifically for the detection of low levels of PrP^{Sc} in fixed tissues from peripheral tissues and brain biopsy of CJD patients. This technique has proved to be a highly sensitive and specific method for PrP^{Sc}, with investigations on vCJD spleen,

Figure 3 Labeling for the prion protein in peripheral tissues in variant CJD. (a) Prion protein immunohistochemistry, demonstrating intense positivity within the ganglion cells of the dorsal root ganglia (KG9 anti-prion protein antibody). (b) Heavy deposits of prion protein within the germinal centers of the tonsil (KG9 anti-prion protein antibody). (c) Paraffin-embedded tissue blot labeling demonstrating intense prion protein staining (blue) within a number of lymphoid follicles in the spleen (3F4 anti-prion protein antibody). (d) Immunohistochemical detection of prion protein within the spleen of a patient who developed asymptomatic variant CJD infection following a red blood cell transfusion (6H4 anti-prion protein antibody).

tonsil, lymph node, and dorsal root ganglion all demonstrating a more intense labeling pattern when compared to conventional immunohistochemistry (Figure 3(c)). A recent study using a highly sensitive Western blot method has identified PrP^{Sc} within skeletal muscle samples taken at autopsy in a subset of vCJD patients. Establishing the distribution of PrP^{Sc} in the periphery and understanding the peripheral pathogenesis of vCJD may also be crucial in the development of a therapeutic strategy, as the site of agent replication would be a practical target for any prophylactic treatments.

The detection of PrP^{Sc} accumulation within appendix tissues removed prior to the onset of disease in vCJD patients was used as the basis of a retrospective prevalence study of evidence of vCJD infection in anonymized tonsil and appendix tissues in the UK. Of 12 674 cases, 3 were positive, indicating that, in addition to the number of clinical cases of vCJD to date in the UK, there may be a larger number of asymptomatic individuals infected with BSE. Two of the three positive appendix cases from this study had sufficient residual tissue for DNA extraction and analysis, showing that both cases were found to be valine homozygotes at codon 129 in the *PRNP* and raising the possibility of asymptomatic infection in this particular genetic subgroup.

PrP^{Sc} Biochemistry

PrP^{Sc} can be distinguished from the normal cellular form (PrP^{C}) of the protein by proteolytic digestion, which results in the complete degradation of PrP^{C}, leaving only the disease-associated form. Western blot analysis of proteinase K (PK)-digested brain homogenate from CJD cases results in a characteristic banding pattern comprising three different PrP glycoforms (di-, mono-, and nonglycosylated PrP). A molecular classification system for human prion diseases has been proposed based on the level of abundance of these three glycoforms and the differences observed in the mobility of the protease-resistant core of PrP, which presumably relates to differences in the size of the protein after PK digestion (Figure 4). This classification system is used as a diagnostic tool to distinguish not only between vCJD and sCJD but also between the different PrP^{Sc} types of sCJD.

The unique etiology and pathogenesis of vCJD is reflected in a highly characteristic PrP^{Sc} isotype, characterized by a glycoform ratio dominated by the diglycosylated band (Figure 4(a)). The predominance of the diglycosylated band was also found to be characteristic of BSE, and of BSE and vCJD transmitted to other species, leading to the proposition that it represented a BSE/vCJD agent 'glycoform signature'

Figure 4 Prion protein isoform (PrP^{Sc}) detection and analysis in variant Creutzfeldt–Jakob disease brain. (a) Western blot analysis of protease-resistant prion protein in the brain from two sporadic Creutzfeldt–Jakob disease (sCJD) patients and a single variant CJD (vCJD) patient. While two PrP^{Sc} types are observed in sCJD cases (type 1 and type 2A), all vCJD cases show a unique banding pattern, referred to as type 2B, which is characterized by predominance of the diglycosylated fragment (3F4 anti-PrP antibody). (b) Western blot analysis showing conservation of vCJD PrP^{Sc} glycoforms following transmission into wild-type RIII mice, although the molecular sizes differ (6H4 anti-PrP antibody).

(Figure 4(b)). The unglycosylated band of PrP^{Sc} in vCJD has a molecular mass of around 19 kDa. N Terminus mapping of PrP^{Sc} from vCJD brain by Edman degradation is centered on serine-97 and is therefore not different in this respect from some other types of human prion disease, including sCJD and kuru. However, the glycoform ratio of the PrP^{Sc} in vCJD is a remarkably consistent feature, irrespective of the brain region sampled.

PrP^{Sc} is readily and consistently detectable in vCJD tonsil, spleen, lymph node, appendix, and gut-associated lymphoid tissue. PrP^{Sc} can also be found at particularly high levels in the vCJD retina, optic nerve, and trigeminal ganglion, but dental tissue specimens appear negative, as do nonnervous tissues in the eye. Both the celiac and stellate ganglia have been shown to be positive for PrP^{Sc} in vCJD, but peripheral nerves have been reported to be negative. Whether the presence of PrP^{Sc} in all these tissues is associated with infectivity will require experimental verification, but experimental transmission from vCJD spleen and tonsil has been reported in inbred mice.

Animal Models for the Study of vCJD

As described earlier, experimental transmission of vCJD to inbred strains of mice was essential as part of a strain typing study to establish the close relationship between the BSE agent and the agent responsible for vCJD. Similar findings were observed following transmission of vCJD and BSE to bovine transgenic mice. Inbred strains of mice have also been used for the detection of infectivity in peripheral tissues in vCJD, such as tonsil and spleen, in which levels of

infectivity were found to be significantly lower than those in the brain. vCJD and BSE have also been transmitted to macaques, in which the neuropathological findings following BSE transmission are remarkably similar to those in vCJD in humans. The macaque model has also been used to investigate the route of spread of the BSE agent in the body following oral transmission, and an attempt has been made to estimate the magnitude of the species barrier between bovines and humans using this model. BSE and vCJD have also been transmitted to a range of transgenic mice that express human PrP with differing codon 129 polymorphisms. The results from these studies indicate that all *PRNP* codon 129 polymorphisms may be susceptible to BSE, but infection does not always appear to result in clinical diseases, raising the possibility of an asymptomatic carrier state under certain conditions.

Transmission of vCJD by Blood Transfusion

In the UK, the presence of infectivity within blood is an important issue in human prion diseases. Four cases of probable transmission of vCJD infectivity following transfusion of nonleukodepleted red blood cells from asymptomatic donors have been identified in the UK. Three of these were accompanied by typical clinical manifestations of vCJD: the incubation period in the first case between transfusion and disease onset was 6.5 years, while vCJD presented clinically in the second and third cases around 8 years following transfusion. The fourth recipient did not develop any clinical symptoms and signs of vCJD, and died 5 years after transfusion. However, PrP accumulation was detected following autopsy, biochemically and by immunohistochemistry in the spleen and a cervical lymph node, but not in the central nervous system, indicating an asymptomatic or preclinical infection (Figure 3(d)). Analysis of the *PRNP* in this asymptomatic case showed heterozygosity at codon 129, indicating that this genotype is also susceptible to vCJD infection. It is possible that the *PRNP* codon 129 genotype may have had an influence on the disease phenotype, since PrP accumulation was not detected in oral and gut-associated lymphoid tissues. However, the absence of involvement of tonsil and gut-associated lymphoid tissues suggests that the likely intravenous route of infection may have contributed to the relatively restricted peripheral disease pathogenesis.

The identification of these cases of secondary transmission of vCJD after blood transfusion indicates that blood is infectious even in the asymptomatic preclinical phase of vCJD. The development of a blood-detection method is therefore of prime concern, not only as a diagnostic tool for CJD but also as an important screening test for verifying the safety of donated blood and blood products.

Current Developments

To date, 165 cases of vCJD have been identified in the UK since the first cases were identified in 1995–96. The number of annual deaths has declined since the year 2000, and the number of likely future cases remains uncertain; however, it now seems unlikely that a major epidemic of vCJD will occur. vCJD has been identified in a number of other countries (Table 5); these cases are attributed according to the country of normal residence at the time of disease onset, which may not necessarily reflect the geographic region in which BSE exposure occurred. BSE exposure of non-UK residents may be related to residence in or travel to the UK, to exported bovine products from a country with BSE, or to exposure to indigenous BSE. In some vCJD cases outside UK there is a history of extended residence in the UK during 1980–96, the period in which there may have been significant human exposure to BSE, although the clinical illness developed many years later while living in another country. In the majority of non-UK cases, the source of BSE infection is uncertain, as there was no history of travel to the UK.

Although it is clear that very large numbers of BSE-infected cattle were likely to have entered the human food chain between 1980 and 1996, it is not certain how many humans have been infected with BSE over this period. It is clear from studies of kuru and iatrogenic CJD that incubation period in human prion diseases can extend to over 40 years, with substantial influence on the incubation period by the *PRNP* codon 129 polymorphism, as most prolonged incubation periods occur in heterozygotes. A recent study in transgenic mice expressing human PrP indicated that the transmission periods following experimental BSE

Table 5 Variant CJD cases worldwide since 1996

Country	*Number of cases*
UK	165
France	22
Ireland	4
USA	3
The Netherlands	2
Canada	1
Italy	1
Japan	1
Portugal	2
Saudi Arabia	1
Spain	1

transmissions were substantially influenced by the *PRNP* codon 129 genotype. These findings indicate that cases of BSE infection in humans with different *PRNP* codon 129 genotypes may present at different time points as compared to the current cases of vCJD in codon 129 methionine homozygotes, due to genetically determined differences in the incubation period. Continuing surveillance of vCJD is required to address this possibility, by monitoring future BSE-related infections (perhaps with a clinicopathological phenotype different from that seen in vCJD) in individuals who are valine homozygotes or heterozygotes at *PRNP* codon 129 in the UK and overseas.

Introduction

Traumatic brain injury (TBI) is clinically classified as either focal or diffuse. Focal TBI most often involves contusion and/or lacerations accompanied by intraparenchymal hematomas. Diffuse brain swelling, vascular alterations, ischemic brain injury, and diffuse axonal injury (DAI) are frequent components of the diffuse TBI spectrum. The sequelae of TBI may be further divided into (1) primary injury (immediate, nonreversible, and dependent upon the physical factors involved in the injury) and (2) secondary or delayed injury (progressing from hours to months following injury and likely to be partially reversible). This secondary injury cascade is complex and poorly understood and includes the breakdown of the blood–brain barrier (BBB), edema formation, vasospasm, ionic dysregulation, impairment and/or uncoupling of energy metabolism, changes in intracranial pressure (ICP) and/or cerebral perfusion pressure (CPP), inflammation, expression of both pathogenic and protective genes and proteins, and activation and/or release of autodestructive factors. Since the pathological sequelae of TBI are multifactorial in nature, an improved understanding of the secondary injury cascade offers a unique opportunity for the development of targeted therapeutic interventions to attenuate cellular damage and improve functional recovery. One area of intense interest and research concerns the posttraumatic alterations in cerebrovascular function and their role in mediating delayed cell death and/or neurologic dysfunction. Here we review the current state of knowledge concerning the importance of vascular changes following TBI.

Pathology of Vascular Disruption Following TBI

Following TBI, mechanical deformation because of compression, shear, and tension can cause a disruption of the blood vessel wall. Depending on the anatomic position of the injured vessel, hemorrhage can occur in the epidural, subdural, subarachnoid, and/or intraparenchymal compartments. Intracranial hematomas are an extremely important lesion that can complicate 25–45% of severe TBI cases, 3–12% of moderate TBI cases, and approximately 0.2% of mild TBI cases.

Epidural Hematoma

Epidural hematoma (EDH) is caused by the vascular disruption of meningeal arteries, meningeal veins, and/or dural sinuses before they enter into the space between the brain and the dura mater. In the majority of cases, EDH occurs as a consequence of skull fracture and stripping of the endosteum and can therefore be considered a complication of fracture and not related to head acceleration (see Table 1).

In 50% of human TBIs, the most common location of an EDH is the squamosal portion of the temporal bone. In this area, the middle meningeal artery is partially embedded in the inner table of the skull and is therefore relatively fixed to the bone and more vulnerable to injury. As the hematoma enlarges, it strips the dura from the skull and forms a circumscribed ovoid mass with progressive compression of brain. Picard and colleagues have shown that craniotomy for prompt evacuation of an isolated acute EDH is one of the most cost-effective surgical procedures with excellent results in term of outcome. Postmortem analysis and experimental studies have shown that neuropathological damage associated with EDH is the result of massive ischemic injury associated with brain compression and low CPP.

Subdural Hematoma

Subdural hematoma (SDH) occurs in the space located between the meningeal layer of the dura and the underlying arachnoid and is often associated with a hemorrhagic contusion, intracerebral hematoma breaking through the arachnoid, the rupture of one or more bridging veins, or the laceration of a cortical artery or vein (see Table 1). The cerebral convexity in the parietal region is the most common location of SDHs. Most SDHs are caused by motor vehicle-related accidents (MVAs), falls, and assaults. During falls, angular acceleration is often high and of short duration. Bridging veins (those portions of the superficial cerebral veins that cross the subdural space to reach venous sinuses) are relatively straight as they cross the subarachnoid space and are therefore highly vulnerable to sudden angular acceleration forces. In elderly patients because of brain atrophy, the bridging veins can be stretched, leading to an increased incidence of SDHs. Infants are also susceptible to SDHs because their bridging veins are thin-walled. In younger adults, MVAs are responsible for 56% of SDHs, while only

12% are caused by falls. The overall mortality rate following acute traumatic SDH ranges from 40% to 75%. If the mass lesion is evacuated early, the prognosis depends primarily on the severity of the underlying injury. Mass effect with hemispheric compression and ischemia is an important mechanism of brain damage following a SDH.

Subarachnoid Hemorrhage

Traumatic subarachnoid hemorrhage (SAH) is caused by the bleeding of surface blood vessels into the subarachnoid space or by the rupture of bridging veins or traumatic aneurysm (see Table 1). Typical locations for SAH are the interpeduncular cistern and the Sylvian fissure. In a retrospective study conducted on 141 patients, Chieregato and colleagues reported that the best predictive factors for poor outcome were subarachnoid blood at admission, assessed by computed tomography (CT) scan, together with the Glasgow Coma Scale (GCS) score. However, in a multicenter prospective study conducted on 1005 patients with moderate or severe TBI, Servadei and colleagues observed that patients with SAH exhibit worse CT scan features, such as subdural hematomas and parenchymal damage, with higher risk for evolving contusion, suggesting that SAH may be an indicator of initial injury severity. Furthermore, progression of contusions usually occurs in locations in which cortical SAH is observed, suggesting that contusions are part of a similar process and that subarachnoid blood is probably an early sign of cortical microbleeding.

Intraparenchymal Hematoma

Traumatic intraparenchymal hematoma (IPH) is caused by the bleeding of an intracerebral or subarachnoid vessel. Most IPHs develop as a complication of a contusion; although they can also be absent from the first CT scan, they may develop later. Delayed traumatic intracerebral hematoma (DTICH) usually occurs in an area of radiologically normal brain in patients with otherwise pathological CT scans. However, DTICH can also occur in areas of contusion on initial CT scan or may appear following resection of surgical brain lesions or resuscitation. The occurrence of traumatic IPHs is five times more common in patients older than 45 years, compared to younger patients, suggesting that age-related changes in the brain parenchyma (such as atrophy) and vasculature may facilitate the development of IPHs following TBI (see Table 1). The most common locations for traumatic IPHs include the frontal and temporal regions, where the brain can impact the roughened inner surfaces of the skull (i.e., orbital roof or sphenoid ridge).

A study by Chang and colleagues showed that over 60% of lesions remain unchanged within the first 3 days of injury, and nearly 40% progress to larger lesions, with 15% becoming larger than 5 cm^3. A majority of studies on traumatic IPH are observational and comparisons of outcome between surgical and nonsurgical groups are difficult. However, current evidence indicates that an IPH that is accompanied by progressive neurological dysfunction, refractory intracranial hypertension, or radiological signs of mass effect may be associated with a poor outcome if left untreated.

Alterations in Cerebral Blood Flow Following TBI

Brain glycogen reserves are extremely limited, and since the brain has no significant storage capacity for glucose, it is highly dependent on blood flow. Inadequate substrate delivery and cerebral blood flow (CBF) are therefore among the most important

factors contributing to mortality and morbidity following TBI. A consistent finding reported in the experimental TBI literature is that CBF is significantly reduced acutely following impact. The degree and time window of this reduction are related to the injury model, the species, and the methodology used to measure CBF.

Ischemia

Measurement of CBF following TBI can identify hypoperfusion. However, because of metabolic derangement, true ischemia in these patients can only be defined by a CBF that is inappropriately low for tissue metabolism.

The classical definition of ischemia has the following implications:

- Reduction of CBF to less than 18 ml per 100 g tissue min^{-1} (coupled with increase in cerebral oxygen extraction fraction/high arteriojugular oxygen content difference ($AJDO_2$) values).
- Reduction of ATP (otherwise termed 'energy failure').
- Increase in anaerobic glucose metabolism, thereby producing lactate.

TBI in rodents reduces cortical CBF distal to the impact by 50%, while CBF in the injury site is reduced by about 95%. Additional experimental studies have reported reduction in ATP content in traumatized cortical regions and elevated lactate levels after severe TBI. In the clinical setting, ischemic lesions, most commonly seen in the hippocampus and basal ganglia, have been detected in the majority (90%) of fatal TBI. In nonfatal TBI, profound reductions of cerebral CBF (CBF $<$18 ml per 100 g tissue min^{-1}) have also been shown in more than 30% of patients during the early (4–12 h) period following TBI. However, high $AJDO_2$ values (above 9 ml/100 ml) have been identified in only a minority of these patients, indicating a coupled CBF and metabolic depression. Since marked heterogeneity of CBF and metabolic patterns in the traumatically injured brain have been demonstrated, focal ischemia could remain undetected by global measurements such as $AJDO_2$. Recent ^{15}O-positron emission tomography studies exploring regional pathophysiology measuring O_2 extraction fraction have shown that within 24 h a small but significant volume of brain tissue is at risk of ischemic damage. Other clinical studies, however, have reported that ischemic levels of CBF are only observed in irreversibly damaged tissue. Therefore the importance of ischemia in delayed neuronal injury following nonfatal TBI remains controversial. In an assessment of the similarities and differences between ischemia and TBI, Bramlett and colleagues have shown that mechanisms that cause cells to die are quite similar, but different for dysfunctional cells that survive the initial insult. The mechanisms underlying cellular vulnerability in ischemia and TBI may therefore be distinct.

Uncoupling of Cerebral Blood Flow and Metabolism

Under normal conditions, CBF is coupled to metabolism whereby cortical activation is followed by CBF increase. Following TBI, several studies have shown that this CBF/metabolism coupling can be lost when acute glucose metabolism increase is associated with a reduction in CBF (**Figure 1**, upper panel). Similarly, human brain PET studies have shown that around cerebral contusions and beneath intracranial hematomas there is an area of increased glucose metabolism together with decreased CBF (**Figure 1**, lower panel). Therefore, the ability of the injured brain to respond adequately to subsequent perturbations that may exacerbate the imbalance between O_2/nutrient delivery and consumption is extremely limited. The concept of the vulnerability of the traumatized brain to secondary insults has been investigated by Jenkins and colleagues, who were the first to show that although neither mild TBI nor brief (6 min) bilateral carotid artery occlusion resulted in detectable hippocampal morphological damage/death, the same severity of incomplete ischemia resulted in profound CA1 hippocampal neuronal death when induced 1 or 24 h following a mild TBI. Therefore in the presence of secondary sublethal challenges (i.e., increased ICP, reduced CPP, fever, seizures), injured cells may undergo irreversible damage.

Posttraumatic Vasospasm

Posttraumatic vasospasm occurs in approximately 25–40% of patients following severe TBI and is associated with the presence of traumatic SAH. In a study comparing 99 patients with posttraumatic SAH to 114 patients with aneurismal SAH, a clear difference was found in distribution, time course of CBF, and neurological changes in the two conditions. Furthermore, the distribution of the low-density areas on the CT scans did not correlate with vascular territories in traumatic SAH patients, suggesting that vasospasm following TBI does not contribute to secondary deterioration. Therefore the importance of monitoring TBI patients for vasospasm is not currently clear.

Molecular Mediators of Vascular Damage after TBI

In addition to CBF changes (*vide supra*), post-TBI changes include morphologic damage to endothelial cells and perivascular cells, increased BBB permeability,

Figure 1 Mismatch of local cerebral metabolic rate for glucose (lCMRglc) and regional cerebral blood flow (rCBF) following traumatic brain injury. (Top) 1 h following experimental traumatic brain injury, the rat brain exhibits evidence of local increase in lCMRglc, utilizing [^{14}C]deoxyglucose autoradiography (left), associated with a reduction of local cerebral blood flow, utilizing [^{14}C]iodoantipyrine autoradiography (right). (Bottom) In brain scans of a person with severe traumatic brain injury, confirmation of a similar mismatch of lCMRglc and rCBF in the tissue beneath a contusion. The computed tomography (CT) scan shows the contusion and the pericontusional tissue (left panel). The pericontusional rim (yellow arrows, middle panel) exhibits an increase of lCMRglc measured with ^{18}F-labeled deoxyglucose positron emission tomography (PET scanning), associated with a reduction of rCBF, measured with ^{15}O-H_2O PET techniques (yellow arrows, right panel). Reproduced by permission of David A Houda, UCLA Brain Injury Research Center.

reduction or abolition of vasodilatory and vasoconstriction responses to changes in mean arterial pressure (MAP), changes in arterial tension of O_2 and CO_2 and blood viscosity as well as in cerebral metabolic activity. It is likely that some aspects of cerebrovascular dysfunction following TBI contribute to the increased sensitivity of the injured brain to secondary hypoxia and hypotension and to the increased mortality and morbidity that occurs due to secondary insults after TBI in humans.

The cerebral circulation is influenced by a variety of vasodilators and vasoconstrictors, and the observed reduction in CBF after TBI may be due to an imbalance in the levels/activity of vasoconstrictors and vasodilators and/or to local microthrombosis.

Calcium

An increase in brain calcium (Ca^{2+}) flux has been documented following several experimental models of TBI. Ca^{2+} entry into neurons may occur through membrane-associated receptors and voltage-sensitive Ca^{2+} channels (VSCCs). Antagonism of these channels using various Ca^{2+} channel blockers has been shown to be associated with attenuation of regional CBF reductions, brain edema, and motor and cognitive deficits following experimental TBI. However, when nimodipine, which blocks L-type VSCCs, was administered 24 h postinjury to severely head-injured patients, no significant clinical benefit was observed, except in a subgroup of patients with SAHs.

Prostanoid, Eicosanoid, and Reactive Oxygen Species

Posttraumatic elevation of intracellular free Ca^{2+} may precipitate an attack on the cellular membrane by activating phospholipases A_2 (PLA_2) and C (PLC), resulting in the release of free fatty acids (FFAs) and diacylglycerol (DAG). Increases in brain FFAs can lead to secondary damage through BBB breakdown and formation of cerebral edema, and, indirectly, via the generation of prostaglandins, thromboxanes, and leukotrienes (cyclooxygenase and lipooxygenase products from arachidonic acid), which may affect CBF and BBB permeability. Figure 2 shows the pathways activated from arachidonic acid and the effect on cerebral circulation of the different products.

Figure 2 Pathways of eicosanoid formation and effects on cerebral circulation. TXA_2, thromboxane A_2; $PGF_{2\alpha}$, PGI_2, PGE_2, PGD_2, prostaglandins; EET, epoxyeicosatrienoic acid; HETE, hydroxyeicosatetraneoic acid; C, vasoconstrictor; D, vasodilator.

Cyclooxygenases 1 (constitutive isoform) and 2 (inducible) have been shown to increase following experimental and clinical TBI as early as 3 h postinjury, together with increases in plasma and tissue levels of prostaglandins ($PGF_{2\alpha}$, PGE_2), prostacyclin, and thromboxane, with an imbalance toward vasocontrictors. Administration of cyclooxygenase (COX) inhibitors has resulted in mixed results, and additional studies are warranted to better understand the effects of COX inhibition on cerebrovasculature and neuroinflammation following TBI. Prostacyclin has also been shown to reduce cortical cell death and to improve compromised perfusion caused by posttraumatic vasoconstriction and microthrombosis following experimental TBI.

In addition, during the process of prostaglandin synthesis from arachidonic acid, reactive oxygen species (ROS) are generated by the mitochondria due to Ca^{2+}-mediated disorganization of the inner mitochondrial membrane, with subsequent disruption of the electron transport chain. Reactive oxygen species formation leads to peroxidative destruction of the cell membrane, proteins, and DNA. Under physiological conditions, ROS are scavenged by endogenous antioxidants, including superoxide dismutase (SOD), glutathione peroxidase, and catalase. Since the amount of ROS production exceeds the scavenging capacity of the cells, increasing the endogenous antioxidative mechanisms may have therapeutic value in TBI.

Adenosine

Adenosine is a major regulator of the cerebral circulation known to cause vasodilation acting on two receptors located on the vascular endothelium and smooth muscle. An increase in cerebral metabolic activity and/or a mismatch between energy production and oxygen consumption results in a rise in adenosine concentration, which in turn can dilate the cerebral arterioles and increase local CBF. Following TBI in rats, interstitial adenosine has been shown to increase in the contusional/pericontusional area and, in humans, in the cerebrospinal fluid (CSF) of patients following TBI. Furthermore, secondary episodes of global brain hypoxia further increase CSF adenosine, suggesting a role during periods of secondary insults following TBI. Agonists of adenosine have been shown to attenuate cerebral hypoperfusion and posttraumatic behavioral deficits following experimental TBI in rats, suggesting that the neuroprotection obtained by adenosine receptors pathways might be due to an increase in CBF.

Nitric Oxide

Nitric oxide (NO) is a vasodilator that has been suggested to play a role in damage, recovery, or both, after TBI. Three different systems are reportedly involved in NO synthesis: endothelial, neuronal, and inducible NO synthase (eNOS, nNOS, and iNOS). lIt has been observed that cerebral tissue NO levels increase transiently and then decrease within 15–30 min following experimental TBI.

When expression/levels of NO synthases are evaluated following TBI, it has been shown that brain tissue nNOS activity and NO levels increase markedly but briefly after TBI, and then decrease below preinjury levels for hours to days. Inducible NOS activity in the brain increases hours to days after TBI and remains elevated up to a week after injury.

In the cerebral vasculature, eNOS immunoreactivity and protein expression increase after TBI. Since CBF might be linked to NO levels, several studies have evaluated the hypothesis that increasing NO levels (or NO synthases activity) results in increased CBF and attenuated damage following TBI. The NOS substrate L-arginine improves CBF and attenuates histological damage after experimental TBI. Nonselective blockade of NOS has also been shown to be either detrimental or without influence on outcome following TBI in rats.

To clarify the beneficial or detrimental effects of iNOS-related NO production, studies employing genetically engineered mice and/or pharmacological inhibition have been performed: mice deficient in iNOS show increased cognitive deficits 15–18 days after TBI, suggesting a protective role of iNOS. This protective role of iNOS was confirmed in a rat model of TBI in which administration of iNOS inhibitors aminoguanidine and L-*N*-iminoethyl-lysine resulted in reduced learning capacity and greater hippocampal cell loss at 3 weeks after injury. It appears possible, therefore, that iNOS activity may exert detrimental effects in the acute postinjury period but can show beneficial effects in the chronic phase. Further work needs to be directed at clarifying the exact role of the different isoforms of NOS to draw a more comprehensive picture of the role of NO following TBI.

Endothelin-1

Endothelin (ET) is a 21-amino-acid peptide with potent vasoconstrictive activity. The ET family comprises ET-1, ET-2, and ET-3. Endothelin is produced in endothelial cells, as well as in several tissues, including the brain, where ET-1 has been found in neurons, glial cells, and choroid plexus cells. Synthesis of ET-1 is stimulated by thrombin, cytokines, transforming growth factor-β, vasopressin, angiotensin II, and oxyhemoglobin, while it is inhibited by NO. Endothelins acts on two receptors, ET_A and ET_B, which have been observed in vascular smooth muscle cells (leading to vasoconstriction through an increase in Ca^{2+}) and endothelial cells (leading to vasodilation through the release of vasodilatory COX products and NO). Following experimental TBI, an increase in ET-1 mRNA expression and protein level has been observed in the brain and CSF, and this is associated with reduced CPP. A relationship has been observed between ET and NO (vasoconstriction and vasodilation) and inhibition of iNOS using antisense iNOS oligodeoxynucleotides following TBI in rodents; this interaction results in reduced synthesis of iNOS and a five- to sixfold increase in ET-1 concentration, both of which are associated with a marked reduction in CBF. In contrast, ET-1 antagonists have been associated with restored vasodilatory capacity of the cerebrovascular system following TBI, suggesting that ET-1 might be a target for therapeutic intervention.

Neuropeptide Y

Neuropeptide Y is a transmitter of the cerebrovascular sympathetic nerves known to induce vasoconstriction and reduction of CBF. It acts on a family of six different receptors localized in the smooth muscle cells of pial arteries and arterioles. In cerebral arteries, the vasoconstriction mediated by neuropeptide Y is mediated by changes in smooth muscle membrane potential and Ca^{2+} increase (either via increased influx or increased release from intracellular stores); this vasoconstriction can be blocked by Ca^{2+} channel blockers such as nimodipine, nifedipine, and verapamil. Following TBI in rodents, concentrations of neuropeptide Y are increased in the pericontusional cortex. In addition, neuropeptide Y-immunoreactive fibers are observed in the injured cortex and ipsilateral hippocampus, suggesting that an increase in cerebral neuropeptide Y concentrations after brain injury may be involved in the pathogenesis of reduced CBF.

Endothelium-Dependent Hyperpolarizing Factor

Recently, an additional endothelial-derived vasodilatory pathway that is different from NO and/or cyclooxygenase-derived products has been identified; this pathway is mediated by endothelium-derived hyperpolarizing factor (EDHF), which acts to hyperpolarize the vascular smooth muscle and activate potassium (K^+) channels on the vascular smooth muscle. Possible candidates of EDHF include epoxides, anandamide, K^+ ion, and an electrical coupling mediated by myoendothelial gap junctions. Following TBI in rodents, EDHF pathways are activated and the resultant vasodilation can be inhibited by charybdotoxin, an inhibitor of large-conductance Ca^{2+}-sensitive K^+ channels, suggestive of a compensatory role of EDHF during conditions characterized by compromised NO. Further work will determine whether the observed phenomenon of EDHF potentiation might be a protective mechanism initiated following cerebrovascular injury.

Genetic Influences/Susceptibility to Vascular Changes after TBI

Apolipoprotein E

Lipoproteins (lipid transporters) are macromolecules that contain lipids and proteins, known as apolipoproteins, including apolipoprotein E (ApoE), which plays a major role in the metabolism of triglyceride

lipoproteins (chylomicrons, chylomicrons remnants, very low-density and intermediate-density lipoproteins) and high-density lipoproteins (HDLs), and in the redistribution of lipids locally among cells. The brain is the second most abundant site of ApoE mRNA synthesis, which occurs primarily in astrocytes, but also in neurons and activated microglia. ApoE is also synthesized in macrophages, where it appears to play a role in modulating cholesterol accumulation. ApoE is the only lipoprotein present in the CSF and may function in redistributing lipids among CNS cells for normal lipid homeostasis, repairing injured neurons, maintaining synaptodendritic connections, and scavenging toxins. Polymorphisms of ApoE can occur as a result of mutation, and can be defined as a genetic locus where the most common allele occurs with a frequency of less than 100% in the general population. The most common polymorphisms are single-nucleotide polymorphisms (SNPs), resulting from a single base variation. The ApoE gene on chromosome 19 has three common alleles ($\varepsilon 2$, $\varepsilon 3$, and $\varepsilon 4$), producing corresponding isoforms of the protein: ApoE2 (Cys112, Cys158), ApoE3 (Arg112, Cys158), and ApoE4 (Arg112, Arg158). These three isoforms differ in their abilities to accomplish critical tasks in the maintenance and repair of neurons.

Contusions in head-injured patients with ApoE4 might be more severe as a result of relatively deficient clotting mechanisms. Prolonged clotting times were also identified in ApoE4 carriers after stroke, providing further evidence that ApoE genotype is of relevance to the coagulation cascade. Animal models have provided further information about ApoE mechanisms and the response of the brain to injury. In normal rodents, ApoE immunoreactivity is found in glia, mostly astrocytes, and is not observed in neurons. After ischemic brain injury, the distribution changes and ApoE is increased in reactive astrocytes and neuropils, but later also in degenerating neuronal processes. This increase in ApoE levels has been interpreted as an attempt of the brain to protect itself. ApoE-deficient mice were found to have a greater extent of neuronal damage than did wild-type mice after TBI and ischemia, which was ameliorated by continuous intracerebral infusion of ApoE. However, different genotypes show specific abilities in the response to brain injury. Vascular factors such as thrombin, released during TBI, may also play an important role in the upregulation of ApoE levels. The increase in ApoE levels after hemorrhagic stroke or TBI may initiate a cascade of events leading to amyloid protein-lipoprotein (Aβ) deposition, neuroinflammation, and cognitive deficits. Increased neuroinflammation in ApoE4 carriers may alter the neurological outcome after TBI (see Table 2). Although ApoE4-associated vascular pathology may influence the outcome in survivors, it seems unlikely to significantly increase the probability of a fatal outcome after TBI, since ApoE4 carriers are equally represented in fatal cases (35%) and in nonfatal

Table 2 Outcome of traumatic brain injury (TBI)

Outcome measure	*Main results of TBI pathology*	*Reference*[a]
Recovery of consciousness	$\varepsilon 4$ found more frequently in patients who did not recover consciousness at 1 year	Sorbi et al. (1995)
Glasgow Outcome Scale	$\varepsilon 4$ associated with unfavorable outcome at 6 months	Teasdale et al. (1997)
Functional and cognitive assessment	$\varepsilon 4$ associated with poorer clinical outcome at 6–8 months	Friedman et al. (1999)
Functional independence measures	$\varepsilon 4$ associated with poorer rehabilitation at 6 months	Lichtman et al. (2000)
Learning/fluency test	$\varepsilon 4$ had poorer memory outcome at 6 months	Crawford et al. (2002)
Glasgow Outcome Scale	$\varepsilon 4$ associated with unfavorable outcome at 6 months	Chiang et al. (2003)
Neuropsychological tests	$\varepsilon 4$ bearers had worse postinjury performance	Sundström et al. (2004)
Hematoma volume/Glasgow Outcome Scale	$\varepsilon 4$ associated with larger hematoma volume and poorer outcome at 6 months	Liaquat et al. (2002)
Glasgow Outcome Scale $\pm$ posttraumatic seizures	$\varepsilon 4$ associated with increased risk of seizures, independent of outcome at 6 months	Diaz-Arrastia et al. (2003)
Confusion index/ischemic damage	$\varepsilon 4$ associated with greater incidence of moderate/severe contusions and severe ischemic damage at autopsy	Smith et al. (2006)
Cerebral amyloid angiopathy	$\varepsilon 4$ associated with cerebral amyloid angiopathy at autopsy	Leclercq et al. (2005)

[a]See full entries in 'Further reading' section.

cases (33%). Cerebral amyloid angiopathy in fatal cases of TBI is considerably more likely to occur in those with a genetic predisposition conferred by possession of an ApoE ε4 allele. Clinical studies of TBI have shown that possession of the ε4 allele of the apolipoprotein E gene is associated with a relatively poor outcome. Teasdale and colleagues demonstrated that 57% of ApoE ε4 carriers had an unfavorable outcome following TBI (defined as dead, in a vegetative state, or with severe disability), compared with 27% of noncarriers of ApoE ε4. Friedman and colleagues reported that only 3.7% of patients with the ε4 allele had a good recovery, compared with 31% of patients without the allele. It has been suggested that ApoE ε4 promotes production of Aβ aggregates, cytoskeleton alterations, and oxidative damage, while also impairing the ability of the brain to repair and regenerate (see Figure 3).

Summary

Traumatic brain damage is a result of an immediate mechanical disruption of brain tissue, (including blood vessels), and delayed physiological, molecular, and cellular events/cascades that are potentially amenable to postinjury therapeutic intervention because of their progressive nature, from minutes to months after the initial trauma. Vascular pathology and alterations in CBF are major contributors to mortality and morbidity following TBI. Traumatic brain injury results in CBF reduction both in the experimental and clinical setting, and the reduced CBF in patients has been shown to render the brain vulnerable to secondary insults and has been associated with an unfavorable neurological outcome. The mechanisms responsible for the observed reductions in regional CBF (rCBF) following TBI have not been fully elucidated. During normal physiological conditions, CBF and metabolism are coupled, in contrast to alterations following TBI, when an uncoupling between CBF (reduced) and glucose metabolism (increased) is often observed. In addition, TBI causes an impairment in cerebral autoregulation, whereby patients are not able to tolerate hypoperfusion and remain vulnerable to hypotension and hypoxia. Since TBI is often followed by an upregulation and release of several vasoactive mediators which act in a complex network, it has been hypothesized that posttraumatic alterations in CBF might be the result of an imbalance between molecules with vasoconstrictive and vasodilatory properties. Alterations in Ca^{2+}, nitric oxide, endothelin, prostanoids, adenosine, neuropeptide Y, reactive oxygen species, and endothelium-derived hyperpolarizing factor have been observed following TBI and have been linked with the observed CBF alterations. In addition, patient genotype appears

Figure 3 Roles of ApoE in lipid redistribution among cells in the central nervous system and ApoE isoform-specific differences in neuropathology. ApoE is synthesized by astrocytes, activated microglia, and neurons. Potential detrimental roles for ApoE4 include (1) enhanced amyloid β-protein (Aβ) production, (2) potentiation of Aβ_{1-42}-induced lysosomal leakage and apoptosis, (3) enhanced neuron-specific proteolysis, resulting in translocation of neurotoxic ApoE4 fragments in the cytosol, where they are associated with cytoskeletal disruption and mitochondrial dysfunction (APP, amyloid precursor protein), (4) increased deposition of amyloid in cerebral cortical and leptomeningeal blood vessels, with consequent thickening of the walls and degeneration of the smooth muscle cells in the media, and (5) decreased levels of plasma vitamin K (vitK), which is a fat-soluble vitamin involved in clotting mechanisms.

capable of influencing both the vulnerability of the brain to injury and the posttraumatic damaging/protective response. Although laboratory investigations in which a single pathway has been modified have shown promising results, further work is warranted to better understand the molecular pathways associated with posttraumatic alterations in CBF/metabolism and to draw a comprehensive picture that will permit the successful translation of therapeutic strategies from animals models to the clinical setting.

Structure

Vasoactive intestinal polypeptide (VIP) and pituitary adenylate cyclase-activating polypeptide (PACAP) belong to a family of peptides shown in Table 1. VIP is processed from a precursor protein that also contains a structurally related and biologically active peptide – peptide histidine methionine amide (PHM). VIP and PHM are co-released and are believed to have distinct functions. PACAP is derived from a gene product distinct from VIP; however, these peptide-encoding genes may have evolved by exon duplication coupled to gene duplication. PACAP is also proteolytically processed from a precursor protein. This precursor protein contains an additional peptide, PACAP-related peptide (PRP), which exhibits sequence homology to PACAP. PRP is found localized in tissues with PACAP, where it displays similar biological effects, albeit at much lower potency. Structurally, both VIP and PACAP possess two helices separated by a central disordered region. Subtle conformation differences between the peptides contribute to the selectivity of the peptides for their receptors.

Gene Regulation

VIP gene expression is regulated by cyclic adenosine monophosphate (cAMP) through a cAMP response element (CRE). However, recent studies showed additional regulation of VIP gene expression through the cooperation of the signal transducers and activators of transcription (STAT) proteins, SMAD, STAT, and activating protein-1 sites. Both ciliary neurotrophic factor and transforming growth factor-β induce the transcription of the VIP gene through a 180 bp cytokine response element in the VIP promotor. Neurospecificity for VIP expression is associated with a restrictive element 1 in the VIP gene that modulates transcription in collaboration with a tissue specifier element.

Similar to VIP, the PACAP gene can be activated through the CRE, to which the CRE-binding protein predominantly binds. The activation of PACAP gene promoter is synergistically enhanced by Ca^{2+}. In addition, the half-life of PACAP is prolonged by Ca^{2+} influx into neurons, indicating an activity-dependent stabilization of particular mRNA species in neurons. Thus, the activity-dependent gene expression is coordinately controlled by Ca^{2+} and cAMP signals not only at the transcriptional level but also at the posttranscriptional level for the cumulative mRNA expression in neurons. Both VIP and PACAP are regulated by neuronal activity. Axotomy has been shown to upregulate VIP expression. Furthermore, depolarization of sympathetic neurons stimulates PACAP and VIP peptide levels and increases the release of the peptides with differing magnitudes and temporal profiles. Both VIP and PACAP are involved in the control of the biological clock through the visual system. Dopamine regulates PACAP mRNA expression in intrinsically photosensitive retinal ganglion cells, and the synthesis and release of dopamine in the retina is regulated by the rod and cone photoreceptors via retinal circuitry.

Mechanism of Action

Receptors

Three receptor subtypes recognize VIP and PACAP: VPAC1, VPAC2, and PAC1. PAC1 binds PACAP with much higher affinity (~1000-fold) than it binds VIP. The VPAC receptors exhibit similar affinity for PACAP and VIP. To date, no VIP-specific receptor has been reported. As a result of alternative RNA splicing, PAC1 has ten variants in human. These alternative forms occur in the third intracellular loop, the N-terminal domain, and the transmembrane domain. The splice variants in the intracellular loop include one or two cassettes that are involved in second-messenger coupling. A variant with a 21-amino-acid deletion of the N-terminal domain influences the selectivity of the two forms of PACAP and the relative potencies of the two peptides in stimulating phospholipase C. Activation of the PAC1 receptor with the transmembrane 4 variant results in Ca^{2+} influx through L-type voltage-sensitive Ca^{2+} channels. Thus, differential receptor expression can contribute to the diversity of responses to PACAP. The VPAC1 receptor has 50% amino acid sequence identity to PAC1, but the VPAC1 has similar affinity for VIP and PACAP. VPAC2, which was cloned initially from rat pituitary, has a distinct pharmacology and localization from those of the VPAC1 and PAC1.

Cell Signaling

The actions of VIP and PACAP are primarily mediated through the production of cAMP, although other cell-signaling mechanisms exist including Ca^{2+} regulation, cyclic guanosine monophosphate (cGMP) / nitric oxide (NO) generation, and activation of phospholipase D and phospholipase C. With regard to cAMP, the activation of adenylate cyclase is achieved through the coupling of the α subunit of G-protein in many tissues. Recent studies indicated that, in addition to nanomolar amounts of PACAP increasing the cAMP levels, subpicomolar concentrations of PACAP can result in a stimulation of the extracellular-signal-regulated kinase-type mitogen-activated protein kinase. Calcium effects associated with these peptides involve multiple pathways that are tissue specific and which can involve either the inhibition of Ca^{2+} currents or mobilization of intracellular Ca^{2+} stores. The complexity of VIP and PACAP signaling is due in part to the multiple receptors and their splice variants combined with receptor activity-modifying proteins (RAMPs) interactions. At least some of the tissue and brain-region response diversity is due to these important interactors that can determine the functional signaling output.

Localization

VIP and PACAP are best known as neurotransmitters or modulating neuropeptides and are present in neurons throughout both the central nervous system (CNS) and peripheral nervous system. However, VIP is also an important immune modulator and can be found in mast cells, eosinophils, B and T lymphocytes, and thymocytes. PACAP has well-recognized endocrine functions and, in addition to its presence in the pituitary gland, is enriched in endocrine and germ cells. PACAP is also expressed in lymphoid tissues, including the spleen, thymus, and macrophages. In the CNS, VIP and PACAP overlap in some hypothalamic nuclei, such as the suprachiasmatic nucleus. However, each peptide has its own unique distribution pattern, with PACAP being the more widely distributed throughout the CNS and being found in highest concentrations in hypothalamic nuclei, where it regulates pituitary functions and is produced, passes through the pituitary stalk, and is stored in the posterior pituitary. In the hypothalamus, PACAP is found co-localized with oxytocin in rats and vasopressin in humans. VIP is most abundant in the cerebral cortex, suprachiasmatic nucleus, amygdala, and striatum, but is also present in the olfactory bulbs, midbrain, hindbrain, and spinal cord. In the peripheral nervous system, VIP and PACAP are found in neurons and ganglia in organ systems throughout the body and are frequently co-localized in the same neurons. However, whereas VIP-containing neurons are mainly found in the intestines, heart, lungs, genital organs, urinary system, and several endocrine organs, nearly all organs contain detectable levels of PACAP, within the highest concentration in the testes followed by the adrenal glands. The receptors, VPAC-1, VPAC-2, and PAC1 are found throughout the CNS and peripheral nervous system, and like the peptides

that bind to them, the receptors overlap but have differing patterns of distribution. VPAC-1 receptor is the least common receptor of the brain and is most dense in the hippocampus, pineal gland, olfactory bulb, and cingulate cortex. However, it is widespread in the periphery, where it is found in the pituitary, adrenal gland pancreas, lung, gastrointestial system, and lymphoid tissues. In the brain, VPAC-2 receptors are widely distributed and are abundant in the hypothalamus, hippocampus, amygdala, olfactory bulbs, and several brain stem nuclei. In the periphery, VPAC2 receptors are extensive and enriched in the pituitary, adrenal gland, pancreas, testis, ovary, and spleen. PAC-1 receptors are the most common and widespread of the PACAP receptors within the brain and can be found in most brain regions. They are particularly plentiful in the olfactory bulbs, cortex, hypothalamus, and brain stem. In the periphery, they have a more restricted distribution and are most dense in peripheral ganglia and anterior pituitary. All three receptors are found on glial cells within the brain. The selective actions of VIP and PACAP can be explained, in part, by the regional differences in the abundance of the peptides coupled with the regional variation in the density and distribution of the receptors and the reduced affinity of VIP for the PAC-1 receptor.

Physiology

Developmental Role

VIP, PACAP, and the three known receptors with which they interact appear during the early postimplantation period of embryogenesis in rodents. The receptors are localized to proliferative zones of the neural tube, indicating important role(s) of these peptides in development. Similar to other neurotrophic molecules, VIP and PACAP exhibit dual functions in the regulation of CNS proliferation. They have important actions during development, and they also exhibit neuroprotective properties following injury. During early CNS development, VIP is known to stimulate mitogenesis, differentiation, neurite outgrowth, and neuronal survival. Whereas VIP promotion of neuronal differentiation and neurite outgrowth occurs in the micromolar to nanomolar concentration range, PACAP has been shown to be more potent in increasing these activities, suggesting that PACAP actions are mediated through the PAC-1 receptor, to which VIP binds with only low affinity. PACAP further promotes the transition from proliferation to differentiation in the embryonic brain by stimulating both withdrawal from the cell cycle and morphological and biochemical differentiation. In addition to the possibly direct actions of VIP on developing cells already discussed, VIP has an important regulatory role in embryonic growth and development, perhaps through the VIP-induced release of other trophic factors in the embryo. VIP treatment of whole-cultured day-9.5 mouse embryos causes a dramatic, dose-dependent increase in growth. In 4 h, VIP-treated embryos grow up to twice the number of somites as untreated embryos (Figure 1). Similar treatment with PACAP was shown to have the opposite effect and to inhibit embryonic growth at high concentrations (Figure 1). Treatment of pregnant mice with an antagonist to VIP during embryogenesis results in fetal microcephaly and growth restriction. Co-treatment with VIP prevents the microcephaly; co-treatment with PACAP does not (Figure 2). These experiments indicate that VIP is necessary for the coordinated of growth and development of the embryo and that PACAP does not share this action. Postnatal examination of offspring of females treated with a VIP antagonist or a PACAP antagonist during embryogenesis reveals that the blockage of VIP action resulted in delays in the appearance of several developmental milestones (Table 2) and a long-lasting retardation in growth retardation. Similar treatment with a PACAP antagonist had no effect on the achievement of developmental milestones (Table 2) or on growth. These experiments illustrate differences in the actions of VIP and PACAP during embryogenesis that may be linked to the differential expression of VIP receptors and/or the peptides in the embryonic neuroepithelium. Although VIP and PACAP produced similar

Figure 1 Treatment of whole-cultured embryonic-day-9.5 mouse embryos with a dose range of peptides demonstrates that vasoactive intestinal polypeptide (VIP) stimulates the growth of embryos in a dose-related manner as measured by somite growth. Pituitary adenylate cyclase-activating polypeptide (PACAP) has no effect at low concentrations, but inhibits growth at high concentrations. Reprinted from Hill JM, Lee SJ, Dibbern DA, Fridkin M, Gozes I, and Brenneman DE (1999) Pharmacologically distinct vasoactive intestinal peptide binding sites: CNS localization and role in embryonic growth. *Neuroscience* 93: 783–791.

Figure 2 Treatment of pregnant mice with the vasoactive intestinal polypeptide (VIP)/neurotensin antagonist during embryonic days 9–11 results in microcephaly and growth restriction in the offspring. Co-treatment with VIP prevents microcephaly, but co-treatment with pituitary adenylate cyclase-activating polypeptide (PACAP) does not. physiological responses in most systems, the actions of these peptides in development appear to be significantly divergent, with the effects on cell division being an example.

Gastrointestinal Effects

VIP and PACAP are widespread throughout the enteric nervous system where they are often co-localized in ganglia and nerve fibers terminating in the blood vessels, intestinal mucosa, and smooth muscle of the gut. PACAP is the more potent neuropeptide in regulating gastrointestinal secretions, where both of these peptides stimulate the secretion of saliva from the submandibular gland and of water and electrolytes from the intestine. VIP and PACAP stimulate the release of insulin, glucagon, and bicarbonate from the pancreas, and by stimulating vasodilation, they promote blood flow throughout the organs of the gastrointestinal system. The peptides cause relaxation of the stomach and lower esophageal sphincter, and they inhibit peristalsis throughout the intestine, resulting in reduced motility of the bowel. Whereas VIP and PACAP have direct effects through innervation of the smooth muscles of the gut, central actions of these peptides can also indirectly influence intestinal relaxation through autonomic connections. In addition, VIP may have immune modulator effects in the

gut through action at receptors on intestinal T lymphocytes. All three VIP/PACAP receptors are found in the digestive tract but with different distribution patterns. VPAC-1 is most abundant in the mucosa and VPAC-2 is more abundant in the blood vessels and smooth muscles. NO is also a potent smooth muscle relaxant, and VIP actions in the gut may be, in part, due to VIP-induced release of NO.

Pulmonary Effects

VIP is one of the most abundant neuropeptides in the respiratory tract, where, along with PACAP, it acts on the shared VIP/PACAP receptors to regulate several airway activities. VIP and PACAP are co-localized in the ganglia and nerve fibers that innervate the tracheobronchial smooth muscles, submucosal glands, and the walls of blood vessels. In addition to having potent effects on bronchial relaxation, VIP and PACAP dilate pulmonary blood vessels, thereby increasing perfusion of the lung, and also stimulate mucus secretion by the glands of the respiratory tract. Furthermore, VIP may also mediate immune mechanisms in the lung through its action as an anti-inflammatory agent. NO is also a known pulmonary vasodilator, relaxes airway smooth muscle, and has immunosuppressive properties. VIP may have an indirect role in these pulmonary activities through its action on NO activity.

Cardiovascular Effects

As the name of the peptide indicates, the vasodilatory effect of VIP has been known since its discovery. However, both VIP and PACAP have substantial effects on the heart and blood vessels. All three of the VIP/PACAP receptors have been detected in the cardiomyoctes, although PAC1 is the most prevalent. VIP and PACAP have been shown to produce positive inotropic and chronotropic effects on the heart. In addition, VIP can augment pacemaker current. Both VIP and PACAP produce significant arterial dilatation in the brain, endocrine glands, and pulmonary system. PACAP displays similar effects in all vascular beds, whereas VIP can differ in response among regional beds. VIP has a much greater effect on arteries than veins, due to differences in receptor density. The response to systemic administration of PACAP has two phases: an initial vasodilatation with a decreased blood pressure, followed later by an increase in blood pressure that is attributed to a vasoconstrictive action secondary to central and sympathetic reflexes.

Endocrine System

Both VIP and PACAP have important actions on endocrine function that is often mediated through their secretagogue action or gene expression of hormones. Early studies demonstrated that VIP released prolactin from the anterior pituitary. These studies were followed by others indicating that VIP and PACAP could release oxytocin and vasopressin from the neural lobe of the pituitary. VIP also releases luteinizing hormone and growth hormone from the pituitary. In contrast, PACAP has been shown to suppress luteinizing hormone secretion and pulse frequency when injected into the hypothalamus. In the pancreas, VIP and PACAP can cause significant insulin release, with the releasing action of PACAP being more potent than that of VIP. VIP acts on the pancreas to release either insulin or glucagon, actions that are dependent on glucose levels. Both VIP and PACAP are present in the testis, where they have effects on sperm motility, steroidogenesis, and germ cell maturation. VIP synthesis and VIP receptors have been observed in female sexual organs, with expression regulated in part by the estrous cycle.

Immune System

PACAP and VIP have multiple functional roles with respect to immune cells that include effects on immune cell proliferation and survival, cell mobility, and regulation of inflammatory responses (Figure 3). The effects of the peptides affect both innate and adaptive immunity. Both peptides have actions that can either suppress or activate inflammation through the regulation of cytokine production and release. Direct inhibition of proinflammatory cytokines such as tumor necrosis factor α, interleukin (IL)-6, and IL-12 from activated microglia and macrophages has been reported. In addition, VIP can upregulate the production of IL-10, an anti-inflammatory cytokine; whereas PACAP can inhibit IL-10 production in lymphocytes. These peptides also have effects on the inhibition, expression, and release of proinflammatory chemokines. Both VIP and PACAP can increase the survival of immune cells that include memory T-helper (Th) 2 cells and thymocytes. PACAP has also been shown to increase the phagocytosis and cell digestion of peritoneal macrophages. Effects of these peptides on immune cell mobility are dependent on the target cells. PACAP can decrease the mobility of lymphocytes while increasing the mobility of macrophages.

Behavioral Effects

VIP and PACAP have been shown to influence several behavioral states in a similar manner. Synaptic terminations of VIP- and PACAP-containing neurons on corticotropin-releasing hormone neurons suggest that these peptides may act centrally to augment stress-related behaviors. Consistent with this hypothesis are the observations that VIP- and PACAP-injected mice show evidence of the stresslike symptoms of increased grooming, locomotor behavior, and reduced food

Figure 3 Schematic of VIP secretagogue actions on astrocytes that regulate neural development. Although the receptor that mediates these actions has not yet been established, very low concentrations (0.1–1 nM) produce the release of a diverse array of molecules. ADNF, activity-dependent neurotrophic factor; ADNP, activity-dependent neuroprotective protein; cAMP, cyclic adenosine monophosphate; G-CSF, granulocyte colony-stimulating factor, IL, interleukin; M-CSF, macrophage colony-stimulating factor; MIP, macrophage inflammatory protein; PN, protease nexin; RANTES, regulated upon activation normal T cell expressed and secreted; TNF, tumor necrosis factor; VIP, vasoactive intestinal polypeptide.

consumption. Although PACAP knockout mice also display hyperactivity, they exhibit reduced anxiety-like behavior. Both VIP and PACAP participate in the regulation of circadian rhythms due to their presence in and innervation of the suprachiasmatic nucleus. Both neuropeptides augment rapid-eye movement (REM) sleep, influence learning and memory activities, and can induce analgesia. Both VIP and PACAP have been associated with the normal expression of social behavior. The inhibition of VIP action during embryogenesis has been linked to abnormal and reduced social interaction in the adult mouse. In addition, PAC-1 knockout mice exhibit an abnormally rapid habituation to novel mice. VIP and PACAP are known to potentiate sexual behaviors and the vasodilatory abilities of VIP have an important role in penile erection and may be associated with female sexual function.

Neuroprotective Effects

VIP and PACAP have neuroprotective effects against the toxic effects of excitatory amino acids, β-amyloid, lipopolysaccharide, viral proteins, and oxidative stress. Neuroprotective effects have been associated with the VPAC2 receptor and PAC1. The protective effects of these peptides are complicated, in that both direct protective effects and indirect actions through the release and production of substances released from glia have been observed. Among the neuroprotective and developmentally significant molecules related to the action of these peptides are nerve growth factor, ciliary neurotrophic factor, brain-derived neurotrophic factor, insulin-like growth factor, cytokines, chemokines, and protease nexin-1. These important mediators of VIP and PACAP action have well-recognized effects on preventing programmed cell death, regulating neurite outgrowth and controlling cell division.

Evaluation of VIP/PACAP interaction with glial cells resulted in the discovery of activity-dependent neurotrophic factor (ADNF) and activity-dependent neuroprotective protein (ADNP). Both VIP and PACAP regulate the expression of ADNP in astrocytes through the VPAC2 receptor. The direction of this regulation for ADNP is age-dependent, younger cells showing increases in mRNA and older cells exhibiting decreases. ADNP was further identified as a protein essential for brain development. Activity scanning studies identified ADNF-9 (also known as SAL – SALLSIPA) in ADNF and neuroprotective agent (NAP) (NAPVSIPQ) as potent neuroprotective peptides. NAP is in phase II clinical trials.

Pharmacology

Knowledge of the functional roles of VIP and PACAP is significantly determined by the discovery of specific agonists and antagonists to the relevant receptors and the generation of mice in which these receptors or their ligands have been genetically deleted or enhanced. The pharmacological agents for VIP and PACAP are limited and mostly confined to analogs of the peptides themselves or chimeric peptides. In regard to antagonists, C-terminal fragments are commonly used that include VIP(6–28) and PACAP(6–38). These peptides lack agonist activity, but do not exhibit subtype receptor specificity. However, the peptide PG (97–269) is an antagonist with a 1000-fold specificity toward the VPAC1 receptor. Recent reports indicate that PG(99–465) is a VPAC2 receptor antagonist. Other antagonists with broader activity among these receptors include hybrid peptides (neurotensin(6–11)-VIP(7–28) and stearyl neurotensin(6–11) VIP(7–28)).

In regard to agonists, Ro25-1392, a cyclic analog of VIP, appears to be the selective for VPAC2 and the agents [Ala^{11,22,28}]VIP and [K15, R16, L27] VIP (1–7)/growth hormone-releasing factor (GRF)(8–27) for the VPAC1 receptor. A high-potency nonselective agonist of VIP has also been described – stearyl norleucine VIP.

Transgenic Mice

Transgenic mice that overexpress or delete VIP/PACAP and their receptors provide an invaluable insight into the biological importance of these peptides. Recent studies demonstrated that these peptides are important in memory, growth regulation, reproductive function, behavior, cardiovascular development, and immune function. Early studies with reduced expression of VIP in adulthood resulted in mice with reduced performance in spatial learning. Deletion of the PACAP gene also produced impaired memory performance and reduced hippocampal long-term potentiation. Recent studies using VIP and VPAC2 receptor knockout mice established that VIP coordinates daily rhythms in the suprachiasmatic nucleus by synchronizing a small population of pacemaking neurons and maintaining rhythmicity in a larger subset of neurons. VIP and PACAP receptor knockout and overexpressing mice show altered immune responses in variety of models. In PAC1 knockout mice, pulmonary hypertension and heart failure are observed after birth. PACAP knockout mice are viable at birth, but exhibit increased postnatal mortality; the underlying cause of this premature death is not yet clear. Interestingly, PACAP knockout mice exhibit a significant decrease in the intake of a high-carbohydrate diet but not a high-fat diet. The phenotype of VPAC2 knockout mice also included retarded growth and had reduced serum insulin-like growth factor-1 levels compared with controls. In older males lacking VPAC2, there was a decrease in fertility rate accompanied by diffuse seminiferous tubular degeneration and hypospermia. Overexpression of the human PAC1 receptor has been shown to produce a dose-dependent hydrocephalus-related abnormality in mice, further emphasizing the important role of PACAP and VIP in brain development.

Role in Disease

The roles for VIP and PACAP have begun to emerge in the areas of cancer, cardiovascular disease, and immune function. In addition to the VIPoma tumors that result in a chronic watery diarrhea syndrome, both VIP and PACAP have been shown to have autocrine growth factor activity for a variety of tumors, including small-cell lung cancer and non-small-cell lung cancer, along with colon and breast cancers. Myocardial fibrosis, heart failure, and pulmonary hypertension have been associated with changes in cardiac VIP or in the responsiveness of the VIP/PACAP receptors. The degradation of VIP appears to be increased in the myocardial fibrosis, resulting in decreased VIP levels. The altered affinity, density, and physiological responsiveness of the receptors suggest that these peptide systems may have important pathophysiological roles in cardiac disease.

Therapeutic Potential

The neuroprotective, antiproliferative, anti-inflammatory, antihypertensive, and bronchodilitary properties of these peptides suggest that drugs directed toward this family of receptors could be very beneficial. However, because of the rapid degradation of the peptides, their use as therapeutics has been limited. Because both of these peptides can release neuroprotective proteins in the CNS, it is possible that agents derived from these VIP/PACAP releasable proteins could have therapeutic value. Current examples for stabilized VIP derivatives include stearyl norleucine VIP and shorter analogs, as well as peptide derivatives of VIP/PACAP-regulated proteins. At present, one such NAP, derived from ADNP, is currently in phase II clinical trials. In regard to immune disorders, recent studies have investigated the therapeutic effect of VIP on experimental autoimmune encephalomyelitis through its effect on the downregulation of inflammation and autoimmune responses. In addition, systemic administration with these peptides attenuated the clinical symptoms and improved the cytokine levels in animal models of rheumatoid arthritis, Crohn's disease, septic shock, and multiple sclerosis. Other potential areas of treatment include erectile and female sexual dysfunction, asthma, diabetes, and skin disorders. Although in its early stages of exploration of therapeutic potential, the development of agents that interact with this family of receptors should provide new and innovative approaches to fill unmet medical needs.

Vasopressin/Oxytocin and Receptors

W S Young III and H Gainer, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Oxytocin (OXT) and arginine vasopressin (AVP) are nine-amino-acid, cyclic neuropeptides (nonapeptides) that differ from one another by only two amino acids, at the third and eighth positions (see Figure 1), and that are very distinct in their functional activities. Some of these activities were discovered over a century ago, when Oliver and Schaefer reported in 1895 that extracts of the neural lobe of the pituitary produced powerful presser effects, now known to be due to AVP. The so-called ocytocin effects of these extracts on mammalian uteri were described by Sir Henry Dale in 1906. The term oxytocin refers to its ability to produce quick birth (induction of parturition), and by 1911 it was realized that there was also a galactogenic effect which evoked milk secretion by the lactating mammary gland. OXT and AVP have the distinction of being the first neuropeptides to be discovered and fully characterized with respect to their structures and functions, and this achievement led to a Nobel Prize in chemistry to Vincent DuVigand in 1955. These nonapeptides are associated *in vivo* with specific 100-amino-acid cysteine-rich proteins known as the neurophysins (NPs), which bind their respective peptides and are co-packaged in the neurosecretory granules in the posterior pituitary, from which they are co-secreted with the peptides.

In addition to their well-known peripheral hormonal actions, such as causing milk let-down during suckling at the lactating breast and their effects on uterine contraction, facilitation of sperm transport in ejaculation, natriuresis (sodium excretion by the kidney) in the case of OXT, and liver gluconeogenesis, vasoconstriction, corticotropin secretion from the pituitary gland, and antidiuresis (reabsorption of water from the collecting ducts of the kidney) in the case of AVP, these neuropeptides also have profound actions within the central nervous system (CNS) (Table 1). OXT injected into the cerebrospinal fluid causes sexual arousal (spontaneous erections) in rats, social pair bonding in female voles, induction of maternal behavior, and reduction of various stress-related events (reduction of anxiety, blood pressure, and cortisol levels; increase of tolerance to pain). OXT is also reported to increase trust and reduce fear, and it may inhibit tolerance to various drugs such as opiates, cocaine, and alcohol. AVP has been implicated in memory formation, aggression, blood pressure and temperature regulation, circadian regulation of endocrine rhythms, and pair bonding in male voles. The absence of these peptides produces various known pathological conditions. Decreased AVP secretion or decreased renal sensitivity to AVP leads to neurogenic or nephrogenic diabetes insipidus, respectively. The consequences of this condition is hypernatremia (increased blood sodium content), polyuria (increased urine production), and polydipsia (increased thirst and drinking). An increased level of AVP secretion produces hyponatremia (low plasma sodium) and a syndrome of inappropriate antidiuretic hormone (SIADH). An impairment of OXT secretion blocks milk let-down during suckling, but does not significantly impair parturition. It has been suggested that a deficiency in OXT secretion might be involved in autism, which also has suggestive linkages to the OXT receptor (OXTR) and one of the AVP receptors, AVPR1a.

The Oxytocin and Vasopressin Peptides

Gene Structures and Evolution

Information about mammalian OXT and AVP nonapeptide genes is presented in Table 2. The structurally related OXT and AVP genes in mammals each contain three exons and two introns, and both genes are located on the same chromosomal locus (chromosome 2 in mice and chromosome 20 in humans) but are transcribed in opposite directions (see Figure 1). The first exons of the AVP and OXT genes code for a signal peptide, the hormone (AVP or OXT, respectively), a three-amino-acid spacer (-Gly-Lys-Arg-), and the first nine N-terminal amino acids of NP (NP-II or NP-I, respectively). The second exon of each gene codes for the highly conserved mid-portion of NP (amino acids 10–76). The third exon of the AVP gene codes for the remaining C-terminal amino acids of NP, a monobasic cleavage site (-Arg-) and the C-terminal glycopeptides (GPs) of 39 amino acids. In contrast, the third exon of the OXT gene codes only for the C-terminal amino acids of OXT-associated NP-I.

It is generally believed that the two mammalian AVP and OXT superfamily branches developed from a common ancestral gene through duplication about 450 Ma. The strong conservation of the NP domain of the different AVP-related prohormones further supports this view. The NP domain is very well conserved and exists in all vertebrate and invertebrate species. Two segments in the NP sequence, which fall within the region encoded by the second exon ($NP_{10–76}$), show 58% homology to one another and 60% at the nucleotide level. This suggests that the

Figure 1 Organization of genes: (a) oxytocin gene; (b) vasopressin gene. Both genes are composed of three exons (indicated by the small solid arrows) separated by two introns (indicated by dotted lines between the exons). The genes are present on the same chromosome, but are transcribed in opposite directions (indicated by the large hollow arrows). Similar gene structures but with variable lengths of intergenic sequences have been found in various mammalian species. The three exons code for preprohormones that contain a signal peptide (SP), AVP (VP) or OXT (OT), neurophysin (NP), and, in the case of AVP, also a glycopeptide (GP) that are liberated from the preprohormone during processing in the transported dense-core vesicles. Adapted from Young WS III and Gainer H (2003) Transgenesis and the study of expression, cellular targeting and function of oxytocin, vasopressin and their receptors. *Neuroendocrinology* 78(4): 185–203.

ANP, atrial natriuretic peptide.

primordial NP gene itself arose from a partial gene duplication. Many amino acid sequences of phylogenetically diverse AVP/OXT-related peptides are now available (see Table 3). Because cyclostomes, the most primitive vertebrate for which there are data, possess only one peptide – vasotocin (which differs from OXT and AVP each by only one amino acid; see Table 3) – it is generally assumed that this peptide was most closely related to the ancestral molecule. Several invertebrate peptides in several phyla have been sequenced and have been shown to contain the critical amino acids in positions 1, 5, 6, 7, and 9 (see Table 3). The first cloning of a cDNA in an invertebrate, the mollusk *Lymnae stagnalis*, which contains the Lys-conopressin preprohormone sequence, permitted a comparison between invertebrates and vertebrates of not only the nonapeptide moiety but also the neurophysin and C-terminal domain. The cDNA coded for a 155-amino-acid preprohormone with high homology to the vertebrate neurophysins (49% identity to human AVP-associated neurophysin), including conservation of all 14 cysteine residues. The significance of these data is that they show that the ancestral gene for the AVP/OXT superfamily was already present in the Archaemetazoa, a stem group from which both vertebrates and invertebrates diverged approximately 600 Ma.

In a dramatic cross-phyla experiment, transgenic rats were made that contained a 40 kb cosmid sequence derived from the isotocin (IT)–vasotocin (VT) gene locus in the pufferfish, *Fugu*. Cell-specific expression of the fish IT gene was found only in the magnocellular OXT neurons in the rat hypothalamus, and this transgene could be physiologically regulated by dehydration in a manner similar to the endogenous gene. This experiment showed that there was sufficient conservation of the cell-specific expression and physiological regulation mechanisms despite an evolutionary distance of 450 My between these species.

OXT and AVP Gene Regulation and Functional Activity

OXT and AVP fibers are found throughout the CNS. However, the expression of the OXT and AVP genes occurs primarily in the hypothalamus and in the magnocellular neurons (MCNs) of the paraventricular nucleus (PVN) and supraoptic nucleus (SON) (Figure 2). There are also parvocellular neurons in the PVN that synthesize corticotropin-releasing hormone (CRH) and co-express AVP, that are secreted in the portal circulation to stimulate the release of adrenocorticotropin (ACTH) from anterior pituitary corticotropes. Parvocellular neurons in the suprachiasmatic nucleus (SCN), the central circadian clock in mammals, also synthesize AVP and are involved in regulating the

[c]Oxytocin mammals include some marsupials.

circadian rhythm of various hormones. There are other parvocellular neurons in the PVN that regulate autonomic functions via projections to the brain stem and spinal cord. Finally, some species have parvocellular neurons elsewhere, such as in the amygdala and bed nucleus of the stria terminalis, that express smaller amounts of AVP or OXT.

The MCNs in the hypothalamo-neurohypophysial system (HNS) have been the most studied with respect to the functional regulation of OXT and AVP gene expression, in large part due to their compact nuclear organization in the CNS; most of the approximately 12 000 cells in the rodent hypothalamus are located in the two bilateral nuclei, the PVN and SON (Figures 2 and 3). The HNS neurons project via well-defined axonal tracts to the posterior pituitary (i.e., the neural lobe), where each axon is estimated to branch into hundreds of nerve terminals and where these axonal branches and terminals represent about 50% of the total tissue mass of the neural lobe. The relatively easy access to the HNS cellular components, the cell bodies in the PVN and SON and the axons in the median eminence, by both stereotaxic and micropunch assay methods, and to the nerve terminals by their presence outside of the blood–brain barrier in the posterior pituitary, have made these MCNs favorite objects of many biochemical and physiological studies. Nevertheless, similar studies have been performed on other neuronal systems that express AVP (e.g., the CRH neurons in the PVN, and the AVP neurons of the SCN); these are briefly described in Table 4.

Figure 2 Immunohistochemical views: (a) vasopressinergic neurons in the hypothalamus; (b) axons in the internal zone of the median eminence; and (c) neural lobe in the posterior pituitary. In (a), the oxytocinergic and vasopressinergic magnocellular neurons in the supraoptic nucleus (SON) and paraventricular nucleus (PVN) project to their axons to the neural lobe (N; shown in (c)), and together with more lateral scattered neurons in the accessory nuclei (HI), constitute the hypothalamo-neurohypophysial system (HNS). The suprachiasmatic nucleus (SCN) contains smaller vasopressinergic (only) neurons, located dorsomedially in the nucleus, which project to the ventral region of the PVN, and is involved in the circadian regulation of various endocrine systems. The PVN also contains both oxytocin- and vasopressin-containing small (parvocellular) neurons that project to the external zone of the median eminence and more caudal CNS regions, including the spinal cord (see **Table 4**). OC, optic chiasm. Scale bar = 1 mm (a).

Figure 3 Double-labeled immunofluorescent view of oxytocin (red)- and vasopressin (green)-containing magnocellular neurons in the supraoptic nucleus (SON) of a lactating female rat. Note in this merged view that a significant number of the neurons in the SON contain both oxytocin and vasopressin. AVP and OXT mRNAs increase in the magnocellular neurons during lactation.

Mature MCNs respond to perturbations in water balance by releasing large amounts of stored AVP and OXT into the general circulation. Hyperosmotic stimuli, such as dehydration or salt-loading, result in an increase in AVP and OXT secretion and in transcription of both genes. Conversely, under hypoosmolar conditions, there is no need for either AVP or OXT secretion, and the release of these peptides is completely shut down, leading to a virtually complete inhibition of the transcription of their genes and the biosynthesis of the nonapeptides. The mechanisms that underlie these changes are still not understood. There are also two types of posttranscriptional regulation found in response to hyperosmolality. The first is an increase in length of the poly (A) tail of the AVP mRNA from around 200 to 400 nucleotides, which does not occur in the OXT mRNA. This change is found in the rat MCNs but not in the mouse. The second change is that during hyperosmolality the short poly (A)-tailed OXT and AVP mRNAs appear to be axonally transported to the MCN nerve terminals in the posterior pituitary. The physiological significance of these two changes is

Table 4 Cellular localization, functions, and physiological regulation of oxytocin and vasopressin in the CNS

Cellular localization	*Function and gene regulation*
Hypothalamic	
Hypothalamo-neurohypophysial system (HNS: PVN + SON)	Osmotic regulation: 2–3 times increase in gene expression in hyperosmolality; ~5 times decrease in gene expression in hypoosmolality
	Lactation (+suckling) and plasticity: increase in neuron soma size; increase gene expression; synaptic remodeling OXT ≫ AVP; dual expression in 15% MCNs; change in burst pattern (suckling) in OXT MCNs
Suprachiasmatic nucleus (SCN) (30% AVP neurons)	Intrinsic circadian rhythm of AVP gene expression + secretion (E box-related)
	Extrinsic factors, for example cAMP via VIP input
Corticotropin-releasing hormone parvocellular PVN neurons (mpdPVN; AVP only)	Stress-regulated increase in AVP gene expression
	Feedback via glucocorticoids inhibits AVP
Dorsal and ventromedial parvocellular PVN neurons (pPVN; OXT and AVP)	Project to brain stem, hindbrain, spinal cord, and forebrain(?)
	Integrates sympathetic anteriodorsolateral and parasympathetic outflow (preautonomic)
Extrahypothalamic	
Bed nucleus of the stria terminalis (BNST)	Local testosterone increases AVP
	Males have 2.3 times more AVP neurons than females
	Developmental effects of testosterone
	Glucorticoids have no effect
Medial amygdala (MeA)	Glucorticoids decrease AVP
	Testosterone increases AVP

AVP, vasopressin; cAMP, cyclic adenosine monphosphate; CNS, central nervous system; MCN, magnocellular neuron; OXT, oxytocin; PVN, paraventricular nucleus; SON, supraoptic nucleus; VIP, vasoactive intestinal polypeptide.

unclear, but it is generally suggested that the increased poly (A) tails produce increased translational efficiency and/or mRNA stability.

The MCNs also contain other co-expressed neuropeptides such as the opioid peptides, enkephalin and dynorphin; neuropeptide Y; CRH; cholecystokinin (CCK); and galanin. The transcription of these co-expressed peptides is also regulated by osmotic stimuli, and they are selectively expressed (e.g., dynorphin and galanin primarily in AVP MCNs, and CRH and CCK in OXT MCNs), generally co-packaged with the AVP or OXT peptides in large dense-core vesicles, and co-secreted in response to neural activity. These co-expressed peptides are secreted both from the MCN nerve terminals in the posterior pituitary and from their dendrites in the hypothalamus. In both cases, they modulate the activities of adjacent cells via either paracrine or autocrine mechanisms.

Both AVP and OXT mRNA increase in the MCNs during lactation as a result of increased gene expression. The level of the OXT mRNA during early lactation is maintained by the suckling stimuli; the removal of the pups causes a decrease in OXT mRNA. This decrease can be inhibited by intraventricular OXT infusion, suggesting that the afferent stimuli activate the OXT MCNs to release OXT from their dendrites, which then act in either an autocrine or paracrine fashion to maintain the increased mRNA levels. Later in lactation (e.g., after 10 days in rats) the increased OXT mRNA becomes less dependent on the suckling stimulus and more on the systemic steroidal milieu.

Pathological Conditions Related to OXT and AVP

Familial neurohypophysial diabetes insipidus (FNDI) is an autosomal dominant disease (rarely recessive) in which mutations in the AVP prohormone cause defects in the synthesis of AVP and, hence, result in a large increase in urine production (polyuria) and fluid intake (polydipsia). In human FNDI, mutations have been observed in either the signal peptide, the AVP moiety, or the NP moiety of the AVP preprohormone. Thirty-two different mutations have been identified in more than 40 pedigrees. The disease is dominant, so one mutant prohormone allele suffices to cause the defect, and the onset of disease symptoms takes several months or years. This suggests that the mutant human AVP prohormone somehow interferes with either synthesis, transport, or processing of the wild–type prohormone. Overexpression of mutant AVP precursors in cell lines with peptidergic properties showed that mutant proteins were largely retained in the endoplasmic reticulum (ER) and that accumulation of precursor caused morphological and probably functional derangement of the ER. These disturbances of the ER appear to be deleterious to the functionality and viability of the MCNs.

The Brattleboro (*di/di*) rat was identified as a mutant of the Long Evans strain that had a hereditary form of diabetes insipidus. This disease is transmitted as an autosomal recessive trait. This pathology was shown to be due to a lack of AVP production by the HNS. Characteristically, water resorption is greatly

impaired in the distal kidney tubules, leading to a massive loss of body fluid. The rats can excrete almost 70% of their body weight in hypotonic urine per day and compensate for the resulting dehydration by drinking an equivalent amount of water. The genetic defect of the Brattleboro rat is the deletion of a single deoxyguanosine within the second exon of the AVP gene. The resulting frame shift alters the amino acid sequence of the NP moiety from residue 64 onward and the entire glycopeptide (GP) region. Due to the new amino acid sequence, 5 of the 14 cysteine residues in NP are missing, and the stop codon within the mRNA is missing, causing translation to continue through the normally noncoding part of the mRNA into the 3′-poly (A) tail and creating a poly-lysine tail at the C-terminus of the precursor. Although the mutant AVP gene is correctly transcribed and spliced, mRNA is not efficiently translated. Therefore, it has been suggested that the expression of the mutant precursor is inhibited by a block at the translational level. In the *di/di* rat, the mutant *di* precursor can be detected in MCNs by immunohistochemistry. Immunoelectron microscopy studies showed that the mutant precursor is retained in the ER and does not reach those secretory granules.

Unlike the situation with AVP, no naturally occurring mutations of the OXT peptide or OXTR genes have been described to date. Most of our information about the consequences of OXT deficiency comes from knockout mice with targeted deletions of the OXT gene. These knockout mice give birth, and there is no apparent difficulty in parturition, although they are unable to suckle their young because the milk-ejection reflex is nonfunctional. The offspring of homozygous mothers survive only with cross-fostering with wild types. Although parturition appears normal in OXT knockout mice, there are data that indicate that OXTR antagonists slow parturition in mice and rats, and the OXT antagonist atosiban slows the onset of deliveries in women with indications of preterm labor. These observations suggest that OXT does play a subtle role in parturition.

Vasopressin and Oxytocin Receptors

Receptor Background

There are two principal classes of AVP receptors: V1 and V2 receptors (AVPR1 and AVPR2, respectively), both of which are seven-transmembrane G-protein-coupled receptors. Activation of the AVPR2 increases cyclic adenosine monophosphate (cAMP) to mediate the classic antidiuretic effects of AVP. The two AVPR1s are coupled to $G_{q/11}$ guanosine triphosphate (GTP)-binding proteins, which along with $G_{\beta\gamma}$ activates phopholipase C (PLC) activity. PLC then generates 1,4,5-inositol triphosphate (IP3) and diacylglycerol (DAG) from phosphatidylinositol 4,5-bisphosphate (PIP2). IP3 facilitates the release of intracellular Ca^{2+} stores, whereas DAG activates protein kinase C to modulate cellular activity. There are two subtypes of the AVPR1: AVPR1a and AVPR1b. In the periphery, AVPR1a mediates the effects of AVP on vasoconstriction and can be found in the liver, kidney, platelets, and smooth muscle. Centrally, AVPR1a is found in a variety of brain nuclei where AVPR1a has been implicated in the regulation of several social behaviors, including social recognition, affiliative behavior, aggressive behavior, and scent-marking behavior.

The AVPR1b (sometimes called V3R) was originally described in the pituitary and finally cloned. Subsequently, AVPR1b was also found in the brain as well as in several peripheral tissues. More recently, AVPR1b has been linked to stress adaptation and aggressive behavior in mice. There is no conclusive evidence for expression of the AVPR2 within the CNS. Transcription of the Arhgap4 gene within the CNS overlaps the AVPR2 and reverse transcriptase–polymerase chain reaction (RT-PCR) analysis must use specific conditions to avoid this contaminant.

Recent work indicated that there are other proteins in the brain that bind AVP (Table 5). The AVP-activated Ca^{2+}-mobilizing receptor protein (VACM-1; Cullin-5) and the dual angiotensin II/vasopressin receptors have widespread neuronal distributions. The former receptor is coupled to the phosphoinositol pathway and the latter to the adenylate cyclase system. The roles of these receptors in the brain, including behavioral roles, are unknown; however, levels of Cullin-5 increase in the cerebral cortex and, to a lesser extent, in the hypothalamus following water deprivation.

The single OXTR appears to transduce the actions of OXT. This receptor was first isolated and identified by Kimura and colleagues. The OXTR is also a member of the G-protein-coupled receptor family. Like other members of this family, the OXTR contains seven transmembrane domains and is similar in structure to the AVP receptors. The OXTR is also coupled to $G_{q/11}$ GTP-binding proteins and $G_{\beta\gamma}$ to cause the hydrolysis of phosphatidylinositol and act through pathways similar to the AVPR1s. Table 5 summarizes genetic information about AVP, OXT, and their receptors.

Central Nervous System Distribution

The distribution of AVPR1a expression within the CNS has been studied primarily using receptor autoradiography and hybridization histochemistry. Receptor autoradiography identifies the locations of binding to the receptor protein, whereas hybridization histochemistry

Table 5 Gene information about vasopressin and oxytocin receptors

Gene	*Species*	*Official gene symbol*	*Chromosome*	*Known exons*	*Amino acids*	*Locus ID*[a]
Vasopressin 1a receptor	Human	AVPR1a	12 (q14–q15)	2	418	552

identifies the cells that transcribe the receptor gene. The former technique was greatly facilitated through the use of specific and potent ^{125}I-labeled AVPR1a antagonists. Prominent AVPR1a binding is present in the rat lateral septum (LS), neocortrical layer IV, hippocampal formation, amygdalostriatal area, bed nucleus of the stria terminalis (BNST), various hypothalamic areas (including the suprachiasmatic nucleus (SCN)), ventral tegmental area, substantia nigra, superior colliculus, dorsal raphe, nucleus of the solitary tract, and inferior olive. AVPR1a binding is moderate throughout the spinal cord, but it has higher binding in the dorsolateral motor neurons in general and all motor neurons in the lumbar 5/6 levels where innervation to the perineal muscles originates.

Neurons containing AVPR1a transcripts are found extensively throughout the rat CNS, being especially prominent, for example, in the olfactory bulb, hippocampal formation, LS, SCN, PVN, anterior hypothalamic area, arcuate nucleus, lateral habenula, ventral tegmental area, substantia nigra (pars compacta), superior colliculus, raphe nuclei, locus coeruleus, inferior olive, area postrema, and nucleus of the solitary tract. Transcripts are also detected in the choroid plexus and endothelial cells. The distributions of AVP (and OXT) binding have been examined in a number of rodent species, and they are remarkably similar. Differences in binding in selected areas may mediate important adaptations or behavioral traits, however; these differences are mentioned in the article when correlations are possible.

The AVPR1b was originally described in the anterior pituitary, where it facilitates the release of adrenocorticotropin (ACTH) from the corticotropes. AVPR1b in the pituitary helps mediate the effects of AVP on the hypothalamic–pituitary–adrenal axis, which is the regulator of the stress response in mammals. AVPR1b mRNA is also found in a variety of peripheral tissues, including the kidney, thymus, heart, lung, spleen, uterus, and breast, although its role in these tissues remains unclear. Only recently have AVPR1b transcripts, as well as AVPR1b immunoreactive cell bodies, been found in the rat brain, including in the olfactory bulb, piriform cortical layer II, septum, cerebral cortex, hippocampus, PVN, SCN, cerebellum, and red nucleus. A more recent study with probes with minimal cross-hybridization potential with the OXTR or AVPR1a transcripts indicates a more restricted presence in the mouse and rat brains, being especially prominent in the CA2 field pyramidal neurons of the dorsal hippocampus. It should be noted, however, that AVPR1b distribution has not been mapped by receptor autoradiography due to the lack of a specific radiolabeled ligand.

Some very provocative work has focused on interspecies and individual variations in the AVPR1a promoter of voles. Across vole species, there are profound differences in social structure and behavior. Prairie voles

(*Microtus ochrogaster*) and pine voles (*Microtus pinetorum*) tend to be social and monogamous, whereas montane voles (*Microtus montanus*) and meadow voles (*Microtus pennsylvanicus*) tend to be asocial and polygamous. These social behaviors are mediated, at least in part, by AVP action on the AVPR1a. There are striking differences in the distribution and density of AVPR1a among these species, and they are postulated to regulate this behavior.

Initially, the location of OXTR expression was determined by receptor autoradiography, using a potent and specific ^{125}I-labeled antagonist. In the rat, OXT binding is found in numerous regions, especially in the hippocampal formation (ventral subiculum particularly), LS, central amygdala (CeA), olfactory tubercle, accumbens nucleus shell, dorsal caudate putamen, BNST, medial amygdala (MeA), and ventromedial hypothalamus (VMH). Binding in the spinal cord is light and confined to the superficial dorsal horn.

Hybridization histochemistry reveals OXTR transcripts in many areas of the rat CNS, including the main and accessory olfactory bulbs, neocortical layers II and III, piriform cortical layer II, hippocampal formation, olfactory tubercle, BNST, medial habenula, VMH, PVN, and SON. Expression is lower in the midbrain, pons, and medulla. Recently, an OXTR-LacZ reporter mouse showed additional OXTR gene expression in the medial septum, parts of the amygdala and mammillary nuclei, and some brain stem nuclei.

The distribution of the OXTR is highly species specific, as is elegantly illustrated in receptor binding differences between two closely related species of voles, the polygamous montane vole and the monogamous prairie vole. Differences in the distributions of the OXTR have also been shown among mice, rats, voles, hamsters, and guinea pigs. These differences in OXTR distribution across species are thought to convey differing behavioral phenotypes. For example, variation in accumbens nucleus OXTR appears to be responsible for spontaneous maternal behavior in virgin female prairie voles.

Experimental Approaches

New pharmacological agents as well as new transgenic and knockout agents promise to expand our understanding of roles of AVP and OXT in the brain. Pharmaceutical companies are devising new agonists and antagonists, including orally active ones, for both medical and research purposes. The linear AVPR1a antagonist HO-LVA has proved to be a useful radioligand for receptor autoradiograhic studies and the orally active AVPR1a antagonist SRX251 shows promise as a serenic by reducing aggression. The AVPR1b antagonist SSR149415 is being investigated as an agent potentially useful in reducing anxiety and depression. It has also been used to confirm the role of the AVPR1b in aggression indicated through knockout studies. Orally active OXTR agents are undergoing studies to determine their value in parturition, although potential behavior consequences will have to be closely followed (e.g., maternal behavior).

Transgenic approaches, especially with knockout lines, are proved to be quite useful. L Young and colleagues showed that the expression of AVPR1a from the monogamous vole in a similar pattern in the mouse produces an increased affiliative response, and they suggest that changing the distribution of a receptor may be an efficient means of changing behavior evolutionarily.

The least well understood of the OXTR and AVPRs, the AVPR1b, was the first one inactivated by homologous recombination in mouse. This mouse line shows decreased social aggression, social recognition, and social motivation. This receptor is abundant on adrenocorticotropes in the pituitary, so it is not surprising that knocking out this gene also blunts the hypothalamic–pituitary–adrenal response to stress. They have also been reported to display a disruption of an animal behavior that is abnormal in schizophrenics, the prepulse inhibition of the startle reflex. These mice also have reduced insulin release from isolated pancreatic islet cells, but fasting blood glucose measurements are normal.

The behavioral effects of the AVPR1a have proved variable between sexes and among labs. The same line (with a different background) showed reduced anxiety-like behavior in males only, as well as reduced social recognition, in one lab, whereas another lab found those behaviors to be normal but observed deficits in olfaction and circadian rhythms. Mice without this receptor have also been shown to have impaired cardiovascular function with reduced blood pressure and baroreceptor reflexes, as well as impaired spatial memory.

Finally, the OXTR knockout has been knocked out. As was seen with the OXT knockouts, female mice were able to deliver their young but not lactate; they also showed poorer nurturing. Adult OXTR knockout males showed decreased social recognition and discrimination and increased aggression, as well.

Vegetative State

B Kotchoubey, University of Tübingen, Tübingen, Germany

© 2009 Elsevier Ltd. All rights reserved.

Definition

Vegetative state (VS) is a state of consciousness characterized by preserved sleep–wakefulness cycle and intact subcortical functions, on the one hand, and the complete lack of subjective awareness, on the other hand. The term 'complete lack' is important, meaning that there is not the slightest feeling such as pleasure versus unpleasantness, etc. Even a minimal sign of any subjective experience or mental process excludes the diagnosis of VS, indicating that the individual is in another state, such as a minimally conscious state (MCS).

The same pathological condition was formerly referred to as 'apallic syndrome,' from the Greek *a-pallic*, meaning 'without cortex.' The notion of apallic syndrome could be directly tested by examining the morphology of cortical damage and the level of the disturbance of cortical functions. As discussed later, VS patients are not apallic; that is, their cortical functions may or may not be lacking. (The opposite is also true: Children born decorticated are not necessarily vegetative.) Hence, the term apallic has been abandoned. Since subjective experience, in contrast to cortical functions, cannot be observed, the notion of VS cannot be directly tested in a similar way.

Therefore, VS is a construct in need of operationalization. Due to this intrinsic problem of addressing first-person events (i.e., subjective awareness or the lack thereof), some authors criticize the notion of VS as inconsistent. The accepted criteria include the following: no evidence of awareness of oneself or one's environment; no evidence of reproducible, purposeful, or voluntary responses; no evidence of language comprehension; and no volitional response to stimuli. This implies that each diagnosis of VS is a philosophical enterprise because the physician should be able to define such concepts as 'purposeful,' 'voluntary,' or 'volitional.' Therefore, the diagnostic process in VS differs considerably from what is usual in neurology. Thus, a chief neurologist can say to his assistant, "go to patient X and check her tendon reflexes," but he cannot say "go to patient Y and check her self-awareness" or "go to patient Z and check if her will is free."

Another problem is that the main diagnostic criteria of VS are negative. What determines the diagnosis is the lack of a certain kind of responses. There is hardly any positive symptom of VS, except the periods of wakefulness which distinguish it from coma.

Occurrence, Etiology, and Time Course

The prevalence of VS in industrial countries is estimated to be 10–100 per 1 million, depending on the inclusion criteria, the level of the development of intensive care, and the frequency of severe brain injuries.

Usually, VS develops from an acute coma; a primary VS (e.g., in dementia) is much less frequent. The most common causes for such a comatose state, later leading to VS, are mechanical head injury, intracranial bleeding (mainly subarachnoidal hemorrhage), and brain anoxia (mainly after cardiac arrest). Approximately 10–15% of all severe (>6 h) coma patients remain vegetative.

VS lasting for more than 1 month is defined as persistent VS (PVS). The Multi-Society Task Force proposed in 1994 the term 'permanent' for VS that persists longer than 1 year or 3 months for traumatic and nontraumatic PVS, respectively. Most recent authors, however, agree that this term should be avoided because it confuses diagnosis and prognosis. In fact, the chances of regaining consciousness after this time (i.e., 1 year for head injuries and 3 months for other causes) are rather low but not equal to zero. Scientific journals have published several well-documented cases of improvement after 15–20 months and even 5 years in PVS. A case of a considerable restoration of functions after 19 years in MCS has been documented and thoroughly investigated. Although most commentators suggest that no such late improvement is possible in PVS, the exact shape of the function relating improvement probability to time, and particularly the point at which this function approaches zero, remains unknown.

Some factors which this function depends on can, nevertheless, be determined. Favorable prognostic factors are young age; traumatic compared to nontraumatic etiology; and a moderate extent of the axonal injury, particularly in the corpus callosum and the dorsolateral brain stem.

Most patients emerging from a prolonged VS remain considerably disabled with regard to their motor (e.g., paralysis) or cognitive functions (e.g., amnesia) or both. As a rule, the later the recovery, the more severe disability remains. This does not mean, however, that a life at this level of disability cannot be of value.

Neuropathology

The morphology of the lesion in traumatic VS involves multiple bleedings in different brain regions

and severe diffuse axonal injury (DAI) leading to the break of interneuronal connections. The most severe DAI is observed in the corpus callosum, upper brain stem (pontine tegmentum and cerebral peduncles), frontotemporal white matter, and the corona radiata. Damage to gray matter is mostly concentrated in the thalamus and basal ganglia, whereas the cortical gray matter can be largely preserved.

The neuropathology of nontraumatic VS is less investigated. Unlike traumatic VS, severe laminar necrosis with considerable neuronal loss in cerebral hemispheres and the hippocampus is depicted, whereas brain stem structures are usually intact. Like traumatic VS, however, thalamic lesions are also frequently found in anoxic and ischemic VS. In some patients, the damage is limited to the thalamus and basal ganglia, with only minimal neocortical lesions.

Therapy

There is no 'gold standard' of therapy in VS that would satisfy the strict criteria of evidence-based medicine. Several methods have been proposed which can roughly be subdivided into four categories. Pharmacological therapy mainly uses activating substances such as tricyclic antidepressants or methylphenidate. Promising results have been reported with dopaminergic drugs, particularly amantadine. Dopaminergic medications such as L-DOPA are especially effective in VS patients with concomitant parkinsonian symptoms (tremor, rigidity, and akinesia) and the corresponding lesions in the dopaminergic pathway. Unfortunately, such patients constitute a relative small subsample of VS patients. Pharmacological interventions appear to be more efficient during the early stage of the disease.

Invasive treatment includes peripheral nerve stimulation (with implanted electrodes or transcutaneously) and deep brain stimulation through electrodes implanted in the medial thalamus or, rarely, the mesencephalic reticular formation. Physical therapies are usually of palliative character and directed at improving posture, preventing contractures, and obtaining a general increase in arousal level. Finally, a very broad range of stimulation techniques includes unimodal and multimodal sensory stimulation, sensory regulation, music and musicokinetic therapy, and social–tactile interaction.

In general, most treatment studies published to date are poorly controlled, many of them being single-case observations. This makes definite conclusions impossible. The first randomized controlled trial of amantadine versus placebo is under way.

Electrophysiological Measures of Cortical Activity

General patterns of the EEG vary widely among VS patients, from a consistent α rhythm to diffuse δ waves or (exceptionally) low-voltage or even isoelectric EEG. Most commonly, slow rhythms of 4–8 Hz dominate; usually they are not blocked by light. This background activity strongly correlates with event-related potentials (ERPs) reflecting cortical processing of stimulus information. Among patients with the predominant 4–8 Hz ('benign EEG'), virtually all have cortical responses to auditory stimuli (vertex N1 component of the ERP), and many possess late ERP components. Moreover, N1 habituates with stimulus repetition, indicating a simple learning process (learning to not respond to insignificant stimuli) in the primary auditory cortex. The late components are still more frequent in patients with reactive α or θ rhythm. On the other hand, among patients with pronounced δ activity or low voltage ('malign EEG'), only a few have a vertex N1 response, and the components later than N1 rarely occur.

One of the most important late ERP components is the parietal P300, a typical brain response to target stimuli. In VS, as in acute coma, a reliable P300 can be obtained in approximately one-third of patients with benign EEG. Another late ERP component frequently observed in VS is mismatch negativity (MMN), which indicates the ability of the auditory cortex to tonal differentiation. Interestingly, the MMN is obtained in VS patients significantly more often, and with a significantly larger amplitude, in response to complex harmonic tones than simple sine tones – a finding which suggests that testing unconscious patients with very simple stimuli may lead to an erroneous conclusion of their cortical 'nonresponsivity.' Two independent prospective studies found that VS patients with an MMN more frequently emerge from the VS 1–6 months after the ERP examination than patients without it. This concurs with the predictive role of the MMN also demonstrated in acute coma.

An ERP sign of semantic processing is the late negative wave N400, which is recorded in healthy individuals to all meaningful words and whose amplitude is shown to be a strong inverse function of the *a priori* probability of the word in the given context. The N400 to semantically inappropriate words (context mismatch) can also be obtained in some VS patients, indicating the ability of the patients' brain to analyze word meaning.

Metabolic Measures of Brain Activity

The average rate of brain metabolism in VS patients is estimated to be less than 50% of that in healthy

controls. This decrease is even stronger than in acute coma and nearly equal to that in profound anesthesia. The metabolic rate is particularly low in the cortex; in subcortical structures it can be higher than in coma but still much lower than in controls. Unfortunately, from the standpoint of diagnostics and research, the large average difference between VS and conscious patients is countereffected by the considerable variance. Some VS patients have a metabolic rate higher than that of patients with intact consciousness, and some healthy students exhibit metabolic activity as low as that in VS.

Also very large is the variance between the metabolic rates in different cortical areas. Many VS patients with extremely low average metabolism show isolated cortical regions with normal or heightened activity. These regions of local activity vary from patient to patient and, most interestingly, appear to correspond to patients' behavior (e.g., a patient with a high metabolic rate in the speech areas frequently uttered single words).

Not only can cortical areas in VS patients be metabolically active but also their activity can be modified by appropriate stimulation. Single case studies in the late 1990s showed that local metabolic activity increases in response to meaningful stimuli (human voice and faces) compared with meaningless stimuli (sounds and chaotic visual patterns). Later studies with larger samples indicated that this activity is usually limited to primary sensory areas, whereas in MCS patients it extends to broader areas comparable to those activated in controls. A connectivity analysis showed that strong positive connections between different brain regions typical for healthy subjects can be lacking or even become negative in VS patients. There are also indications that regaining consciousness is accompanied by restoration of the normal connectivity. On the other hand, this restriction of activation to the primary cortical areas may be a function of simple stimulation because a few studies employing more complex stimuli suggest that higher-level cortical regions (e.g., the fusiform gyrus) can also be activated in VS patients.

To summarize, the results of electrophysiological and metabolic studies are in good agreement. Both demonstrate that large regions of cortical activity can remain intact in VS patients, indicating that at least in some of them the cortex is able to perform a complex analysis of stimulus information including an analysis of word meaning. A possible disagreement concerns major qualitative differences between patient subgroups. Whereas in metabolic studies the largest difference tends to coincide with the clinical distinction between VS and MCS, electrophysiological studies frequently find larger differences in cortical reactivity within the groups of VS and MCS patients. Neither finding directly indicates the presence of conscious awareness because cortical processing, even at the semantic level, can occur subconsciously.

Vegetative State and Neural Correlates of Consciousness

After several decades of ignoring, the modern psychology and neuroscience are presently actively interested in the problem of human (and animal) consciousness. From an analytical perspective, conscious phenomena are frequently subdivided into dynamic aspects versus content aspects, wakefulness versus awareness, or nontransitive consciousness('just consciousness') versus transitive consciousness ('consciousness of'). The transitive consciousness is further subdivided into simple sentience (pain, pleasure, sensitivity to colors, sounds, etc.) and self-awareness (including self as the agent of actions, thinking, etc.). From this point of view, VS presents the model of dissociation between the transitive and nontransitive consciousness: By definition, patients are awake but not aware of anything. Investigations of VS can therefore clarify the issue of neural correlates of consciousness (NCC). Namely, because VS patients do not possess subjective experience, any brain activity found in these patients can be eliminated from the list of possible NCC, and any brain region remaining intact in VS is therefore not a seat of subjective awareness. Conversely, those brain processes and brain activations which are lacking in VS but present in patients with preserved elementary consciousness (e.g., MCS) are candidates for the role of NCC.

This unbeatable logic, however, is based on two important assumptions: (1) that the definition of the VS is consistent, and (2) that the rate of diagnostic errors is low enough to neglect, when comparing VS and MCS groups, the possibility of some patients being incorrectly assigned. As stated previously, the former assumption is regarded by many authors as problematic and the latter is blatantly wrong. Thus, VS research cannot directly identify brain mechanisms of awareness, but it can yield useful hints which should be compared with other indications based on *a priori* or *a posteriori* criteria.

A priori criteria are such that if a being fulfills them, everybody will believe that the being is conscious. An example of such a criterion is that the being's responses follow our complex verbal instruction. The problem with these criteria is their high conservatism. Thus, the ability to follow verbal instructions proves not sentience but self-awareness and concentrated attention. *A posteriori* criteria are those we develop from the results of empirical studies of consciousness beyond

the VS domain (e.g., studies of sleep, anesthesia, and brain responses to subliminal stimuli).

Three completely different cases must be separated when we discuss the issue of 'conscious awareness in VS.' First, it is possible that patients are conscious just because they are misdiagnosed; they are not in VS. Second, patients correctly diagnosed as VS can demonstrate signs of consciousness because they are examined at the beginning of recovery. Finally, it cannot be excluded that some day we will have to modify our definition of VS in such a way that admits some VS patients possessing elements of subjective awareness. Although these possibilities may be difficult to disentangle in some patients, they should at least be clearly distinguished at the logical level. The main difference is that in the last two cases, only elementary consciousness (e.g., pain or pleasure) can be present, whereas in the first case (diagnostic error) a patient may even possess high levels of reflexive awareness.

An example of the confusion in this domain is a study, broadly commented on in scientific journals and magazines, in which VS patients were told to imagine either playing tennis or walking through their apartment. Surprisingly, one patient demonstrated distinct patterns of brain activation (recorded with functional MRI) over precentral and parietal regions during the two instructions, respectively. Consistently following verbal instructions during several trials requires high concentration. Even subjects with slightly disturbed consciousness (e.g., healthy but extremely tired individuals) would not be able to produce such a result. Therefore, the patient in question was obviously misdiagnosed; perhaps she was in a locked-in state. Nonetheless, all commentaries ignored this simple fact and claimed that the data 'reveal consciousness in VS.'

Several theoretical attempts have been undertaken to integrate VS findings into the broader context of the present-day *a posteriori* evidence of NCC. These attempts are summarized in the following hypotheses:

1. Consciousness requires, at least, the activity of secondary sensory and associative regions of the cortex. Accordingly, VS is characterized by the lack of activity in these 'higher-level' areas despite the preserved activity in the primary sensory and motor areas.
2. The substrate of consciousness is not particular brain regions but a widely distributed network of synchronized activity across many cortical regions. Accordingly, VS is primarily a disconnection syndrome in which various cortical areas and local processing modules remain working, but their integration is lacking.
3. Consciousness depends on the functioning network linking the medial parietal structures (posterior cingulum and precuneus) with the thalamus and prefrontal cortex.

The three hypotheses are partially, but not completely, compatible with each other; each can be supported by many, but not all, empirical findings. Thus, a frequently cited PVS patient, consistently demonstrating both behavioral and neurophysiological evidence for preserved activity in Broca and Wernicke areas, is a case for hypothesis 2 but against hypothesis 1. Possibly, each hypothesis explains only a subset of all VS patients, and the subsets covered by different hypotheses partially overlap.

The Problem of Pain Sensation

The postulate that vegetative patients cannot experience pain and suffer is particularly controversial since numerous ethical issues depend on it. The empirical basis of this controversy is rather narrow. Modern neuroimaging studies indicate that pain perception is associated with the activity in several cortical areas, including the primary and secondary sensorimotor cortex, insula, operculum, the anterior cingulate gyrus, and possibly also the supplementary motor area and the prefrontal cortex. These areas are not typically damaged in VS. On the other hand, the subcortical structure most closely related to pain sensation is the thalamus, and thalamic lesions are very frequent in VS. Therefore, one may assume that the thalamic pathology is critical for the presumable loss of pain experience in VS. To the author's knowledge, two studies directly addressed this issue by recording changes in brain metabolism during painful stimulation. One of them (with 15 VS patients) found significant responses to pain stimuli in each patient, comparable with the corresponding responses of control subjects, in the thalamus and the primary sensorimotor cortex but not in other pain-related structures. In the other study, in contrast, seven VS patients did not exhibit any response to pain in the thalamus; however, significant responses were obtained in the primary and secondary somatosensory cortex, posterior insula, postcentral gyrus, and the cingulate cortex. The issue of possible pain sensation in VS is thus still open; in any case, as the authors of the latter study concluded, "a residual pain-related cerebral network remains active in long-term PVS patients."

Ethical Issues

MEDLINE lists 423 publications on VS between January 2005 and March 2007; 215 of them (51%) were devoted to ethical aspects of the syndrome,

compared to less than 2% that concerned the neuropathology of VS. These data demonstrate how important the ethical considerations on VS are publicly regarded.

A common mistake is that the ethical discussion is being carried out between particular institutions – in the simplest version, 'the modern science' and 'the Church,' each defending a particular ethical position. The opposite is true: Almost every position is represented within each institution participating in the discussion. Even within the Catholic Church, with its tradition of subordination to authorities, opinions of various theologians and bishops vary widely. This holds true even more so for other congregations, such as Protestants or Jews, for which no Vatican-like institution exists.

The most important ethical issue concerns the possibility and necessity of life-prolonging measures, such as artificial nutrition and hydration (ANH), in chronic PVS. If ANH is a medical intervention (as many, but not all, medical and religious authorities believe), it can and in some cases even should be withheld or withdrawn. If it is a part of simple care, like feeding (the view held, for example, by Pope John Paul II), its withholding or withdrawal can be regarded as killing by omission. Another aspect concerns the chances of VS patients to regain consciousness. Whenever these chances are sufficiently high, all life-prolonging interventions appear ethically justifiable. Unfortunately, all empirical statements are probabilistic; that is, they describe populations and not individual patients. Thus, even if we knew that the chance of clinical improvement for a given PVS patient is, for example, 1 in 100, this would not prevent the family of the patient from hoping that 'their patient' is that 1 in 100.

The third aspect of the problem of ADH withdrawal relates to the alleged inability of VS patients to suffer. Obviously, the claim that a patient is completely unable to experience any aversive sensation is very strong and difficult to prove. However, any level of uncertainty in this question is unacceptable because if only a slight subjective experience is possible, the patient would die in tantalizing agony. Only a few decades ago, many believed that newborns could undergo surgery without anesthesia because they were unable to experience pain.

A different, though related, ethical issue is not about treatment and care but, rather, about scientific investigation of VS patients. An important ethical rule states that patients unable to give informed consent may only participate in experiments if they can themselves benefit from the participation. If, however, the results can be used not for the participants but for other patients, the study is unethical because it implies that some humans are exploited, without their consent, for the sake of other humans. Another rule states that a decision under uncertainty should be based on the best available knowledge, even if it is not exact. Both rules appear reasonable, but in combination they lead to a paradox. According to the second rule, we may withdraw ANH even if we are not completely sure that the patients would not suffer. According to the first rule, however, we cannot perform experiments to clarify the question of whether they do not suffer because such experiments would use aversive stimuli applied on a group of patients, whereas the results would probably be useful only for the next generation of patients. Thus, from the standpoint of formal ethics, letting patients starve may be more ethical than presenting them with slight electrical shocks.

Neuroscience alone cannot resolve these ethical problems because they are based on conceptual questions that are, at least partially, beyond empirical research: What is person? Which value is higher – the life of a person or his or her autonomy? What are the appropriate costs for helping a severely ill patient, and must such a patient be cured at any price, even at the price of depriving many other patients of the therapy they need? However, empirical knowledge is necessary, although not sufficient, for ethical decisions because on the basis of wrong knowledge, even the best intentions can result in increased harm and suffering of other people. This happens because ethics is about means, not about ends. If one's intentions are the best, one can nonetheless be unethical if one use wrong means, and this occurs when one do not know the right means. Therefore, to paraphrase Francis Bacon, knowledge is ethical.

Thus, we should distinguish between the two things. Using VS patients to study general problems (e.g., the nature of consciousness) is unethical unless these studies are beneficial for participating patients. However, research on VS patients to enhance our knowledge about their condition (i.e., VS) is ethical by definition unless the potential harm of the examination outweighs the potential increase in knowledge. Do we now prohibit pain research on VS patients because we believe that weak electrical stimulation can seriously harm them or, rather, because we are afraid to obtain results putting our previous knowledge, and our previous practice, in question?

VelociGene and VelociMouse: High-Throughput Approaches for Generating Targeted Mutations in Mice on a Genome-Wide Scale

D M Valenzuela and G D Yancopoulos, Regeneron Pharmaceuticals, Tarrytown, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The sequencing of the human and mouse genomes, which resulted in the identification of thousands of genes whose function had not yet been explored, provided an exciting new challenge for the scientific community. Because engineering-specific gene mutations in mice is perhaps the most powerful way to explore mammalian gene function, major new efforts were initiated with the goal of generating defined mutations for every gene in the mouse genome. Unfortunately, available technologies at this time did not allow for such large-scale efforts. Until this point, engineering mutations in mice was usually carried out for a single gene at a time because each gene mutation required highly customized, laborious, and time-consuming efforts by a highly skilled practitioner. The new initiatives intended to dramatically change the scale at which targeted mouse genetics could be carried out. In the United States, leaders in the field proposed the Knockout Mice Project (KOMP), soon followed by a funding initiative from the National Institutes of Health (NIH). Likewise, European Union scientists proposed and received funding for the European Conditional Mouse Mutagenesis. Additional major initiatives were set forward, such as the North American Conditional Mouse Mutagenesis Project sponsored by Canada. Some of these efforts proposed utilizing random gene trap methodology, which could approach the scale envisioned but which would not allow deliberate targeting and custom engineering of a gene of interest. The ability to generate custom gene mutations in a specific target gene, but scaled to efficiently allow mutation of every gene in the mouse genome, would require development of new technologies.

The deliberate engineering of custom mutations in a specific mouse gene requires the genetic modification of mouse embryonic stem (ES) cells by approaches that utilize the built-in homologous recombination machinery of the mammalian cell. The first step in this process requires construction of a DNA 'targeting vector' that contains the desired genetic alteration, which can then be transferred into the cell via homologous recombination. For example, the deliberate deletion of a gene's entire coding region requires the construction of a targeting vector containing 'homology arms' corresponding to the sequences just upstream and downstream of the desired deletion, with the region to be deleted replaced with a selectable gene (e.g., a Neo gene encoding G418 drug resistance) and perhaps a reporter gene (e.g., β-galactosidase). Construction of the targeting vector has traditionally relied on highly skilled personnel using standard but laborious and time-consuming molecular biology techniques, such as restriction enzyme digestions, ligations, Southern blot hybridizations, and long-range polymerase chain reaction (PCR). After a targeting vector is introduced into ES cells by electroporation, the homologous recombination machinery of the cell matches the targeting vector homology arms with endogenous chromosomal sequences and performs double homologous recombination that results in the replacement of the endogenous target sequence with the introduced sequence in the targeting vector. Correct targeting is a rare event, and a larger proportion of cells incorporate the targeting vector in a nontargeted, random fashion. Both random and correctly targeted cells generate clones in the appropriate selection medium, so the surviving clones need to be genotyped to identify the correctly targeted ones, a process that traditionally relied on highly customized assays individually developed for each targeting experiment. As in the case of targeting vector construction, genotyping methods usually employ labor-intensive molecular technologies such as Southern hybridization and/or long-range PCR. Using these traditional approaches, the generation and screening for targeted mutations in ES cells is a highly customized and laborious process for each gene of interest.

Once an ES cell carrying the desired mutation is generated and identified, production of mice from this ES cell using conventional technologies is also quite tedious and time consuming. Conventional technologies involve injection of the targeted ES cell into the cavity of normal blastocyst-stage embryos ('host embryos'), which results in the generation of mice that are composed of cell lineages derived from both the injected ES cells and the normal host embryo and therefore are chimeric in nature. The resulting chimeras are not useful for phenotypic studies and need to be bred to wild-type animals of appropriate coat color to test for germ line transmission of the correct genotype. Thus, for an average experiment, 6–12 or more chimeras need to be crossed, their progeny genotyped, and the resulting heterozygous mice, if any, crossed to generate homozygous animals in large

enough numbers to be able to perform phenotypic studies. In many cases, the mice need to be crossed even further and for several generations to be able to bring the modified alleles into an appropriate genetic background suitable for phenotyping. In all, the mouse breeding necessary to generate useful cohorts may take from 6 months to several years. The problem is even more acute when 'conditional' knockouts are required or when the effect of two or more genetic modifications in the same mouse needs to be studied – for example, when generating polygenic models or conditional mutations under the control of a regulated gene such as CreERt2. The additional genetic complexity usually requires even further crosses, sometimes using complicated breeding schemes.

Using this traditional albeit time-consuming and cumbersome set of technologies, many targeted mouse lines have been successfully generated and analyzed, including targeted mice for many genes of neurological interest, such as for the neutrotrophic factors nerve growth factor, brain-derived neurotrophic factor, neurotrophin-3, neurotrophin-4, ciliary neurotrophic factor, and glial cell line-derived neurotrophic factor, which provided incredible insights into the normal roles of these gene products in the mouse. However, due to the limitations outlined previously, these technologies are eminently unsuitable for high-throughput production and even the most talent-laden and well-resourced research laboratories could only produce a handful of targeted mouse lines per year.

Thus, in order to meet challenges of the magnitude proposed by the international mouse knockout initiatives, it was necessary to develop transforming technologies that would allow targeted mutations on a genomewide scale in the mouse. VelociGene and VelociMouse represent important new technological approaches, developed in direct response to these challenges, that have resulted in dramatic compression of the time and effort required to generated phenotypable mice and thus have revolutionized the technology landscape for the generation of genetically modified mice. These technologies were selected by the NIH to play a major role in the genomewide KOMP initiative.

VelociGene: High-Throughput Gene Targeting in ES Cells

Just as development of the automated DNA sequencer enabled large-scale efforts that succeeded in sequencing the entire genome, high-throughput approaches were necessary to address the next major challenge of assigning function to the entire set of genes within the genome. In order to overcome the limitations of conventional approaches to gene targeting in ES cells, VelociGene introduced two critical advances: (1) the use of bacterial homologous recombination (BHR) to rapidly create large numbers of large targeting vectors from bacterial artificial chromosomes (BACs) and (2) the use of these BAC-based large targeting vectors to efficiently generate and screen for mouse ES cells carrying the desired mutations.

Generating Large Targeting Vectors

Early advances exploited BHR so as to modify large plasmids, such as BACs, by allowing controlled and transient homologous recombination in BAC-bearing bacteria. This is achieved by introducing a plasmid containing the coding sequences of three λ phage proteins that mediate homologous recombination in *Escherichia coli*, red exo (alpha), red bet (beta), and gam (γ) under the control of the arabinose promoter, allowing transient and highly regulated expression of their encoded recombinogenic proteins (**Figure 1(a)**). Working together, these proteins have the ability to perform homologous recombination between a linear segment of DNA and a circular plasmid such as a BAC containing a segment of mouse chromosomal DNA with the target gene. For this to occur, the linear DNA segment is configured to contain some operative sequences, such as an antibiotic selection marker flanked by homology 'arms' identical to sequences present in the intended BAC target (**Figure 1**). Under appropriate antibiotic selection, only bacteria containing the intended BAC modification (e.g., a deletion of the target gene exon) can be obtained and their DNA used for ES cell targeting. In this way, VelociGene taps into a powerful BHR mechanism to generate large targeting vectors in a single overnight reaction, without the need for extensive, multistep, skill-intense molecular biology work.

The advantages of generating BAC-based targeting vectors using BHR are of great significance: BACs have high stability, may propagate up to 300 kb DNA, and can be easily produced and isolated. Thus, a BAC containing a full gene, or an array of multiple genes, can be modified to delete a single nucleotide, a single functionally significant domain, or a full family of genes with essentially the same amount of effort. Also, because of the dramatic simplification of the technical manipulations, many BAC-based targeting vectors could be generated simultaneously in an assembly-line fashion. Thus, standard, premade, off-the-shelf cassettes containing the appropriate reporter gene and selection genes can be prepared for BHR by ligating homology arms (easily made by PCR) and then used as linear molecules to electroporate into recombinogenic bacteria containing the BAC intended

Figure 1 VelociGene vector construction and targeting screen. (a) A reporter selection cassette (in this example containing β-galactosidase (LacZ) and Neo) with homology arms corresponding to flanking areas of the target gene is electroporated into a bacteria containing the target BAC and recombinogenic proteins (red alpha, red beta, and gam). The appropriate antibiotic selection scheme results in the generation of a targeting vector. (b) The targeting vector is then linearized and electroporated into ES cells and the cells are subjected to selection, in this example by using G418. (c) The genomic DNA from resistant ES cell clones are subjected to a quantitative PCR loss-of-allele (LOA) assay which compares the amplification of the target gene to reference genes. Cells which have undergone specific targeting lose one of their targeted alleles with respect to the reference gene, and this is reflected as an increase of one PCR cycle (ΔC_T) compared to the reference genes. The right panel shows a sample LOA screening of a 96-well plate, which shows five identified targeted clones.

for modification. A simple antibiotic selection scheme will result in the production of the desired BAC targeting vector.

However, in order to use these BAC-based, long targeting vectors to modify ES cells, a seemingly intractable problem needed to be resolved: The length of the targeting vector homology arms, sometimes in the hundreds of kilobases, precluded the use of standard tools for ES cell genotyping, such as Southern analysis or long-range PCR. The VelociGene solution was the development of an assay that would rely on a novel loss-of-endogenous allele (LOA) assay.

Using Large Targeting Vectors to Efficiently Target Mouse ES Cells

In order to make possible the use of large targeting vectors for ES cell gene targeting, VelociGene developed an LOA assay which uses real-time quantitative PCR (qPCR) to count the number of intact copies of the targeted allele compared to the number of copies of reference genes (Figure 1(a)). Thus, correctly targeted ES cell clones should necessarily show the loss of one of the targeted alleles, whereas random integrants should retain both copies of their target DNA (screening of X-linked target genes is essentially the same except for an adjustment to the presence of a single targeted allele). The method uses two target-specific primer sets (forward and reverse PCR primers and a qPCR probe that recognizes the PCR product) corresponding to the upstream and downstream end of each targeted deletion (Figure 1((a)) and compares each of these target-specific qPCRs to up to six reference qPCRs for a total of up to 12 assays per construct for each ES clone. A robotic workstation assembles the qPCRs in optical 384-well clear reaction plates and the mixtures are cycled in a qPCR instrument. For each qPCR, the cycler's software determined the threshold cycle (C_T), the point in the PCR at which the fluorescence signal reached the

preset threshold. We calculated the difference in the C_T values (ΔC_T) between the target-specific uPCRs and dPCRs and each of the reference PCRs. Since most of the ES cell clones were not expected to have sustained a targeted loss of allele, we screened for ES cell clones whose ΔC_T values were consistently greater than the median ΔC_T for the population by approximately one cycle, as expected for a clone that has lost one of the two targeted alleles.

This approach was validated by extensive quality control of the ES cells and mice derived from them. The quality control included confirmatory fluorescent *in situ* labeling and analysis of the upstream and downstream areas of the targeted zone. One significant advantage derived from the use of large targeting vectors is a high targeting efficiency (on the order of 5% or more) without the need of using isogenic DNA or positive/negative selection. This method has proved to be highly consistent and with a very low false-positive and failure rate. The LOA assay not only allowed the use of BAC-based vectors for targeting but also made possible parallel processing and automation of the ES cell screening process. ES cell DNA preparation, assay configuration and sample handling, qPCR assay, and data collection and handling are all done either automatically or largely so. These developments allow the assaying of multiple targeting projects simultaneously with a throughput that can vary from several hundred to several thousand targeted ES cell lines a year.

VelociMouse: Rapid Generation of Genetically Modified Mice Suitable for Phenotyping

For functional studies, the next step after the generation of the targeted ES cells is the generation of mice. Following implementation of VelociGene approaches which allowed for the rapid generation of hundreds or thousands of specifically targeted ES cell clones, generation of mice from these ES cells represented the new bottleneck in the mouse genetics field. The most widely used conventional technology to generate mice from targeted ES cells requires microinjection of ES cells into host embryo blastocysts to generate chimeras. One major limitation of this method is that chimeras, by their very nature, are unsuitable for phenotypic studies because they consist of a mixture of tissue lineages derived from both the targeted ES cells and the host embryo cells and thus need to be test crossed to find those chimeras whose genital ridge is sufficiently derived from the targeted ES cells to allow for germ line transmission of the targeted allele. The 'transmitting' mice – that is, those mice producing heterozygous pups – are then used to generate additional heterozygous mice, which in turn are used to generate homozygous cohorts in numbers suitable for phenotyping. Thus, once targeted ES cells are generated, the production of homozygous cohorts requires several months of tedious and usually expensive breeding. The situation becomes even more difficult when studying multiple targeted alleles in the same mice because each needs to be generated individually, as described previously, and then crossed into a single mouse. Thus, using the blastocyst injection technology, mice generation from ES cells is a major bottleneck in the process of gene functional analysis. As the development of the VelociGene technology allowed the parallel processing and industrialization of the mouse ES cell targeting, the mouse generation bottleneck became more acute, making it necessary to search for faster and more economical methods to generate mice suitable for phenotypic studies.

To accelerate the time to an observable phenotype, some investigators use tetraploid embryos as hosts for their ES cells, which can result in generation of F0 mice that are almost completely ES cell derived and thus immediately available for phenotypic analysis. The basis for this method is a particularity of tetraploid cells that allows them to produce only extraembryonic tissues such as the placenta and chorion, whereas the epiblast and embryo proper are primarily derived from the targeted ES cells. Unfortunately, generation of live animals using the tetraploid approach is an inefficient process, the technique requires certain low-passage hybrid strain ES cell lines, and it often fails to yield viable mice when inbred strain ES cells are used. In addition, the resulting F0 mice can possess up to 2% host contamination, exhibit poor viability, and have other abnormalities (e.g., changes in growth rates and body weight) unrelated to the introduced genetic mutation, complicating phenotypic analyses. Although the tetraploid approach is an advance over the blastocyst method in terms of speed to phenotypable mice, its drawbacks limit its usefulness for large-scale functional genomic efforts.

The main technological breakthrough of VelociMouse involves the use of a laser beam to introduce a perforation of the zona pellucida of an eight-cell embryo and then using that perforation to introduce the targeted ES cell into the embryo (**Figure 2**) to efficiently generate viable and healthy F0 generation mice that contain no more than 0.1% host contamination. Most important, the resulting F0 generation mice (derived from ES cells targeted to have heterozygous or homozygous mutations) can directly be used in phenotyping analyses: We demonstrated that phenotypes defined in these F0 mice are

Figure 2 Comparison of conventional and VelociMouse mouse generation technologies. (a) Conventional injection of targeted ES cells into mouse blastocysts results in mixing of the ES cells with the preexisting epiblast, producing mice derived from both the ES cells and the cells from the host embryo (chimeras). In this example, C57BL/6 ES cells were injected into C57BL/6 (albino) host embryos, generating mice with a chimeric black and albino coat color. Chimeras need to be bred to the appropriate mouse genetic background to demonstrate germ line transmission to the next generation. (b) In contrast, VelociMouse technology uses a laser-assisted perforation of the zona pelucida of an eight-cell embryo, allowing for the microinjection of ES cells into the perivitaline space. In this example, C57BL/6 ES cells were injected into C57BL/6 (albino) host eight-cell embryos, resulting in F0 mice which exhibit 100% black coat color that were proven to be fully derived from the microinjected ES cells.

indistinguishable from those observed in conventionally derived F1 and F2 generation mice. Because this new approach greatly accelerates time to mouse phenotyping analyses, we termed it VelociMouse.

VelociGene and VelociMouse Allow for High-Resolution Localization of Gene Expression, Thus Allowing Targeted Phenotyping for Function Elucidation

VelociGene technology allows for the precise deletion of the entire coding region of a gene of interest – the only way to ensure that the targeted allele is definitively null – while simultaneously also allowing precise replacement of the coding region with a reporter gene, such as β-galactosidase or green fluorescent protein. Thus, a single mouse line can be created that can initially be used to provide high-resolution localization of sites of expression of the gene of interest and subsequently used to understand the functional consequences resulting from complete lack of expression of that gene. For the initial expression studies, mice heterozygous for the deletion/reporter allele can be used that still retain a single unperturbed

allele of the gene of interest, and such heterozygous mice often suffer little or no functional implications, allowing elucidation of the normal expression patterns of the gene. For the subsequent functional studies, mice homozygous for the deletion/reporter allele are generated (either by mating heterozygous mice or by generating VelociMice from homozygously targeted ES cells). Using such approaches, we have been able to generate high-resolution reporter profiles for hundreds of genes, allowing for precise localization of individual cells expressing a gene of interest (Figure 3). Such profiles can play a very useful role in guiding subsequent phenotypic analyses of the gene of interest. For example, the realization that a gene is only expressed in a small collection of neurons in the nervous system can allow for very targeted (and very limited) phenotyping of behaviors and functions associated with that neuronal subset. Such targeted phenotyping can save an enormous amount of time and effort that would normally be wasted if each mutant mouse line was indiscriminately subjected to widespread routine phenotyping without regard to the site of action of the gene – for example, wasting effort by performing immune phenotyping studies for a gene expressed only in the nervous system.

Using a combination of reporter profiling and targeted phenotyping, we have efficiently elucidated the function of many genes, dozens of which have already been published. For example, VelociGene targeted mice for the Lhx6 gene were used to delineate a neuronal pathway mediating innate reproductive behaviors from the amygdala to the hypothalamus. Another mouse line targeted for the peripheral myelin protein 22 gene was used to determine that the protein product is complexed with $\alpha_6\beta_4$ integrin, and that the absence of this protein alters the Schwann

Figure 3 Gene expression profiling and targeted phenotyping in VelociGene mice. (a) Targeted mice containing a LacZ reporter in the NMUR2 gene showed expression in restricted areas of the brain and dorsal horn of the spinal chord. The expression in the trigeminal tract indicated potential function of NMUR2 in the nociceptive response. (b) Hot plate tests for the nociceptive response show impaired response of the null NMUR2 mice compared to their wild-type littermates.

cell basal lamina and causes developmental abnormalities in peripheral nerves. VelociGene targeted mice have generated phenotypes leading to important new realizations in many areas of biology outside of neurobiology, such as that the Delta-like 4 gene product is critical for developmental and tumor angiogenesis, or that a particular microRNA (miR-155) is critical for the formation of germinal centers in immune organs.

The large-scale capabilities provided by VelociGene and VelociMouse, particularly when coupled with the genomewide KOMP initiative, seem likely to continue to make important contributions to all of biology.

Vergence Eye Movements

Introduction

When we shift our gaze from a far object to a near object, our eyes converge, the lenses of our eyes modify their focus (accommodate), and our pupils often constrict; these combined responses are termed the near triad. The vergence system, which controls binocular alignment, that is, the angle between the two eyes, aligns both foveas with the object of interest, permitting fusion of the retinal images into a single percept. Failure or insufficiencies of this system result in diplopia, or double vision. The accommodation system adjusts the shape of the lens of each eye to bring the new object into focus. These combined vergence and accommodation responses are often termed the near response. The third component of the near triad is the pupil constriction that often accompanies the near response. This article reviews our current knowledge of the systems involved in the near triad and their interconnections.

The Near Response

To better understand the geometry underlying vergence eye movements, consider those eye movements that are required to look between far and near objects (Figure 1). If we want to look at the mountains, we align the lines of sight at infinity and adjust the power of the lenses of our eyes to infinity as well. While viewing the mountains (Figure 1(a)), a snowflake on the window will have a crossed binocular disparity and will be blurred. Therefore, to transfer our gaze to the snowflake we have to converge our eyes and accommodate. While viewing the snowflake (Figure 1(b)), the mountains will have an uncrossed binocular disparity – that is, to compensate for it we have to uncross our eyes, and be out of focus. To return our gaze to the mountains we have to diverge our eyes and disaccommodate. As illustrated in Figure 1, in natural environments vergence and accommodation demands co-vary in a geometrically predictable fashion. As a consequence, the vergence and accommodation systems in primates are closely cross-coupled with shared vergence/accommodation neural elements. Although these interactions are presumably distributed throughout the brain, in a schematic of the underlying neural control of the near response like the one in Figure 2, it is common to merge them into a single pair of cross-links (CA and AC).

When we transfer our gaze to a new object at a different distance, the blur and the binocular disparity inputs to the blur/accommodation controller and the disparity/convergence controller are no longer zero. The two central controllers are activated, producing the appropriate dynamic accommodation and convergence signals needed to transfer our view to the new object. The dynamic changes in dioptric power of the lenses and eye alignment elicited by these controllers reduce the amount of blur and binocular disparity on the two retinas, and these changes are detected by the visual system (visual feedback). Vergence and accommodation responses end when the binocular disparity and blur of the new object of interest reach zero. In humans, the visual loop delay – the time between the occurrence of a visual change and an altered response – is slow (150–200 ms for vergence and approximately 350 ms for accommodation). To more rapidly monitor the progress of the response, the vergence system also has an internal feedback mechanism, which is nonvisual and thus can operate with a much shorter loop delay (Figure 2). This local feedback uses a neural copy of the vergence motor command as an indirect real-time estimate of the eye movement (corollary discharge). It is most likely that the accommodation system operates with a similar local feedback, but no conclusive data are available at this time. As is the case for all other oculomotor subsystems, the vergence and accommodation commands reaching the motor neurons are composed of both dynamic signals (velocity pulses), needed to reduce the damping effects on the dynamic of the motor response by the mechanical viscoelastic and inertial components of the orbital tissues, and sustained commands (position steps), needed to maintain the new vergence and accommodation levels at the end of the movement. To generate the required position steps, it is probable that dynamic signals are integrated ('neural int' in Figure 2) by neurons located in the midbrain and/or the cerebellum.

Historically it was assumed that divergence eye movements and disaccommodation were the passive results of a decrease in convergence and accommodation tonic signals, respectively. The discovery, in several areas of the macaque brain, of separate populations of neurons which encode either convergence and accommodation or divergence and disaccommodation indicates that divergence and disaccommodation are under dynamic control as well. Therefore, vergence and accommodation responses reflect the balance between the activity of two subsystems with opposite signs that act in a push–pull fashion.

Figure 1 Geometry of the near response. (a) When we look at the mountains through a window, the lines of sight are aligned at infinity (vergence angle = 0°) and the focus of the lenses (L) is also at infinity (accommodation = 0 diopters). The images of the mountains are aligned on the two foveas (F), in focus, and are fused into a single percept. The lines from the two eyes to the target can be considered as two sides of a triangle, with the base formed by the interocular separation (IOS). The images of a snowflake on the window will fall on the temporal retina of each eye, at an angle equal to tan(0.5 × IOS/distance), where distance is the distance of the object from the eye. For adults, the average IOS is 6.5 cm, and, for a window at 20 cm, this angle corresponds to 9°. The temporal, or crossed, disparity error (i.e., the total angular deviation, with sign, from the two foveas) is therefore 18°, which is also the amount of convergence that we would have to generate to align the two lines of sight on the snowflake. This disparity, and the associated vergence movement, can also be expressed in meter-angles. A meter-angle is defined as the amount of convergence needed to align the eyes on an object located at 1 m. A disparity of 18° is well outside Panum's fusional area (the disparity range over which the brain can fuse disparate images into a single percept), and the snowflake therefore appears diplopic. With the lens of both eyes focused at infinity, the snowflake will also appear blurred, with an accommodation error equal to 1/distance = +5 diopters, with the distance expressed in meters. This numerical value is also the amount of disparity/vergence error when expressed in meter-angles. (b) To transfer our view from the mountains to the snowflake we must converge our eyes by a total of 18° (+5 meter-angles), and accommodate by +5 diopters. Now the mountains are diplopic and out of focus. Their projections are on the nasal retina of each eye, with a total uncrossed disparity error of 18° (−5 meter-angles), and with a focusing error of-5 diopters. To return to the mountains we will uncross (i.e., diverge) our eyes by a total of 18° (−5 meter-angles), and disaccommodate our lenses by −5 diopters.

When vergence and accommodation demands co-occur, the crossed connections between the vergence and accommodation systems are not clearly evident. To demonstrate the influence of the vergence system on the accommodation system, one can view a three-dimensional scene through pinholes. This greatly increases the depth of focus of the eye and hence eliminates the blur cue. This situation is simulated by the

Figure 2 A cross-coupled model of the vergence and accommodation systems. This model applies to the near response (convergence and accommodation), but the same schematic applies to the far response (divergence and disaccommodation). The blur/accommodation controller is depicted as a box with blur as dynamic input. The presence of a blur signal generates a compensatory accommodation command (velocity pulse). To maintain the new accommodation state at the end of the movement, the dynamic signal is integrated by the neural integrator (neural int) and the positional step is added, with sign, to the existent tonic accommodation. The progress of the accommodation response is controlled by both a nonvisual internal local feedback, which uses the motor command itself as estimate of the ongoing lens change, and a visual feedback. The blur visual feedback (dashed line) and the summing junction (retina) are not neural elements, but a representation of the effect of the ongoing accommodation response on the visually perceived blur. When blur is zeroed the response ends. Exactly the same mechanism applies to the convergence response, which ends when the binocular disparity is zeroed. During a transfer of gaze in depth, a copy of the blur-driven accommodation response (BA), output of the blur/accommodation controller, is sent to the convergence system as an accommodation-driven convergence command (cross-link AC). A copy of the disparity-driven convergence (DC), output of the disparity/convergence controller, is sent to the accommodation system as a convergence-driven accommodation command (cross-link CA). The sum of the BA and CA contributions will give the actual accommodation response (AR). The sum of the DC and AC contributions will give the actual convergence response (CR). Crossed contributions from the vergence to the accommodation systems become evident by using pinholes, simulated by the opening of the pinhole switch. This device greatly increases the depth of focus, with both mountains and snowflake now in focus. Thus, during the transfer of gaze, the input to the blur/accommodation controller remains zero (no blur cues), but the binocular disparity will activate the disparity/convergence controller, which output (DC) will generate not only a convergence response, but by way of the cross-link with the accommodation system (CA), also an accommodation response. Similarly, one can eliminate the binocular disparity input while maintaining the blur input by covering one eye (monocular viewing switch). Under this condition, there is no binocular disparity, and the disparity/convergence controller is not active. Nevertheless, the blur of the target will activate the blur/accommodation controller, which output (BA) will not only generate an accommodation response, but also a convergence response by way of the cross-link with the convergence system (AC).

opening of the pinhole switch in Figure 2. On the other hand, one can eliminate binocular disparity input while maintaining blur input by covering one eye (monocular viewing). This situation is simulated by the opening of the monocular viewing switch in Figure 2.

When we ask a patient to wear prisms to correct their binocular alignment or to wear lenses for accommodative correction, we are effectively requiring that the patient maintains the output of the other system unaltered, that is, to dissociate vergence and accommodation. If the patient has normal cerebellar function, long-term adaptive changes will compensate for these conflicts by modifying the tonic vergence and accommodation signals and/or the strength of the cross-links between the two systems.

Vergence and accommodation responses are also elicited (Figure 2) by an object seen moving closer or farther from us (visual looming); and by a forward or

a backward movement of the head. Translational head movements are detected by the otoliths in the inner ear, acting as linear accelerometers. A forward head movement will generate vestibularly driven convergence, while a backward head movement will generate vestibularly driven divergence. Their vestibular origin is confirmed by the fact that they are also observed in the dark. Furthermore, Figure 2 shows that the vergence and accommodation outputs serve to drive pupillary responses, the third component of the near triad.

The Vergence System

The main visual cue directly eliciting vergence eye movements is binocular disparity. The presence of a disparity error means that the images of an object fall on noncorresponding positions in the two retinas, and, if this error is too large for the two images to be fused into a single percept (i.e., beyond Panum's fusional area), the object will be seen as diplopic. There are two, apparently separate, disparity-driven vergence subsystems. A short-range system, termed the fusional vergence system, has a functional disparity range of approximately 1–2°. This system is specifically designed to achieve and maintain alignment of the foveal and parafoveal images within Panum's fusional area (motor fusion), and requires that the images of the object on the two retinas are almost identical to one another. The second system, termed the coarse or long-range system, does not require precise matching of the retinal images. It is able to detect widely disparate images such as those of the snowflake or the mountains, and to elicit the appropriate vergence eye movements (Figure 1).

Vergence-Related Cortical Areas

Short-range disparity-sensitive neurons have been reported in several cortical areas in the macaque monkey, including striate visual area V1; extrastriate visual areas V2, V3, V3A, and V4; middle temporal (MT) area; medial superior temporal (MST) area; lateral, ventral, and caudal intraparietal (LIP, VIP, CIP) areas; frontal eye fields (FEFs); and supplementary eye fields (SEFs). Several of these areas are also vergence sensitive (i.e., encode aspects of the motor command) and blur and/or accommodation sensitive. Cortical areas MST, FEF, and SEF are believed to be directly or indirectly involved in the generation of vergence and accommodation motor commands (Figure 3).

Area MST is directly linked to the generation of ultrashort latency (~80 ms in humans) reflexive vergence responses elicited by sudden changes in depth of a large textured visual scene. In the rhesus monkey, the activity of many MST cells significantly leads these vergence responses, and the population average of the MST neural activity matches the tuning curve of the oculomotor response. The restricted functional range of these reflexive responses is compatible with them forming part of the short-range circuitry. Other researchers, using small targets, have found that a substantial fraction of MST cells respond during voluntary sinusoidal smooth tracking in depth.

The prearcuate frontal eye field area contains cells displaying activity that is significantly correlated with both vergence and accommodation motor commands, as illustrated in Figure 4. The temporal properties of these neural responses indicate that this

Figure 3 A schematic diagram of the neural pathways controlling vergence eye movements in primates. FEF, frontal eye fields; SEF, supplementary eye fields; MST, medial superior temporal area; mNRTP, medial nucleus reticularis tegmenti ponti; DLPN, dorsolateral pontine nuclei; vPF, ventral paraflocculus; cFN, caudal fastigial nucleus; IP, interpositus; VN, vestibular nuclei; SOA, supraoculomotor area.

Figure 4 Example of a near-response cell in the prearcuate frontal eye field area of the macaque monkey. (a) Responses of the cell to multiple presentations of a small target stepped from far to near. The single trials are synchronized with the onset of the vergence response. (b) Responses of the same cell to multiple presentations of a small target sinusoidally oscillating in depth. VL, vertical position trace of the left eye; HR, horizontal position trace of the right eye; HL, horizontal position trace of the left eye; VA, vergence angle trace; AVV, average vergence velocity trace; AVA, average vergence angle trace. The spike raster, the activity of the neuron during each presentation, recorded with a microelectrode, is shown as a sequence of ticks, each representing the occurrence of a spike. Each line of the raster corresponds to one presentation; Frequency is the average frequency of the firing of the cell. Panel B addresses two important points regarding the nature of the signal encoded by this cell. The first is derived from the trace labeled AD (average disparity). With the animal successfully tracking the moving target, there is only a minor dynamic disparity error, but the responses of the cell are as robust as in panel a. This indicates that it is encoding the vergence motor command, or a corollary of a vergence motor command, and not a (visual) disparity signal. Further evidence that this cell is not visually driven is shown by the maintenance of the firing when the target (TARG) is briefly extinguished and the animal is in total darkness. The firing continues to follow the vergence response. The location of this event is marked by the brief interruption of the target trace near the middle of panel b. A latency analysis also suggested that many of these cells change their firing activity with respect to the onset of the motor response (lead time) early enough to be actually driving the observed vergence response. Scale $= 4^\circ$, and $20^\circ\,s^{-1}$. Adapted from Gamlin PDR and Yoon K (2000) An area for vergence eye movement in primate frontal cortex. *Nature* 407: 1003–1007.

region contains neurons directly involved in the generation of vergence eye movements. Comparable results have been found in the caudal frontal eye fields. Neurons within the macaque SEF display motor-related responses during sinusoidal vergence tracking.

In humans, lesions of areas comparable to the macaque MST produce profound deficits in the ability of a patient to generate vergence responses, as well as in performing fronto-parallel smooth-pursuit tracking responses. These observations are consistent with MST being a major center for motion processing in three-dimensional space. Lesions of the FEF region produce deficits in vergence, saccades, and smooth-pursuit eye movements, indicating that this region is a sensorimotor area responsible for the generation of these voluntary eye movements. In contrast, damage to the SEF area fails to produce any major deficits in vergence tracking. This suggests that, as is the case for the saccade-related and fronto-parallel pursuit-related activity, the SEF is involved in planning more complex motor behaviors. Deficits in these functions would not be expected to interfere with the execution of simple visually driven oculomotor tasks.

Vergence-Related Subcortical Areas

The most important subcortical structures between the MST and FEF vergence-related cortical areas and the cerebellar vergence-related areas are the basilar pontine nuclei medial nucleus reticularis tegmenti pontis (mNRTP) and dorsolateral pontine nuclei (DLPN). These nuclei have cells that respond during vergence responses, and electrical microstimulation of mNRTP neurons produces changes in vergence state. Figure 5 shows an example of a convergence neuron (panels a and b) and of a divergence neuron (panels c and d) in mNRTP. The mNRTP primarily projects to the cerebellar vermis, which innervates the caudal fastigial nucleus; the DLPN primarily projects to the ventral paraflocculus, which innervates the vestibular nuclei as well as two of the deep cerebellar nuclei – the interpositus and dentate. Consistent with these connections, vergence signals are found in the caudal fastigial nucleus and the ventral paraflocculus. Lesions in the dorsal vermis in monkeys induce a convergence bias during monocular fixation in the absence of disparity cues, and chemical inactivation of the caudal fastigial nucleus impairs vergence eye movements.

Midbrain Premotor Neurons

It was known for many years that vergence eye movements are usually spared in patients with internuclear ophthalmoplegia, where damage to the medial longitudinal fasciculus (MLF) prevents conjugate eye movement signals from reaching medial rectus motor neurons from the contralateral abducens nucleus. This suggested the existence of a vergence motor pathway that was independent of the saccadic and frontal smooth-pursuit pathways. It is now known that vergence commands reach the medial rectus motor neurons directly from near-response cells in the supraoculomotor area (SOA) and not through the MLF. These cells connect monosynaptically to medial rectus motor neurons and appear to be part of a final common pathway for all vergence responses. Examples of the activity of SOA convergence and divergence cells during step changes in depth of a small target are illustrated in Figure 6. These cells do not fire for saccades or fronto-parallel smooth pursuit.

Behavior of Motoneurons

A symmetric convergence response, in which both eyes rotate inward by the same amount, is associated with contraction of the medial rectus muscle (agonist) of both eyes and relaxation of the lateral rectus muscle (antagonist) of both eyes. For divergence, the two actions are reversed. The motor neurons innervating the medial rectus muscles are located in the oculomotor nuclei, while the motor neurons innervating the lateral rectus muscles are located in the abducens nuclei. Figure 7 illustrates an example of activity of a left-eye medial rectus motoneuron during a rightward saccade and a convergence response. Since both responses rotate the left eye to the right, the motoneuron is active for both types of eye movements. More generally, the motor neurons innervating the extraocular muscles respond during all eye movements but with differing sensitivities, and these sensitivities vary from cell to cell.

The Accommodation System

Increased accommodation is achieved by deformation of the lens capsule and matrix by contraction of the ciliary muscle, which is innervated by postganglionic, parasympathetic neurons in the ciliary ganglion. The suspensory ligaments act as passive antagonists. Disaccommodation is achieved by relaxation of the ciliary muscle, with the suspensory ligaments acting as passive agonists. Accommodation and disaccommodation responses have somewhat different dynamics, most likely due to the different anatomical aspects of the two responses. The primary tonic and dynamic inputs to the ciliary muscle are from the parasympathetic autonomic nervous system; the sympathetic system exerts a weak, tonic inhibitory action. Antidromic activation has shown that accommodation-related Edinger–Westphal (EW) neurons connect monosynaptically to the ciliary ganglion by way of the oculomotor nerve.

Figure 5 Examples of a near-response cell (a, b) and a far-response cell (c, d) in the medial nucleus reticularis tegmenti pontis (mNRTP) of the macaque monkey. (a) The response of an mNRTP near-response cell to a single far-to-near step of a small target. This cell is practically silent at far and has a robust tonic firing when the animal is converged. The initial higher firing during the convergence eye movement proper indicates that this cell has also some velocity sensitivity. (b) The static positional sensitivity of the cell as dependence of the tonic firing rate of the cell with the static vergence angle, expressed in meter-angles (MA). (c) The response of an mNRTP far-response cell to a similar target step. The cell had a strong firing when the animal was aligned at far, but it has a much lower firing when the animal is converged. This is confirmed by the plot of the position sensitivity of this cell (d), which has the slope opposite to the convergence cell in panel b. Trace abbreviations as in **Figure 4**. Scale = 4°. Adapted from Gamlin PDR and Clarke RJ (1995) Single-unit activity in the primate nucleus reticularis tegmenti pontis related to vergence and ocular accommodation. *Journal of Neurophysiology* 73: 2115–2119.

The sources of accommodation input to the EW nucleus are poorly understood. Direct connections exist from the fastigial nucleus and the posterior interpositus nucleus of the cerebellum. Also, the near- and far-response neurons in the supraoculomotor area immediately surrounding the EW nucleus are presumed to contribute to the accommodation response, but a monosynaptic connection from SOA to the EW has yet to be demonstrated. Shared neural control of vergence and accommodation is also reported in the prearcuate and caudal frontal eye fields, and the medial nucleus reticularis tegmenti pontis (Figure 3).

The Pupillary Near Response

The primary function of pupil responses is to adjust retinal irradiance on the basis of the ambient light. There is strong evidence that the neural circuitry underlying the pupillary light reflex is primarily subcortical, albeit with some cortical influence. Also, as with a camera lens, the diameter of the pupil (aperture) affects the amount of optical aberration of the lens and the depth of focus; a small pupil diameter reduces aberrations and increases the depth of focus, which is the most likely role for the pupillary near response.

Pupil diameter is determined by the degree of contraction of two antagonist muscles, the sphincter pupillae and the dilator pupillae. Contraction of the sphincter causes pupil constriction (miosis), and it is largely under parasympathetic control. Contraction of the dilator (or radial) muscle causes pupil dilation (mydriasis), and it is largely under sympathetic control. The parasympathetic projections to the sphincter pupillae muscle arise from preganglionic neurons in the Edinger–Westphal nucleus which project, by way of the oculomotor nerve, to

postganglionic neurons in the ciliary ganglion. The ciliary ganglion innervates both the iris sphincter and the ciliary muscle of the lens. The afferent component of the pupillary light reflex pathway is composed of direct retinal projections from intrinsically photoreceptive ganglion cells to the pretectal olivaris nucleus (PON), which projects bilaterally to the Edinger–Westphal nucleus.

Figure 6 Continued

Figure 7 The oculomotor final common pathway. Conjugate commands and vergence commands reach the medial rectus motoneurons through separate pathways. The conjugate command is received through the crossed medial longitudinal fasciculus and the vergence command is received directly from the vergence burst-tonic neurons in the supraoculomotor area. Nonetheless, there is no evidence for distinct anatomical or functional separation of the motoneurons on the basis of the type of oculomotor command they receive: all motoneurons are active, to some extent, for all types of oculomotor behaviors. Medial rectus muscles contract for adducting (toward the nose) horizontal eye rotations, and relax for eye rotations away from the nose. If the final common pathway hypothesis is correct, a motoneuron innervating the medial rectus muscle of the left eye will increase its firing for both conjugate saccades to the right and for convergence. Consistent with this hypothesis, the medial rectus motoneuron reported here shows a clear pulse-step response during convergence (panel a) as well as during a rightward saccade (panel b). For a direct comparison, the amplitude of the vergence response is 4°, requiring a rightward rotation of the left eye of 2°, and the saccade amplitude is 2°, and therefore also requiring the same rightward rotation of the left eye by 2°. The positional and dynamic sensitivity of a motoneuron to the different oculomotor commands will depend on the strength of the synaptic connections from the different pathways. The cell in the example has comparable vergence and saccadic sensitivity, but, at the population level, the sensitivities vary along a continuum and largely independently from each other. Trace abbreviations as in **Figure 4**. Scale = 4°. Adapted from Gamlin PDR and Mays LE (1992) Dynamic properties of medial rectus motoneurons during vergence eye movements. *Journal of Neurophysiology* 67: 64–74.

The pupillary responses that occur with changes in viewing distance correspond to the changes in accommodation (far to near) and disaccommodation (near to far) that occur (i.e., pupil diameter decreases when focusing from far to near and increases when focusing from near to far). This is likely due to a cross-coupling of the accommodation and parasympathetic pupil pathways in the Edinger–Westphal nuclei. Direct contributions from the vergence system to the pupillary near response may be secondary to their actions on accommodation and therefore are indicated by a thin line in **Figure 2**. Other factors may contribute to the pupillary near response since there are some reports of accommodation/disaccommodation changes that are not accompanied by pupil responses.

In some clinical cases, dissociation occurs between the pupillary light reflex and the pupillary near response. The Argyll–Robertson pupil describes the condition where the near response is preserved while the light reflex is absent.

Figure 6 Four examples of vergence-related cells in the supraoculomotor area (SOA) of the macaque monkey. (a1/a2) The cell is an SOA convergence burst cell. This cell is strongly active during the convergence response but it is not active during fixation, and it is never active during divergence (a2). (b1/b2) An SOA divergence burst cell. It does not fire during a convergence eye movement (b1), while it does during the divergence response (b2). During fixation between vergence movements, vergence angle has to be maintained by the contribution of tonic vergence signals. (c1/c2) An example of an SOA convergence burst-tonic cell. When the animal is diverged, this cell has a low tonic firing rate that significantly increases when the animal converges. (d1/d2) An example of an SOA divergence burst-tonic cell. During convergence eye movements the firing rate of the cell significantly decreases but increases during divergence eye movements. By using dissociated vergence/accommodation cues it was found that these cells carry both vergence and accommodation signals and it is possible that they directly drive the Edinger–Westphal accommodation cells. Trace abbreviations as in **Figure 4**. Scale = 4°. Vertebrate Eyes: Evolution

R D Fernald, Stanford University, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Light is the premier source of information for many species, and the selective pressure to use this information led to the evolution of eyes. How did eyes evolve? Darwin, the great English naturalist who first brought the systematic explanatory power of evolution to bear on the bewildering biological complexity of our planet, believed that eyes offered a special challenge to evolutionary thinking because they are such "organs of extreme perfection and complication."

Nearly a century and a half later, new discoveries ranging from molecular to macroscopic levels of analysis now provide an answer to the question of how eyes evolve. The evolution of photodetection led to eyes that show natural selection acting at both the organ and the molecular levels. The repeated use of key regulatory gene sequences in eye development and lens formation raises the question of why some transcription factors are regularly recruited to build eyes. Because we can analyze the evolution of structural gene sequences relatively easily, many phyolgenetic relationships among the components of eyes are known. However, the difficulty of tracing exact selective forces that shaped the regulation of gene expression in eyes and elsewhere has made it difficult to understand the evolution of such complex organs.

Structural and Functional Adaptations

Despite the great variety of eyes in the animal kingdom, the laws of physics have constrained optical solutions for collecting and focusing light to just eight types of eyes. To be useful, animal eyes cannot be simple photon detectors but, rather, produce an image by comparing light arriving from different directions.

The likely sequence of evolutionary steps leading to eyes began with simple eyespots in the early Cambrian period, 570–500 Ma. Such photosensitive spots would discriminate between light and dark but could not record complex light patterns. Eyespots that invaginated would add the capacity to detect the direction of incident light and additional receptors could enhance usefulness. Duplication of an existing pit may have led to compound eyes, whereas duplication of receptors may have led to a chambered eye. Adding an optical system in front of the photosensitive elements would increase collection of light and, if it produced an image, would dramatically improve the usefulness of an eye.

The addition of optical systems to eyes led to the evolution of strikingly similar ocular structures in distinctly unrelated animals, such as fishes and cephalopods. The chambered or camera-like eyes in these two lineages are similar in many details, despite the fact that their owners are phylogenetically quite distant. Both evolved spherical lenses to achieve sufficient refractive power for focusing light underwater, but the inverted retinal layers of fishes (and all vertebrates) are distinctly different from the noninverted, somewhat simpler retinae of cephalopods. Both eye types have photoreceptor cells that use related opsin molecules to detect light but very different transduction cascades. Thus, macroscopically, these eye types and the animals bearing them are not remotely homologous, but there are some similarities in the molecules used during development. The exploitation of homologous genes to build nonhomologous eyes may lie at the heart of understanding eye evolution and evolutionary processes more generally.

Of approximately 33 animal phyla, approximately one-third have no specialized light-detecting organ, one-third have light-sensitive organs, and the remaining third are animals with eyes. Image-forming eyes exist in six of 33 extant metazoan phyla (Cnidaria, Mollusca, Annelida, Onychophora, Arthropoda, and Chordata) which account for 96% of known species alive today, meaning that eyes must be useful. Eyes have many features in common because their optical features ultimately depend on the physical properties of light, which travels in straight lines, consists of electromagnetic radiation, varies in wavelength, etc. For example, eyes have evolved to be sensitive within a narrow range of wavelengths, relative to the broad spectrum of energy produced by sunlight, because early evolution occurred in water, which selectively filters what we know as light. Selection for biochemical mechanisms sensitive to this limited range of wavelengths set the sensitivity that emerged during subsequent evolution. Although nonaquatic species moved to land where they were exposed to a significantly broader spectrum of electromagnetic radiation from the sun, animal eyes are limited to vision within the narrow band dictated by our origins in water. Some insect and fish species evolved additional receptor types for ultraviolet light, but the more common restricted sensitivity reflects just how profound early evolutionary solutions persist in evolved organs.

Photon Capture

Both vertebrate and invertebrate eyes transduce photons into cellular signals using seven-tramsmembrane

spanning opsin proteins (30–50 kDa) that combine with a retinal chromophore based on vitamin A. Opsins arose before eyes and evolved into at least seven distinct families. Opsin gene duplications gave rise to the independent evolution of three-color vision in Old and New World primates. Wavelength sensitivity in photoreceptors is modulated by amino acid side groups adjacent to the chromophore binding site in the seventh transmembrane domain of opsins, and evidence of natural selection can be seen in the arrangements of these residues.

The two primary photoreceptor types use different families of opsins packed into different membrane specializations and use different transduction cascades. Vertebrate photoreceptors use members of the ciliary opsin family, so called because these are incorporated into specialized cilia. In contrast, invertebrate photoreceptors use members of the rhabdomeric opsins formed into rhabdoms, hence the name. In vertebrates, the photoreceptors produce hyperpolarizing potentials using a phosphodiesterase cascade which provides amplification. In invertebrates, photoreceptors are depolarizing, using a phospholipase C cascade with amplification provided as the TRP channels open.

We have detailed knowledge about the evolutionary relationships among opsin molecules, and in particular, the adaptive radiation of pigment types due to natural selection for particular wavelength responses has been described for some special cases (e.g., east African cichlids and squirrelfish). However, there is a great deal of variance in spectral sensitivities arising from specific selective advantages for one solution over another. Detailed comparisons between terrestrial vertebrates and insects, for example, revealed that there are not unique solutions to encoding both spatial and spectral information. Mammals and bees use long wavelength receptors for luminance and color vision, whereas flies and birds have evolved separate sets of photoreceptors for the two purposes.

Capacities of eyes vary greatly depending on their ultimate structure. For example, resolution of an image (e.g., subtended degree) differs by approximately 13-fold among vertebrates and even more between vertebrates and invertebrates, and it is a function of photoreceptor size and spacing. Eagles have the greatest acuity, which is approximately 10^5-fold greater than that found in planaria. Similarly, a comparison of relative sensitivities among vertebrates reveals a range of 4×10^5 between highly sensitive deep-sea animal vision and human foveal vision. Animals clearly have evolved eyes with resolution, sensitivity, and wavelength detection to match their needs, even as those needs change during their life history.

The greatest variety of eyes exists among invertebrates, which have both camera eyes (e.g., cephalopods) and compound eyes (e.g., *Drosophila*). Moreover, invertebrates also have the greatest variety of eye number and location on given species. Whereas vertebrates settled on paired, chambered eyes with lenses on the head, invertebrate species may have multiple, nonpaired eyes and eyes in remarkable locations. For example, certain butterflies have light-detecting organs located such that darkness signals successful copulation. A visual system in the planula of a box jellyfish, *Tripedalia cystophora*, has been described that has eyecups directly connected to motor cilium. In this case, there is no nervous system to process visual information because the eyes are a complete sensorimotor system unto themselves.

Lenses: Multiple Protein Types and Gene Sharing

All biological optical systems fall into one of three classes based on image formation: images formed via shadows, via refraction (e.g., lens and/or cornea), or via reflection. The most common eyes collect light through an aperture and focus it with a lens onto photoreceptor cells specialized to convert photons into neural signals. Some eyes exist without pupils and even without lenses (*Nautilus*), but eyes that evolved to give their owners a clear view of the environment on a short timescale do have lenses. Could lenses that consist of tightly packed proteins provide some insight about how eyes evolved?

In vertebrates, lenses are formed from modified epithelial cells with high concentrations of soluble proteins, known as 'crystallines' because of their organized packing into arrays. In contrast, in most invertebrates, the lens proteins are secreted by specialized cells of the eye. Lenses of mitochondrial origin have been found in the two pairs of eyes of the parasite *Neoheterocotyle rhinobatidis*. Despite their distinct origins, both vertebrate and invertebrate lenses must have their constituent proteins distributed to produce a radial gradient of refractive index that is low at the edge of the lens and high in the center. A particular gradient of refractive index is essential for vision in animals living in water, but gradients are also found in terrestrial vertebrates and invertebrates.

Until quite recently, approximately ten crystalline proteins found in lenses were thought to be unique to lens tissue having evolved for this function. Of the large number of crystallines, α, β, and γ crystallines are specialized lens proteins in vertebrates although α and β are related to heat shock protein and schistosome egg antigen, respectively. However, the remaining vertebrate although α and β are lens proteins are not conserved but, rather, comprise a diverse group, many of which are used as enzymes elsewhere in the

body. Surprisingly, most of these taxon-specific lens proteins are actually products of the same genes as the enzymes, and this double use has been termed 'gene sharing.' For example, a crystalline protein in the duck lens is similar to a metabolic enzyme, argininosuccinate lyase, and both the lens protein and metabolic enzyme are encoded by the same gene, not by duplicated genes, although such sharing may have been a prelude to gene duplication. This molecular opportunism is so effective that it has also occurred both in cephalopods and in *Drosophila*. One possibility is that since lenses need the production of a relatively large amount of protein, genes that can be easily upregulated in other tissues might be preferentially selected.

Perhaps the most remarkable example of a lens from an unusual source is found in the brittlestar (*Ophiocoma wendtii*), which forms crystal lenses as a part of its skeletal armor from calcite crystals. The crystals, oriented to bring light onto the photoreceptive surfaces in the body, focus the light much as corrective lenses might, and they effectively concentrate the light by approximately 50 times.

The common cellular strategy of assembling lenses from diverse proteins seems to be a convergent evolutionary solution that has occurred in many vertebrates independently. The exquisite gradient of the refractive index which evolved in vertebrates and invertebrates alike resulted because it is the only way known to make an optically useful lens. What remains unknown is how diverse proteins are assembled through folding and organized to preserve key properties of transparency and suitable refractive index gradient along the axis of the lens. The challenge for understanding lens development is to identify the mechanisms responsible for organizing diverse proteins into a functioning lens. This knowledge could provide useful insights about eye evolution from the perspective of lens assembly.

Origins of Eyes

Logically, eyes might be monophyletic, having evolved from a single progenitor, or polyphyletic, having arisen more than once during evolution, and views on this have switched back and forth throughout the years. A comparison of overall structure, photoreceptor types, developmental origins of eye tissue, position of receptor axons, and other anatomical markers among eyes using current fauna suggested that eyes evolved not once but at least 40 different times, and possibly many more. This 'multiple-origins' hypothesis, based on morphological evidence, was later challenged by results from molecular experiments. A single, well-conserved 'master' gene, *Pax6*, can initiate eye construction in diverse species, suggesting that eyes might have arisen from a single ancestor. Since this original debate, there have been several salient discoveries that suggest eyes arose more than once and we carry the evidence within our own eyes.

Eye development requires morphological transformations of newly generated tissue regulated by multiple genes with expression patterns overlapping in time and space. Eyes develop from the prospective forebrain, beginning in the eyefields, which are made up of cells of the anterior neural plate. As the prosencephalon grows, this region moves forward until the optic groove forms and the neuroectoderm of the groove locally contacts the surface ectoderm, inducing the lens placode. As the placode invaginates to form the lens vesicle, the optic vesicle forms the bilayered optic cup, which ultimately becomes the eye. The interaction between the optic vesicle and the lens placode was identified as the 'organizer of the lens' by Spemann. The presumptive lens arises from the lens placode, a thickening of the ectoderm in contact with the optic vesicle. Coincident with this change is the onset of expression of proteins that will form the lens. Other structures of the eye are formed by large- and small-scale tissue movements, caused and accompanied by the expression of tissue-specific genes at that site. The cornea arises from the surface ectoderm over the lens and from migrating mesenchyme derived from the neural crest. Many of the original observations about the role of specific tissue bits in these processes resulted from exquisite embryonic manipulations related to transplantation experiments. With well-described macroscopic change in hand, the next challenge is to synthesize the phenomenological, macroscopic morphological observations with molecular explanations of eye development and understand what this tells us about evolution.

The morphological process of eye development has been viewed as a set of steps toward a final tissue arrangement. Underlying this apparently straightforward sequence of large-scale events, however, are distributions of gene expression with substantial overlap in both time and space. Gene expression is closely regulated, and specific gene products are used repeatedly, which makes the causal relationships difficult to conceptualize. Nonetheless, progress in characterizing the genes responsible for particular steps in eye development has been quite rapid. Functions for at least 15 transcription factors and several signaling molecules have been described in human and mice eyes, based on developmental disorders and/or molecular manipulations. As with other molecular actors, both the transcription factors and the signaling molecules expressed during ocular development are also developmentally important in a wide range of other tissues, meaning that combinatorial expression patterns are important.

As is now well known, the paired box gene 6 (*PAX6*), a member of the family of genes that encode transcription factors with a homeodomain and a paired domain, appears to be important in eye formation across many species. The remarkable demonstration that *PAX6* can induce eyes where they should not be ('ectopic') in *Drosophila*, and similar subsequent demonstration in vertebrates, led to the suggestion that there might be 'master control genes' responsible for development and differentiation of ocular tissue in many species. Subsequent work has shown that the idea of a master control gene is a misnomer, however, since a suite of genes are required, collectively, to initiate eye development, and transcription factors are a necessary part of the initiation process. Nonetheless, it is remarkable that some of the same genes appear in the context of eye development, despite great evolutionary distance among the owners of the eyes. How this might have occurred is discussed later.

In *Drosophila*, development of the photoreceptor array in the eye is known to require seven genes which work in combination with particular signaling systems through a complex regulatory network. Deletion of any one of the seven key genes causes loss or radical reduction of the *Drosophila* eye, and deletion of all but one can cause formation of an ectopic eye. Moreover, many of these genes play a role in developmental cascades used in formation of the kidney, muscle, and other organs. Thus, the master gene hypothesis is not supported because the whole collection of genes is needed to produce a reasonable eye. Eye development appears to require new ways of thinking about how complex tissues are made and how such organs arose in evolution. The widespread and redundant activities of specific genes during ocular development suggest that building eyes requires the orchestrated activity of a suite of molecular actors.

As described previously, the diversity of eyes confirms their dynamic evolutionary past. Explosive speciation, or the 'big bang' of animal evolution, happened during the Cambrian, when existing eye types appear to have improved radically, coincident with the onset of carnivory and predation. Many selective forces were likely at work, including perhaps the first instances in which light enabled behavioral signals, so no predominant selective force can be claimed. The rapidity of eye evolution has always been a question, but computer simulations show that approximately 2000 sequential changes could produce a typical image-forming eye from a light-sensitive patch. With reasonable estimates, this suggests that an eye could evolve in less than half a million years, making the virtual explosion of eyes during the Cambrian seem reasonable. After the Cambrian, three phyla emerged: arthropods, mollusks, and chordates. Although these groups all use the opsin molecule to capture light, details of the structure and function of their eyes differ considerably.

Functional Evidence about Eye Evolution

Until recently, the photo detection systems we understood well were localized primarily to eyes and pineal glands and a few other sites in the body such as the skin. For each of these, a canonical opsin and related transduction cascade were known. Specifically, ciliary structures associated with specific G-proteins are known from vertebrate eyes, and microvilli associated with inositol phosphate signaling cascades are known from invertebrate eyes. However, recently each of these phototransduction cascades was found in unexpected organisms. The polychete ragworm (*Platynereis dumerilii*), in addition to the rhadomeric photoreceptors in its eyes, has ciliary photoreceptors in the brain and typical types of opsins associated with each photoreceptor type were localized only with that type (e.g., vertebrate opsin in the brain and invertebrate opsin in the eye). This means that the two main types of 'eyes' exist in a worm.

Correspondingly, in vertebrates, a small population of intrinsically photosensitive retinal ganglion cells have been discovered that play key roles in the regulation of nonvisual photic responses. These rely on melanopsin, first identified in vertebrate melanophores, brain, and eyes. Melanopsin is in photosensitive ganglion cells which comprise a non-image-forming system that can detect the presence or absence of light and are required for normal light-induced circadian phase shifting. Subsequent functional analyses showed that retinal melanopsin functions via a phototransduction cascade that resembles invertebrate opsins and, similar to invertebrates, has intrinsic photoisomerase activity. Therefore, not only do vertebrates carry a version of the invertebrate visual transduction system with them but also it is used in a variety of ways, including to provide information to the 'image-forming' visual system.

Taken together, these findings show that at least two kinds of photoreception existed in the Urbilateria, before the split into three Bilateria branches at the Cambrian, and, importantly, each of these branches still carries versions of these two systems. Considering that seven families of opsin have been described in humans, we can expect more surprises in the detection of light. The additional opsins discovered recently have not been functionally characterized, but the evidence suggests that there are no more opsins to be discovered. Even so, determining how all the existing opsins work together is a daunting challenge.

How Did Eyes Evolve?

Eyes exist in a variety of shapes, sizes, optical designs, and locations on the body, but they all provide similar information about wavelength and intensity of light to their owners. Different tissues have been recruited to build lenses and retinas across the phyla. In contrast, all eyes share the same mechanism of absorbing photons which has been conserved across phylogeny, namely the opsin–chromophore combination. Despite new findings yielded by powerful molecular techniques, all evidence still suggests that eyes have a polyphyletic origin, as underscored by the discovery that two photodetection systems had evolved prior to the split of the Urbilateria into three families. Clearly, non-homologous eyes contain homologous molecules responsible for many structural, functional, and even developmental features. Given a growing list of homologous gene sequences among molecules in the eye across vast phylogenetic distances, the challenge is to discover what makes the eyes of *Drosophila*, squid, and mouse so different. Understanding these differences is probably more difficult than determining what they have in common.

It seems increasingly evident that as eyes have evolved, different functional mechanisms have been generated by recruiting existing gene programs. From genome sequencing, we know that there are far fewer genes in organisms than previously thought, so the use and reuse of genes and their products in combinatorial assemblies as reported for known genomes makes sense. In the development of eyes, this seems to be the rule, not the exception. Specifically, in the evolution of eyes, it seems likely that light sensitivity evolved early in the Cambrian in the form of a proto-opsin molecule in association with the chromophore retinal. This molecular combination, sensitive to light, became associated with genes such as *pax6*, *eya*, and others. It seems likely that this combination was recruited and worked well in early evolution of eyespots and other light-sensing organs.

Important insights about how regulatory gene networks might have evolved come from what is called the 'hox paradox.' During development, orthologous genes are expressed in superficially similar domains during embryonic development of very different organisms (e.g., *Drosophila* and mouse), yet these embryos produce adults that are anatomically quite distinct, having very few structures with common ancestors. Although not completely resolved, one resolution of this paradox is that there has been evolutionary convergence in the use of some genes and hence apparent homology, which seems to be the likely scenario for the evolution of eyes. Some genes have been recruited into regulatory gene networks repeatedly, possibly committed early in evolutionary history and kept because they simply work well.

As different eye types evolved over time, there was probably repeated recruitment of particular gene groups, not unlike improvisational groups of actors, interacting to produce candidates for selection. The evolutionary fiddling through which various combinations or routines were tried could have led to numerous parallel evolutionary paths for eyes as we now envisage.

From this, two different mechanisms for transmitting the photic information to surrounding cells were selected for – one in ciliary and one in rhadomeric photoreceptors. These two systems are likely present in all organisms as described previously for worms and mice. The major surprise is that both of these transduction systems persisted with each selected as the primary visual system for a major branch of animals. In vertebrates, these independently evolved phototransduction systems now collaborate in eyes to deliver information about light to our brains. Therefore, the answer to the question of whether eyes evolved from a single prototypical eye (monophyletic), or whether they evolved repeatedly (polyphyletic), appears to be that quite evidently eyes arose at least twice and probably many times.

Vertigo

E Smouha and G Wanna, The Mount Sinai School of Medicine, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Dizziness, a very common neurological complaint, can be caused by a variety of disorders affecting the vestibular, visual, and somatosensory systems; cerebellar, motor, and extrapyramidal systems; or cardiovascular, metabolic, and psychological systems. Classification of the patient's complaint is essential.

It is useful to divide dizziness into one of four categories: vertigo, imbalance, disequilibrium, and light-headedness. Vertigo is defined as a hallucination of motion of the body or the environment, and may be rotatory or linear. Vertigo is a cardinal symptom of vestibular system disease, which may be of peripheral or central origin. Imbalance (unsteadiness) is defined as impaired ability to maintain the intended orientation of body in space. Imbalance usually signifies chronic vestibular or neurological disease. Disequilibrium, or a feeling of 'drunkenness' or disorientation, may be vestibular, neurologic, multisensory, metabolic, or psychogenic in origin. Light-headedness (syncope or near-syncope) is cardiovascular or cerebrovascular in origin, or occasionally metabolic (e.g., hypoglycemia), but almost never vestibular.

The vestibular system is phylogenetically old and neurologically hard-wired, therefore its function is inapparent during normal activity, and its output can be difficult to measure. Its purpose is to stabilize the head in space, to stabilize eye movements during movement of the head, and to help stabilize body movements during stance and gait. The balance system is not accorded the status it deserves alongside the other 'five senses'; because it works seamlessly in the background, its function is often not recognized until a deficit occurs, at which time normal activity becomes nearly impossible.

The vestibular system works in concert with two other afferent systems – the visual system and the somatosensory (proprioceptive and exteroceptive) system – to maintain balance. The three stabilizing systems overlap sufficiently to compensate (partially or completely) for each other's deficiencies. Vertigo may represent either physiologic stimulation or pathologic dysfunction in any of the three systems.

Anatomy and Physiology of the Vestibular System

A basic understanding of the vestibular system is essential. A brief summary is offered here; excellent reviews can be found elsewhere (see 'Further reading' section). The vestibular apparatus consists of five bilaterally paired organs, producing redundant responses from the right and left sides: the utricle and saccule ('otolothic' organs), which sense linear acceleration and head tilt, and the lateral, superior, and posterior semicircular canals, which sense angular acceleration in three planes of space (Figure 1).

The utricle and saccule are dilatations of the membranous labyrinth, each of which has an end organ called the macula. The macula of the utricle lies in the horizontal plane and senses to-and-fro acceleration, such as in a car. The macula of the saccule lies in the vertical plane and senses up-and-down movement, such as in an elevator. Each macula is covered by a gelatinous membrane, in which many small calcium carbonate crystals (called otoliths or otoconia) are embedded. The receptor cells, vestibular hair cells, project 50–70 cilia (stereocilia) up into the gelatinous membrane plus one large cilium, the kinocilium. The otoliths have a high specific gravity, and their weight will bend the cilia in the direction of the gravitational forces. The hair cells are organized in an orderly array toward or away from a central line in the macula called the striola. The hair cells have directional sensitivity. Bending of the stereocilia in the direction of the kinocilium leads to opening of ion channels in the cell membrane, causing depolarization; bending of the stereocilia away from the kinocilium causes closure of the ion channels and hyperpolarization (Figure 2). The hair cells synapse with sensory endings of the vestibular nerve. Normally, the first-order neuron has a resting tonic discharge, firing at a rate of 100 Hz. Bending of the cilia toward the kinocilium leads to an increase of the impulse rate, and bending of the cilia away from the kinocilium leads to a decrease of up to 0 Hz. In this way, the system provides neural encoding of both the intensity and the direction of the acceleration.

The three semicircular canals (SCCs) are arranged at right angles to one another so that they represent all three planes in space. The lateral (or horizontal) SCCs are horizontal when the head is bent 30° forward. The superior (or anterior) and posterior SCCs

Figure 1 Classical drawing by Brodel of the membranous labyrinth of the inner ear.

Figure 2 Diagram of the vestibular hair cell response. With the head at rest, there is a tonic resting discharge rate in the first-order vestibular neuron. Movement of the head in one direction causes distortion of the stereocilia toward the kinocilium, leading to membrane depolarization and an increase in the discharge rate of the first-order vestibular neuron. Movement in the opposite direction leads to bending of the stereocilia away from the kinocilium, resulting in membrane hyperpolarization and a decrease in the discharge rate. The neural response is therefore encoded for intensity and directionality.

are oriented in an oblique-vertical plane. The superior SCC projects 45° forward, while the posterior SCC projects 45° backward. The right superior and left posterior SCCs are oriented in the same plane, as are the left superior and right posterior canals, so that information provided by each pair is complementary; flow of endolymphatic fluid excites one SCC and inhibits its partner. The receptor organ in the SCC is the

crista ampullaris within the ampulla, a membranous dilatation of the SCC located near the vestibule. The crista is covered by a gelatinous mass of high specific density, the cupula. Hair cells are arranged in an orderly array along the crista, with their cilia embedded in the cupula.

Each SCC senses angular acceleration in its plane of space. When the head begins to rotate in any direction, inertia causes the fluid to remain stationary relative to the SCC. The relative fluid flow bends the cupula, causing depolarization of hair cells on one side and hyperpolarization on the other. As with the utricle and saccule, the first-order vestibular neuron from each SCC has a tonic resting discharge that increases with stimulation (or decreases with inhibition), providing neural encoding for the change in intensity and direction of angular movement. As the head begins to rotate, the rate of discharge increases. With continued rotation, the excess discharge of the hair cell gradually subsides as the cupula returns to its resting position.

Beyond simply providing awareness of rotational motion, the main function of the SCCs is to stabilize gaze during head movement. This is mediated through the vestibuloocular reflex (VOR). Without such a system, it would be impossible to maintain a stable image on the retina while the head is moving quickly through space. When the head is suddenly rotated, signals from the SCCs cause the eyes to rotate in a direction equal and opposite to the rotation of the head. In the case of head rotation in the horizontal plane, the flow of endolymph fluid causes one lateral SCC to be stimulated and its contralateral partner to be inhibited. The VOR pathway travels from the SCCs through the vestibular nuclei and the medial longitudinal fasciculus (MLF) to the oculomotor nuclei (III, IV, and VI), and crosses the midline to provide excitatory and inhibitory signals to both eyes, resulting in conjugate eye movements. After a horizontal head-turn, the VOR causes the ipsilateral medial rectus and the contralateral lateral rectus muscles to contract, and the ipsilateral lateral rectus and contralateral medial rectus muscles to relax, resulting in deviation of the eyes away from the direction of the head-turn. In the real world, head movements are complex and multiplanar. Each SCC responds to the vector of movement in its own plane of space, and each SCC controls eye movements in its own plane.

The VOR is one of four systems that control eye movements. The VOR is a high-gain system, and stabilizes the image of the target during fast head movement. The optokinetic system fixates the image during slow target movement, as the target 'slips' across the periphery of the retina. Saccades (eye jumps) provide for quick changes of visual targets. Smooth pursuit allows the eyes to follow a slow-moving target through space.

Nystagmus is a jerking eye movement that is generated by the vestibuloocular system. A rapid rotation of the head causes the eyes to deviate in an equal and opposite direction, in order to remain fixated on a visual target. A slow, sustained rotation of the head also causes the eyes to deviate, but when they reach the endpoint of gaze, a saccade automatically intervenes to return them to midline. With a sudden rotation, such as on a carousel, physiologic nystagmus occurs, in which a slow deviation of the eyes away from the direction of rotation is followed by a quick automatic reset to the midline. With continued rotation, the nystagmus stops (as the fluid within the SCC 'catches up' to the rotation of the head).

Physical Examination of Vertigo and Imbalance

Physical exam should consist of complete evaluation of the ears, nose, and throat and central nervous system (CNS), with particular attention to cranial nerves, eye movements, gait, and balance.

Nystagmus and Lesion Localization

Nystagmus that occurs spontaneously is an important sign of vestibular system disease, and is valuable for differentiating peripheral from central forms of vertigo. Peripheral vestibular disorders produce nystagmus that is unidirectional, with its quick component directed away from the side of the lesion, and with greatest intensity when gazing toward the quick component ('Alexander's law'). Peripheral nystagmus exhibits visual fixation suppression – that is, it is accentuated in darkness and suppressed when fixing on a visual target. Central causes of vertigo, on the other hand, produce nystagmus that may be bidirectional or direction-changing, and that does not suppress with visual fixation.

Because of visual fixation suppression, vestibular nystagmus may not be apparent at the time of physical examination. Frenzel glasses (backlit myopic lenses) or electronystagmography (ENG) using eye electrodes or infrared videography are helpful for detecting and recording clinically latent nystagmus. The head thrust test, performed by grasping the patient's head and applying a brief head thrust first to one side and then to the other, is a sign of a peripheral vestibular lesion. The test is abnormal when a head thrust toward the damaged side produces a corrective saccade, and signifies a decreased vestibular response on that side.

Clinical Correlations

Broadly speaking, there are five types of vertigo that have an otologic (peripheral vestibular) cause:

1. continuous vertigo, resulting from acute unilateral vestibular loss (e.g., vestibular neuritis),
2. episodic vertigo (Ménière's syndrome),
3. paroxysmal positional vertigo (benign paroxysmal positional vertigo),
4. bilateral vestibular loss (ataxia + oscillopsia), and
5. superior semicircular canal dehiscence (SCD) syndrome or perilymph fistula (PLF).

Labyrinthine vertigo must be differentiated from central causes. Vestibular migraine ('migraine-associated dizziness') has increasingly been recognized as a cause of episodic vertigo. The clinical pattern of vertigo is very important for the diagnosis of peripheral vestibular dysfunction. However, duration remains the most important clinical feature in the diagnosis.

Vertigo Lasting Days to Weeks

The syndrome of continuous vertigo of sudden onset, absence of auditory symptoms, and attendant vegetative symptoms is usually caused by vestibular neuritis (believed to be of viral origin), but the same symptom complex can also occur after any sudden, unilateral loss of vestibular function, such as temporal bone trauma, acoustic neuroma surgery, infarction, etc. Physical examination in the acute phase will reveal horizontal–rotatory nystagmus with the quick component directed away from the side of the lesion. The nystagmus will have visual fixation suppression, and may only be apparent with Frenzel glasses or ENG. Patients will also demonstrate past pointing (drifting of outstretched hand with eyes closed), falling toward the side of the lesion on Romberg testing (standing with feet together, eyes closed), and ataxic gait veering toward the side of the lesion. These acute findings normally subside within 3–5 days, but imbalance and gait ataxia may persist for 4–6 weeks. Initial management is supportive and symptomatic for vertigo and nausea. Complete resolution is expected to occur spontaneously as time passes – first by a cessation of the tonic resting discharge of the contralateral side, then by CNS relearning, as a gradual increase in the spontaneous discharge of the diseased side takes place. In cases of slow or incomplete CNS compensation ('uncompensated vestibular neuritis'), vestibular rehabilitation physical therapy is very effective.

Vertigo Lasting Minutes to Hours

Episodic vertigo is usually due to endolymphatic hydrops, distension of the inner ear membranes, and may be primary (Ménière's disease) or secondary (otic syphilis, delayed endolymphatic hydrops, Cogan's disease, recurrent vestibulopathy). Patients with typical Ménière's disease have recurring attacks of vertigo, sensorineural hearing loss, tinnitus, and, sometimes, a fluctuating fullness in the ear. The etiology is unknown. The disease is usually unilateral, but may become bilateral in 10–15% of cases. The hearing loss fluctuates in the early stage of the disease, and progresses as time goes on, often to a moderately severe level. The audiogram is the most useful diagnostic test, usually showing sensorineural loss at the low frequencies. ENG may show reduced caloric response in the affected ear, but is often normal.

Treatment consists initially of low-salt diet (<2000 mg of sodium day^{-1}) and diuretics (usually acetazolamide or a thiazide). The majority of patients respond to conservative medical treatment. In cases of failure of medical treatment, partial chemical labyrinthectomy can be performed using intratympanic gentamicin. The dosage and method of administration vary among practitioners, but biweekly injections of gentamicin (40 mg ml^{-1} for 30 min is typical) may be administered, with the endpoint of treatment being the elimination of vertigo or the development of imbalance or hearing loss. Treatment results in elimination of vertigo in 70% of patients, with a 30% chance of worsened hearing and 2% risk of deafness. Surgical treatments are also performed in refractory cases. Endolymphatic sac decompression is about 60% effective, with a low risk of complications. The putative mechanism of action is drainage of the distended endolymphatic space. Results may not be any better than placebo surgery. Vestibular nerve section is highly effective ($>85\%$) but requires an intracranial operation with attendant risk of cerebrospinal fluid (CSF) leak and neurologic compromise. Labyrinthectomy is nearly 100% effective in eliminating vertigo, at the expense of total loss of hearing. This procedure should never be performed if bilateral disease is suspected.

Patients with otic syphilis present with interstitial keratitis and Ménière's-like hearing loss vestibular symptoms. Treatment consists of penicillin and steroids. Cogan's syndrome patients have interstitial keratitis, Ménière's-like hearing loss, vestibular symptoms, and nonreactive tests for syphilis. The hearing loss is bilateral and progressive, without spontaneous improvement, and frequently becomes profound. Treatment is mainly corticosteroids and cyclophosphamide.

Patients with delayed endolymphatic hydrops present with symptoms identical to those of patients with Ménière's disease, except that their hearing loss is severe and precedes vertigo by years and may even be congenital. The episodic vertigo is

invariably separate from the initial hearing loss. Treatment is medical, the same as for Ménière's disease, but surgery should be avoided since the condition is often bilateral.

Vestibular Ménière's disease, or benign recurrent vestibulopathy, produces episodic vertigo similar to Ménière's disease, although without audiologic symptoms. Treatment is symptomatic and supportive when required. The disease is often self-limited. Many if not all of these cases may be caused by vestibular migraine (see later).

Vertigo Lasting Seconds

Benign paroxysmal positional vertigo is the hallmark of vertigo lasting only seconds. Typically the patient experiences a severe rotatory vertigo associated with a change in head position, such as lying, turning in bed, reaching for the top shelf, or bending. The Dix–Hallpike (or Nylen–Barany) positional maneuver is diagnostic, and reproduces this symptom, along with geotropic, rotatory nystagmus. The response is unilateral, occurs with the affected ear down, has a brief latency (<10 s) and short duration (15–45 s), and demonstrates fatigability with repeat testing. The pathophysiology is the migration of otoconia, small crystals of calcium carbonate, from the utricle less often to the lateral or superior SCC. BPPV is usually idiopathic but can occur after head trauma, chronic otitis media, vestibular neuritis, or age. BPPV should be differentiated from central disorders; positional nystagmus that is continuous, bilateral, or without significant vertigo, should raise suspicion.

BPPV is quite disturbing for patients but has a very good prognosis. The particle repositioning maneuver, also known as the Epley maneuver, is highly effective. In this maneuver, the patient's head is moved from a sitting position into the inciting Dix–Hallpike position, then to the opposite side, then 180° to a near-prone position, then upright again (see Figure 3). The cycle is then repeated until the nystagmus is completely extinguished. This procedure is 80–90% effective in eliminating vertigo, and works by redistributing the microparticles of calcium from the posterior SCC into the vestibule. Patients can also treat themselves at home (Brandt–Daroff maneuvers). Surgical treatment with posterior SCC occlusion or singular neurectomy is rarely necessary because the problem is usually self-limited.

Bilateral Vestibular Loss

Bilateral vestibular loss is almost always symptomatic and very debilitating; the most common causes are drugs (aminoglycosides or cisplatin) and idiopathic degeneration. Patients complain of oscillopsia (eye bobbing) with minimal head movements, inability to fixate the horizon while walking, severe disequilibrium, and gait instability. Physical examination reveals gait ataxia (broad based) and loss of dynamic visual acuity (loss of >2 lines on the Snellen eye chart while the head is passively rotated). Diagnosis is made by demonstrating loss of bilateral caloric response (including ice water) on ENG, and severely decreased gain on rotational chair testing. Patients compensate partially over time, using the visual and somatosensory systems; however, recovery is incomplete most of the time. Vestibular physical therapy is helpful but not always curative. Artificial vestibular prosthetic devices such as BrainPort have shown early promise.

Vertigo of Variable Duration: Inner Ear Fistula and Superior Semicircular Canal Dehiscence Syndrome

Inner ear fistula Perilymphatic (inner ear) fistula (PLF) mimics other disorders, such as Ménière's disease, infection, acoustic neuroma, and lesions of the central nervous system. It can occur in the setting of trauma, cholesteatoma, or otosyphilis; spontaneous PLF probably does not occur. On examination, patients have vertigo and deviation of the eyes with external pressure on the tragus ('positive fistula test'). PLF after trauma is initial managed with bed rest,

head elevation, laxatives, and monitoring of hearing and vestibular function. In case of failure of conservative treatment, middle ear exploration is indicated, with fat patching of the oval/round window. PLF resulting from cholesteatoma should be treated by tympanomastoidectomy with or without removal of matrix from the lateral semicircular canal. Otosyphilis is diagnosed by Hennebert's sign (positive fistula test in the presence of an intact tympanic membrane) and a positive fluorescent treponemal antibody (such as FTA-Abs) test, and is treated with benzathine penicillin and steroids.

Superior semicircular canal dehiscence syndrome In 1998, Dr. Lloyd Minor first described superior canal dehiscence (SCD) syndrome. The typical signs of SCD syndrome are sound- and/or pressure-induced vertigo, and occasionally constant and often disabling disequilibrium and unsteadiness. The syndrome is caused by dehiscence of bone overlying the superior semicircular canal. These patients develop vertical–torsional eye movements (aligned with the plane of the superior semicircular canal on the affected side) in response to loud sounds or maneuvers that change middle ear or intracranial pressure. High-resolution computed tomography (CT) scan performed in the plane of the superior SCC is very important to confirm diagnosis. Surgical procedures through the middle cranial fossa approach, to plug or resurface the superior canal, are effective in resolving the symptoms.

Vertigo of Central Origin

It is possible for vertigo of CNS origin to exist without any other associated neurological signs. Vertigo that is continuously present for weeks without abating is generally not the result of a peripheral vestibular abnormality. CNS vertigo usually is less severe and more vaguely characterized, compared to peripheral vertigo, with mild vegetative responses. Physical examination may demonstrate nystagmus with central features: upbeating or downbeating nystagmus, direction-changing nystagmus on gaze or positional testing, and continuous (rather than paroxysmal) positional nystagmus. The absence of visual fixation suppression with Frenzel glasses or ENG is strongly suggestive of a central etiology.

Possible CNS causes of vertigo include vestibular migraine, vertebrobasilar insufficiency, cerebellar or lateral medullary infarction, and acoustic neuroma. Vestibular migraine (or 'migraine-associated dizziness') has become increasingly recognized as a cause of vertigo, and may account for many cases of episodic vertigo without auditory symptoms ('vestibular Ménière's disease). Vertigo attacks are spontaneous in onset, lasting minutes to hours, often accompanied by phonophobia or photophobia, and occur in patients with a history of motion sickness and/or classical migraine. The underlying pathophysiology may involve a defective calcium channel, primarily expressed in the brain and inner ear. Treatment with a variety of antimigraine drugs has been effective, including acetazolamide or topiramide, beta-blockers, and calcium channel blockers.

Cerebrovascular disease, including vertebrobasilar insufficiency and cerebellar or lateral medullary infarction, can also cause vertigo of the central type. Associated neurological signs such as dysarthria, incoordination, numbness, or weakness are usually present, but vertigo can also exist in isolation. Vertebrobasilar insufficiency can also cause drop attacks. MRI scanning is diagnostic.

Acoustic neuroma (or, more correctly, vestibular schwannoma) is a benign tumor that arises from the vestibular division of the eighth cranial nerve and involves the internal auditory canal and cerebellopontine angle. It usually presents with unilateral, progressive sensorineural hearing loss. Mild vestibular symptoms such as disequilibrium are common, but vertigo by itself is rarely a presenting complaint. Very large tumors can cause cerebellar compression leading to gait ataxia and, sometimes, coarse, bidirectional gaze-evoked nystagmus ('Brun's nystagmus'). Gadolinium-enhanced magnetic resonance image scan of the posterior fossa will demonstrate the pathology. Treatment is by surgical excision or stereotactic radiation.

Conclusion

Vertigo can be a vexing problem for physician and patient. A basic understanding of the physiology of the vestibular system, coupled with a knowledge of the common patterns of vestibular pathology, will lead to proper diagnosis and therapy in the majority of patients.

Vesicle Pools

J B Sørensen, Max-Planck-Institute for Biophysical Chemistry, Göttingen, Germany

© 2009 Elsevier Ltd. All rights reserved.

Synaptic transmission is caused by the fusion of small neurotransmitter-containing synaptic vesicles at active zones. The steps leading to the fusion of a vesicle start with the invasion of the presynaptic terminal by an action potential (AP), which triggers the opening of voltage-gated calcium channels. The ensuing calcium influx leads to a local increase in the calcium concentration and the calcium-dependent exocytosis of synaptic vesicles. The liberated neurotransmitter diffuses across the postsynaptic cleft and activates postsynaptic receptors, leading to changes in the postsynaptic cell.

The Concept of a Vesicle Pool

Despite the large pool of synaptic vesicles, and hence neurotransmitters, present in most synapses, repetitive stimulation of a synaptic contact often leads to synaptic depression, whereby the synaptic output is decreased until reaching a plateau value, which can be maintained for a longer time. In the 1950s, this phenomenon was attributed to the depletion of a pool of available neurotransmitters, and it was later combined with the quantal hypothesis and the vesicle hypothesis to indicate the depletion of a pool of synaptic vesicles – often referred to as the readily releasable pool (RRP) – constituting only a small fraction of the total number of vesicles in the synapse. Upon arrival of an AP, vesicles from this pool fuse with the plasma membrane, whereas the other vesicles in the synapse do not. During high-frequency stimulation, the readily releasable vesicles are released faster than the pool is replenished, leading to depletion of the pool and decrease of the synaptic strength.

The vesicle pool concept has since been extended considerably to include a multitude of different pools. Today, a vesicle pool can be taken to mean a population of vesicles in a similar or identical state. The underlying assumption is that synaptic or secretory vesicles pass through a limited number of discrete states before fusing with the plasma membrane. However, the question of whether vesicles are in a similar state depends on which vesicle property is effectively assayed in a given investigation. Therefore, the vesicle pool terminology is partly overlapping. For instance, electrophysiologists measuring the postsynaptic output of a synapse are likely to focus on whether a vesicle is releasable or not, whereas a morphologist, who searches for the position of the vesicle in the synapse, will use other categories, such as whether the vesicle is found close to the plasma membrane ('docked vesicle pool') or not.

Quantitative Treatments of the Readily Releasable Pool Concept

A simple quantitative treatment of the RRP concept follows from Figure 1. If N is the number of vesicles in the RRP, p is the probability that a vesicle in the RRP will undergo release during an AP, and q is the postsynaptic current elicited by the fusion of one vesicle (the quantal size), then an AP will result in the postsynaptic current (PSC):

$$\mathrm{PSC} = N\ p\ q$$

Immediately after the release, the RRP size will be $N(1-p)$, and if the fraction of available vesicles released by an AP and the quantal size remain constant, then the next stimulus will results in a PSC:

$$\mathrm{PSC} = N(1-p)\ p\ q$$

where we have assumed that recovery of the RRP between stimuli is so slow that it can be neglected. The ratio of the first two PSCs in a high-frequency train is therefore $(1-p)$ if all our assumptions hold (which, however, will not be the case in many instances). The recovery of the RRP is often assumed to be reversible and follow an exponential time course, and hence the plateau level of RRP size (or synaptic strength) will be proportional to the recruitment speed and inversely depend on the frequency of the train and the release probability.

The previous treatment is an example of a vesicle state model, in which synaptic output or exocytosis strength is modeled as a function of the state in which the vesicles are in (release-ready or not). An alternative model type, often used during statistical/quantal analysis, is the release site model, in which the behavior of discrete release sites is considered. In this case, the equation

$$\mathrm{PSC} = N\ p\ q$$

still holds, but the meaning of N and p has changed: N is now the number of release sites, and p is the probability that a vesicle is released from a release site. The latter quantity will depend both on the probability that a release site is occupied and on the probability that the occupying vesicle will fuse. Thus, it

Figure 1 The simplest possible release model encompassing a readily releasable pool (RRP) and a reserve pool (RP). The RRP is refilled from the RP through a reversible process often referred to as priming. Upon arrival of an action potential, the vesicles in the RRP fuse with a uniform probability, *p*.

is important to consider which form of the model is assumed or implied in any given work. Generally, vesicle state models are popular for modeling exocytosis from neuroendocrine cells, where the number of vesicles seems to be rate limiting for release, whereas release site models are often used for neuronal synapses, which have many vesicles but a very limited number of release sites.

Measurements of RRP Size

The size of the RRP is an important quantity because it defines the total synaptic strength of a synapse, which does not rely on pool replenishment. Thus, it gives the total ability of a synapse to respond to fast stimulation. The size of the pool is most often measured by applying a depleting stimulus. The challenge is to be able to release all of the RRP fast enough so that the pool size is not contaminated with replenished vesicles, which would lead to overestimation of the size. Conversely, failure to release the whole RRP would lead to underestimation.

RRP Measurement by Repetitive Stimulation

By applying a fast train of APs, the ensuing synaptic depression can be used to estimate the size of the RRP, provided that a strong depression is seen (Figure 2(b)). In this method, the cumulative PSC amplitude (or charge) is plotted as a function of time (or stimulus number). The first AP results in relatively large PSCs, but as synaptic depression occurs, the PSC amplitude decreases and finally reaches a plateau, which represents the recruitment process. The cumulative plot therefore approaches a straight line. By fitting a line to the late part of the cumulative plot, the RRP size can be found by extrapolating to zero. The size of the first PSC divided by the RRP gives the initial release probability ($p = \mathrm{PSC}_1/\mathrm{RRP}$). The RRP size estimate will be more accurate the more depression is seen, that is, the higher the release probability (and the slower the recruitment). In order to increase depression, measurement can be done in the presence of an elevated extracellular calcium concentration.

RRP Measurement by Sustained Calcium Elevation

Another way of delivering a depleting stimulus is by increasing the presynaptic calcium concentration, either by sustained depolarization (caused, for instance, by high extracellular [K^+]) or by photorelease of caged Ca^{2+}. In the latter method, a photolysable calcium chelator is introduced into the cell, and a strong flash of UV light is used to elicit a jumplike increase in the calcium concentration. Simultaneous postsynaptic measurements, or measurements of the increase in cell membrane capacitance, if possible, reveal the size of the RRP (Figure 2(a)). An advantage of flash photolysis is that the calcium concentration increase is spatially homogeneous, which allows the simultaneous determination of the calcium dependence of the release process. The main disadvantage is that photorelease of caged calcium requires access to the presynapse, which has limited the use of this method to neuroendocrine cells and a few synapses which are large enough to be patch clamped directly.

RRP Measurement by Hypertonic Pressure

The application of an extracellular solution made hypertonic by sucrose addition results in the release of synaptic vesicles. If the solution is hypertonic by 500 mOsm, the release process is biphasic, with a large initial peak and a smaller sustained plateau (Figure 2(c)). This release pattern indicates that a specific pool of vesicles has been released. When integrating the PSC over time, the release of the pool is clearly set off from the slower process, which is assumed to represent pool refilling. It is usually stated that the vesicles released by hypertonic solution are 'primed' for release, and the pool is often denoted as – or even defined as – the RRP. It is not known exactly how an increase in hypertonic pressure causes synaptic vesicles to fuse, but it does not depend on calcium influx and it might be caused by a stress-induced conformational change in the exocytotic machinery.

RRP Measurement by Fluctuation Analysis

Since synaptic transmission is quantal in nature, analysis of the fluctuations during release can be used to obtain the quantal parameters *N*, *p*, and *q*. In its simplest form, this analysis takes its starting point in

Figure 2 Three different ways of measuring the size of the readily releasable pool (RRP). (a) Flash photorelease of caged Ca^{2+} in combination with membrane capacitance measurements in a mouse chromaffin cell. The cell was patched in the whole-cell configuration and infused with calcium-sensitive dyes and a photolysable calcium chelator. At the time indicated by the arrow, the cell was subjected to a flash of UV light, which broke down part of the cage and led to an increase in $[Ca^{2+}]_i$ (top; preflash $[Ca^{2+}]_i$ is indicated by the dotted line). Immediately after the flash, the capacitance increased, indicating the fusion of vesicles with the plasma membrane. Fitting of a sum of exponentials (red curve) helped separate the size of the RRP and slowly releasable pool (SRP) from the near linear sustained-release component. (b) A high-frequency (40 Hz) train delivered to a patch clamped autaptic hippocampal neuron in order to deplete the RRP. The left panel shows the postsynaptic current (stimulus artifacts are blanked). It is easily seen that synchronized release displays fast run-down during the train. The right panel indicates the cumulative EPSC amplitude as a function of time. The gray regression line was fitted to the late part of the plot and extended toward zero. The intercept with the ordinate axis defines the size of the RRP. (c) A brief (3.5 s) pulse of extracellular solution made hypertonic by the addition of 500 mM sucrose delivered to a patch clamped autaptic hippocampal neuron. The release has a clear burst component, which subsides toward a steady level. The part of the trace between the arrows was integrated over time and displayed in the right panel. The integrated trace was fitted with a straight line, which was then extrapolated toward the beginning of the sucrose application. The intercept with the ordinate axis identifies the approximate size of the RRP. (a) Courtesy of Ralf Mohrmann. Data for (b) and (c) courtesy of Ignacio Delgado-Martínez.

the previous equation, which gives the mean peak PSC amplitude:

$$\mathrm{PSC} = N\ p\ q$$

According to binomial statistics, the variance of the PSC amplitude will be

$$\mathrm{Var} = N\ q^2\ p(1-p)$$

If we divide the variance with the mean, we get

$$\mathrm{Var/PSC} = q(1-p)$$

If the quantal size, q, is known, this relationship can be used to calculate first p and then N. The value of q can be estimated from analysis of spontaneous release events. The value of N obtained using this method probably corresponds to release sites rather than the number of release ready vesicles. A number of more complicated variants of fluctuation analysis exist, which are based on the analysis of covariance of PSC size or the analysis of higher cumulants.

On the Agreement between RRP Size Measurements

Given the different techniques used to measure RRP size, an important question is whether these measurements are in agreement with each other. In other words, are the vesicle pools measured and denoted 'RRP' in each case really identical, or do different methods measure different vesicle pools? Crucial for the answer to this question is the cross-depletion experiment in which the RRP is exhausted by one method (e.g., a train of APs) and then immediately probed using another method (e.g., direct calcium elevation). If the pool measured by both methods is the same, the second stimulation method should not elicit any response – or a very small response, due to some recovery between stimulations. Importantly, the cross-depletion experiment has to be performed with both sequences of the stimuli to ensure that the pool measurements agree and do not just overlap each other.

The most complete analysis of RRP size measured by different methods is available for the calyx of Held synapse in the auditory brain stem. This giant synapse is amenable to direct patch clamping of pre- and postsynaptic compartments, which allows detailed electrophysiological measurements, as well as capacitance measurements and flash photolysis of caged Ca^{2+}. For this synapse, repetitive stimulation gave an RRP size of 600–800 quanta. The repetitive stimulation method relies on the assumption that the quantal size, q, remains constant during a train, which might not necessarily be the case. Nonstationary PSC fluctuation analysis allows the determination of q and therefore estimation of RRP independently of differences in q. This gave an RRP size of 900 quanta. However, estimation by sustained calcium elevation gave larger numbers: 2200–2400 quanta when depolarization was used and 1800 quanta after photorelease of caged Ca^{2+}. These discrepancies may partly be due to differences in protocol because higher pool estimates were reached when cyclothiazide was used to prevent postsynaptic receptor desensitization and thereby changes in q. Another explanation is that during AP-driven release, vesicles situated inside calcium 'microdomains' around open calcium channels experience a high calcium concentration and fuse, whereas vesicles located farther away from calcium channels do not. However, during sustained calcium elevation, these 'distant' vesicles are also reached by the calcium signal and are fused. Yet another explanation is that certain vesicles might have an intrinsically lower release probability and are therefore only fused when the calcium signal persists over a longer period of time.

Another preparation used extensively for estimating RRP size is cultured hippocampal neurons. Being a culture system, it is amenable to the rapid application of hypertonic solutions, which represents an easy way of estimating RRP size. The analysis of sucrose and AP-elicited PSCs in autaptic cultures led to the conclusion that the pool released by sucrose is the same as that employed when release is evoked by APs. High-frequency stimulation led to a similar decrease of AP-evoked PSCs and sucrose responses (cross-depletion). Likewise, sucrose application similarly decreased AP-evoked PSCs and a second sucrose application (cross-depletion). The RRP as measured by sucrose application amounts to approximately 10–12 quanta per synapse. Notably, this number agrees fairly well with the number of docked vesicles measured by electron micrographs. In this case, therefore, primed vesicles might equal docked vesicles. In one study it was reported that when short 20 Hz trains were used to determine the RRP in glutamatergic neurons, the resulting pool estimate was much smaller than when determined by sucrose application. Increasing the length of the train and/or the extracellular calcium concentration made the RRP larger, as determined by repetitive stimulation. This is not surprising because, as discussed previously, RRP determination by train stimulation is better the larger the release probability. However, this result indicates that the RRP determined by different methods may be different. Most likely, during short trains vesicles distant to calcium channels are not released, whereas they are readily released by hypertonic stimulation or direct calcium elevation.

Replenishment of the RRP

Whereas the size of the RRP is important for the overall ability of the synapse to respond to high-frequency stimulation, the rate of RRP replenishment determines the ability to sustain transmitter output over a longer period of time. Thus, it is important to understand how RRP replenishment is regulated.

The most important finding is that high-frequency stimulation in itself stimulates RRP recovery, and the available evidence from cerebellar, hippocampal, and brain stem synapses indicates that this is due to the increase in intracellular $[Ca^{2+}]_i$ during trains, and in one case (the calyx of Held) it has been shown to depend on calmodulin. Thus, a stimulus that might lead to depletion of the RRP at the same time stimulates refilling in order to preserve the functionality of the synapse. Similar data have been obtained from neuroendocrine cells, such as adrenal chromaffin cells. In these cells, calcium-dependent refilling depends partly but not entirely on the activation of protein kinase C (PKC). In addition, refilling of the releasable pools is dependent on hydrolyzable ATP in both adrenal chromaffin cells and pancreatic β cells. An important difference between chromaffin cells and neurons is that in the former the basal $[Ca^{2+}]_i$ directly sets the size of the RRP, whereas in neurons the RRP size seems to be independent of $[Ca^{2+}]_i$ and only the refilling rate is calcium dependent. The former result is expected in vesicle state models, whereas the latter result is predicted by release site models because the number of release sites sets an upper boundary on RRP size.

Molecular Arrangement Underlying RRP Vesicles

Current research addresses the molecular machinery that underlies the formation of readily releasable vesicles. It is generally believed that so-called priming factors help preassemble an exocytotic machinery between the vesicle and plasma membrane, thereby making the vesicle release ready. The minimal calcium-dependent fusion apparatus seems to consist of the SNARE complex and one or more synaptotagmin isoforms, which act as calcium sensors for release. Most priming factors are believed to interact with these two classes of proteins.

One of the first priming factors to be identified was Munc13-1, whose elimination led to synaptic vesicles that were arrested at the priming step. According to one theory, Munc13-1 exerts its effect by binding to one of the SNAREs, syntaxin 1, in a conformation which assists the formation of the SNARE complex. Later investigations implicated many other proteins in vesicle priming, including the small monomeric G-protein Rab3 and the two Rab3-interacting proteins Rabphilin and RIM (Rab3-interacting molecule). It has also been suggested that the primed vesicle state might involve the formation of SNARE complexes in an intermediate state of assembly between the vesicle and plasma membranes. If this is the case, priming factors might exert their effect by modifying partial SNARE assembly.

Another important question is how the priming reaction and RRP size are regulated at the molecular level in the cell. Diacylglycerol, intracellular calcium, protein kinase A, PKC, and CamKII, as well as the lipid PIP_2, have been found to regulate RRP size and replenishment in different cells. However, the effector molecules for these second messengers have only been identified in a few cases. Phosphorylation of various presynaptic proteins has been implicated in different cell types. However, since the modus operandi of the priming and fusion machinery is not understood in detail, it is still not fully understood how these phosphorylation events regulate RRP size.

Other Vesicle Pools

From a physiological standpoint, RRP is often considered the most important vesicle pool because it is from this pool that vesicles are preferentially released during electrical stimulation. However, the vesicle pool concept is used to treat a number of other vesicle populations, corresponding to vesicles in different states.

The Reserve Pool

This pool concept is in most cases complementary to RRP, meaning all vesicles which are currently not in the RRP but which might be recruited through the process of priming. In later treatments, in which more releasable pools are assumed, the reserve pool usually denotes those vesicles not present in one of the more specific pools.

The Recycling Pool

The recycling pool of vesicles comprises all those vesicles which participate in synaptic recycling (i.e., both RRP vesicles and slowly releasable vesicles) as well as nonreleasable vesicles which are available for priming. Intrinsic to the concept of the recycling pool is the idea that a portion of the vesicles might not take part in active recycling under normal conditions but constitute a pool outside of the recycling pool, which might be recruited in certain circumstances. The recycling pool concept is often used in experiments in which synaptic vesicles are stained and destained with styryl dyes.

The Immediately Releasable Pool

The immediately releasable pool (IRP) is an important vesicle pool in many systems. The IRP consists of those release-ready vesicles which are closely co-localized with calcium channels. During depolarization, these vesicles experience the high calcium concentration within the so-called 'microdomains' or even 'nanodomains' close to open calcium channels. Consequently, they are more likely to fuse than are vesicles localized farther away. The only difference between these vesicles and the other RRP vesicles is the localization, and consequently the IRP can be considered a subset of the RRP. When stimulated by sustained and spatial homogeneous calcium elevation, the IRP and RRP vesicles fuse with identical kinetics. The estimation of the fraction of the RRP co-localized with calcium channels is done by stimulating the cell with repetitive short depolarizations to release the IRP, followed by stronger stimulation (e.g., by photorelease of caged calcium) to release the entire RRP. Such investigations have shown that in mouse chromaffin cells the IRP makes up approximately 25% of the RRP (35 vesicles out of 140). In contrast, in β cells almost all RRP vesicles are found co-localized with L-type calcium channels. Thus, the importance of this pool varies with the cell type.

The Slowly Releasable or 'Reluctant' Pool

Experiments carried out using photorelease of caged calcium revealed a vesicle population fusing with approximately tenfold slower kinetics than the RRP in chromaffin cells. This slowly releasable pool (SRP) seems to deliver the vesicles for filling the RRP since refilling of the RRP coincides with a temporary depression of SRP size. Thus, a linear arrangement of the SRP and the RRP was suggested. The RRP is absent in synaptotagmin 1 knockout mice, whereas the SRP persists, indicating that the association of synaptotagmin 1 with the exocytotic machinery is the distinguishing feature of RRP vesicles.

Also, neuronal synapses have slowly releasable or 'reluctant' vesicles. Depolarization of the calyx of Held terminal causes two phases of neurotransmitter release – a fast and a slow one. The faster releasable pool is replenished slowly, whereas the slower releasable pool displays faster replenishment. For this reason, the SRP might be important for maintaining neurotransmitter release during high-frequency stimulation. Furthermore, it has been found in both the calyx of Held and hippocampal neurons that the release probability of releasable vesicles is depressed soon after high-frequency stimulation (i.e., during recovery), which is in agreement with a faster recovery of reluctant vesicles or with the notion that vesicles have to pass through this state to become readily releasable.

An important outstanding problem is how the reluctant vesicles in neuronal synapses should be interpreted. There are two possibilities. One is that these vesicles are distinct from – or at least in a state distinct from – fast releasable vesicles and therefore characterized by a lower release probability. This is the same interpretation as for chromaffin cells. The other possibility is that the reluctant vesicles are identical to faster releasable vesicles except that they have a localization farther away from calcium channels. In the latter case, the vesicles would be part of the RRP but not part of the IRP, and strictly speaking it would not be necessary to operate with the concept of an SRP.

The Docked but Unprimed Pool

Comparisons of vesicle docking in electron microscopy (EM) micrographs and electrical measurements of the size of the RRP in neuroendocrine cells (chromaffin cells) have shown that the docked vesicle pool is much larger than the RRP. Also, inclusion of the SRP does not eliminate the discrepancy, so it is widely assumed that a pool of docked but unprimed vesicles must exist. In contrast, in hippocampal neurons the RRP size and the size of the docked pool seem to be in agreement. Thus, the docked but unprimed pool (UPP) might be a special feature of neuroendocrine cells. These vesicles might serve to replenish the SRP and RRP after release, even though this has not been directly shown. The notion of a UPP relies on the assumption that RRP and SRP vesicles are docked to the plasma membrane. This has been questioned in experiments in which recycling RRP vesicles were stained and localized using EM. These vesicles were found scattered in the vesicle cluster rather than docked to the plasma membrane. In neuroendocrine cells, visualization of fusing vesicles showed that vesicles inside the cell could undergo fusion. These and other observations have led to the claim that RRP vesicles might not be docked to the plasma membrane. However, in the first case, recycling vesicles and not the RRP vesicles were stained. In the second case, fusion of vesicles inside the cell occurred during the course of seconds after sustained calcium elevation. Since the recruitment of vesicles is calcium dependent, it is expected that under these conditions docking, priming, and fusion would occur within this time frame. When we restrict the concept of an 'RRP' to mean those vesicles that can be released within a few milliseconds (in neurons) or within a few tens of milliseconds (neuroendocrine cells), the conclusion that these vesicles must be predocked to the plasma membrane seems unavoidable.

The High Calcium-Sensitive Pool

In some neuroendocrine cells (chromaffin cells, β cells, and derived cell lines), a small pool of vesicles with a very high sensitivity to calcium has been described.

These vesicles are released fast at 1 or 2 μM of calcium, a concentration at which the fusion rate constant of RRP vesicles is almost two orders of magnitude slower. Cross-depletion experiments showed that these vesicles are distinct from IRP vesicles. Thus, they are not co-localized with calcium channels. Interestingly, the high calcium-sensitive pool (HCSP) seems to be more strongly regulated by phorbol ester and protein kinases than the RRP. This vesicle pool might represent a specialization to secretion in response to global calcium elevation due to release from internal stores. No counterpart to the HCSP has been described in neurons.

The Spontaneously Released Pool

Results from molecular studies of neurons have led to the identification of several manipulations that affect evoked release much more than spontaneous release. Generally, it seems that spontaneous release is more tolerant to changes in the composition of the exocytotic apparatus than evoked release. Studies of styryl dye staining/destaining of recycling vesicles showed that vesicles stained during spontaneous vesicle cycling were released with a slower intrinsic rate than vesicles stained with evoked activity. These and other observations led to the postulation of a special pool of spontaneously released vesicles that might recycle independently of the 'evoked pool' of vesicles. On the other hand, in the calyx of Held it was shown that the modification of spontaneous and evoked release by phorbol ester could be accounted for by the allosteric modification of the calcium sensor of a single pool of vesicles – the RRP. Thus, the spontaneously recycling pool concept remains controversial. The problem is that the spontaneous pool is defined by its slow release rate, and therefore it is not subject to rapid depletion and cross-depletion experiments. It is possible that another pool – for instance, the reluctant pool – could supply vesicles for spontaneous release. In certain circumstances – depending on the rate of interconversion between this pool and the RRP – this pool might appear kinetically isolated from evoked release.

Conclusion: The Pool Concept

The releasable vesicle pool concept has provided a useful framework for thinking about plasticity phenomena in neurons and neuroendocrine cells. The distinction between vesicle pool size, release probability or, equivalently, release rate constant, and pool replenishment allows for a detailed kinetic analysis, which can now be combined with molecular manipulations to identify the underlying causes. The extension of the pool concept to encompass any population of vesicles in similar or identical states has led to the identification or postulation of numerous vesicles pools, which has extended and refined our understanding but also made the situation somewhat more complicated and raised many questions regarding definitions. In this respect, it is important to remember that the definition of a vesicle pool is largely operational – that is, defined by the way in which the pool is assessed. With this in mind, the vesicle pool concept will remain fruitful to the field of neurotransmitter release.

Vesicular Neurotransmitter Transporters

R J Reimer, Stanford University School of Medicine, Stanford, CA, USA

Introduction

A little more than 50 years ago, Katz and colleagues demonstrated that acetylcholine was released at the frog neuromuscular junction in packets containing thousands of molecules. It was later proposed that the neurotransmitter is stored at the nerve terminal in small vesicles and that the fusion of these vesicles with the plasma membrane leads to release of the neurotransmitter. Subsequent physiological, anatomical, biochemical, and molecular studies have established that synaptic transmission, defined by the quantal release of neurotransmitters through exocytosis of synaptic vesicles, is the primary mechanism for information transfer in nervous systems of all organisms.

Because classic neurotransmitters such as acetylcholine are synthesized in the cytoplasm, a mechanism is required for their uptake into synaptic vesicles. Storage of neurotransmitter in synaptic vesicles has a number of theoretical advantages. First, it permits the simultaneous release of thousands of neurotransmitter molecules and allows a rapid rise in the synaptic cleft concentration. Second, vesicular storage sequesters neurotransmitter away from the cytoplasm. The maintenance of low cytoplasmic concentrations facilitates the efficient reuptake of released neurotransmitter and, in the case of monoamines, may reduce toxicity. Third, it provides a large pool of releasable neurotransmitter in nonrecycling reserve vesicles. Last, it imparts the potential for the simultaneous co-release of neuromodulators with a neurotransmitter and even co-release of two different classes of neurotransmitters.

Biochemical studies defined synaptic vesicle transport activities that mediate the uptake of the classic neurotransmitters. Four unique transport systems have been characterized: one for monoamines, a second for acetylcholine, a third for γ-aminobutyric acid (GABA) and glycine, and a fourth for glutamate. The transport processes facilitate the rapid refilling of vesicles and can generate lumen-to-cytoplasm concentration gradients of greater than 10^4. Recent molecular studies have identified the proteins that catalyze these processes. As expected, separate multitransmembrane domain proteins mediate each of the four biochemically described activities (Table 1 and Figure 1). The characterization of these proteins has generated specific molecular markers for cells that release a given neurotransmitter and has led to the identification of potential mechanisms for regulating neurotransmitter release.

Vesicular Neurotransmitter Transport Is Driven by a Vesicular Proton Electrochemical Gradient

Unlike Na^+-dependent plasma membrane transporters, the vesicular activities couple uptake to a proton electrochemical gradient ($\Delta\mu H^+$) across the vesicle membrane (Figure 1). This gradient is generated by a vacuolar-type H^+-adenosine triphosphatase (ATPase) that couples the hydrolysis of one adenosine triphosphate (ATP) molecule to the inward transmembrane movement of two protons. Recent data suggest that there is a single ATPase on each synaptic vesicle. Each pump is a multimeric complex containing cytoplasmic (V1) and transmembrane (V0) domains, with both domains composed of several polypeptide subunits.

The proton electrochemical gradient generated by the H^+-ATPase has a chemical (ΔpH) and electrical ($\Delta\psi$) component. Under normal physiological conditions there is a 1–2 pH-unit gradient and a 40–80 mV potential across the synaptic vesicle membrane. Due to the size of synaptic vesicles, a membrane potential (inside positive) is rapidly generated as protons are transported into the vesicle. This creates an energy barrier for the inward movement of protons that cannot be overcome by the H^+-ATPase and limits the pH gradient that can be achieved. However, anions such as Cl^- can permeate the synaptic vesicles membrane and reduce $\Delta\psi$. The reduction in membrane potential lowers the energy barrier and facilitates further H^+-ATPase activity with formation of a larger ΔpH. It has been suggested that a major regulatory mechanism for acidification of intracellular vesicles, including synaptic vesicles, is the flux of Cl^- through channels. The primary mediator of the Cl^- conductance in synaptic vesicles is believed to the ClC3, a member of the ClC family of chloride channels.

The dependence of all of the vesicular neurotransmitter transport activities on $\Delta\mu H^+$ is well established. Bafilomycin, a specific inhibitor of the vacuolar H^+-ATPase, the proton ionophores carbonyl cyanide *m*-chlorophenylhydrazone (CCCP), and carbonylcyanide *p*-(trifluoromethoxy) phenylhydrazone (FCCP) reduce vesicular storage of all neurotransmitters. The dependencies of the different transport systems on the chemical and electrical components of $\Delta\mu H^+$ have been determined by selectively reducing ΔpH and $\Delta\psi$. Nigericin, a H^+/K^+ exchanger, and weak bases such as ammonium sulfate are used to selectively

Table 1 Synaptic vesicle transporters

Transporter	*SLC designation*	*Substrate*	*Affinity*	*Predicted stoichiometry*	*Expression pattern*	*Sample inhibitors*
VMAT1	SLC18A1	Monoamines	Low micromolar	$2H^+/1MA^+$ exchange	Adrenal medulla, enterochromaffin cells	Reserpine
VMAT2	SLC18A2	Monoamines including histamine	Low micromolar	$2H^+/1MA^+$ exchange	Monoaminergic neurons in the brain, sympathetic postganglionic neurons, mast cells	Reserpine, tetrabenazine
VAChT	SLC18A3	Acetylcholine	Low millimolar	$2H^+/1ACh^+$ exchange	Cholinergic neurons in the central, peripheral, and autonomic nervous systems	Vesamicol
VGAT/VIAAT	SLC32A1	GABA and glycine	Low millimolar	Unknown	Inhibitory neurons, islet cells	γ-Vinyl GABA
VGLUT1	SLC17A7	Glutamate	Low millimolar	Unknown	Neocortex, cerebellar cortex, hippocampus	Evans blue, rose Bengal, DIDS
VGLUT2	SLC17A6	Glutamate	Low millimolar	Unknown	Thalamus, cerebellar and brain stem nuclei	Evans blue, rose Bengal, DIDS
VGLUT3	SLC17A8	Glutamate	Low millimolar	Unknown	Astrocytes, monaminergic, GABAergic, cholinergic neurons	Evans blue, rose Bengal, DIDS
ZnT3	SLC30A3	Zinc	Unknown	Unknown	Glutamatergic neurons	
ClC3		Chloride		Unknown	Broad	DIDS
Vacuolar H^+-ATPase			~ 0.1 mM	$2H^+$/cycle	Broad	Bafilomycin
SV2 (A, B, and C)		Unknown			All neurons and neuroendocrine cells

reduce ΔpH, whereas valinomycin, a K^+ ionophore, and increasing concentrations of permeant anions are used to selectively reduce $\Delta\psi$. With these approaches, it has been shown that the vesicular monoamine and acetylcholine transport systems depend primarily on ΔpH, GABA transport relies on both ΔpH and $\Delta\psi$, and glutamate transport relies almost exclusively on $\Delta\psi$ (Figure 1). These bioenergetic differences presumably reflect a combination of differences in substrate charge and the stoichiometry of coupling.

In addition to its role in proton translocation, the V0 domain has also been implicated in formation of the exocytotic fusion pore. Earlier biochemical studies identified the membranous subunit of the vacuolar H^+-ATPase as the mediatophore, a membrane protein complex that facilitates the release of acetylcholine at the synaptic cleft. This finding has been complemented by more recent genetic studies with *Saccharomyces cerevisiae* and *Drosophila melanogaster* that implicate the V0 domain in formation of membrane fusion pores. To form part of the fusion pore requires the dissociation of V1 and V0. In yeast, regulated dissociation of the two complexes has been shown to occur, suggesting that a similar process could occur at the synapse. Dissociation of V1 could allow for V0 on synaptic vesicles to interact with other membrane structures such as the plasma membrane, but could also function as a mechanism for limiting the vesicular proton electrochemical gradient and neurotransmitter accumulation.

Vesicular Monoamine Transport Is Mediated by Two Homologous Proteins

Studies on chromaffin granules, large intracellular vesicles from chromaffin cells of the adrenal gland, led to the characterization of a transport activity that mediates the vesicular accumulation of monoamines, including dopamine, norepihephrine, epinephrine, and serotonin. The subsequent molecular identification of the vesicular monoamine transporter resulted from a screen for genes from PC12 cells (an adrenal gland-derived cell line) that confer resistance to the parkinsonian neurotoxin MPP^+ in a sensitive cell line. MPP^+ bears a structural similarity to the monoamine neurotransmitters, and the resistance apparently results from

Substrate charge	+1	+1	0	–1
Protons per cycle	2	2	1 – 2	1 – 2
Net charge per cycle	+1	+1	+1 – 2	+2 – 3

Figure 1 Stoichiometry and bioenergetic dependence of the vesicular neurotransmitter transporters. A vacuolar type H^+-ATPase on synaptic vesicles generates a proton electrochemical gradient. The gradient consists of a pH gradient and a transmembrane potential of approximately -60 mV (inside positive). The different transporter families have different dependencies on the two components of the gradient – VMATs and VAChT are most dependent on the pH gradient, VGAT can be driven by either the pH or electrical gradient, and VGLUTs are most dependent on the electrical gradient. For monoamine and acetylcholine transporters, the stoichiometries have been determined, but for VGAT and VGLUTs the specifics of energetic coupling remain to be determined. $\Delta\psi$, electrical gradient; ADP, adenosine diphosphate; ACh, acetylcholine; ATP, adenosine triphosphate; GABA, γ-aminobutyric acid; Glu, glutamate; gly, glycerin; MA, monoamine; NT, neurotrophin; Pi, inorganic phosphate; VAChT, vesicular acetylcholine transporter; VGAT, vesicular GABA transporter; VGLUT, vesicular glutamate GABA transporter; VMAT, vesicular monoamine transporter.

the sequestration of the toxin inside vesicles, away from its primary site of action in mitochondria. The cloned vesicular monoamine transporter VMAT1 is predicted to have 12 transmembrane domains and is structurally related to the bacterial drug-resistance transporters. In addition to mediating the uptake of MPP^+, VMAT1 also transports dopamine, norepinephrine, epinephrine, and serotonin. VMAT1 is expressed by cells of the adrenal medulla, by neurons in sympathetic ganglia, and by other nonneural cells that release monoamines. In contrast, neuronal populations in the nervous system express the closely related VMAT2. The substrate specificity for the two isoforms is similar, and the apparent affinities for the monoamines are in the low micromolar range for both transporters, though VMAT2 has a slightly higher apparent affinity for all monoamines. In addition, only VMAT2 appears able to transport histamine at physiological concentrations, consistent with its expression by histamine-releasing mast cells. The high affinity of the VMATs may reflect a need to keep cytosolic concentrations of the relatively toxic monamines low.

Transport by the VMATs involves the exchange of two lumenal protons for one protonated molecule of transmitter carrying a net single positive charge and, thus, the outward movement of one net positive charge. For a vesicular pH gradient of ~ 1.5 pH units and membrane potential of ~ 60 mV, this predicts the accumulation of transmitter inside vesicles at concentrations 10^4–10^5-fold greater than those in cytoplasm. This is consistent with the micromolar and near-molar catecholamine concentrations measured in the cytosol and vesicles, respectively. Because osmotic forces limit the free transmitter concentration to ~ 150 mM, a fraction of the measured concentration, it has been suggested that the formation of macromolecular complexes consisting of a proteinaceous core, ATP, and the catecholamines reduces the effective osmolarity inside the vesicle.

The broad specificity of these transporters may be of particular importance in epinephrine-releasing cells. In these cells, VMATS transport dopamine into secretory vesicles, where the transmitter is converted to norepinephrine by the action of the dopamine β-hydroxylase, an enzyme restricted to the vesicle lumen. Norepinephrine then exits the vesicle, most likely through the action of VMATs, into the cytoplasm where it is converted to epinephrine by the action of phenylethanol-amine-*N*-methyltransferase. Epinephrine is then transported back into vesicle,

again presumably by VMATs. Although these last two steps probably occur through heterologous exchange (e.g., lumenal norepinephrine is exchanged for cytoplasmic epinephrine with no net proton movement), epinephrine released by exocytosis passes through VMATs three times.

Two well-characterized inhibitors act on the VMATs: reserpine and tetrabenazine. Both VMATs are irreversibly inhibited by reserpine, which initially showed clinical promise as an antihypertensive medication. The depressive effects of reserpine led to its more limited use but helped to formulate the original monoamine hypothesis of affective disorders. Reserpine appears to interact with the transporters near the site of substrate recognition. Tetrabenazine reversibly inhibits VMAT2, but is markedly less effective as an inhibitor of VMAT1. It has a limited clinical use in the treatment of some movement disorders. Amphetamines and 3,4-methylenedioxy-*N*-methylamphetamine (MDMA, or extasy) act as weak bases to reduce the vesicular ΔpH. Loss of this driving force for the vesicular transporters leads to the efflux of the lumenal contents into the cytoplasm and subsequent release through reversal of the plasma membrane transporters. The specificity of their effects (amphetamines lead to dopamine and, to a lesser extent, norepinephrine release, whereas MDMA leads to serotonin release) is thought to be due to selective uptake by the plasma membrane transporters. The association of polymorphisms in the VMAT1 gene with an increased risk for bipolar disorder also suggests a link between vesicular monoamine transport and molecular psychopathology.

A major mechanism for the regulation of vesicular neurotransmitter transport appears to involve changes in protein trafficking. VMATs undergo phosphorylation by casein kinase, and this posttranslational modification influences their retrieval from maturing large dense-core vesicles (LDCVs). Because sorting to LDCVs versus synaptic vesicles determines the site and mode of transmitter release, the regulation of transporter trafficking has great potential to influence signaling. In particular, differential trafficking of VMAT2 in midbrain neurons can lead to the release of dopamine from exocytosis at their cell bodies and dendrites, if trafficked to LDCVs, or axon terminals, if trafficked to synaptic vesicles. Regulation of VMAT activity by the heteromeric G-protein $G_{\alpha o2}$ has also been demonstrated. It appears that intralumenal monoamines activate the G-protein and downregulate uptake. This may be a mechanism to assure consistency in quantal size and may also serve to limit the efflux of the neurotransmitter through reverse transport once a vesicle has been filled.

The Vesicular Acetylcholine Transporter Is Structurally Related to the Vesicular Monoamine Transporters

The electric ray organ of *Torpedo californica* was an early source of synaptic vesicles. Subsequent to the determination that these vesicles are filled with acetylcholine, a specific activity for acetylcholine transport was characterized. The molecular identification of the transporter, however, required genetic studies in *Caenorhabditis elegans*. A screen for nematode mutants resistant to aldicarb, an inhibitor of acetylcholinesterase, identified *unc17*, a gene encoding a protein closely related to the VMATs. Based on the similarity to the VMATs, it was predicted that unc17 functions as an acetylcholine transporter and that the resistance phenotype results from the reduced release of acetylcholine. The binding of vesamicol, a known inhibitor of vesicular acetylcholine transport, was also found to be absent in membrane fractions from the *unc17* animals. Subsequent studies on the mammalian ortholog demonstrated that the protein is indeed a vesicular acetylcholine transporter.

In vertebrates, the vesicular acetylcholine transporter VAChT is expressed in cholinergic neurons in the central, peripheral, and autonomic nervous systems, including the basal forebrain neurons, lower motor neurons, and parasympathetic neurons. In an interesting genomic structure, the VAChT gene lies within the first intron of the gene encoding choline-acetyltransferase, the enzyme that catalyzes the synthesis of acetylcholine from choline and acetyl CoA. This structure, which suggests a spatial component to transcriptional regulation of factors conferring cholinergic characteristics to a neuron, is conserved from *C. elegans* to humans.

Like VMATs, VAChT recognizes a cationic substrate and depends primarily on ΔpH. VAChT has been postulated to have a similar stoichiometry of one cytosolic ACh^+ exchanged for two luminal H^+. In contrast to VMATs, which have substrate affinities in the low micromolar range, the mammalian VAChT exhibits an apparent affinity of approximately 1 mM. The higher affinity of VMATs may reflect a need to keep cytoplasmic levels of potentially toxic monoamine transmitters low. The measured quantal size at the neuromuscular junction ($\sim$10 000 molecules) is approximately fivefold larger than that expected for the 150 mM vesicular acetylcholine concentration predicted by osmotic limits. This suggests that, as with monoamine storage, mechanisms exist to limit the osmotic effects of acetylcholine in synaptic vesicles.

The vesicular acetylcholine transport can be inhibited by vesamicol and several related compounds. Vesamicol competitively inhibits transport by binding to a cytoplasmic domain on VAChT with a K_d of approximately 5 nM. Vesamicol binding can be used to estimate transporter number, but neither vesamicol nor its analogs are currently used clinically.

Vesicular GABA and Glycine Transport Activities Are Mediated by a Single Protein

The primary excitatory and inhibitory neurotransmitters in the mammalian brain are the amino acids glutamate and GABA. There are no sources of readily purified glutamatergic or GABAergic vesicles, as there are for monoaminergic and cholinergic vesicles (e.g., chromaffin granules and electric organ synaptic vesicles, respectively). Early biochemical studies defining vesicular transport systems for these neurotransmitters were, therefore, carried out on mixed synaptic vesicles purified from either the bovine or rodent brain. As for VMATs and VAChT, molecular characterization of the vesicular glutamate transporters (VGLUTs) and vesicular GABA transporter (VGAT) relied on additional information from molecular genetic studies.

The molecular identity of the vesicular VGAT was determined from a screen for *C. elegans* genes involved in GABAergic synaptic transmission. One gene identified in the screen, *unc47*, encodes a multitransmembrane domain protein that is localized to synaptic vesicles in GABAergic neurons. The functional characterization of a vertebrate ortholog confirmed that the protein mediated vesicular GABA transport. As predicted from studies with purified synaptic vesicles, VGAT mediates the uptake of GABA with an apparent affinity in the low millimolar range and uptake can be driven by ΔpH or $\Delta\psi$. VGAT also recognizes glycine as a substrate, but with a lower affinity, and is therefore also referred to as for vesicular inhibitory amino acid transporter (VIAAT).

VGAT shows no sequence similarity to VMATs or VAChT. Rather, it belongs to a large family of amino acid transporters. This family includes the proteins responsible for the transport activities biochemically defined as amino acid transport system N and system A. The latter is responsible for much of the active amino acid uptake by mammalian cells. Characterization of the function and cellular and subcellular localizations of these transporters suggests that the system N transporters and system A transporters mediate glial glutamine release and neuronal uptake, respectively, in the glutamine–glutamate cycle. This intercellular metabolic pathway is involved in the recycling of synaptically released glutamate and, to a lesser extent, GABA.

VGAT is expressed in GABAergic and glycinergic neurons as well as in the pancreas and has been reported to be expressed in the glial cells of the pineal gland. The targeted disruption of the VGAT gene in mice leads to a marked reduction in the synaptic release of GABA and glycine. The loss of the transporter leads to embryonic lethality, failures in gut withdrawal, and formation of a cleft palate. It is suggested that these defects are secondary to the loss of inhibitory neurotransmission and resulting paralysis.

Vesicular GABA transport can be competitively inhibited by amino acids, including glycine and β-alanine. Transport can also be competitively inhibited by γ-vinyl GABA, a derivative of GABA. γ-Vinyl GABA has been used in the clinical treatment of epilepsy and is known to inhibit GABA transaminase, an enzyme that metabolizes GABA. The mode of action for γ-vinyl GABA as an antiepileptic drug is thought to be through its effects on GABA transaminase, but the inhibition of vesicular GABA transport could have an effect by increasing the nonvesicular release of GABA.

Vesicular Glutamate Transporters Define Glutamatergic Neurons

Glutamate is the principal excitatory neurotransmitter in the mammalian central nervous system. Three unique vesicular glutamate transporters (VGLUT1, -2, and -3) have been identified. VGLUT1 was initially isolated in a screen for mRNA transcripts upregulated in cultured neurons by subtoxic doses of the excitotoxin *N*-methyl-D-aspartate (NMDA). Structural similarity to a class of proteins characterized as inorganic phosphate transporters led to an initial impression that the protein was a Na^+-dependent phosphate transporter and to a temporary designation of the protein as brain-specific Na^+ dependent inorganic phosphate transporter (BNPi). Although subsequent studies have demonstrated that the primary function of the protein is synaptic vesicle glutamate transport, some controversy remains regarding the role of the protein in phosphate transport.

The expression of VGLUT1 is limited to a subset of glutamatergic neurons in the brain. The highly homologous protein VGLUT2, also initially characterized as a phosphate transporter and named differentiation-associated Na^+-dependent inorganic phosphate transporter (DNPi), has a nearly complementary pattern of expression with one of the two proteins present in all established glutamatergic neurons. In general, VGLUT1 predominates in the neocortex and cerebellar cortex, whereas VGLUT2 predominates in the

brain stem nuclei, thalamic nuclei, and cerebellar deep nuclei. The septal nuclei, nuclei of the diagonal band, and hypothalamus also express VGLUT2. Although all cortical layers express VGLUT1, layer IV of frontal and parietal cortex and layers IV and VI of temporal cortex also express VGLUT2. Conversely, VGLUT2 predominates in the thalamus, but certain thalamic nuclei such as the medial habenula express VGLUT1. In the hippocampus, dentate gyrus granule cells express only VGLUT1, whereas pyramidal neurons from CA1 through CA3 express VGLUT1 as well as lower levels of VGLUT2. In the amygdala, the medial and central nuclei express VGLUT2, and the lateral and basolateral nuclei express VGLUT1.

The third vesicular glutamate transporter, VGLUT3, is expressed in neurons not classically considered glutamatergic. Immunohistochemical and *in situ* studies indicate VGLUT3 is expressed in GABAergic, serotonergic, dopaminergic, and cholinergic neurons as well as astrocytes. Recent findings suggest that VGLUT1 and VGLUT2 are expressed in astrocytes as well, but these studies are in isolated and cultured cells, not in intact tissue.

Glutamate uptake by the VGLUTs depends primarily on $\Delta\psi$ rather than ΔpH, with apparent affinities in the low millimolar range. Interestingly, the VGLUTs do not appear to recognize aspartate. This is consistent with studies of synaptic vesicles and suggests that aspartate is not readily accumulated in synaptic vesicles through an active transport system. Vesicular glutamate transport shows a biphasic dependence on chloride with an optimum at 2–10 mM, and recent studies with purified VGLUT1 suggest that glutamate transport requires Cl^-. Like VMAT transport, VGLUT transport also appears to be regulated by $G_{\alpha o2}$; specifically, $G_{\alpha o2}$ reduces the chloride dependence of transport. The role of chloride in vesicular glutamate transport is further complicated by the finding that the expression of VGLUT1 appears to increase the vesicular Cl^- conductance.

Although the VGLUTs exhibit similar transport activities, they are expressed in cells with very different properties. For example, compared to VGLUT1-containing neurons, VGLUT2 neurons, in general, have a lower firing rate and a higher probability of release. The three isoforms also appear to have different subcellular localizations that could influence glutamate-release characteristics. Most notably, VGLUT3 is expressed in vesicular structures within the dendrites of some neurons in the hippocampus and striatum, suggesting a role in retrograde signaling. Further, two polyproline domains, which are present in the C-terminal cytoplasmic tail of VGLUT1 (but not VGLUT2 or -3), mediate interactions with the endocytic protein endophilin. This interaction may regulate synaptic vesicle recycling and the mode in which VGLUT1 is internalized. Recent studies indicate that VGLUT1 and VGLUT2 are present in multiple copies on synaptic vesicles. Correcting for the number of vesicles containing the transporters, it is estimated that there are ~ 9 copies of VGLUT1 and ~ 14 copies of VGLUT2 in the synaptic vesicles in which they are expressed. Although not directly demonstrated, a similar stoichiometry probably exists for the other vesicular neurotransmitter transporters.

Several compounds that inhibit vesicular glutamate transport have been identified. These include the dyes Evans blue and rose Bengal. In addition, the stilbene derivative 4,4′-diisothiocyanatostilbene-2,2′-disulfonic acid (DIDS), a compound commonly used as an inhibitor of anion channels, inhibits vesicular glutamate transport. Most known inhibitors have a limited utility because they are membrane impermeant, with the exception of rose Bengal. No inhibitors unique for specific isoforms have been identified.

Neuromodulators Are Also Stored in Vesicles and Released through Exocytosis

Synaptic vesicles mediate the release of neuropeptides and small molecules other than the classic neurotransmitters. Neuropeptides enter the lumen of the secretory pathway in the endoplasmic reticulum through cotranslational translocation and are sorted to the secretory vesicle pathway, where they undergo processing to form the biologically active species. After release, it is believed that neuropeptides are degraded and not repackaged. Of the synaptically released small-molecule neuromodulators, zinc and ATP are the best characterized. NMDA and GABA receptors contain binding sites for zinc, and zinc exerts a direct effect on excitatory and inhibitory neurotransmission. ATP activates both ionotropic and G-protein-coupled receptors. As with the classical neurotransmitters, the exocytotic release of these compounds requires transport into synaptic vesicles.

The multitransmembrane domain protein ZnT3 has been implicated in zinc uptake by synaptic vesicles. ZnT3 belongs to a family of zinc transporters and localizes to synaptic vesicles. Mice deficient in ZnT3 show a loss of zinc staining from hippocampal neurons, and the expression of ZnT3 in PC12 cells increases vesicular zinc staining. Although ZnT3 transport has not been directly demonstrated, these findings strongly support a role for ZnT3 in synaptic vesicle zinc transport. The phenotype of ZnT3-deficient mice is mild, with the most striking abnormality being an increased susceptibility to seizures.

Chromaffin granules, platelet dense-core vesicles, and synaptic vesicles contain concentrations of ATP

many fold higher than cytosolic concentrations, suggesting active vesicular uptake. ATP transport has been demonstrated in chromaffin granules and synaptic vesicles, and the process appears to depend on $\Delta\mu H^+$. It has generally been assumed that ATP is co-stored only with monoamines and acetylcholine, as an anion to balance to cationic charge of those transmitters. However, the extent of ATP storage and release by different neuronal populations remains unknown, and the proteins responsible for ATP uptake by secretory vesicles have not been identified.

One of the first synaptic vesicle membrane proteins to be identified was SV2. This protein is a multitransmembrane domain protein with limited structural similarity to the VMATs and VAChT. The protein was identified in synaptic vesicles from *T. californica*, and three isoforms (A, B, and C) have been identified in mammals. The expression patterns of the vertebrate proteins show partial overlap and together cover essentially all neurons. Targeted disruption of isoform A and both isoforms A and B demonstrates that these proteins are crucial for normal brain function in mice. Although a specific biochemical function was not been defined by these studies, it has been suggested that SV2 might be involved in regulating the size of the readily releaseable pool of vesicles or Ca^{2+} homeostasis at the nerve terminal. SV2 is thought to be the binding site for botulinum A toxin entry into neurons and to be a binding site for the anti-seizure medication levetiracetam. It has also been suggested that the long sugar chains on SV2 serve as a smart-gel that regulates the release of neurotransmitters for the fused vesicle by limiting diffusion (Table 1).

Summary

The vesicular uptake of neurotransmitters is a requirement for the quantal release of neurotransmitters. Earlier biochemical studies that identified four primary activities have been complimented by the molecular identification of unique proteins that mediate vesicular neurotransmitter transport activities. The cloned transporters can be divided into three structural families – the VMATs and VAChT; VGAT; and the VGLUTs. All the transporters are driven by the proton electrochemical gradient generated by the vacuolar H^+-ATPase. Multiple copies of a given transporters are present on a single synaptic vesicle, suggesting that expression levels and regulated trafficking may play roles in modulating synaptic vesicle filling. A greater number of transporters in the vesicle increases the rate of filling and, if there is a significant leak, also leads to an increase in the steady-state concentration of transmitter achieved. Although the potential for the modulation of the vesicular neurotransmitter transporter activities has been established, the extent to which neurotransmitter accumulation and synaptic transmission are regulated by vesicular transporter density, G-protein-mediated modulation, and the co-storage of other small molecules such as zinc and ATP remains to be determined.

Vesicular Sorting to Axons and Dendrites

Neuronal Polarity – Axons versus Dendrites

What Is Neuronal Polarity?

Neuronal polarity refers to the fact that neurons elaborate two distinct types of processes, namely, axons and dendrites. Axons and dendrites differ from each other in terms of morphology, molecular composition, and function. Functionally, dendrites are largely responsible for receiving signal inputs from other neurons, and axons are responsible for generating and propagating the signal output in the form of trains of action potentials. Action potentials are propagated directionally along the axon to the axonal nerve terminal. At the nerve terminal, synaptic vesicles filled with neurotransmitters await the arrival of action potentials. The resulting calcium influx into the presynaptic terminal causes fusion of synaptic vesicles with the plasma membrane and emptying of neurotransmitters into the synaptic cleft. Neurotransmitters then bind to the appropriate neurotransmitter receptors on the postsynaptic side of the synapse, which results in opening of ion channels and transmission of the electrical impulse from the presynaptic to the postsynaptic cell. Neuronal polarity thus underlies vectorial electrical signaling by vertebrate neurons.

Why Is Neuronal Polarity Important for Neuronal Function?

To ensure the proper conduction of electrical signals, channels and receptors have to be distributed to the correct locations. For instance, synaptic vesicle proteins are concentrated in synaptic vesicles clustered at presynaptic terminals, whereas neurotransmitter receptors are concentrated at postsynaptic sites, precisely apposing the presynaptic terminals. In addition, a very large number of voltage-gated channels show compartmentalized distribution and are not present evenly along the plasma membrane. For example, voltage-gated sodium channels are enriched at axon initial segments and nodes of Ranvier, where they function to initiate and regenerate action potentials, respectively. A large number of potassium channels are not distributed homogeneously in the neuronal plasma membrane either, but rather to axons, or to distal or proximal dendrites, depending on channel type. The exact combination of numbers and location of these channels determines and regulates neuronal excitability. Equalizing the distribution of channels and receptors to uniformity on the membrane would affect the excitability and firing properties of the neuron and lead to dysfunctional and/or nonfunctional circuits. Neuronal function therefore relies on successfully compartmentalizing the neuronal plasma membrane and creating a multitude of molecularly distinct subdomains (Figure 1). In addition to plasma membrane compartmentalization, axons and dendrites also differ in the organization of cytoplasmic components, cytoskeletal elements, and the relative preponderance of membrane-bound organelles.

Compartmentalizing the Plasma Membrane – Multiple Pathways

Most cell surface receptors in neurons are not evenly distributed to dendrites, soma, and axons but rather show enrichment in certain domains, that is, their distribution is polarized. At the most basic, one can distinguish proteins enriched on the axon from proteins enriched on the soma and dendrites, the somatodendritic domain. Furthermore, many proteins are found enriched in smaller subdomains of the somatodendritic or axonal domains, such as synapses, distal or proximal dendrites, soma, axon initial segments, or nodes of Ranvier (Figure 1). Several mechanisms contribute to the nonhomogeneous distribution of receptors and channels in the membrane: (1) Proteins can be specifically targeted to axons or dendrites from the secretory pathway. (2) After reaching the surface, they can diffuse laterally until they bind to appropriately placed cytoskeletal scaffolding proteins, which restricts their diffusion to inappropriate domains. (3) And they can be internalized via endocytosis when they are not in the correct place. These mechanisms can act alone or in combination on any given protein to ensure the correct steady-state distribution. It is an open question whether proteins localized to smaller subdomains, such as synapses or nodes of Ranvier, arrive there directly in a targeted fashion from the secretory pathway or are secreted more generally in a larger area in the vicinity of their final destination. If secretion were not spatially precise enough to deliver proteins to synaptic sites or initial segments or nodes of Ranvier, the resident proteins would become concentrated at the correct site in a multistep process using postinsertion mechanisms such as lateral diffusion, clustering, and/or endocytic removal. Even if secretion were spatially precise, maintenance of the correct localization might still require clustering and tethering to cytoskeleton in order to prevent diffusion away from the correct locale.

Figure 1 Compartmentalizing the neuronal plasma membrane. Vertebrate neurons contain a large number of distinct plasma membrane domains with distinct composition (diagram on left, actual neuron on right).

The Secretory Pathway in Neurons

Basic Features of Secretion

The secretory pathway has been studied in detail for decades, especially in nonneuronal cells, and its basic features are conserved in all cell types, including neurons. Membrane proteins are cotranslationally inserted into the endoplasmic reticulum (ER), where they fold. They exit the ER at specialized ER exit sites and make their way to the Golgi apparatus via the ER–Golgi intermediate compartment (ERGIC). The Golgi apparatus contains a number of thin membrane sacks which are held together in a stack. The stack closest to the ERGIC is the *cis*-Golgi, followed by the medial and then *trans*-Golgi stacks. Each stack contains different enzymes which modify the traversing membrane proteins. The major modification that takes place in the Golgi is glycosylation. After leaving the *trans*-Golgi, membrane proteins enter the *trans*-Golgi network (TGN), which is made up of a large number of loosely associated tubules and vesicles. The TGN is a major sorting station where proteins ('cargo') are segregated into distinct vesicles that take them to either the plasma membrane or the endosomal system. Signals in the cytoplasmic tail of membrane proteins bind to specific adaptor complexes (such as adaptor protein (AP) 1), which mediate the enrichment of the appropriate cargo molecules and the subsequent assembly of coat structures. The assembling coat deforms the lipid bilayer into a vesicle and allows budding. One of the coats assembled at the TGN is clathrin, but less-well-studied nonclathrin coats are also involved in some budding steps. Clathrin is rapidly disassembled from a newly budded vesicle, which travels (mostly along microtubules) to its destination, the plasma membrane or endosomes. Specific microtubule motor proteins (kinesins) are required for linking and transporting specific transport vesicles along microtubules. All the steps described are highly regulated and carried out by complex molecular machinery (see the section titled 'Molecular targeting machinery'). The final step is fusion of the transport vesicle with the appropriate target membrane, a process requiring a set of matching proteins on the vesicle and target membrane. The matching proteins are called soluble *N*-ethylmaleimide sensitive fusion protein attachment receptors (SNAREs), and many different members of this family regulate fusion steps at distinct sites.

Regulated versus Constitutive Secretion

Classically, two types of secretion have been distinguished: constitutive and regulated. Most membrane addition occurs via constitutive fusion of post-TGN vesicles with the target membrane and is not regulated by extracellular signals. In many specialized cell types, secretion of certain cargoes occurs only in response to a signal, such as extracellular hormones or electrical stimuli. Molecules secreted by regulated secretion frequently reside in a distinct class of vesicles, called dense-core vesicles, based on their distinct appearance by electron microscopy. Synaptic vesicle fusion in nerve terminals occurs in response to membrane depolarization and calcium influx and can be viewed as another example of regulated secretion. The classical neurotransmitters, though, are stored in small, clear synaptic vesicles which do not contain a dense core. It is becoming increasingly clear that some of the secretion pathways considered historically to be constitutive are also subject to regulatory control by extracellular signals.

Endosomal Secretion

In addition to the biosynthetic secretory pathway, membrane proteins can also be secreted from the endosomal system. The endosomal system consists of a multitude of tubular and vacuolar organelles which receive cargo both from the cell surface after endocytosis and from the TGN. Proteins taken up by endocytosis at the plasma membrane first enter early endosomes, from which they are rapidly (within 5–8 min) trafficked to several other endosomal compartments. Depending on the cargo, proteins can either cycle back to the surface or be degraded in lysosomes. Recycling cargo returns to the cell surface either directly from the early endosome or via an intermediate stopover at a distinct tubulovesicular endosome, called the recycling endosome. Recycling to the surface from the recycling endosome is also polarized and results in secretion in distinct sites of the plasma membrane. The endosome and the TGN are therefore the major sorting stations for polarized secretion of membrane proteins. Degradative cargo fails to recycle from the early endosome and enters the degradative pathway to lysosomes via late endosomes. Late endosomes and lysosomes have a very low pH and appear under electron microscopy as multivesicular bodies and/or organelles filled with dense material. Lysosomal hydrolases inside lysosomes then degrade the proteins.

Neuronal Adaptations of Secretion

Neurons are arguably the most complex cell type in the body. Their surface area is many times larger than that of most other cells. They have a very complex architecture with functionally distinct domains positioned very far from the cell body. These unique characteristics create special demands, not only in terms of the sheer capacity for lipid and protein synthesis, but also in terms of the organization and regulation of secretion. Nonneuronal cells typically possess only one Golgi stack, localized near the centrosome on one side of the nucleus. Neurons similarly contain a large somatic Golgi organized in stacks. It is now clear that specialized secretory compartments exist in dendrites, and probably even in dendritic spines, in addition to the somatic Golgi. Are all membrane proteins produced in the somatic Golgi, no matter whether their final destination is the soma, the dendrites, or the far-away axon terminals? The dendritic Golgi compartments (named 'Golgi outposts') are particularly prominent in the large apical dendrites of pyramidal neurons and often localized at branch points. It is not yet known whether only a subset of cargoes traffics via the dendritic Golgi or how transport through the Golgi outposts is regulated. In any case, Golgi outposts would be uniquely situated to polarize a subset of secretory traffic toward sites near the final destination of the cargoes. This 'outsourcing' of a subset of traffic pathways to Golgi outposts may simplify the task of spatial segregation of membrane components. The unique architecture of neurons has led therefore to specializations of the protein production pathways. A second way in which neurons simplify the spatial problem of secretion is by locally translating some messenger RNAs in dendrites and also in axons. A subset of messenger RNAs is not translated in the soma but rather transported via specialized machinery to the dendrites, where its translation is locally regulated.

Polarized Membrane Traffic in Epithelial Cells – a Useful Analogy for Neurons?

Many other differentiated cells elaborate distinct plasma membrane domains. The best-studied examples are epithelial cells, which have distinct apical and basolateral plasma membrane domains. Many membrane proteins, such as influenza hemagglutinin, are targeted to the apical domain, whereas vesicular stomatitis virus G-protein is targeted to the basolateral domain. Much work, in particular on the Madin-Darby canine kidney (MDCK) cell line, has led to the following model of polarized membrane traffic: apical and basolateral proteins are segregated away from each other into distinct carrier vesicles at the level of the TGN. The efficient sorting of membrane proteins in the TGN requires specific signals in the cytoplasmic tail of basolateral receptors. Several classes of basolateral targeting signals have been identified. One is a tyrosine-based motif characterized by an essential tyrosine in the context of YXXϕ (where X represents any amino acid and ϕ is a bulky hydrophobic residue). The other is a dileucine-based motif characterized by two consecutive leucine residues. Both signals have been implicated as internalization signals at the plasma membrane as well. Several of these signals mediate direct binding to adaptor complexes (such as AP1B), which ensure enrichment of cargo to small membrane regions, recruitment of clathrin coats, and formation of budding vesicles. Additional basolateral signals not related to tyrosine- or dileucine-based motifs have also been identified. The newly budded vesicles then transport to the appropriate membrane domains, where their fusion is controlled by other molecular complexes, such as the exocyst complex and SNAREs.

Similarly, apical targeting signals have been identified. Unlike basolateral signals, apical signals frequently map to extracellular/lumenal domains or to

residues near transmembrane domains of apical proteins. Several apical signals residing in the cytoplasmic tail of apical receptors have also been described. The machinery for apical targeting is relatively less well understood. How a lumenal targeting signal in the interior of the TGN can be recognized by apical targeting machinery is not well understood, but proteins such as MAL have been shown to affect apical targeting efficiency. Lipid composition also plays a crucial role in apical targeting of some proteins. Lipids with saturated fatty acid chains tend to associate tightly with cholesterol and glycosphingolipids and segregate into tiny islands of special lipid composition, called lipid rafts. Several apical proteins show higher affinity for lipid raft domains than for nonraft domains and cluster there. Preferential affinity for lipid rafts could therefore provide a mechanism for enriching and clustering of apically destined membrane proteins.

Mapping of Dendritic and Axonal Targeting Signals

On the basis of the observation that influenza hemagglutinin, which is apical in MDCK cells, targets to axons in neurons, while vesicular stomatitis virus G-protein, which is basolateral in MDCK cells, targets to the somatodendritic domain of neurons, it has been proposed that the mechanisms underlying polarized membrane trafficking in the two cell types are conserved. Experimental tests of this idea have revealed remarkable conservation of some processes, but also unique mechanisms in neurons.

Dendritic Signals

Both tyrosine-based and dileucine motifs resembling basolateral signals have been identified as targeting signals in several dendritic proteins. Tyrosine-based motifs are involved in the dendritic targeting of low-density lipoprotein receptor, transferrin receptor, and Delta/Notch-like epidermal growth factor-related receptor. Shal-family K channels and glycine transporter 1b use dileucine motifs for dendritic targeting. A dileucine motif also mediates dendritic targeting of serotonin receptors 5-HT1A/1B and of neuronal nicotinic acetylcoline receptor α7. Nevertheless, not all dileucine motifs result in somatodendritic enrichment. It is interesting that some motifs associated with dendritic targeting are not related to basolateral targeting motifs, such as the motifs in the cytoplasmic tails of neuroligin-1, glutamate receptor (GluR) 1, and metabotropic glutamate receptor (mGluR) 1a. A novel phenylalanine-based motif has recently been identified to direct telencephalin to neuronal dendrites. Clearly, the full catalog of dendritic signals is still to be determined, together with the machinery and regulation for each of the distinct classes. Whether the kind of dendritic signal present in a protein regulates any aspects of spatial fusion or retrieval is unknown.

Axonal Signals

As described for basolateral dendritic signals above, axonal signals can in some instances share characteristics with apical targeting signals. For instance, the extracellular/lumenal domains of some axonal proteins (i.e., the cell adhesion molecule (CAM) L1/neuron–glia (Ng) CAM) and β-APP) are sufficient for axonal targeting. In the case of NgCAM, the extracellular domain is also active in apical targeting in MDCK cells. As for apical signals, the molecular mechanisms underlying recognition and execution of lumenal axonal signals are not known. Just as in apical targeting, association with lipid rafts may provide a necessary step for axonal targeting of some proteins (especially glycophosphatidylinositol-linked proteins, such as Thy1 and prion protein), but not of others (e.g., NgCAM). Sorting into the axonal compartment can also be a result of posttranslational modifications, such as palmitoylation. Palmitoylation is essential for effective targeting of growth-associated protein-43 and glutamic acid decarboxylase-65 to the presynaptic clusters in axon and for exclusion from dendrites. The palmitolyated domains reside in the N-terminal region of the proteins.

An increasing number of axonal targeting signals have recently been mapped to cytoplasmic sequences, even though not all targeting signals could be mapped precisely. In particular, the cytoplasmic tails of mGluR7, 5-HT1B, γ-aminobutyric acid (GABA) transporter, and GABA transporter-3 have been reported to mediate axonal targeting of these proteins in neurons. Sequences responsible for targeting of KCNQ2 to the axon reside in the membrane proximal region and conserved A domains of the KCNQ C-terminal tail; the exact motifs, however, are still unknown. Recently, a novel signal, RRK tripeptide, resembling the RXR ER retention motif, found in the C-terminal region of mGluR1b, has been shown to be sufficient and necessary for axonal targeting of the protein in retinal ganglion neurons but not in hippocampal neurons.

Clearly, axonal targeting signals are diverse, and the mechanisms of their execution are poorly understood. For most of the signals mapped, it is unknown whether the signal promotes lateral enrichment into axonally destined vesicles in the TGN, association with axonal motors, competence for fusion with axonal secretion sites, anchoring and restriction of diffusion in axons, or retrieval by endocytosis from inappropriate sites. There are a number of examples

of axonal targeting, though, from which some mechanistic insights have been gleamed. For instance, targeting of the potassium channel Kv1.2 and Kv1.3 to the axonal compartment requires the tetramerization domains (T1) which lie in the intracellular N-terminal regions. The T1 domain is also required for interaction with the Kvβ subunit and this interaction of T1 might also contribute to axonal targeting of these channels. A second mechanism relates to the involvement of endocytosis and is discussed next.

A Role for Endosomes in Axonal Targeting Pathways

Two pathways have been identified which result in axonal accumulation in an endocytosis-dependent manner, selective endocytosis/retention and transcytosis. For several axonal proteins, the axonal targeting motifs mapped to endocytosis signals. These observations gave rise to the idea that axonal enrichment might not arise solely, or even primarily, from polarized secretion from the TGN to axonal domains but rather from the preferential endocytosis of 'misplaced' somatodendritic receptor pools coupled to specific retention/anchoring in the correct axonal domain. A selective endocytosis/retention pathway may account for the axonal enrichment of voltage-gated sodium channels, vesicle-associated membrane protein 2, and nicotinic acetylcholine receptor α4. A second endocytosis-dependent pathway to the axon is via transcytosis, that is, initial delivery to the somatodendritic domain, followed by endocytosis and transport to the axonal plasma membrane from somatodendritic endosomes. This pathway operates for L1/NgCAM and for the polymeric immunoglobulin receptor.

Molecular Targeting Machinery

A membrane protein has to navigate successfully a multistep pathway to reach the final location on either dendrites or axons. These steps include lateral enrichment into axonally or somatodendritically destined vesicles in the TGN, association with axonal or dendritic motors, competence for fusion with axonal or dendritic secretion sites, anchoring and restriction of diffusion in axons or dendrites, or retrieval by endocytosis from inappropriate sites. Each of these steps is subject to regulation and can, at least in principle, be carried out in a selective and discriminating manner for somatodendritic and axonal proteins. Regulatory molecules for each of these steps are therefore involved in the polarized distribution of membrane molecules. Several classes of regulators are well characterized in nonneuronal membrane traffic, and their exact roles in neurons are now under investigation.

Adaptor Complexes

Adaptor complexes (AP) (four distinct ones in mammals: AP1–4) are involved in protein sorting from the TGN to endosomes or to and from the plasma membrane. Adaptors are tetrameric complexes comprised of two large subunits, a medium subunit μ and a small subunit σ. Adaptors can bind to known sorting motifs in the cytoplasmic tail of receptors and promote the receptors' inclusion into forming vesicles. As such, adaptor complexes are considered part of the sorting machinery for polarized trafficking in epithelial cells. Adaptors likely play similar roles in neuronal trafficking. The most studied clathrin-associated adaptor, AP-2, binds endocytosis motifs and mediates synaptic vesicle formation and receptor trafficking from the plasma membrane via endocytosis. In the nematode, *C. elegans*, the μ subunit of AP1 interacts with odorant receptor ODR-10 and mediates sorting to dendrites in olfactory neurons *in vivo*. Similarly, the μ subunit of AP-4 binds to the C-terminal of ionotropic glutamate receptor delta 2 in brain and may thereby mediate targeting of the receptor to the dendrites of Purkinje cells. AP3 is known to be involved in lysosomal cargo sorting. In neuron, AP-3B is thought to serve neuron-specific functions, such as neurotransmitter release in GABAergic neurons. Beside the classic AP complexes, sorting of certain membrane proteins requires interaction with specific interacting proteins. Four small transmembrane α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) regulatory proteins (TARPs) constitute a family of stargazin-related proteins. Maturation and translocation of AMPA receptors from an intracellular site to the cell surface requires TARPs. This indicates that TARPs act as an adaptor in trafficking of AMPA receptors early in the biosynthetic pathway.

Exocyst Complex

The exocyst is a multiprotein complex originally found in yeast and required for polarized exocytosis. Its proposed role is to mark the site of vesicle fusion and regulate the fusion event. The exocyst plays important roles in membrane trafficking events, such as synaptogenesis and neurite outgrowth, required for neuronal development. The Sec8 subunit of the exocyst interacts with PDZ domain-containing synapse-associated protein (SAP) 102 and participates in the dendritic trafficking of newly synthesized *N*-methyl-D-aspartate receptors from the ER. In addition, Sec8 also mediates intracellular AMPA receptor targeting within the dendritic spine, possibly through PDZ-dependent interactions with synaptic scaffolding molecules. In *Drosophila*, the sec15 subunit of the exocyst

is required for targeting of specific cell adhesion and signaling molecules to the correct exocytic site, but not for synaptic vesicle release.

Rab Proteins

Rab proteins are small guanosine triphosphatases which regulate protein transport along the endocytic and exocytic pathways in all cell types. Rabs participate in vesicle budding, membrane fusion, and interactions with the cytoskeleton. Rab proteins are important for neuronal function because alterations in Rab protein regulation can lead to mental retardation in humans. In neurons, rab11 has emerged as a mediator of vesicle transport by coupling to myosin Vb to mediate GluR1 trafficking. Similarly, Rab8, which has an exclusive somatodendritic distribution, is involved in transport of proteins to the dendritic surface in neurons. In addition, Rab8 associates with exocyst in the recycling endosome and participates in targeting and delivery of AMPA receptors to the postsynaptic membrane.

Points of Regulation

It is now clear that polarized distribution to axons and dendrites can take place along multiple pathways, such as direct vesicular targeting from the TGN, indirect targeting via transcytosis, selective endocytosis/retention, and potentially others. These pathways are used differentially by different proteins, based on the signals present. It is also clear that the machinery regulating these various steps can be regulated, which opens up the possibility that, even if the signals are not changing, the pathway and/or final location can change. For instance, the same protein can be axonal in one neuronal cell type but somatodendritic in another. The same protein can also be localized differently at different developmental stages in the same neuron. In addition, pathway choice can be regulated by activity or by ligands. A striking example of the latter is the targeting of the type 1 cannabinoid receptor, which is modulated by constitutive activation.

Vestibular Influences on Cognition

Vestibular Areas in the Cortex

The vestibular system, long described as a sensory system, elicits reflexive eye movements such as the vestibuloocular reflex (VOR). The VOR helps us to keep our gaze fixed on a target while we move our head. Research interests have focused on the neuronal circuits underlying the VOR and computational models have been developed to describe the underlying neuronal network. The VOR has become a suitable paradigm to study how the brain implements a sensorimotor reflex; however, vestibular afferent pathways not only project to brain stem areas, which then elicit eye movements, but also reach other areas in the brain. These include the hippocampus (either directly or via thalamic nuclei) as well as cortical areas identified in primate studies to receive vestibular input (e.g., the area 2v at the tip of the intraparietal sulcus, area 3av in the central sulcus, area 7 in the inferior parietal lobule, and the parietoinsular cortex). More recently, measures of human brain activation by means of neuroimaging techniques (e.g., functional magnetic resonance imaging or positron emission tomography) during caloric stimulation of the semicircular canals or galvanic stimulation of the vestibular system have widely confirmed the existence of these vestibular-related areas. It is noteworthy that some cortical vestibular areas also project back to the vestibular nuclei.

The cortical vestibular areas are interesting because knowledge about them is a necessary prerequisite to explore the influence vestibular stimulation can have on cognitive functions. The relation between vestibular information and cognitive functions is twofold. First, we can study how vestibular information influences cognitive functions, and second, we can study how cognitive influences modify the perception of vestibular stimuli. Regarding the first point, it is particularly interesting to explore which cognitive tasks are affected by vestibular processing, and in what way. The second point studies how influences of cognitive origin can alter the perception of vestibular stimuli. These types of influences are often referred to as 'top-down' information, which can affect relatively early processes. Top-down processing has been studied intensively in many areas of visual perception, but there still is only scarce evidence for its role in the context of vestibular stimulation.

As already mentioned, neurophysiological evidence suggests that several cortical areas receive vestibular input (relevant for the first point), and there also are corticofugal projections from higher cortical areas to lower areas in the brain stem (relevant for the second point).

Influence of Body Tilt on Cognitive Tasks

It needs to be determined which cognitive functions are influenced by vestibular information, and which are not. It is at least conceivable that concomitant vestibular stimulation acts just like an additional task, which absorbs limited cognitive resources, which are then no longer available for the primary task. In this case, vestibular information would act in a rather unspecific way, and any type of cognitive function would be affected in nearly the same way. However, there is evidence that body tilt information from the otoliths has specific effects on cognitive functions.

Body Tilt Influences on Visual Perception Tasks

We first consider the example of orientation acuity, which illustrates how visual perception is influenced by body tilt. When upright persons have to judge the orientation of test stimuli (e.g., two subsequent sine wave gratings in a two-alternative forced-choice paradigm), the acuity estimates show clear meridional anisotropies; orientation acuity is higher for the principal upright and horizontal axes when compared to oblique axes. It was often tacitly assumed that orientation acuity is determined by the orientation of the test stimuli with respect to retinal coordinates. When the head was tilted sideways, however, the meridional variation interacted with head orientation. This finding contradicts an explanation based solely on retinotopically tuned neurons, which cannot explain the effect of head tilt. Similar influences of head tilt were found for other types of visual tasks ranging from visual illusions to visual search.

With perfectly upright observers, no effect of body tilt can possibly unfold, and only when tilted observers are tested can the retinal and gravitational reference frames be decoupled. Interestingly, single-cell recordings from monkey and cat studies further support the influence of body tilt information on early visual cortex. Even though the empirical evidence is still scarce, the findings demonstrate compellingly that orientation selectivity of neurons in early visual cortex is not defined exclusively in retinal coordinates, but rather follows the gravitational upright orientation.

These neurons are in the service of orientation constancy, which is the ability to perceive our environment as stable and upright despite the fact that head tilts inevitably influence how the world outside projects onto the retina. To compensate the potentially disturbing influence of head tilt, the brain uses the information from the otoliths, which signal the amount of head tilt. The otoliths are the primary sensory source of information about head tilt, even though a possible contribution of another gravity-receptive sensory system located in the trunk cannot be ruled out completely. In any case, retinal image shifts due to head tilts are compensated for, thus ensuring orientation constancy. How internal coordinate transformations of retinal coordinates can influence perception is strikingly illustrated by transient room-tilt illusions following central or peripheral vestibular disorders. Upright patients perceive the orientation of their visual environment as upside down or tilted by 90°. Room-tilt illusions are thus an example of what happens when the otherwise functioning visual–vestibular interaction is impaired.

These findings illustrate how performance in simple visual psychophysical tasks can change when the participants are no longer in a perfectly upright body position. In the following sections we shift the focus from the encoding of visual stimuli to information already stored in memory, and describe how higher cognitive functions can be modified by vestibular information.

Body Tilt Influences on Mental Imagery Tasks

What is the spatial frame of reference used by information already stored in memory? Do changes in body tilt influence how we perform mental operations? One of the most studied functions in cognitive psychology is mental imagery. It draws on the ability to generate, inspect, and transform images in our mind. An example of the latter is mental rotation, which is the ability to rotate images in one's mind. It is used when we see objects in an unusual orientation – for example, upside down. To still recognize the objects we need to match the image from the sensory input with a representation stored previously in memory. The more the objects are tilted away from their natural and upright orientation, the longer it takes for observers to respond (e.g., to name the object). It needs to be defined, however, what 'upright' means. Does upright refer to retinal coordinates (which is an egocentric frame of reference) or to a gravitational frame of reference (which is an allocentric frame of reference and therefore independent of the observer)? Again, in the upright body position it is impossible to decouple the two reference frames because they are fully aligned. Only when the observers are tilted can we draw conclusions about their relative influence.

Studies on mental rotation Empirical results have revealed an influence of body position – for example, with letterlike symbols as stimuli in a mental rotation task. Specifically, an observer's' performance was better when the stimuli were aligned with the gravitational vertical than with the retinal vertical. This implies that at least some representations are stored with respect to the gravitational vertical. More recently, the frame of reference has been studied in the context of face perception. Earlier research on face perception has shown that inversion of facial features such as mouth and eyes within an otherwise right-side-up face looks extremely grotesque (the face of a former British prime minister has been used in a well-known demonstration of this), but this grotesqueness disappears almost completely when the face is viewed upside-down (i.e., when picture is rotated by 180°). This phenomenon has been explained by a mental rotation process, which is simply overtaxed by keeping track of all configural information between facial parts when upside-down faces are rotated mentally. In the current context, it is of interest whether the perception of faces is determined by their orientation with respect to eye coordinates. If this were the only factor, changes in body position would not matter. After testing face perception in a variety of different body positions, it turned out that in a body position of 135° roll tilt (the head is between horizontal and upside down), it was more difficult to detect changes in the faces, whereas no such effect was present in the upside-down body position. This suggests that a gravitational frame of reference is involved in the perception of faces, even though the nature of the underlying mechanism is not resolved.

The subjective visual vertical The effect of head-down body positions has been investigated in other studies. For example, the subjective visual vertical shows largest errors in body tilt positions around 135°. Interestingly, not only the deviation from the physical vertical but also the variance reaches its maximum in positions around 120° and 150° roll tilt (whereas in the upside-down body position, 180°, there is much less variance and the errors are smaller). Therefore, the spatial reference information for the perception of the vertical is less reliable, and as a consequence, observers have difficulties in these positions in unambiguously judging the orientation of visual stimuli. In head-down positions around 135°, the deviation between the retinal up and the perceived gravitational is largest and exceeds more than 90° (this is also true for the upside-down body position but there the reference frames are again aligned, albeit in exactly opposite directions). It is noteworthy that observers sometimes report a

paradoxical experience when they are in a head-down body position. Some observers tend to perceive two different but distinct verticals, rather than just an increased range of uncertainty.

It has been assumed that less precise sensory information from the otoliths is related to the lack of confidence about the direction of gravity in exactly these unusual body positions. In analogy to the blind spot on the retina, it has been hypothesized that there also is a body tilt stimulus for which there are many less utricular or saccular hair cells with the corresponding direction specificity. It is, however, not yet certain whether the psychophysical results reported in head-down positions can be explained entirely by the properties of receptor physiology. Nevertheless, situations which lead to ambiguous or insufficient perception make the use of cognitive influences more likely, and they may eventually help in resolving what the actual stimulus was.

Currently, there is compelling empirical evidence for the role of body tilt information on perceptual and cognitive tasks, but no theory has yet been proposed describing how these influences can unfold, and what the underlying neuronal mechanisms are. More experimentation is still needed, since many studies varied two body positions only (e.g., upright and lying on the side in the horizontal position), and this is not sufficient to reveal the function the body tilt influence follows. Also, the stimulus dimensions need to be explored more thoroughly – for example, the effect of gravity on the perception of natural scenes may even exceed the effect on faces, because – unlike faces – natural scenes always appear gravitationally upright.

Studies in microgravity Instead of tilting the observers, exposure to microgravity is yet another way to change vestibular information – in particular, the information from the otoliths about the direction of gravity. Astronauts, during long-term missions, experience microgravity onboard the spaceship during several days. A short-term exposure to microgravity for about 20 s can also be reached on Earth by means of parabolic flight protocols onboard an airplane. During microgravity, the astronauts can move freely inside the cabin and receive no sensory input that directly indicates the direction of the vertical. When the pull of gravity is absent, the resting discharge level becomes the only afferent signal from the otoliths. It has been suggested that perceptual consequences can unfold from asymmetries between the otolith discharge levels from the right and left inner ear, and this still is discussed in the context of space motion sickness, for which no clear predictive measure has yet been found. On Earth, however, the presence of gravity provides a strong enough stimulus to override these possible asymmetries.

Interesting in the context of microgravity are orientation illusions. Astronauts are able to voluntarily assign a spatial frame of reference to their environment. They can choose which wall inside the spaceship becomes the floor. On Earth, this is determined by the presence of gravity, and only in the horizontal plane do we sometimes get confused regarding our orientation within the environment (e.g., when ascending from a subway we often start walking in the wrong direction, not taking into account a turn we just made underground).

Still, much research is needed to better understand the effects of microgravity on cognitive functions, both in terms of short-term and long-term exposure. The latter is important because it also includes the effects of a possible adaptation to the new environment. To date, only few studies on cognitive functions have been carried out in microgravity, and some studies report no change when compared to performance on the ground. This finding is not so surprising because, unlike body tilts on Earth, microgravity does not induce any changes in the direction of gravity. Vestibular and visual cues are not in conflict and the observers rely on visual information, such as upright persons on the ground. It has to be noted that only few cognitive studies have been carried out in microgravity, and it would be premature to rule out a yet unexplored effect on other cognitive functions.

Influence of Whole Body Movement on Cognitive Tasks

The preceding findings were obtained under static conditions. The vestibular influence is thus of otolith origin, since any semicircular effects of prior head or whole-body movements dissipated by the time the measurements began. Measurements during whole-body rotation are much more difficult to obtain. For example, the VOR can interfere with the visual encoding of stimuli used for a cognitive study, and this may confound the interpretation of the results. Yet another difficulty is to define an appropriate control condition, in which the body remains stationary. The absence of any vestibular stimulation is easy to achieve but there are several other factors, which are just not controlled for when comparing the results from the same task during the experimental condition (with vestibular stimulation) and the control condition (body and head are still). Inevitably, body movement entails stimulation of other sensory systems, such as skin receptors during acceleration or deceleration of the body (e.g., when we feel pushed backward into the seat during an airplane's takeoff). Not only is it

hard to isolate the vestibular system, but the body movement can be experienced just as generally more distracting or even discomforting and therefore can impair performance in the task. Yet another difficulty is of technical nature. Vestibular stimulation requires acceleration or deceleration as stimulus, and not movement at constant velocity, which is not based on any vestibular stimulation. For example, constant yaw rotation around the body longitudinal axis is no longer perceived when the eyes are closed; the person in this situation feels stationary as long as the head is not moved, which then likely results in cross-coupled acceleration stimulation. To sum up, it is not at all trivial to conduct research with clearly defined vestibular stimuli, and, in addition to this, it requires carefully designed tasks if one wishes to measure at the same time performance in a cognitive task.

Visual–Vestibular Interaction

Caloric and galvanic vestibular stimulations have become widely used techniques in vestibular research, and when combined with neuroimaging they have enabled researchers to explore the human brain areas during vestibular stimulation. They have the advantage that one can isolate the vestibular stimulation, and that they can be used while the body is stationary. They provide ways to produce the percept of body movement even though the body remains perfectly still.

Converging evidence based on several studies using different techniques points to a mutual inhibition between vestibular and visual stimulation. During vestibular stimulation the visual cortex is deactivated, and, likewise, during large-field visual stimulation the vestibular cortical areas are deactivated. Such a mutual inhibition serves the purpose of minimizing sensory conflicts. The deactivation of the visual cortex can help suppress inappropriate visual input during vestibular nystagmus.

Why is this mutually inhibitory interaction between visual and vestibular information relevant in the context of cognitive tasks? Independent research in cognitive neuroscience has provided a wealth of knowledge about the role of early visual cortex in visual mental imagery. When study participants have vividly imagined previously memorized images, several neuroimaging studies found early visual activation, in particular when the task required to picture details in images. During caloric stimulation this part of the brain is deactivated and hence it could be expected that imagery abilities are impaired. This was in fact the case, whereas a control task with knowledge-based questions (designed so that they have low imagery content) showed no change during caloric stimulation. This suggests that the influence caloric stimulation has on cognitive tasks is specific and does not generally distract attention.

The role of attentional demands on vestibular processing has also been studied, and the results show that monitoring of orientation is impaired when the level of disorientation is high enough. It has also been shown that cognitive tasks such as backward counting can impair accuracy in orientation tasks. This suggests that monitoring orientation using vestibular information requires mental effort and is therefore not entirely automatic.

Still, however, there is only scarce evidence about how vestibular information relates to cognitive tasks. To date, there is not yet a systematic approach to study cortical vestibular processes and to what extent these brain areas are shared with cognitive functions.

Vestibular System

J C Glover, University of Oslo, Oslo, Norway

This article is reproduced from the previous edition © 2004, Elsevier B.V.

Introduction

The vestibular system detects motion and gravity and initiates movements to maintain balance and orientation. It consists of a set of sensory organs in the inner ear, sensory afferents that link the sensory organs to the brain stem, a set of vestibular nuclei within the brain stem, and the projections of these nuclei to interneurons and motor neurons in the brain stem and spinal cord. Although the vestibular reflexes mediated by these projections are highly stereotyped, the vestibular system interacts extensively with the visual and proprioceptive systems, and its activity is influenced by the cerebellum and cortex to provide a high degree of adaptability.

Vestibular Sensory Organs and Afferents

The sensory apparatus of the vestibular system comprises much of the labyrinth of the inner ear (which also includes the acoustic sensory apparatus, the cochlea). The two mirror-symmetric labyrinths are complex bony structures lined with an epithelium and containing a fluid called endolymph. Separate regions of the epithelium are specialized by the presence of mechanoreceptive hair cells. Each labyrinth contains five vestibular sensory organs, whose mechanoreceptive portions are located within or near the vestibule of the labyrinth, hence the name 'vestibular' system (Figure 1(a)). The vestibular sensory organs can be classified into two types on the basis of structure and function: the otolith organs and the semicircular canals.

Otolith Organs

The otolith organs, the utricle and saccule (Figure 1(b)), detect linear acceleration. In humans, their mechanoreceptive epithelia (the maculae) bear respectively about 30 000 and 16 000 hair cells. The hair bundles of the hair cells are attached to a gelatinous sheet called the otolithic membrane, in which are embedded numerous calcite particles, or otoconia (literally, 'ear dust'). During an acceleration in the plane of the macula, the mass of the otoconia deflects the otolithic membrane and thus the hair bundles. The hair cells are oriented in various directions in a systematic pattern across the macular surfaces, thereby allowing responses to linear acceleration in any direction within the plane of the macula. The saccules are oriented vertically and parasagittally, whereas the utricles are oriented horizontally. Thus, in a person standing upright and motionless the saccules are selectively stimulated by the acceleration caused by gravity, whereas in a person lying motionless on his or her side the utricles are selectively stimulated by the acceleration caused by gravity. Movements cause additional linear accelerations and are detected by the appropriately oriented hair cells in one or both pairs of otolith organs.

Semicircular Canals

The three semicircular canals are endolymph-filled rings specialized to detect angular acceleration. Each canal has a swelling, called the ampulla (Figure 1(c)), which contains the mechanoreceptive epithelium (the ampullary crista). In humans, each crista bears about 7000 hair cells. The hair bundles of the hair cells are inserted into a gelatinous mass (the cupula), which spans the diameter of the ampulla. During an angular acceleration, the endolymph within the canal, by virtue of its inertia, lags behind the canal itself, just as water within a rotated glass lags behind the wall of the glass. This deflects the cupula and the hair bundles. Unlike the situation in the otolith organs, the hair cells of each semicircular canal have the same orientation and, therefore, respond only to angular acceleration within the plane of the canal. The three canals are oriented perpendicular to each other, however, such that angular acceleration in any given plane is coded as a vector sum of the responses of the individual canals. The horizontal canals lie in a nearly horizontal plane (actually horizontal when the head is titled down about 25°). The anterior and posterior canals are oriented at angles to the sagittal plane, such that the posterior canal on one side lies in the same plane as the anterior canal on the other side (Figure 2).

Vestibular Afferents and Efferents

The vestibular afferents, which number about 20 000 on each side in humans, derive from sensory neurons within the vestibular ganglion (Scarpa's ganglion), nestled in a small cavity in the skull just medial to the labyrinth. These neurons extend a distal axon that contacts and receives synapses from the hair cells, and a proximal, or central, axon that extends into the

Figure 1 Anatomy of the labyrinth. (a) The labyrinth (purple) with associated vestibular and cochlear ganglia and nerves. (b) Structure of the macula in an otolith organ. (c) Structure of the ampulla in a semicircular canal and deflection of the cupula by an angular acceleration. Figure 2 Location of the labyrinths in the skull, viewed from the top of the head. Color coding indicates the semicircular canals that share the same planar orientation, and which therefore are inversely activated by the same rotation. Adapted from Kandel ER, Schwartz JH, and Jessell TM (1991) *Principles of Neural Science*, 3rd edn. New York: Elsevier, with permission from Elsevier.

brain stem via the vestibular portion of the VIIIth cranial nerve. The central axons terminate on neurons within the vestibular nuclei in the pons and medulla and within the vestibulocerebellum (flocculonodular lobe of the cerebellum).

Some vestibular afferents fire phasically during accelerations produced by movements of the head, while others also fire tonically, providing constant information about the acceleration caused by gravity. Resting firing rates can be as high as 100 Hz or more. Because the two labyrinths and thus the orientation of hair cells in the various vestibular sensory organs are mirror symmetric, many head movements will produce an increase in afferent activity on one side and a decrease in afferent activity on the other side. For example, a leftward rotation of the head in the horizontal plane will increase the firing rate of horizontal canal afferents on the left side and decrease the firing rate of horizontal canal afferents on the right side (Figure 3). This change in the symmetry of activity on the two sides changes the activity in central structures and thereby triggers reflexive movements.

Asymmetry in vestibular activity can also be produced pathologically or experimentally, with severe effects on balance and orientation.

Most people have experienced vertigo and inability to maintain a constant posture following spinning in one direction for several seconds, or from the intake of too much alcohol, which reversibly changes the specific gravity of the otolithic membranes and the cupulae. Similarly, particles lodging on the otolithic membranes, loss of hair cells, damage to the vestibular nerve, or lesions within the brain stem can all cause vertigo and loss of balance. Menière disease is an example of such a vestibular pathology. Its etiology is poorly understood but appears to involve a disruption of endolymph drainage, leading to abnormally high pressure within the affected labyrinth. Clinicians induce changes in the balance of vestibular activity to assess the patency of central vestibular connections. Common techniques for achieving this include caloric stimulation of the inner ear on one side, and rotation of the patient on a specially constructed chair called the Bárány chair (named after Robert Bárány, who received the Nobel Prize in Physiology or Medicine in 1914 for his studies of the physiology and pathology of the human vestibular apparatus).

The vestibular nerve also conveys efferent axons from the brain stem to the vestibular sensory organs. These efferents appear to control the excitability of the hair cells, thus altering the sensitivity of vestibular afferents to stimulation.

Figure 3 Effects of rotating the head to the left (large arrow) on activity in horizontal canal afferents. The inertia of the endolymph in the horizontal canals leads to deflections of the hair cells in opposite directions on the two sides. This causes complementary changes in the activity of the horizontal canal afferents (red axons) during the rotation (black bar).

Vestibular Nuclei and Their Projections

The vestibular nuclei are anatomically identifiable collections of neurons located in the dorsolateral regions of the pons and medulla. In humans and other mammals, four different nuclei can be distinguished: the superior nucleus, the lateral (or Deiters') nucleus, the medial nucleus, and the inferior (or descending) nucleus. Each of these nuclei projects to various targets in the brain and spinal cord, including (1) the oculomotor, trochlear, and abducens nuclei, which mediate eye movements; (2) reticular and spinal neurons involved in movements of the head, trunk, and limbs; (3) vestibular portions of the cerebellum; (4) the thalamus, for relaying vestibular information to cortical centers; and (5) other vestibular nuclei. Projections to movement-related centers are highly specific and mediate the stereotyped vestibular reflexes, such as the vestibulo-ocular and vestibulospinal reflexes. Projections to the thalamus, relayed on to the cortex, contribute to the conscious perception of self-movement and of orientation within the external environment.

Although the projections from the different anatomically defined vestibular nuclei are characteristic, the nuclei exhibit substantial overlap in terms of their projections to specific targets. Recent anatomical studies indicate, however, that projections to specific targets derive from largely separate, coherent clusters of vestibular neurons. Thus, different sets of vestibular neuron clusters project to the spinal cord,

Figure 4 Overview of selected central vestibular pathways subserving the vestibulo-ocular and vestibulospinal reflexes. Superimposed on the vestibular nuclei (S, superior; L, lateral; M, medial; D, descending) are vestibular neuron clusters projecting to the oculomotor and trochlear nuclei (left side) and to the spinal cord (right side). Color coding indicates projections in different tracts (mlf, medial longitudinal fascicle; mvst, medial vestibulospinal tract; lvst, lateral vestibulospinal tract) and on different sides of the brain stem (ipsilateral, contralateral).

to the ocular motor neurons, and to the cerebellum. Moreover, the clusters projecting to these major targets are further subdivided according to their projection in specific axon tracts and whether they project selectively ipsilaterally or contralaterally (Figure 4). A given projection-specific cluster may be restricted to a subregion of one of the anatomically defined nuclei or overlap two or more of the nuclei.

This mosaic projection map within the population of vestibular neurons appears to be set up by highly determinate pattern-forming mechanisms operating during embryonic development of the brain stem. Afferents from the different vestibular sensory organs are presumably mapped onto the various neuron clusters of this projection map in such a way as to provide appropriate activation of the targets of the vestibular nuclei.

The vestibular nuclei receive projections from the cortex, the cerebellum, subcortical visual centers, and the spinal cord. Vestibular circuitry is therefore embedded within larger networks involved in the integration of vestibular, visual, and proprioceptive information. This provides an ongoing global control of eye and body orientation in the dynamic context of voluntary movement and external perturbations.

Vestibular Reflexes

The projections from the vestibular nuclei mediate two main classes of reflexes: the vestibulo-ocular reflexes and the vestibulospinal reflexes.

Vestibulo-ocular Reflexes

Vestibulo-ocular reflexes involve the activation of the motoneurons that innervate the extra-ocular muscles. The function of these reflexes is to maintain the orientation of the eyes in space during head movements so that the visual image remains stable on the retina. This is accomplished by the generation of eye movements that are equal and opposite to head movements. In the absence of such compensatory eye movements the visual image would shift wildly, particularly during nonvoluntary movements of the head, and visual orientation would be extremely difficult if not impossible.

Because the circuitry underlying the vestibulo-ocular reflexes is interconnected with networks that mediate other ocular reflexes as well as voluntary eye and head movements, these various movements are normally well coordinated. The same interconnections, however, can also lead to illusions, such as the illusion of self-movement when sitting in a motionless train and viewing a slowly moving train on a neighboring track.

Vestibulospinal Reflexes

Vestibulospinal reflexes involve the activation of spinal motor neurons that innervate neck, trunk, and limb muscles. The function of these reflexes is to maintain balance and body orientation in the face of ongoing perturbations. Like the vestibulo-ocular reflexes, the vestibulospinal reflexes are fast, providing compensatory movements that counteract and protect against the potentially injurious results of tripping or falling. Patients with vestibular disturbances risk bodily harm because these compensatory movements are deficient or absent.

Just as the vestibulo-ocular reflexes are coordinated with other reflexes and vision, the vestibulospinal reflexes are coordinated with other spinal reflexes and the vestibulo-ocular reflexes. This coordination is an essential element of our daily activities. An example is the coordination of the vestibulospinal reflex and the cervicospinal reflex (a proprioceptive reflex that generates limb movements in response to activation of neck proprioceptors). Each of these reflexes initiates unilateral limb extension when the head is tilted appropriately, but on opposite sides of the body (Figure 5). Tilting the neck while keeping the trunk motionless activates both reflexes, which

Figure 5 Coordination of vestibulospinal and cervicospinal reflexes. (a) Normal position. Tilting of head and trunk together relative to space (b) stimulates the vestibular apparatus only and elicits limb extension on the same side as the tilt and limb flexion on the opposite side. Tilting the trunk while keeping the head motionless (c) stimulates neck proprioceptors only and elicits limb flexion on the same side as the tilt and limb extension on the opposite side. Both of these responses serve to maintain balance. Tilting the head while keeping the trunk motionless (d) stimulates the vestibular apparatus and neck proprioceptors simultaneously. The reflex responses cancel out. Reproduced from Kandel ER, Schwartz JH, and Jessell TM (2000) *Principles of Neural Science*, 4th edn. New York: Elsevier, with permission from Elsevier.

therefore cancel out. In patients with vestibular pathology, a similar neck tilt will cause the patient to fall immediately to the same side because the cervicospinal reflex is activated alone. This uncomfortable (and potentially harmful) result can be experienced by healthy people following the vestibular imbalance produced by spinning in one direction for several seconds.

Plasticity and Adaptability

The vestibular reflexes, though highly stereotyped, exhibit plasticity at several levels, from hair cells to central synapses, allowing for adaptive changes in response. The following examples illustrate the range of plasticity. (1) Some vestibular afferents adapt to sustained stimulation, a feature that probably involves both mechanical adaptation of the hair cells and accommodation of the afferent nerve fibers. The result is an automatic diminution of reflex responses, for example, during protracted rotation. (2) Compensatory changes in central activity occur over time as a consequence of vestibular imbalance. Thus, the vertigo that results from a lesion of the vestibular apparatus or nerve on one side eventually diminishes, an effect that appears to involve a readjustment of neural activity within the vestibular nuclei. (3) Vestibular reflexes exhibit plastic changes in gain when the resultant movements do not achieve the desired result. For example, the vestibulo-ocular reflex is designed to maintain a stable image on the retina. If the reflex movement is incorrect (too large or too small relative to the head movement), the image will slip on the retina. Such a mismatch in head and eye movement can be created immediately by placing prisms or magnifying lenses in front of the eyes. Any such situation that causes retinal image slip will lead over the course of days to an appropriate adjustment of the magnitude and even direction of the reflex eye movement. This form of plasticity requires the involvement of the cerebellum and appears to be effected within specific regions of the vestibular nuclei. (4) Vestibular reflexes are under continuous voluntary control, which allows for rapid adaptive changes associated with different contexts of movement and orientation. For example, we can extinguish the vestibulo-ocular reflex during voluntary head rotations if the situation demands that we maintain eye position relative to the head instead of relative to space. This technique is used by ballet dancers and figure skaters during spinning maneuvers to avoid disorientation and dizziness. Volitional modulation of vestibulo-ocular and vestibulospinal reflexes is probably an important element in the learning and execution of novel movement sequences, an essential element in athletics and dance as well as daily life.

Necessity for Vestibulo-Autonomic Responses

It has been appreciated for over 100 years that signals from the vestibular system can influence the brain circuitry that coordinates nausea and vomiting. Thus, the most commonly appreciated vestibulo-autonomic responses are those associated with motion sickness. Less obvious are the contributions of the vestibular system to coordinating the alterations in blood distribution in the body and respiratory muscle activity that are needed during movement and changes in posture. Nonetheless, considerable evidence collected from both animal models and human studies has now established a role for the vestibular system in maintaining homeostasis during postural alterations.

Head-up tilts of quadrupeds, like standing in humans, typically results in the pooling of blood in the venous circulation of the lower body and a decreased return of blood to the heart. Because Starling's law of the heart stipulates that cardiac output is directly related to the venous return to the heart, these postural changes can lead to a sudden decrease in blood pressure. In order to maintain stable blood pressure during posturally related challenges to the cardiovascular system, it is necessary to produce vasoconstriction in the lower body, to increase the resistance in the vasculature and reduce peripheral blood pooling. As described in the following discussions, the vestibular system rapidly triggers this compensatory response at the onset of movements involving head-up orientations of the body.

Changes in posture can also affect the resting length of the respiratory muscles, requiring alterations in the activity of these muscles if ventilation is to remain constant. For example, head-up rotations of quadrupeds and standing in bipeds can alter the resting length of the diaphragm, when the muscle is no longer supported by the abdominal contents. The vestibular system acts to stabilize the resting length of the diaphragm during head-up orientations of the body, mainly by producing an increase in the tone of the abdominal muscles and thereby preventing the abdominal organs from sinking into the abdominal cavity. The activity of some upper airway muscles also increases during certain postural alterations. This increase in muscle activity is most evident when humans assume a supine position or when quadrupeds are oriented head-up, as these postures allow the tongue to fall toward the back of the throat and potentially obstruct the airway. There is evidence suggesting that the vestibular system participates in triggering changes in activity of muscles such as the tongue protruder genioglossus, in order to maintain patency of the airway during postural changes.

Studies of Vestibulo-Cardiovascular Responses in Animal Models

A number of studies conducted on a variety of animal species have shown that electrical stimulation of the vestibular nerve elicits changes in the activity of sympathetic nervous system efferents, including fibers innervating arterioles in skeletal muscle. Selective natural stimulation of vestibular afferents produced by head rotations in animals with extensive denervations (transection of cranial nerves IX and X and the cervical dorsal roots) to eliminate nonlabyrinthine inputs that could be elicited by the head movement also affects sympathetic nerve discharges and blood pressure. In particular, rotating the head nose-up produces increases in sympathetic nerve activity. The response characteristics of vestibular-elicited alterations in sympathetic nervous system activity suggest that the responses are elicited by inputs from otolith organs, with little contribution from the semicircular canals. Removal of vestibular inputs through a bilateral vestibular neurectomy or bilateral lesions placed in the caudal vestibular nuclei results in lability in blood pressure during 60° head-up rotations of anesthetized or conscious cats (see Figure 1). This blood pressure lability is at least partly a reflection of decreased vasoconstriction in and increased blood flow to the lower body following the vestibular lesions (see Figure 2). Presumably, blood pooling in the lower body results in decreased venous return to the heart and thus a reduction in blood pressure. Cumulatively, these findings show that the vestibular system participates in adjusting blood distribution in the body and thus blood pressure during postural alterations.

The vestibular system has very specific influences on sympathetic nervous system outflow. Only those sympathetic nerve fibers that innervate vascular smooth muscle, as opposed to targets such as smooth muscle in the wall of the gut, respond to vestibular stimulation. Moreover, the vestibular system has distinct influences on vasoconstrictor fibers innervating blood vessels in the same tissue, skeletal muscle, but which are located in different body regions. Accordingly, stimulation of vestibular afferents or removal of

Figure 1 Effects of 60° head-up tilts and bilateral lesions of the caudal vestibular nuclei on the ability of a conscious cat to maintain stable blood pressure. Top row: Blood pressure measured from the abdominal aorta. Bottom row: Orientation of the animal's body. Prior to placing chemical lesions bilaterally in the caudal vestibular nuclei, blood pressure increased slightly during head-up rotations of the animal's body (left column). After the lesions, blood pressure dropped at the onset of the tilts (right column). For more information about the experimental design, see the work of Mori and co-workers.

Figure 2 Changes in blood flow through the femoral artery (top panel) and resistance of the hind limb vasculature (bottom panel) during 60° head-up tilts of a conscious cat. Values are expressed as percent changes from baselines prior to tilts. When vestibular inputs were intact (solid blue lines), blood flow decreased to the hind limb during tilts as a result of increased hind limb vascular resistance. This response presumably prevented blood pooling in the lower body. In the first week following removal of vestibular inputs (Post-W1, red dashed lines) as well as during the subsequent 3 weeks (Post-W2–4, green dashed lines), the ability to reduce blood flow to the hind limb during head-up tilts was attenuated. Symbols indicate post-lesion responses that were significantly different from those prior to lesions ($P < 0.05$, MANOVA combined with LSD post-hoc tests).

vestibular inputs through a bilateral vestibular neurectomy produces different effects on blood flow to the forelimb and hind limb. As noted previously, vestibular inputs trigger vasoconstriction in the hind limbs during head-up rotations (Figure 2); this vasoconstrictor response is much smaller in the forelimbs. These observations show that vestibular signals do not elicit nonspecific 'fight or flight' responses that involve simultaneous increases or decreases in sympathetic outflow to many tissues and body regions. Instead, particular vestibular inputs (i.e., those elicited during head-up rotations) produce specific effects on the cardiovascular system that are appropriate to prevent peripheral blood pooling during postural alterations.

Experiments employing anatomical, neurophysiological, and lesion techniques have established the most direct neural pathways that mediate vestibular influences on the sympathetic nervous system; these pathways are summarized in Figure 3. Lesions placed caudally within the medial and inferior vestibular nuclei abolish sympathetic nervous system responses to stimulation of vestibular receptors. This region of the vestibular nuclei does not play a primary role in producing vestibulo-spinal or vestibulo-ocular responses, and may be predominantly involved in triggering autonomic responses required during postural

Figure 3 Minimal neural pathways that mediate vestibular influences on cardiovascular regulation. These pathways include the caudal vestibular nuclei, interneurons in the lateral medullary reticular formation, and bulbospinal neurons in the rostral ventrolateral medulla that make connections with sympathetic preganglionic neurons in the thoraco-lumbar spinal cord. Because vestibulo-cardiovascular responses vary between body regions, parallel neural pathways that receive distinct labyrinthine signals presumably control blood flow in different vascular beds.

alterations. Vestibular signals are relayed to sympathetic nervous system preganglionic neurons in the thoraco-lumbar spinal cord via bulbospinal projections from the rostral ventrolateral medulla (RVLM). This region of the reticular formation also mediates a variety of other cardiovascular responses generated through alterations in sympathetic nervous system outflow, and the same RVLM neurons integrate signals from vestibular end organs, baroreceptors, and perhaps other sources. However, RVLM neurons do not receive direct inputs from the vestibular nuclei; labyrinthine signals are relayed to the RVLM through interneurons located in the lateral medullary reticular formation. As discussed in the previous paragraph, vestibulo-sympathetic responses are patterned, and differ between body regions. The neural circuitry that mediates vestibular influences on sympathetic nervous system outflow must have the capability of producing such intricate responses. For example, bulbospinal neurons in the RVLM that influence blood vessels in the forelimb presumably have different responses to labyrinthine inputs than do RVLM neurons that regulate blood flow to the hind limb.

Although removal of vestibular inputs through a bilateral vestibular neurectomy compromises the ability to adjust blood distribution in the body and blood pressure during postural alterations, these deficits resolve over time. In contrast, lesions placed bilaterally within the caudal vestibular nuclei result in impaired cardiovascular responses to alterations in posture that persist for a longer period. In addition, the combination of a bilateral vestibular neurectomy with ablation of the cerebellar uvula produces a long-lasting inability to adjust blood pressure during postural changes. These findings have led to the following two hypotheses: (1) recovery of compensatory cardiovascular responses following peripheral vestibular lesions is accomplished at least in part through plasticity in the caudal regions of the vestibular nuclei that participate in autonomic regulation and (2) the occurrence of the plastic alterations in the caudal vestibular nuclei requires inputs from the cerebellar uvula. These notions are supported by the observations that the caudal vestibular nuclei receive substantial inputs from sensory receptors in addition to those in the labyrinth, and that these nonlabyrinthine inputs are sufficient to generate changes in the activity of vestibular nucleus neurons during postural alterations. Thus, a variety of sensory inputs likely contribute to producing compensatory cardiovascular responses during postural alterations; this multisensory processing presumably provides for a highly accurate appraisal of the challenges being imposed on the cardiovascular system and permits precise compensatory adjustments in blood flow and blood pressure.

Studies of Vestibulo-Respiratory Responses in Animal Models

Experiments similar to those discussed in the previous section have established that the vestibular system elicits alterations in respiratory muscle activity during postural alterations. Electrical or selective natural stimulation of vestibular receptors produces changes in the activity of respiratory muscles or nerves innervating those muscles in anesthetized animal preparations. The activity of many respiratory muscles is affected by vestibular stimulation, although vestibulo-respiratory responses are particularly prominent in the abdominal muscles and the tongue protruder muscle genioglossus (see Figure 4). Removal of vestibular inputs through a bilateral labyrinthectomy has two effects on respiratory muscle activity: (1) a decrement in the responses of the muscles to postural alterations and (2) an increase in background muscle activity. This observation suggests that the vestibular system has two parallel roles in regulating breathing. The physiological significance for labyrinthine signals affecting the spontaneous activity of respiratory muscles remains to be determined.

A variety of parallel neural pathways appear to mediate vestibular system influences on respiratory muscle activity. The same region of the caudal vestibular nuclei that participates in generating vestibulo-cardiovascular responses also is critical for labyrinthine signals to affect breathing. Historically, premotor respiratory neurons were thought to be mainly confined to two columns located in the lateral reticular formation of the caudal medulla, the so-called brain stem respiratory groups. Although some neurons in the respiratory groups respond to vestibular stimulation, functional lesions that inactivate the neurons or their axons do not eliminate vestibulo-respiratory responses. Furthermore, vestibular stimulation can produce an increase in activity of respiratory pump muscles without affecting the firing of respiratory group neurons. Thus, premotor neurons in addition to those in the respiratory groups must make synaptic contacts with respiratory motoneurons. The locations of these neurons were determined through studies in which a transneuronal tracer, pseudorabies virus, was injected into the diaphragm, abdominal musculature, and genioglossus. These experiments showed that additional premotor respiratory neurons are located in two regions: the medial medullary reticular formation and the spinal gray matter. Neurophysiological studies have shown that both of these neuronal populations receive labyrinthine signals and participate in relaying labyrinthine signals to respiratory motoneurons. Additional studies will be required to establish the specific role that each group of neurons plays in generating vestibulo-respiratory responses.

Figure 4 Averaged electromyogram (EMG) responses recorded from the diaphragm, the genioglossus, and the abdominal muscle rectus abdominis subsequent to electrical stimulation of the ipsilateral vestibular nerve (using a five-shock train of stimuli of 500 μA intensity; stimulation indicated by a red bar beneath each trace). The EMG responses for the genioglossus and rectus abdominis were prominent, but those for the diaphragm were small.

Studies of Vestibulo-Autonomic Responses in Humans

Whereas a number of studies conducted on human volunteers have considered vestibular-cardiovascular responses, only a few experiments have addressed vestibular influences on breathing. It is difficult to delineate a definitive role for the vestibular system in autonomic regulation in humans due to the evolution of redundant and overlapping homeostatic systems. In animal models, it is possible to perform lesion studies that completely remove particular sensory inputs; such experiments are impossible in humans. Nonetheless, a variety of experimental approaches have revealed that vestibular stimulation can lead to alterations in autonomic nervous system activity and obvious cardiovascular effects in humans.

Studies employing changes in head orientation have shown that the vestibular system has immediate and sustained influences on cardiovascular control. A number of researchers have utilized a specific maneuver, head-down neck flexion (HDNF), to provide relatively selective stimulation of the vestibular apparatus. Activity of sympathetic nervous system efferent fibers in peripheral spinal nerves increases during HDNF, as does vascular resistance. It has been hypothesized that peripheral vasoconstriction elicited by vestibular stimulation shunts blood flow to susceptible vascular beds during changes in body position that potentially compromise cardiac output and perfusion of the brain. Furthermore, evidence collected from human studies has led to the premise that the vestibular system triggers a coordinated and patterned vascular response to protect vulnerable vascular beds as opposed to global vasoconstriction. A study using Doppler ultrasonography to monitor gross cerebral blood flow during vestibular stimulation in humans verifies this postulate. Figure 5 demonstrates that cerebral vascular resistance decreases during HDNF relative to that measured during a similar maneuver where the neck was extended; in contrast, the same stimulus produces vasoconstriction in the peripheral vasculature. Interestingly, the attenuation of arterial resistance in the cerebral vessels occurred only when study participants underwent baroreceptor-unloading equivalent to that occurring during standing. This finding indicates a potential interaction between vestibular and baroreceptor afferent signals (see preceding section, 'Studies of vestibulo-cardiovascular responses in animal models') that results in a physiologically appropriate response.

Further information regarding the vestibulo-sympathetic reflex in humans has been obtained using an experimental paradigm called off-vertical axis rotation (OVAR). In this paradigm, participants are seated in a chair tilted slightly off Earth-vertical and are spun at constant angular velocity such that head position with respect to gravity constantly changes, producing a continually varying stimulus to the vestibular otolith organs. OVAR elicits alterations in activity of sympathetic nervous system efferents coursing in peripheral nerves; sympathetic efferents fire more when the nose is rotated upwards (forward linear acceleration) and less when the nose is oriented downwards. The short latency of the sympathetic efferent responses to OVAR suggests that the effects are due to activation of otolith organs, and not visceral afferents such as baroreceptors.

Other methods for activating vestibular receptors, including linear acceleration of the body using a sled, also produce cardiovascular responses in humans.

Figure 5 Beat-by-beat changes in brain blood vessel resistance (expressed in arbitrary units) during head-down maneuvers in a single individual with simulated orthostatic stress (baroreceptor unloading). The solid line indicates cerebral blood vessel resistance determined when the head was in the control position (head extension), while the broken line represents resistance determined during head-down neck flexion (HDNF). The inset graph shows the consequences of baroreceptor unloading on the maximal changes in cerebral resistance (expressed as mean ± SE) during neck flexion or extension. The filled bars indicate the effects of head position changes alone while the open bars indicate the effects of head maneuvers in combination with baroreceptor unloading. Filled bars represent the condition when the neck was flexed while open bars indicate the control condition ($n = 6$).

Changes in blood pressure elicited by linear acceleration were significantly smaller in individuals with a loss of vestibular inputs, suggesting that the responses in normal individuals were due to otolith organ stimulation. These findings support aforementioned research conducted using animal models and suggest that the vestibular system participates in homeostatic control at the very onset of movements and postural changes. Vestibulo-autonomic responses provide for feedforward adjustments in blood pressure, unlike responses triggered by baroreceptors that are elicited only after blood pressure has been altered. Baroreceptor and vestibular afferent information are integrated in the brain stem to provide an appropriate autonomic response during alterations in body position that provide a potential threat to the maintenance of stable blood pressure.

Clinical Implications of Dysfunction of Vestibulo-Autonomic Responses

Damage to a labyrinth on one side typically leads to vertigo, nausea, vomiting, and other autonomic disturbances. However, recovery generally occurs quickly due to the tremendous capacity of the vestibular system to undergo plastic changes when sensory inputs are altered. Plastic changes in the vestibular system during spaceflight may partly explain the occurrence of postspaceflight orthostatic intolerance, or inadequate perfusion of the brain when standing. Alterations in the pattern of inputs from the vestibular otolith organs to the central nervous system occur during spaceflight because the otolith organs are no longer exposed to constant gravitational forces. Thus, the otolith organs are no longer affected by tilting the head, as occurs on Earth. It is well established that exposure to an altered gravitational environment evokes significant adaptation in the vestibular system, and alters the gain of responses elicited by signals from the otolith organs. Attenuation of vestibulo-cardiovascular responses during spaceflight may partly explain why some astronauts, upon their return to Earth, have difficulty in maintaining adequate blood flow to the brain when standing.

Some evidence suggests that patients with bilateral loss of vestibular inputs may be more prone to suffering from orthostatic intolerance than individuals with a normal vestibular system. In addition, certain anxiety disorders that include autonomic symptoms have been linked with dysfunction of the vestibular system; it is possible that the aberrant vestibular signals in these patients could contribute to their alterations in blood pressure and breathing. These observations suggest that clinicians treating patients with vestibular disorders should be mindful that these conditions could lead to autonomic disturbances that also require medical attention.

Vestibulo-Ocular Reflex

D E Angelaki, Washington University School of Medicine, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

The vestibulo-ocular reflexes (VORs) are a group of eye movements whose goal is to rotate the eyeball in a particular direction and with a specific speed such that the world remains stable on the retina during head movement. Two different types of VORs are distinguished, depending on whether the head movement consists of a rotation or a translation. The former elicits the rotational or angular VOR (RVOR; e.g., when the head rotates to the right, the RVOR causes the eyes to rotate to the left, such that gaze remains stable in space). The latter elicits the translational VOR (TVOR; e.g., when the head translates to the right, the TVOR can rotate the eyes to the left to compensate for the relative motion of near targets on the retina). Even though natural head movements comprise both rotations and translations, there are characteristic differences between the RVOR and the TVOR so their properties are presented separately here.

Rotational or Angular Vestibulo-Ocular Reflex

A purely RVOR is the ocular responses elicited by rotation of the head or body in darkness about an axis roughly centered in the interaural axis of the head. Under these conditions, only the semicircular canals (but not the otolith organs) in the inner ear are effectively stimulated and provide the sole drive to rotate the eyes. The RVOR represents a phylogenetically old reflex. Many invertebrates and all vertebrate species, from amphibians, reptiles, and birds to nonhuman primates, have the ability to reflexively rotate their eyes opposite to the direction of head rotation, keeping the visual world stable on the retina. This superb ability for a very fast (<10 ms) gaze stabilization response comes about because of a fast transduction process and a most direct three-neuron arc pathway (Figure 1).

The RVOR is organized in a simple push–pull arrangement using signals from both labyrinths. During rightward head rotation, for example, primary afferents from the right horizontal semicircular canal increase their firing rates (Figure 1, pink lines). This increase in activity is conveyed by excitatory neuron projections via the vestibular nuclei to both motor neurons and internuclear neurons in the left (contralateral) abducens (IV) nucleus. The internuclear neurons in the left abducens nucleus convey this activity on to the medial rectus motor neurons in the right oculomotor nucleus (III). Activation of these pathways results in a simultaneous contraction of the lateral rectus muscle of the left eye and the medial rectus of the right eye (Figure 1, pink lines). Thus, both eyes rotate simultaneously to the left (black open arrows). Because of bilateral symmetry of the premotor circuitry, the decrease in the firing rates of the primary afferents from the left canal during rightward head rotation results in a parallel reduction in the tension of the antagonist muscles (i.e., the left medial rectus and the right lateral rectus; Figure 1, blue lines). This push–pull organization further supports the appropriate yoking of the eyes in the opposite direction to head movement.

The three-neuron arc schematic in Figure 1 is not sufficient to elicit appropriate RVOR. This is because the afferent signal from the semicircular canals is proportional to velocity, whereas the compensatory eye movement requires eye position changes. To convert velocity to position requires temporal integration (just like in calculus). At high frequencies (>0.5 Hz), the viscoelastic properties of the ocular plant (eyeball, muscles, and surrounding tissue) provide the second integration. At low frequencies, however, neural integration becomes necessary. Thus, the RVOR is thought to consist of two parallel processes, as illustrated in the classic Robinson diagram in Figure 2. The presence of both direct and neural integrator parallel pathways ensures that the correct proportion of velocity and position commands are delivered by the brain to the plant at all frequencies of natural head movement. In the absence of such an indirect integrator pathway, the response to a head rotation would bring the eye to the correct position, but subsequently eye position would drift back because the motor neurons would lack the tonic component to compensate for the elastic restoring forces of the eyeball (in Figure 2, compare the dashed and solid black lines). This is exactly what happens after lesions of brain stem and cerebellar structures that are thought to participate in this neural integration (e.g., the prepositus hypoglossi and the interstitial nucleus of Cajal). It is generally thought that the indirect integrator pathway is shared by all conjugate eye movement systems (saccades, pursuit, and the VORs), although the direct pathways are at least partly segregated for different types of eye movement (i.e., VORs, pursuit, or saccades).

For small head rotations, when the compensatory ocular deviation is small (10–15°), the RVOR is

Figure 1 The push–pull organization of the horizontal (yaw) RVOR. The direct path consists of a short trisynaptic reflex consisting of vestibular afferents (eighth nerve), the vestibular nuclei, motor neurons in the VI (abducens) and III (oculomotor) nuclei and the lateral rectus (LR) and medial rectus (MR) muscles. When the head rotates to the right, the right horizontal semicircular canal afferents increase their firing rates, whereas the left afferents decrease their activities (pink vs. blue colors, respectively). The excitation/inhibition is transmitted to the contralateral/ipsilateral abducens (VI) through neurons in the right/left VN, respectively. Internuclear neurons in the abducens nuclei cross the midline and terminate in the contralateral medial rectus motor neurons (III). Thus, motor neurons in the left VI and right III fire at a higher frequency, whereas those in the right VI and left III fire at a lower frequency. As a result, the left LR and right MR muscles contract, whereas the left MR and right LR muscles relax and both eyes rotate leftward. c.n., cranial nerve.

Figure 2 Schematic diagram of the classic Robinson-style model for the RVOR. Semicircular canal signals reach the motor neurons through a set of two parallel pathways: a direct route through the vestibular nuclei (three-neuron arc) and an indirect pathway that functions like a neural integrator ($\int dt$) and is thought to include cells in the prepositus hypoglossi and vestibular nuclei. As a result of these parallel pathways, a pulse of head velocity is converted into a sustained change in eye position (solid lines). Without the integrator pathway, eye position would decay to zero within a few hundreds of milliseconds (dashed line).

manifested as a slow deviation in eye position, having a rate of change that should ideally match the velocity of head rotation. For larger head rotations, the RVOR is typically manifested as nystagmus, a sawtoothlike (zigzag) pattern in which slow deviations in eye position are interleaved with oppositely directed quick phases (reflexive saccades) that keep eye position within the oculomotor range (Figure 3(a), top traces). Similar to the interaction of saccades and pursuit, ocular nystagmus might reflect two different control strategies, in which slow phases reduce the velocity error between eye motion and head motion and fast phases reduce the position error to keep the eyes centered in the orbit. The involuntary fast-phase segments of the RVOR are generally ignored to facilitate the analysis of the more salient slow-phase compensatory response segments (Figure 3(a), bottom trace).

The effectiveness of the RVOR is often characterized by its gain, which is defined as the ratio of the velocity of the nystagmus slow phase over the velocity of head rotation. Species differences exist in the exact value of RVOR gain. In monkeys, the horizontal RVOR gain in darkness is close to ideal (0.9–1) and appropriate in phase over a frequency range of ~0.1–4 Hz. In humans, the RVOR gain is much lower and more variable, ranging from 0.5 to 0.8 over a similar frequency range. This variability in the human RVOR gain could be due to different cognitive sets. For sinusoidal rotations, in addition to its gain, RVOR dynamics are also quantified by computing what is called the phase shift, defined as the timing difference between the actual eye velocity and that required to perfectly compensate for head rotation.

The compensatory function of the VOR extends to high frequencies. Although they are not a natural stimulus to the VOR, very high (up to 25–50 Hz) or very low (down to 0.01 Hz) frequencies are often tested. The RVOR gain continues to be high at these high frequencies, with a nearly perfectly compensatory phase. At very low frequencies, however, gain declines and progressively larger phase leads are introduced. This is partly due to the fact that the dynamics of the semicircular canal afferents, which provide the sensory drive for the RVOR, are high-pass sensors of head velocity, with a lower corner frequency of approximately 0.03–0.04 Hz in primates and cats. Thus, when the RVOR is studied using an abrupt change in head velocity followed by a maintained constant velocity rotation (often referred as a step in head velocity), the initial transient

Figure 3 Interactions between the RVOR and optokinetic nystagmus (OKN): (a) nystagmus in response to a step of velocity (platform rotation) in darkness; (b) slow-phase eye velocity in response to a step in surround velocity, generating OKN and optokinetic after-nystagmus (OKAN); (c) slow-phase eye velocity in response to platform rotation in the light. In (a), the top traces illustrate horizontal eye position, whereas the bottom traces plot slow-phase eye velocity (the large positive and negative spikes reflect the occurrence of fast phases). The solid red line in the lower trace illustrates the semicircular canal afferent time course, which is much shorter than that of the RVOR. In (c), all stimuli consisted of horizontal rotation at 60° s^{-1}. Note that during rotation in the light the postrotatory RVOR and OKAN slow-phase velocities are oppositely directed (in a and b). Thus, the two afterresponses cancel one another and postrotatory responses during rotation in the light are small (c). Reprinted from Raphan T and Cohen B (1985) Velocity storage and the ocular response to multidimensional vestibular stimuli. In: Berthoz A and Melville Jones G (eds.) *Reviews of Oculomotor Research*, vol. 1, pp. 123–143. Oxford: Elsevier, with permission from Elsevier.

ocular response to the step decays out over several seconds (Figure 3(a)), as expected because the canals cannot transduce a constant velocity stimulus. Sudden cessation of rotation, then, is encoded by the semicircular canals as a step in the opposite direction, eliciting a response typically referred to as the postrotatory nystagmus (Figure 3(a)).

The time of decay of the RVOR during constant velocity rotation can be characterized by its time constant, which can be empirically defined as the time over which eye velocity to a step of head velocity decays to 63% of its peak value. In most species, including primates, cats, and rabbits, the rate at which the RVOR response to a step in head velocity decays out is slower than would be expected on the basis of the dynamics of the semicircular canals. The difference represents a prolongation or perseveration of the raw vestibular signal and researchers have proposed that it reflects a central processing of afferent information referred to as the velocity storage integrator. Although such low-frequency or very long-duration stimuli are totally unnatural, particularly when delivered in darkness, they have been very useful experimentally in studying both the dynamics of the RVOR and multisensory interactions.

An example of such interactions via the velocity storage integrator occurs between VOR and optokinetic responses. In particular, the RVOR cannot provide gaze stability during maintained rotation (Figure 3(a)). Instead, under natural circumstances (e.g., self-rotation in the light), sustained image stabilization is provided by the visual system that generates optokinetic nystagmus (OKN). The optokinetic reflex is classically considered to be the reflexive ocular response to the en bloc motion of a large visual field that aims to match slow-phase eye velocity to the velocity of the visual surround, providing a low-frequency complement to the RVOR. In the laboratory, the OKN system is usually stimulated by rotating a large patterned drum around the stationary subject. Under these circumstances, the nystagmus pattern generated in species with foveal vision typically consists of a fast-velocity rise (Figure 3(b), black arrow), followed by a slower increase in eye velocity to a steady-state level that is proportional to the rotational velocity of the drum. Following the cessation of drum rotation, eye velocity declines to zero gradually, after an occasional initial quick drop that is similar to the fast rise (optokinetic afternystagmus (OKAN); Figure 3(b)).

Figure 4 Properties of the TVOR: (a) for the same displacement, the angular deviation of the target on the retina depends on its proximity; (b) horizontal eye velocity (TVOR) amplitude during lateral motion is larger the nearer the target; (c) idealized optic flow pattern during forward motion while fixating straight ahead; (d) horizontal eye velocity (TVOR) amplitude during forward motion depends on target position; (e, f) the ocular following reflexes (OFRs) also depends on viewing distance. In (c), shades from red to blue illustrate the transition from the fovea to the retinal periphery. In (d), data plot eye velocity of the right and left eyes while fixating one of three targets ~15° to the left (red), straight ahead (green), or 15° to the right (blue). In (e), the graph shows conjugate horizontal eye velocity in response to tangential optic flow; in (f), the graph shows vergence eye velocity in response to radial optic flow. Upward deflections illustrate leftward eye velocity (b, d), rightward eye velocity (e), or increasing convergence (f). The numbers on each trace indicate viewing

The slow component of OKN–OKAN appears designed to perfectly complement the RVOR. Despite the fact that during constant-velocity rotation eye velocity decays to zero, the same rotation in the presence of a visual surround elicits a steady-state nystagmus pattern that is sustained indefinitely, as necessary to compensate for the applied stimulus (Figure 3(c)). This happens because the OKN builds up at approximately the same rate as the RVOR decays. Similarly, when head rotation is suddenly halted, OKAN cancels out the postrotatory vestibular nystagmus pattern, such that eye velocity drops quickly to zero. These visual–vestibular interactions are impaired after lesions that also impair velocity storage. Activation of the otolith system during rotations that change head orientation relative to gravity also improves the low-frequency RVOR properties. Similar to OKN, these otolith effects on the low-frequency RVOR are also mediated through the velocity storage mechanism.

Translational Vestibulo-Ocular Reflex

The TVOR results from the activation of the otolith afferents in the inner ear. It represents the functional equivalent of the RVOR during translation, although its properties are geometrically more complex than those of the RVOR. This occurs because, unlike the RVOR, in which a head rotation is compensated by an eye rotation (i.e., the stimulus and response are in similar units), a translational displacement must be compensated by an eye rotation, a nontrivial transformation that depends on target proximity (Figure 4). For example, during the same lateral displacement, nearby objects move on the retina more rapidly than distant ones (in Figure 4(a), curved arrows differ, straight arrows are the same). Thus, if a nearby object needs to be stabilized on the retina, the eyes should rotate by an amount that is larger the closer the target to the subject. Indeed, the horizontal compensatory eye movements that are elicited during lateral motion in darkness do indeed scale with target distance; the closer the target, the larger the evoked eye movement (Figure 4(b)). Similar to the RVOR, compensatory responses to translation occur at relatively short latency (10–12 ms; Figure 4(b)).

Unlike the uniform optic flow experienced during head rotation (in which all spatial locations in the visual field are uniformly represented on the retina), the optic flow experienced during translation can be complex, particularly when we are moving along a direction that is nearly parallel to the gaze (e.g., moving forward while looking straight ahead). In this case, we experience an expanding visual scene in which objects at the periphery of the visual field move much faster than those in more central portions of the retina (similar as in the star-field screen saver on my computer). This pattern of optic flow (typically referred to as radial flow) is complex because objects also appear to move in different directions depending on their spatial location within the visual field (Figure 4(c)). Thus, during forward motion, the retinal slip of a nearby object differs in both size and direction, depending on its location within the visual field. Furthermore, because forward motion is associated with distance changes, we must converge our eyes in order to keep images on corresponding locations on the two fovea. The reverse is true during backward motion, in which ocular divergence is necessary.

Obviously, no single eye movement could generally result in stabilization of the whole visual field during translation. Thus, unlike the RVOR, which is a full-field image stabilization reflex, the goal of the TVOR is to selectively stabilize images on the fovea. This occurs by scaling the vestibular signal not only by the inverse of target distance (Figure 4(b)), but also by eye position (Figure 4(d)). For example, when we move forward and look straight ahead, our eyes move little (Figure 4(d), green traces). But when we look to the right, forward motion causes the eyes to move further to the right (Figure 4(d), blue traces). The reverse is true when we look to the left, with a TVOR response to the left (Figure 4(d), red traces). Notice that the two eyes move disjunctively, consisting of either a purely vergence or a combination of vergence and conjugate eye movements. However, although the direction of the evoked eye movement is typically consistent with geometric predictions, the primate/human TVOR is typically undercompensatory for near-target viewing, with gains of only approximately 0.5.

The residual retinal image motion remaining after a less than ideal TVOR can be nulled by complementary visual stabilization mechanisms, known as the ocular following reflexes (OFRs). To generate OFRs, visually sensitive neurons in extrastriate visual cortex

distance (in centimeters); vertical dashed lines indicate motion onset. decode either the pattern of optic flow (planar during lateral motion or radial during forward motion) or the disparity cues associated with motion-in-depth. Planar optic flow (e.g., experienced by a subject who looks off to one side during motion) elicits conjugate OFRs (Figure 4(e)). In contrast, when the subject looks in the direction of heading, disjunctive (vergence) visually driven eye movements are elicited (Figure 4(f)). A most characteristic feature of these responses is their very short latency for a visually driven mechanism (monkeys, <60 ms; humans, ~85 ms). Because the OFR shares the viewing distance dependence of the TVOR, the TVOR and OFRs are thought to share central pathways.

Notably, the TVOR differs from the RVOR also in the fact that the ability to manipulate retinal flow by generating compensatory eye movements during translation and to optimize visual acuity on the central retina appears to represent a specific feature of the primate and human visual systems. Lateral-eyed species, like the rabbit, that lack a fovea and a smooth pursuit system do not generate eye movements that compensate for the visual consequences of translation during self-motion. As in the primate oculomotor system, image stabilization during translation serves mainly foveal vision and stereovision, so the absence of a well-developed compensatory TVOR in animals that lack foveal vision might not be surprising.

Tilt Vestibulo-Ocular Reflex

These exists an additional effect of otolith system activation on reflexive eye movements because primary otolith afferents detect not only translational acceleration but also changes in the orientation of the head relative to gravity. Thus, an otolith-driven tilt response also exists, whose function is to maintain the orientation of the eyes constant in space during head tilts. This reflex includes the generation of torsional eye movements during head roll (counterrolling) or vertical eye movements during head pitch (counterpitching). (Please note that the direction of the evoked eye movement is described here relative to the head; i.e., vertical refers to eye rotation about the head's interaural axis, and torsional refers to eye rotation about the head's naso-occipital axis.) This ability to use a gravity-sensing mechanism to maintain gaze relative to the horizon is of paramount importance for lateral-eyed afoveate species that typically lack a well-developed saccadic system. But such functional utility for these tilt responses has lost its advantage in the primate oculomotor system, in which static ocular counterrolling and counterpitching in primates and humans has a gain of less that 0.1. Significantly, unlike afoveate species in which this reflex operates exclusively through slow eye movements, modulation of both slow and fast phases occurs in primates and reflects a change in the orientation of Listing's plane and primary eye position. Thus, the tilt otolith-ocular reflex in frontal-eyed animals might be less related to gaze stabilization but more fundamentally coupled to reference frames.

Plasticity

The VOR is a highly modifiable reflex. In essence, although the VOR acts independently of visually mediated eye movements, the brain continuously monitors its performance by evaluating the clarity of vision during head movements. When head turns are consistently associated with image motion across the retina, the RVOR undergoes plastic gain changes in the direction appropriate to improving the compensatory ability of the reflex. For example, when we view the world through spectacles that magnify or miniaturize the visual scene, RVOR gain (in darkness) increases or decreases accordingly. The reflex behavior can adapt over several minutes, hours, and days. During short-term adaptation, the RVOR gain can be adjusted by exposing the subject to a motion stimulus coupled with an abnormal visual stimulus. For example, head rotation paired with the rotation of an optokinetic visual stimulus at the same speed but in the opposite direction results in an increase of the RVOR gain. Similarly, rotating the subject and visual surround in tandem can be used to train the RVOR gain toward zero. For long-term adaptation, an animal is typically fitted with magnifying lenses to increase the gain, miniaturizing lenses to reduce the gain, or reversing prisms to reverse the direction of compensatory eye movement responses.

When mismatched visual-vestibular stimuli are used to adapt the RVOR gain at a single frequency, changes are typically frequency selective, with the largest effects being observed at the adapting frequency. In contrast, gain changes are less robust at other frequencies and are typically accompanied by phase lags or leads relative to an ideal response. RVOR training with brief versus longer-duration stimuli produces differential effects on the gain and dynamics of the RVOR, with longer-duration stimuli inducing larger effects on RVOR dynamics. It is also possible to adapt RVOR gain in opposite directions at low versus high frequencies or during the two directions of motion. Static head position relative to gravity, the position of the eye in the orbit, and the pattern of head movement have all been used as contextual cues for gating different vestibular responses. In addition, many studies have demonstrated an ability to adapt to injured

Figure 5 Schematic illustrating otolith and semicircular canal signal projections to the vestibulo-cerebellum and the vestibular nuclei. The vestibular nuclei, which receive not only vestibulo-ocular signals but also information related to OKN, OFR, pursuit, and saccades, projects directly to extraocular motor neurons. OFRs, ocular following reflexes; OKN, optokinetic nystagmus.

states, including peripheral and central vestibular damage. Often RVOR gain adaptation is accompanied by changes in gaze-holding performance, with the degree of alterations being dependent on training context. Furthermore, disconjugate adaptation of the RVOR can occur, for example, by wearing prisms in front of one eye.

Otolith-ocular reflexes are also subject to adaptive control. For example, both the direction of evoked eye movement and how it depends on target position within the visual field have been shown to be modifiable. Prolonged centrifugation can lead to changes in the VORs, although prolonged exposure to static tilt does not change ocular counterrolling. Context-specific fast (~100 trials) motor learning in the TVOR can also be induced when monkeys are repeatedly subjected to a brief head translation while trying to maintain binocular fixation on a world-fixed or subject-fixed visual target for juice rewards.

Neural Pathways

A unique characteristic of the VORs is that they are generated exclusively from subcortical circuits that involve the lower pons/medulla and cerebellum. Three main structures participate in the generation of the VORs: the vestibular nuclei, the cerebellar flocculus/ventral paraflocculus, and the most posterior lobules of the vermis (lobule X) (Figure 5). The cerebellar areas are often commonly referred to as the vestibulo-cerebellum because they receive both direct and indirect vestibular afferent projections. The vestibular nuclei house both the direct vestibulo-ocular connections (comprising the three-neuron arc pathway; Figures 1 and 2), as well as some of the indirect projections involved in neural integration (Figure 2). The vestibulo-ocular processing through the cerebellar flocculus/ventral paraflocculus is involved in both neural integration and VOR plasticity. Finally, the posterior cerebellar vermis is primarily involved in otolith signal processing and controls the properties of the RVOR at low frequencies. Signals from both areas of the vestibulo-cerebellum project to the vestibular nuclei, where they directly contribute to the generation of the VORs.

The vestibular nuclei represent the final premotor center for all types of slow eye movements, including not only the VORs but also OKN, OFR, and pursuit (Figure 5). Many neurons in the vestibular nuclei also show a burst or pause in activity during saccades and fast phases of vestibular nystagmus. Several types of vestibular nuclei neurons have been described, differing in their response properties to rotation, saccades, and smooth pursuit eye movements. In particular, the position-vestibular-pause (PVP) cells are thought to represent the second-order neuron in the three-neuron arc pathway (Figures 1 and 2). Eye-head cells, on the other hand, are thought to be involved in VOR adaptation, many receiving inhibitory projections from Purkinje cells in the cerebellar flocculus/ventral paraflocculus.

Conclusion: Natural Behavior

The VORs represent some of the most well-understood sensorimotor actions. In particular, because of its simplicity, its phylogenetically preserved properties, and well-defined neuronal properties, the RVOR was in the forefront of discovery during the latter part of the twentieth century. The TVOR, on the other hand, having geometrically more complex properties and being phylogenetically newer, remains less well understood. In everyday activities, of course, the two VORs are both elicited in tandem. Furthermore, most often the head is not fixed relative to the body. Current research in the field focuses on understanding these additional features of vestibulo-ocular processing, including the roles of other motor and cognitive influences.

Introduction

The vestibular system detects the motion and orientation of the head in space. Although vestibular sensation is typically not perceived consciously, anyone who has experienced a vestibular pathology can attest to how critical this sense is for our daily life. Anatomical specializations of the vestibular end organs within the inner ear enable the transduction of both angular (via the semicircular canals) and translational (via the otolith organs) accelerations, permitting the central nervous system (CNS) to sense head motion in all six degrees of freedom. Information detected by the vestibular system initiates a series of reflexes that can stabilize our visual axis during running or walking via the vestibulo-ocular reflex and maintain head and body posture via vestibulospinal pathways. For example, when we accidentally slip and begin to fall forward, a series of reflexes is initiated that maintains our center of gravity and protects our head and body from injury.

The maintenance of head and body posture requires the development of muscular forces at multiple body segments. Accordingly, the vestibulospinal pathways distribute vestibular information to all levels of the spinal cord. This article focuses primarily on vestibular projections to the cervical spinal cord, and it is likely that the thoracic and lumbar projections share many of the same organizing principles. This article also examines the neuromuscular control of other types of head movements, such as orienting head movements that help redirect the line of sight. Voluntary movement of the head requires the contextual suppression of the reflexive mechanisms that serve to stabilize the head. From an overall perspective, many of the challenges faced by the CNS in controlling head motion (e.g., contextual gating of reflexes, control of a highly complex and seemingly redundant neuromuscular plant) mirror those present in other motor systems, such as the limb.

Anatomical Organization of Vestibulospinal Pathways

Neural information transduced by the vestibular end organs is transmitted to the four vestibular nuclei located in the rostral medulla and caudal pons. Afferents from the semicircular canals project primarily to the superior and medial vestibular nuclei, although minor projections reach the lateral and inferior vestibular nuclei. The otolith organs project primarily to the inferior vestibular nucleus, and projections to the lateral, medial, and superior vestibular nuclei have been found in a variety of species. Much of the processing of positional and movement information necessary for vestibular reflexes takes place within the vestibular nuclei. For example, many neurons within the vestibular nuclei receive converging information from both otolith receptors and one or more canal pairs. As a result, individual vestibular neurons can encode both angular and translational components of head motion. Such convergence can be used to disambiguate tilts and translations. In addition, neurons within the vestibular nuclei also receive major afferent projections from the cerebellum, the accessory optic system, and the contralateral vestibular nuclei, as well as proprioceptive signals arising from all levels of the spinal cord and from the reticular formation. These converging, and occasionally reciprocal, projections provide the vestibular nuclei with the information necessary to integrate the incoming vestibular information with the visual, proprioceptive, and contextual cues necessary for the production of an appropriate motor response.

Efferent projections from the vestibular nuclei distribute information about head motion and head position with respect to gravity to many different parts of the brain. Major targets include oculomotor nuclei, reticular and spinal centers concerned with whole-body motion, the vestibular regions of the cerebellum, the thalamus, and also the contralateral vestibular nuclei via commissural connections. These commissural fibers provide the pathways by which information from pairs of corresponding semicircular canals and otolith organs can be integrated.

The vestibular system produces reflexive postural adjustments of the head and body through two major descending pathways to the spinal cord: the lateral vestibulospinal tract (LVST) and the medial vestibulospinal tract (MVST; Figure 1). The LVST arises primarily from neurons within the lateral (Deiter's nucleus) and inferior vestibular nuclei. The LVST projects to all levels of the ipsilateral spinal cord, running within the anterior funiculus of the spinal cord before terminating directly onto both motor neurons and interneurons within lamina VII to IX of the cervical, thoracic, and lumbar spinal cord. The MVST originates primarily from the medial vestibular nucleus, although lesser projections arise from the inferior and lateral nuclei. In contrast to the LVST, fibers of the MVST project bilaterally, terminating in

Figure 1 Projection of vestibular afferents to vestibular nuclei, and trajectory of medial and lateral vestibulospinal tracts.

lamina VII to IX of the cervical spinal cord, where they contact interneurons, motor neurons, and propriospinal neurons.

In addition to their contributions to the vestibulospinal tracts, neurons within the vestibular nuclei send branches to wide areas of the reticular formation, ranging from the medulla to the midbrain, and to the interstitial nucleus of Cajal and the Forel's Field H (FFH). These areas in turn have projections to the spinal cord that include direct connections to motor neurons. These indirect pathways thus form a parallel channel by which vestibular information can contribute to vestibulospinal reflexes and provide another means by which vestibular information can be integrated with other sensory, motor, and contextual signals.

Functional Physiology of Vestibulospinal System

The LVST and MVST primarily mediate different components of the vestibulospinal reflexes. For example, the actions initiated by signals carried along the LVST are primarily carried out by the proximal muscles of the body, including the muscles of the limb. Axons of many LVST neurons give off collaterals in many different segments of the spinal cord, ensuring the coordination of different muscle groups during postural control. In contrast, projections from the MVST primarily mediate the vestibulocollic reflex (VCR) and accordingly project mainly to the axial muscles of the neck. The projections of vestibulospinal neurons are patterned depending on their source of input. For example, MVST neurons receiving inputs from the saccule and/or the canals terminate predominantly, but not exclusively, at cervical spinal segments. Most neurons of the LVST receive utricular input, and ~20% of these have axons that reach the lumbar segments of the spinal cord. Finally, vestibulospinal neurons that contribute to the MVST and receive input from the vertical canals predominantly innervate upper cervical spinal cord segments. These findings are consistent with behavioral observations in humans that the VCR is more active in the pitch than the yaw plane.

The most basic circuitry for the VCR is a three-neuron arc similar to the circuitry of the vestibulo-ocular reflex. The three-neuron VCR consists of a primary vestibular afferent, a vestibulocollic neuron, and a neck muscle motor neuron. Returning to our example of the person falling forward, the integration of signals mainly from the saccule and vertical semicircular canals within the vestibular nuclei initiates a reflex that results (via the MVST) in the recruitment of dorsal neck extensor muscles and the inhibition of ventral neck flexor muscles. The result is an upward head motion, opposite to the direction in which the person is falling. By distributing signals to multiple levels of the spinal cord, the vestibulospinal reflexes carried along the LVST and MVST coordinate an appropriate whole-body response that serves to protect the head and body from impact and stabilize the body's center of gravity.

As will be described in the section titled 'Biomechanical comparisons of eye and head movement,' the anatomical organization of the muscles of the neck is highly complex. There are more than 20 pairs of neck muscles that can potentially generate head motion through a structure (the neck) that spans multiple individually mobile cervical segments. Recent work, primarily carried out in cats, has demonstrated that the CNS recruits a consistent synergy of neck muscle activation to generate the VCR. For example, signals from each semicircular canal are distributed to an appropriate set of neck muscles to produce compensatory head movements in the same plane as the plane of the stimulated canal (Figure 2). This mapping is done by single MVST neurons that receive a particular combination of canal input and then innervate a functional set of multiple neck muscles. In this way, they implement a canal-dependent head movement synergy. Additional evidence shows

Figure 2 Convergent input patterns and pathways from the six semicircular canals to motor neurons supplying six different neck muscles. Open and closed circles represent excitatory and inhibitory neurons, respectively. Note how the motor neuron innervating a given muscle receives a unique and homogeneous pattern of input from the six semicircular canals. A, anterior; H, horizontal; P, posterior canals; MN, neck motor neuron; MLF, medial longitudinal fasciculus; Nucl., nucleus. Reproduced from Sugiuchi Y, Kakei S, Izawa Y, and Shinoda Y (2004) Functional synergies among neck muscles revealed by branching patterns of single long descending motor-tract axons. *Progress in Brain Research* 143: 411–421, with permission from Elsevier.

that the 'hardwired' functional synergy contacted by single MVST neurons may also be used by the reticulospinal and tectoreticulospinal systems. The advantage of this organization may be twofold. First, the use of a consistent set of muscular synergies by descending MVST neurons simplifies the control of head motion by decreasing the degrees of freedom about which head motion can be generated. Second, sharing of the same muscular synergy across different descending systems may aid the contextual control of voluntary versus externally applied head motion. The generation of voluntary head movement, for example, through the tectoreticulospinal system, requires the transient suppression of the VCR, which would otherwise be counterproductive. Hardwiring the vestibulospinal and tectoreticulospinal system into the same muscular synergies may optimize the neuromuscular responses to voluntary versus externally applied head motion.

Other Descending Pathways Involved in Controlling Head Motion

The vestibulospinal tracts are one of a number of descending pathways that can control head movement and posture. Head motion can also be generated via reticulospinal, tectospinal or tectoreticulospinal, interstitospinal, and corticospinal pathways that exert their influence via direct connections onto neck muscle motor neurons or via indirect connections through intercalated reticulospinal neurons or spinal interneurons. The convergence of multiple descending pathways onto neck muscle motor neurons reflects the diversity of function that head movements may fulfill. In addition to contributing to body posture and balance via the vestibulospinal tracts, and depending on the species in question, head movements can serve such diverse behaviors as orienting, feeding, grooming, communicating, fighting or other

predator behaviors, and even prehension (seen, for example, when a cat carries a kitten). Each of these tasks is associated with a particular set of control criteria that are likely effected through the combined actions of multiple descending systems.

Much has been learned recently about the neural mechanisms controlling head motion during gaze shifts that redirect the line of sight. Because the eyes are effectively blind during gaze shifts, the CNS places a premium on shifting gaze as quickly and as accurately as possible. Although smaller gaze shifts can typically be generated by rapid saccadic eye movements within the head, gaze shifts greater than $\sim 20^\circ$ usually involve coordinated motion of the eyes within the head and the head within space. The control of large gaze shifts represents an instance of motor control wherein the movement of the variable in question (here, the line of sight) depends on the nested movement of multiple body parts.

A key structure in the control of gaze shifts is the superior colliculus (SC). Recent evidence has demonstrated that neural activity within the SC encodes the desired gaze shift rather than the underlying component movements of either the eyes or the head. Thus, the decomposition of this gaze-related command emanating from the SC into the appropriate motor commands to move both the eyes and the head occurs within the downstream circuitry. Precisely how this is done remains an open question in oculomotor research. Anatomically, the signal output from the SC is transmitted to neck muscle motor neurons via two major separate pathways: one through pontomedullary reticulospinal neurons for horizontal head motion and the other through neurons in FFH in the mesodiencephalic junction for vertical head motion. In both the pontomedullary reticular formation and the FFH, two subgroups of spinal-projecting neurons are found. The descending axon of the first subgroup gives off a number of collaterals which arborize into premotor centers controlling eye motion (Figure 3(a)). In contrast, no such collaterals are found for the second subgroup (Figure 3(b)). Presumably, these subgroups allow for both coordinated and separate control of eye and head movements. Both the pontomedullary reticular formation and the FFH receive inputs from higher cortical areas, likely providing a substrate by which voluntary control of eye–head coupling may be generated.

Biomechanical Comparisons of Eye and Head Movement

As the above results demonstrate, the neural control of the eyes and head can be intimately related. Similar neural substrates for shared control of the eye and head have also been demonstrated in the vestibular system, wherein some second-order vestibular nuclei project to both eye and head premotor centers. A more complete understanding of the functional role of both vestibular or reticulospinal eye–head neurons requires neurophysiological investigations in awake, behaving animal subjects (usually cats or monkeys). However, investigation of the functional role of eye–head neurons in motor control is hindered by the very different biomechanics of the eye and the head. Comparatively, the eye is the far simpler of the two structures. Eye movements are generated by six extraocular muscles which operate on a motor plant dominated by viscous and elastic resistive forces. More than 40 years of study on oculomotor control with the head restrained has yielded a refined understanding of the neuromuscular events that cause eye motion, to the point that the eye movements themselves can serve as a proxy for the underlying neuromuscular control. For example, an eye movement of a certain amplitude and direction allows one to infer, with a fairly high degree of precision, the underlying spatial (i.e., the particular muscles) and temporal patterns of muscle activity that generated the eye movement.

The biomechanical and musculoskeletal realities of head motion do not permit a similar level of inference. Biomechanically, the head can be viewed as an inverted pendulum connected to a tilted beam, as in humans and most quadrupeds the head is held at the top of a more or less vertically oriented cervical column. The center of mass of the head lies anterior to the vertebral column, such that the head would fall forward were all head–neck muscles to relax. The head has a considerable mass (usually about 4–5 kg), and accordingly is endowed with substantial inertia (approximately $0.02\,\mathrm{kg\,m^2}$ for axial/yaw rotation and 0.03–$0.04\,\mathrm{kg\,m^2}$ for frontal/pitch and lateral/roll flexion). Anatomically, head movements in humans and animals can be generated by the recruitment of more than 20 pairs of neck muscles that interconnect the skull, cervical vertebrae, and shoulder girdle. Many of these neck muscles cross two or more joints, span multiple sites of attachment, and are divided into multiple compartments by architectural specializations. The 20 pairs of neck muscles also vary substantially in size and force-generating capacity. The largest muscles tend to be located in the most superficial layers of the neck and, as a consequence of their large cross-sectional areas and lever arm, have the greatest capacity to generate torque. In contrast, the deeper layers of the neck are invested with much smaller muscles that tend to have simpler anatomical structures. The muscles in Figure 4, which are taken from the dorsal neck of the monkey, depict

Figure 3 Axonal trajectories of single reticulospinal tract neurons (RSTs) in the pontomedullary reticular formation, revealed by intraaxonal staining with horseradish peroxidase. (a, b) Low-magnification views of axonal trajectories of two RSTs from the nucleus reticularis pontis caudalis (NRPc; (a)) and three RSTs from the nucleus reticularis gigantocellularis (NRGc; (b)). Note that the axons of the two NRPc–RSTs give off axon collaterals into the pontomedullary reticular formation on their way to the spinal cord, while such collaterals were rare in the three NRGc–RSTs. a number of superficial and deep neck muscles that would, based simply on their gross anatomy, appear to have similar pulling directions. If one thinks only about a single motor task, then the head–neck motor system would seem to contain a number of such muscular redundancies. However, the adaptations of particular muscles reflect functional optimizations for the full gamut of head movement tasks: muscles which appear to be redundant in one task may not be so in another.

Such considerations of neck muscle biomechanics and anatomy demonstrate why it is difficult, if not impossible, to infer the spatial and temporal patterns of neck muscle recruitment based simply on the kinematics of a head movement. Even a detailed knowledge of neck muscle morphometry, including descriptions of fiber type, cross-sectional area, tendon arrangements, and pinnation angle, is often insufficient to identify the functional role played by a neck muscle in a given head movement. Furthermore, patterns of muscle recruitment will depend on a number of other factors as well, including the recruitment of other muscles. Most of the muscles of the neck are attached at both ends to bones that move, so their action will depend on the stability and position of the origin and insertion of the muscle.

Figure 4 Anatomical sketches of some of the muscles of the dorsal neck in the monkey, illustrating the apparent redundancy in the musculoskeletal organization of the head and neck. Electromyograph recordings demonstrate that splenius capitis (SP cap), rectus capitis posterior major (RCP maj), and obliquus capitis inferior (OCI) contribute to a horizontal head turning synergy. Biventer cervicis (BC), complexus (COM), and obliquus capitis superior (OCS) contribute to a vertical head movement synergy that tends to pitch the head upward.

Electromyographic Recordings of Neck Muscle Recruitment

Chronically indwelling electromyogram (EMG) electrodes have been implanted in both superficial and deep neck muscles in cats and monkeys, permitting the characterization of the patterns of neck muscle recruitment during a variety of head movements and postures. The advantage of this approach is that it permits the direct observation of the neuromuscular signals issued to the head plant with a high degree of both spatial and temporal precision, circumventing the biomechanical complexities inherent in head motion. This work has revealed a number of findings. First, all head movements and postures are associated with recruitment of the smaller, deeper muscles of the neck. Recruitment of the more superficial neck muscles is added to this synergy for more eccentric postures or for larger and faster head movements. Second, the initial posture adopted by the animal influences both the timing and the pattern of neck muscle recruitment. For example, cats can be trained to generate head turns in both their customary posture, with the cervical column oriented vertically, and a second posture, with the cervical column oriented more horizontally. In both postures, a posturally independent set of neck muscles is recruited, perhaps reflecting connections hardwired through the tectoreticulospinal system. In the more horizontal posture, this basic synergy acts in concert with a second set of ancillary neck muscles, reflecting posturally dependent recruitment that presumably regulates the mobility of the cervical column and adjusts the net muscular forces. Such a strategy reduces the redundancy of the head–neck system and may also simplify the computation of appropriate muscular synergies for different behavioral tasks.

Recordings of neck EMG can also be combined with neurophysiological and behavioral approaches to gain additional insights into the brain stem and cortical control of head motion which could not be made simply through the kinematic analysis of eye–head gaze shifts. For example, recent work combining neck EMG recordings with stimulation of both the SC and the frontal eye fields has revealed that the current thresholds required to evoke neck EMG responses are frequently less than the current thresholds required to evoke eye–head gaze shifts. A second pertinent observation was reached by examination of the patterns of neck muscle recruitment following the onset of a visual target. Figure 5 shows the activity of a number of muscles that contribute to head turns. Even though the head is restrained, these muscles are far more active when a visual target is presented on the ipsilateral side (i.e., leftward targets for left muscles). Of particular interest is how the onset of recruitment of these muscles occurs ~90 ms after ipsilateral target presentation, regardless of the ensuing gaze shift reaction time (asterisk in Figure 5). At the extreme, muscles can be activated up to 150 ms in advance of gaze shift onset. The implication of these findings is that circuits in the brain stem, presumably downstream from the SC, permit the delivery of an orienting command to the head while a decision to commit to a gaze shift is still ongoing. Such selective gating may, at least in part, be due to the paramount importance of foveal vision. Alternatively, or perhaps additionally, such selective gating may help prime neck muscles earlier to compensate for the head's considerable inertia.

Afferent Information from Neck Muscles

A unique feature of the head–neck system is that it provides the linkage between the body and a mobile

Figure 5 Activity of multiple neck muscles in a head-restrained monkey following the presentation of a visual target either 30° to the left (left column) or right (right column). Each subplot shows the magnitude of electromyograph (EMG) activity (in color) for ~50 trials (individual trials are stacked along the *y*-axis), with time proceeding along the *x*-axis and aligned on the time of target onset (white vertical dashed line). Trials have been ordered by the reaction time of the ensuing saccade (white squares). Note the band of EMG activity, depicted by the asterisks, that occurs ~90 ms after ipsilateral target presentation (e.g., left targets for left muscles), regardless of the time of the ensuing saccade. Reproduced from Corneil BD, Oliver E, and Munoz DP (2004) Visual responses on neck muscles reveal selective gating that prevents express saccades. *Neuron* 42(5): 831–841, with permission from Elsevier.

platform (the head) in which the major exteroceptive sense organs are mounted (e.g., the eyes, ears, and nose). Consequently, the position of the head relative to the body must be integrated within many sensorimotor transformations. Neck muscles are not simply motor organs but also contribute afferent information relating the position of the head relative to the body. Indeed, a striking observation is that the density of muscle spindles in the deeper muscles of the neck is among the highest in the body, comparable only to the fine muscles of the finger. Despite the rich endowment of muscle spindles in the neck, the segmental spinal reflexes (e.g., the monosynaptic stretch reflex) are paradoxically weak.

The afferent information from the neck likely serves two general roles for sensorimotor control. First, afferent information from the neck plays an integral role in the control of body posture through its integration with vestibular signals. Transient loss of neck muscle afferent information induces debilitating effects that resemble vestibular pathologies, affecting not only head movements but also posture, locomotion, and reaching. Symptoms of cervical vertigo, including dizziness, ataxia, and nystagmus, have long been recognized to follow whiplash and other types of neck muscle damage. Such symptoms can be reproduced experimentally when neck muscle receptors are anesthetized or stimulated by vibrating the muscles of the neck. In the normal human and animal, the short-latency cervical reflexes (e.g., the cervico-ocular and cervicocollic reflex) are thought to operate at a relatively low gain, but the convergence of neck muscle afferent information with visual and vestibular information in the cerebellum, vestibular nuclei, reticular formation, and vestibular cortex emphasizes its role in the multisensory control of body posture. The gains of the cervico-ocular and cervicocollic reflexes increase following vestibular trauma or with aging, presumably through the recruitment of plastic mechanisms that compensate for the compromised or decreasing vestibular sensation.

A second role of neck proprioception is to unequivocally signal the position of the head relative to the body for developing motor programs. Knowledge of the current position of a body segment is a prerequisite to moving it accurately. Neck muscle afferent information reaches higher oculomotor centers in the parietal and frontal cortices, where it appears to be integrated into developing plans for action. Although convergence of vestibular and neck muscle afferent information occurs in some cortical areas, in others the information remains segregated. From a motor control standpoint, it is imperative that the organism knows both the position of its head relative to its body and the position of its head in space.

Summary

The vestibulospinal system initiates a series of whole-body reflexes whose function is to stabilize body posture and protect the head and body from potential injury. VCRs target the axial muscles of the neck by recruiting hardwired muscle synergies to produce compensatory head movements. Such hardwired synergies, which are also present in other descending head control pathways, are necessary to simplify the control of a motor structure as complicated as the head. Head movements are also intimately related to eye movements, fulfilling behavioral goals to stabilize or redirect the line of sight. Finally, neck muscles are not simply motor organs but also provide a

refined sense of head-on-body position necessary for postural control and sensorimotor integration. Overall, an appreciation of the neural strategies used by the CNS to control head motion may reveal principles which generalize to other aspects of motor control. Like the limb (and unlike the eye), the head is a highly complex motor structure characterized by significant inertia, and proprioceptive feedback from the muscles must be integrated into places for action. However, unlike the limb, much of the neural circuitry responsible for the sensorimotor control of head movement lies in the brain stem and is accessible to contemporary recording techniques.

Vibrissa Movement, Sensation and Sensorimotor Control

D Kleinfeld, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Rats use their vibrissae, an array of long, pliable hairs that can be actively swept through space, to interrogate objects in their local physical environment (Figures 1(a) and 1(b)). As rats search and locomote, they must be able to gauge the position of the ground beneath them and walls and obstacles around them. This suggests that the sense of touch is used in multiple ways. First, touch provides a means to establish the nature of a surface texture. Is it smooth or rough? Second, touch is used to establish the shape of an object. Third, touch is used as a means to determine the location of an object with respect to the body image of the rat. Is the object to the front or the side? The notion of interpreting touch in the context of body coordinates implies that reference signals of vibrissa position are an essential aspect of sensation.

The neuronal encoding of environmental and positional clues, and the anatomical circuitry that turns these clues into motor plans, form the material of this article. It begins by delineating a number of tasks that rats may be trained to accomplish solely through the use of their vibrissae. These serve to focus our presentation on neuronal pathways that are directly relevant to an understanding of vibrissa sensorimotor control. The article then discusses the anatomy of the vibrissa pathway in detail, with an emphasis on the mechanical properties of the vibrissa *per se*, as well as the motor plant that drives the vibrissae. This leads into a presentation of electrical signaling along the vibrissa pathways, followed by consideration of the neuronal computations that are supported by these signals. The article closes with a discussion of open issues. As an aid to reading the literature, common abbreviations are given in Table 1.

Behavior

Vibrissae somatosensation is an active sensory process. Rodents sweep their vibrissae through space largely in unison and with a rhythm that varies between 5 and 25 Hz. The dynamics of this process can be extracted from high-speed videography or from measurements of the electrical activity of the muscles that drive the vibrissae (Figure 1(c)). What tasks can animals accomplish with this active process? A basic function of the vibrissae is to evaluate the terrain in front of the animal. Thus, for example, blind rats with intact vibrissae will leap across wider gaps than rats without vibrissae. This observation is a building block of a commonly used paradigm to determine whether rats can discriminate among surfaces with different textures (Figure 2). Here, rats foveal whisk as they crane across each of two gaps (Figure 1(c)). This posture allows them to sense and evaluate a texture on the far side of the gap. Only one of the two textures is paired with a reward, that is, water or food, which the animal can receive by jumping across the gap. The accumulated data from these experiments suggest that trained animals may recognize a corrugated surface whose pitch is as fine as 15μm and differentiate among surfaces whose relative difference in pitch is as small as 5%. Last, these experiments reveal that the amplitude of whisking may change upon contact (Figure 2(a)(2)) and thus provides a means to manipulate sensorimotor feedback.

The vibrissae convey spatial information that is sufficient to allow rats to distinguish between barriers whose lateral distance from the snout varies by less than 5%. In one task, rats are trained to distinguish between a wide versus narrow aperture (Figures 2(b)(1) and 2(b)(2)). A rat waits in a main chamber until a sliding door opens, after which it enters a small chamber that contains a nose poke, that is, a place for the snout that keeps the rat's head relatively fixed during the task. Once the snout is positioned, two panels close from the sides to form a symmetric, variable-width aperture. Animals are required to judge whether the aperture is the wider or narrower of two possible widths and report their choice by moving to additional nose pokes in the main chamber, that is, a right nose poke for the narrow aperture and a left nose poke for the wide aperture (Figure 2(b)(1)). The correct choice is rewarded. An interesting result is that, as the vibrissae are incrementally trimmed from the normal complement of 20 or more down to one and then zero, the performance on this task is a linearly decreasing function of the number of vibrissae that remain (Figure 2(b)(2)).

Variants of the above fine-discrimination task require the animal to report symmetric versus asymmetric apertures. In a related task, animals are trained to report the shift in the horizontal position between pins placed on each side of the face (Figure 2(c)(1)). This latter task probes the bilateral acuity of the vibrissa system. It is interesting that rats perform this task better with only a single column, referred to as arc, of vibrissae rather than all their vibrissae (Figure 2(c)(2)). The typical displacement that could be distinguished with an arc was 1.5 mm, which corresponds to an angular displacement of 6° in these experiments.

Figure 1 Example data for different modes of whisking. (a) Exploratory whisking, also referred to as symmetric whisking. Shown are successive strobed video images of a rat, using darkfield illumination, as it moves its vibrissae during an exploratory whisk cycle. The animal was trained, while blindfolded, to whisk in search of a food tube (not shown). Successive frames are at intervals of 33 ms. Unpublished data. (b) Asymmetric whisking as a result of contact between the vibrissae and a wall. Protraction commences approximately synchronously on both sides of the snout; the filled white squares show the tracked vibrissae in the rear arcs. At $t = 65$ ms, a deflection occurs on a forward vibrissa; the filled white circle indicates the point of contact with the vertical surface. Protraction then ends on the side ipsilateral to the contact, and the contralateral vibrissae reach maximum protraction in the whisk cycle subsequent to the initial contact. Adapted from Mitchinson B, Martin CJ, Grant RA, and Prescott TJ (2007) Feedback control in active sensing: Rat exploratory whisking is modulated by environmental contact. *Proceedings. Biological Sciences/The Royal Society* 274(1613): 1035–1041. A similar pattern of asymmetric whisking as animals change their head position has been reported by Hartmann (Towal RB and Hartmann MJ (2006) Right-left asymmetries in the whisking behavior of rats anticipate head movements. *Journal of Neuroscience* 26: 8838–8846). (c) Example of sequential foveal and exploratory whisking observed via the rectified electromyogram of the intrinsic muscles. The solid line is the low-pass filtered signal. Adapted from Berg RW and Kleinfeld D (2003) Rhythmic whisking by rat: Retraction as well as protraction of the vibrissae is under active muscular control. *Journal of Neurophysiology* 89: 104–117.

Beyond issues of discrimination, rats make use of vibrissa somatosensation to encode the location of objects relative to their face as they explore their environment with large-amplitude whisks (Figure 1(a)). In part, the ability of rats to use their vibrissae to sense a platform across a gap implies that they are sensitive both to touch and to the forward thrust of their vibrissae. Nonetheless, the question remains as to whether rodents encode the position of their vibrissae as they whisk (Figure 3(a)). This issue was addressed in terms of an operant conditioning paradigm in which rats were trained to discriminate between different angles of a pin relative to the area of the cheek that hosts the vibrissae, called the mystacial pad (Figure 3(b)). These animals were trained to press a lever at a high rate if the rewarded stimulus (S+), corresponding to a pin at a specified location, was presented. No reward occurred for a stimulus at a second location (S−). Rats with a single vibrissa were able to perform this task (Figure 3(c)). Further, they performed it without bias to vibrissa location and with few, relatively brief contacts. This implies that rats must make use of a reference signal of vibrissa position as they determine where touch occurs relative to their mystacial pad.

Whisking

Within laboratory settings, animals will typically whisk in bouts of five to 50 individual whisks with a continuum of behaviors. Nonetheless, three different motifs appear to be common. The first is exploratory whisking, which occurs when animals whisk in air without contact or with only light contact (Figure 1(a)). In this case the stroke on a given whisk approaches 70°, and a total field of up to 160° may be covered as the animal slowly shifts the set point of its whisk. Such whisking is extremely regular and typically occurs with a frequency between 7 and 12 Hz and a mean of 9 Hz. In particular, the bandwidth of exploratory whisking is at theoretical limits for a perfect oscillator, which implies that the motor drive may be described as a sinusoidal oscillation with a constant frequency.

The second whisking motif, asymmetric whisking, occurs when animals make contact with a large object, such as a wall, while they whisk (Figure 1(b)). It also occurs if they turn their head to the side while whisking. Asymmetric whisking lasts for only one to three whisk cycles. The final motif is referred to as foveal whisking and occurs when animals thrust all

Table 1 Common abbreviations

Abbreviation	*Meaning*
ALBSF	Anterior lateral barrel subfield, a region of parietal cortex
CPG	Central pattern generator
EMG	Electromyogram
FN	Facial nucleus
ICMS	Intracortical microstimulations
IoN	Infraorbital branch of the trigeminal nerve
L1, ..., L6	Neocortical layer 1, ..., layer 6
LFP	Local field potential
M1	Primary motor region of neocortex
MUA	Multiunit activity
PMBSF	Posterior medial barrel subfield, a region of parietal cortex
PO	Posterior medial nucleus, a region of dorsal thalamus (also POm)
PrV	Trigeminal nucleus principalis
RSU	Regular spiking unit
S1	Primary somatosensory region of neocortex (also SI)
S2	Secondary somatosensory region of neocortex (also SII)
SpVC	Spinal nucleus caudalis
SpVI	Spinal nucleus interpolaris
SpVO	Spinal nucleus oralis
TCU	Thalamocortical unit
TG	Trigeminal ganglion
TN	Trigeminal nucleus
VMCtx	Vibrissa primary motor cortex
VPM	Ventral posterior medial nucleus, a region of dorsal thalamus
VL	Ventral lateral nucleus, a region of dorsal thalamus
ZI	Zona incerta, a region of ventral thalamus

their vibrissae forward to palpate an object ahead of them, as occurs when they try to detect a landing on the far side of a gap (Figure 2(a)). In this case the stroke is much reduced, typically to 20°, and the extrinsic muscles, the muscles that pull on the mystacial pad and include *M. nasolabialis*, *M. maxolabialis*, *M. nasalis*, and *M. transversus nasi*, are relatively inactive as they can apply little torque when the mystacial pad is fully extended. The frequency of foveal whisking is high, ranging between 15 and 25 Hz, and rats can readily switch between foveal and exploratory whisking (Figure 1(c)).

Systems Description of the Sensorimotor Plant

The anatomy of the vibrissa system provides the foundation for understanding the neuronal basis of whisking and vibrissa-driven behaviors. Like other sensorimotor systems, the vibrissa system is organized as a set of nested loops, with the vibrissae and the motor plant that drives the vibrissae as the common focus of all loops (Figure 4). The ascending branches of the loop receive and process sensory input, and the descending branches can control the motor plant that drives the vibrissae. It is important to remember that, as a closed feedback system, both sensory and motor signals can appear at all levels and stages of the nervous system. Only in extreme cases, such as induced paralysis of an identified pathway, can one isolate a touch signal from a motion signal that leads to touch.

The Follicle

The front end of the vibrissa system is the vibrissa–follicle complex (Figure 5). The lower 4 mm of the vibrissa is buried in the follicle, which is innervated by two sets of trigeminal sensory nerve terminals that originate from the trigeminal nucleus. One set innervates the deep end of the follicle (DVN in Figure 5) and the other innervates the superficial end (SVN in Figure 5). Together, these nerve fibers form the infraorbital branch of the trigeminal nerve (IoN).

The sensory nerves contain eight morphologically distinct sensory terminals, for which two classes of responses appear to dominate. One is the rapidly adapting receptors, whose responses return to baseline within 200 ms of stimulation, and the other is the slowly adapting receptors, which enable the vibrissa to follow vibrations as fast as 1200 Hz over extended periods. The latter responses are believed to make use of small cells called Merkel cells, localized to the follicle as intermediates between the hair and the sensory nerve terminal. The follicles, although composed exclusively of soft tissue, contain cavities that are under the control of the autonomic nervous system and engorge with blood when the animal is active. This results in a fixture that is likely to form a stiff mechanical coupling between the vibrissa and the sensory nerve terminals.

The sensory fibers in the follicle are sensitive to motion of the embedded vibrissa and thus encode contact between an object and the vibrissa. More information is gleaned if the impact on contact and the distance of the contact point to the skin, that is, the radial distance along the vibrissa, can be encoded. One likely possibility is that the reaction forces along the follicle shift as the point of impact moves relative to the center of mass of the vibrissa. Thus the pattern of these forces can be used to gauge the magnitude, distance, and direction of impact.

The Mystacial Pad

The cheek on each side of the rat's face contains a thickening in the skin that is called the mystacial pad. The pad contains an array of follicles organized as five rows and four or more arcs. In addition, there are four additional large caudal vibrissae, denoted the

Figure 2 Behaviors that involve fine vibrissa-based comparisons. (a)(1) Schematic of a gap-crossing task in which rats crane across one of two equally spaced gaps to assess the relative roughness of textured tubes. Animals are trained to examine both textures and then jump from the perch on the start platform to the appropriate jump platform. The gap between the start and jump platforms can be adjusted with a slider to change the difficulty of the task. (a)(2) The effects of surface contact on the amplitude of vibrissa movements in one rat. The

straddlers, which interdigitate among the rows (insert, Figure 5). The hairs in the most dorsal row, that is, row A, point upward above the head and, curiously, are barbered as animals determine dominance. The hairs in the ventral row, that is, row E, tap the ground as the animal locomotes and presumably help maintain the altitude of the head. The middle rows, labeled B through D, appear important to exploration and the location of objects.

Brain Stem Loop

Sensory input from reaction forces generated in the follicles leads to a signal that transverses the IoN and projects to one or all four nuclei that form the trigeminal complex (Figure 4). These include the principal sensory nucleus (PrV) and the three spinal nuclei, denoted oralis (SpVO), interpolaris (SpVI), and caudalis (SpVC). The afferents form several somatotopic representations, referred to as barrelettes, of the ipsilateral vibrissae. Efferents from the PrV, SpVC, and SpVI nuclei project to motor neurons in the lateral subnucleus of the ipsilateral facial nucleus, which sends motor output to the muscles of the mystacial pad. This completes the lowest-order brain stem sensorimotor loop (∗ in Figure 4).

The trigeminal nuclei further interact among each other. Neurons in the PrV nucleus receive excitatory input from both the SpVC and SpVI nuclei and inhibitory input from the SpVi nucleus. The latter forms a local inhibitory loop that, possibly in concert with descending inputs from high-order areas, provides a means to filter sensory information at the level of the brain stem.

Muscles of the Mystacial Pad

What is the underlying musculature that drives the vibrissae? Protraction begins with contraction of the external protractor muscles in the skin, *M. nasalis* (Figure 6(a)). This shifts the center of mass of the follicle, as well as the point of egress of the vibrissae, toward the snout. A second group of muscles, which appear as slings that wrap around each follicle, contract next and rapidly propel the vibrissae forward. These muscles are unique to animals that whisk and are denoted the intrinsic muscles (Figure 6(b)). Last, as protraction reaches its maximum extent, activation of the sling muscles wanes and a pair of external retractor muscles, *M. nasolabialis* and *M. maxolabialis*, activate and restore the vibrissae to their initial position (Figure 6(a)). The measured sequence of muscle activation, together with the measured motion of the vibrissae along an anterior–posterior (A–P) axis, illustrates this process (Figure 6(c)). Last, it is possible to construct a mechanical model of the mystacial pad that is based on the known anatomy, elastic constants of the tissue, and force curves for the muscles (Figure 6(d)). The model serves as a means to reconstruct the position of the vibrissae from the measured electrical activation of the vibrissae.

Of critical importance, exploratory whisking occurs in the absence of sensory feedback. Moreover, the phase relation between the various muscle groups that mediate whisking is unchanged. This suggests the existence of coupled central pattern generators in the brain stem that drive the three phases of rhythmic whisking (Figure 6(c)).

angular displacement of different vibrissae are seen to decrease when they contact a texture as opposed to sweep the air without contact. Panels (a)(1) and (a)(2) adapted from Carvell GE and Simons DJ (1990) Biometric analyses of vibrissal tactile discrimination in the rat. *Journal of Neuroscience* 10: 2638–2648; see also Carvell GE and Simons DJ (1995) Task- and subject-related differences in sensorimotor behavior during active touch. *Somatosensory and Motor Research* 12: 1–9. A similar task was pioneered by Guic-Robles (Guic-Robles E, Valdivieso C, and Guajardo G (1989) *Behavioural Brain Research* 31: 285–289) and recently extended to mice (Celikel T and Sakmann B (2007) *Proceedings of the National Academy of Sciences of the United States of America* 104: 1395–1400). (b)(1) Apparatus for a task to test distance discrimination. The width of the aperture is adjusted between two values, 'narrow' or 'wide.' Differences of 1.5 mm, that is, 62 mm vs. 63.5 mm, were generally irresolvable, but differences of 3 mm were resolvable. At the start of each session, the rat is placed in the outer reward chamber with the sliding door closed. When the door is opened, the rat enters the center discrimination chamber, centers in the nose poke, and samples the aperture with its vibrissae. The rat then backs into the outer reward chamber and pokes its nose into either the left or right nose poke to receive a water reward: a left nose poke if the aperture is narrow and a right nose poke if the aperture is wide. (b)(2) Mean percentage of correct discriminations for an ensemble of rats in which vibrissae were sequentially and systematically removed. Note the decrease in performance with the total number of vibrissae removed. Panels (b)(1) and (b)(2) adapted from Krupa DJ, Matell MS, Brisben AJ, Oliveira LM, and Nicolelis MAL (2001) Behavioral properties of the trigeminal somatosensory system in rats performing whisker-dependent tactile discriminations. *Journal of Neuroscience* 21: 5752–5763; see also Shuler MG, Krupa DJ, and Nicolelis MA (2002) Integration of bilateral whisker stimuli in rats: Role of the whisker barrel cortices. *Cerebral Cortex* 12: 86–97. (c)(1) Apparatus for a task to test fine discrimination in horizontal offsets of two bilaterally spaced bars. The horizontal locations of the poles were changed between trials in steps of 0.1 mm. At the start of each session, the rat enters the center discrimination chamber, centers in the nose poke, and samples the poles with its vibrissae. The rat then backs into the outer reward chamber and pokes its nose into either the left or the right reward cell to receive a water reward; a specific offset is randomly paired with a specific side for each rat. (c)(2) Distribution of performance thresholds after discrimination training with the complete C row of vibrissae, after trimming down to one vibrissa, C2, and retraining, and for control animals with no vibrissae. (c)(1) and (c)(2) adapted from Knutsen PM, Pietr M, and Ahissar E (2006) Haptic object localization in the vibrissal system: Behavior and performance. *Journal of Neuroscience* 26: 8451–8464.

Figure 3 Behavior that involves the confluence of touch and position signals during exploratory whisking. (a) Cartoon that depicts a task to detect the position of an object relative to the rat's head with only one vibrissa. This task differentiates between labeled line-schemes that involve multiple vibrissae but no knowledge of vibrissa position and haptic-schemes that depend on both touch and position neural streams (dashed arrows) but do not require multiple vibrissa. (b) Details of the training and testing arena. Discrimination trials begin when an animal trips the nose poke sensor, which causes either the rostral or the caudal stimulus pin to descend into the vibrissa field. Lever presses in response to the rewarded, that is, S+, stimulus, either the rostral or caudal pin for each animal, result in a drop of water in the fluid dispenser. Lever presses in response to the unrewarded, that is, S−, stimulus have no effect. (c) Cumulative behavioral responses for one session, averaged separately over S+ and S− trials. The line and shaded regions give the mean ±2 standard error of measurement cumulative lever press counts. The gray arrows at 0.5 s mark the time after which the error regions remain nonoverlapping. Adapted from Mehta SB, Whitmer D, Figueroa R, Williams BA, and Kleinfeld D (2007) Active spatial perception in the vibrissa scanning sensorimotor system. *PLoS Biology* 5: e15.

Midbrain Loop

A intermediate-level loop incorporates the superior colliculus and includes connections that cross the midline (Figure 4). The superior colliculus is a laminar, midbrain structure in which each layer is nominally devoted to integrating sensory and motor information relevant to a particular sensory modality. In rat, the intermediate and deep layers of the colliculus appear to be devoted to general somatic sensorimotor processing, with the more

Figure 4 Cartoon of the anatomy of nested, vibrissa sensorimotor loops. The proposed connections are gleaned from the work of very many laboratories and provide a coarse roadmap of the flow of neuronal signals. Only pathways of direct relevance to active sensing with vibrissae are shown, with the most studied areas, from the perspective of electrophysiology, shown in yellow. Subdivisions of each area that are not shown in the figure may be described below. Basal ganglion pathways (Mercier BE, Legg CR, and Glickstein M (1990) *Proceedings of the National Academy of Sciences of the United States of America* 87: 4388–4392; Deniau JM, Kita H, and Kitai ST (1992) *Neuroscience Letters* 144: 202–206), are not included as they have only recently received attention in the vibrissa community (Hoffer ZS, Arantes HB, Roth RL, and Alloway KD (2005) *Journal of Comparative Neurology* 488: 2–100). Nor has the loop between neocortex and the hippocampus been considered (Buzsaki G (1996) *Cerebral Cortex* 6: 81–92; Chrobak JJ, Lorincz A, and Buzsaki G (2000) *Hippocampus* 10: 457–465), a bias that reflects current ignorance in the role of these structures in sensorimotor control. The asterisk labels the shortest sensorimotor feedback pathway, which is a single-synapse from the principal trigeminal nucleus to the lateral aspect of the facial nucleus. Hindbrain loops: (vibrissae → trigeminal ganglion) The vibrissae are innervated by both slowly and rapidly adapting sensory afferents (**Figure 1**) that originate from the infraorbital nerve (Dorfl J (1985) *Journal of Anatomy* 142: 173–184; Rice FL A, Mance A, and Munger BL (1986) *Journal of Comparative Neurology* 252: 154–174; Leiser SC and Moxon KA (2006) *Journal of Neurophysiology* 95: 3125–3145). (Trigeminal ganglion → trigeminal nucleus) Sensory inputs from the trigeminal ganglion project to the principal sensory nucleus (PrV) and the spinal trigeminal nuclei oralis (SpVO), interpolaris (SpVI), and caudalis (SpVC; Torvik A (1956) *Journal of Comparative Neurology* 106: 51–132; Clarke WB and Bowsher D (1962) *Experimental Neurology* 6: 372–383). The PrV and SpVI nuclei and the magnocellular portion of SpVC have somatotopic maps of the vibrissae ('barrelettes'; Ma PM and Woolsey RA (1984) *Brain Research* 306: 374–379); SpVO receives sensory input from the vibrissae yet does not contain a map (Belford GR and Killackey HP (1979) *Journal of Comparative Neurology* 188: 63–74; Belford GR and Killackey HP (1979) *Journal of Comparative Neurology* 183: 305–322). Last, there is particularly high internuclear connectivity among the SpVC and SpVO nuclei (Jacquin MF, Chiaia NL, Haring JH, and Rhoades RW (1990) *Somatosensory and Motor Research* 7: 399–420). The PrV nucleus receives collateral excitatory input from the SpVC and SpVI nuclei and inhibition from the SpVI nucleus (Furuta T, Timofeeva E, Nakamura K, et al. (2008) Inhibitory gating of vibrissal inputs in the brainstem. *Journal of Neuroscience* 28: 1789–1797). (Trigeminal nuclei → facial nuclei) The facial nucleus contains five subnuclei, of which the lateral subnucleus is involved in vibrissa control (Papez JW (1927) *Journal of Comparative Neurology* 42: 159–191; Martin MR and Lodge D (1977) *Brain Research* 38: 206–210). Vibrissa areas SpVC, PrV, and SpVI connect to the lateral subnucleus, primarily through ipsilateral projections. The trigeminal loop is closed by direct projection from PrV, SpVC, and SpVI to the facial nucleus (Erzurumlu RS and Killackey HP (1979) *Journal of Comparative Neurology* 188: 75–86; Hattox AM, Priest CA, and Keller A (2002) *Journal of Comparative Neurology* 442: 266–276) and indirect pathways within the hindbrain via the pontomedullary reticular formation (Dauvergne C, Pinganaud G, Buisseret P, Buisseret-Delmas C, and Zerari-Mailly F (2001) *Neuroscience Letters* 311: 109–112;

rostral and lateral areas responding to vibrissa-related inputs from the contralateral trigeminal nuclei. Descending afferents from the superior colliculus project to the lateral subnucleus of the contralateral facial nucleus to complete the loop. An additional input that converges to the same laminae arises from ipsilateral vibrissa primary motor (M1) cortex.

Zerari-Mailly F, Pinganaud G, Dauvergne C, Buisseret P, and Buisseret-Delmas CJ (2001) *Journal of Comparative Neurology* 429: 80–93). The direct projection, and possibly the indirect projection, is predominantly excitatory and results in positive feedback (Nguyen Q-T and Kleinfeld D (2005) *Neuron* 45: 447–457). (Facial nucleus → vibrissae) The lateral aspect facial nucleus sends projections to the intrinsic muscles surrounding each vibrissa (Arvidsson J (1982) *Journal of Comparative Neurology* 211: 84–92; Dorfl J (1982) *Journal of Anatomy* 135: 147–154; Dorfl J (1985) *Journal of Anatomy* 142: 173–184; Arvidsson J and Rice F L (1991) *Journal of Comparative Neurology* 309: 1–16), and medial aspects are believed to project to the extrinsic muscles (**Figures 2(a)–2(c)**; Klein B and Rhoades R (1985) *Journal of Comparative Neurology* 232: 55–69; Isokawa-Akesson M and Komisaruk BR (1987) *Experimental Brain Research* 65: 385–398). The lateral subnucleus of the facial nucleus contains a somatotopic map of the vibrissae (Martin MR and Lodge D (1977) *Brain Research* 38: 206–210). Midbrain loops: (trigeminal nuclei → superior colliculus) The trigeminal nuclei project to vibrissa somatotopic areas of the superior colliculus (Drager UC and Hubel DH (1976) *Journal of Neurophysiology* 39: 91–101; Killackey H and Erzurumlu R (1981) *Journal of Comparative Neurology* 201: 221–242; Huerta M, Frankfurter A, and Harting J (1983) *Journal of Comparative Neurology* 220: 147–167; Steindler DA (1985) *Journal of Comparative Neurology* 237: 155–175; Bruce LL, McHaffie JG, and Stein BE (1987) *Journal of Comparative Neurology* 262: 315–330; Jacquin M, Barcia M, and Rhoades RW (1989) *Journal of Comparative Neurology* 282: 45–62; Benett-Clarke CA, Chiaia NL, Jacquin MF, and Rhoades RW (1992) *Journal of Comparative Neurology* 320: 323–338); Hemelt ME and Keller A (in press) Superior colliculus control of vibrissa movements. *Journal of Neurophysiology*. The connection from nucleus SpVI appears to be the strongest (Killackey H and Erzurumlu R (1981) *Journal of Comparative Neurology* 201: 221–242; Huerta M, Frankfurter A, and Harting J (1983) *Journal of Comparative Neurology* 220: 147–167; Jacquin M, Barcia M, and Rhoades RW (1989) *Journal of Comparative Neurology* 282: 45–62); it terminates in the intermediate and deep layers of the lateral and rostral aspects of the colliculus. The projections from the trigeminal ganglia to colliculus are likely to be collaterals of projections to thalamus (Benett-Clarke CA, Chiaia NL, Jacquin MF, and Rhoades RW (1992) *Journal of Comparative Neurology* 320: 323–338; Mantle-St. John LA and Tracey DJ (1987) *Journal of Comparative Neurology* 255: 259–271). (Superior colliculus → facial nucleus) The intermediate and deep layers of the colliculus project to the lateral subnucleus of the facial nerve nucleus (Isokawa-Akesson M and Komisaruk BR (1987) *Experimental Brain Research* 65: 385–398; Miyashita E, Keller A, and Asanuma H (1994) *Experimental Brain Research* 99: 223–232; Miyashita E, and Shigemi M (1995) *Neuroscience Letters* 195: 69–71). (Trigeminal nuclei → cerebellum) The trigeminal nuclei provide vibrissa sensory input to the cerebellum via a direct pathway, that is, the SpVI nucleus projects directly to the cerebellum (Woolston DC, LaLonde JR, and Gilson JM (1982) *Journal of Neurophysiology* 48: 160–173), and two indirect pathways, that is, the SpVI and SpVC nuclei project via the inferior olive climbing fibers and the PrV, SpVI, and SpVC nuclei project via pontine mossy fibers (Huerta M, Frankfurter A, and Harting J (1983) *Journal of Comparative Neurology* 220: 147–167; Steindler DA (1985) *Journal of Comparative Neurology* 237: 155–175; Jacquin M, Barcia M, and Rhoades RW (1989) *Journal of Comparative Neurology* 282: 45–62; Mantle-St. John LA and Tracey DJ (1987) *Journal of Comparative Neurology* 255: 259–271; Smith RL (1973) *Journal of Comparative Neurology* 148: 423–446; Watson CRR and Switzer III RC (1978) *Neuroscience Letters* 10: 77–82; Swenson RS, Kosinski RJ, and Castro AJ (1984) *Journal of Comparative Neurology* 222: 301–311). Projections from the trigeminal nuclei to the inferior olive overlap those from the olive to the cerebellum; the target areas in the cerebellum include *crura* I and II and the paramedian lobule and uvula (Huerta M, Frankfurter A, and Harting J (1983) *Journal of Comparative Neurology* 220: 147–167; Watson CRR and Switzer III RC (1978) *Neuroscience Letters* 10: 77–82); all these areas have facial receptive fields. (Superior colliculus ↔ cerebellum) The colliculus sends projections to the cerebellar cortex, including target areas *crura* I and II, through both the inferior olive and the pons (Kassel J (1980) *Brain Research* 202: 291–305). The deep cerebellar nuclei send a projection back to the colliculus (Lee HS, Kosinski RJ, and Mihailoff GA (1989) *Neuroscience* 28: 725–734; Westby GW, Collinson C, and Dean P (1993) *European Journal of Neuroscience* 5: 1378–1388; Westby GW, Collinson C, Redgrave P, and Dean P (1994) *European Journal of Neuroscience* 6: 1335–1342) to form a 'colliculus → cerebellum → colliculus' loop. Forebrain loops: (trigeminal nuclei → dorsal thalamus) The PrV nucleus sends ascending projections to ventral posteromedial (VPM) thalamic nuclei, and the SpVI nucleus sends projections to posterior (PO) nuclei and to the ventral-lateral area of VPM (VPM-vl) thalamus as well as the dorsal-medial area of VPM (VPM-dm) thalamus (Lund RD and Webster KE (1967) *Journal of Comparative Neurology* 130: 313–328; Smith RL (1973) *Journal of Comparative Neurology* 148: 423–446; Erzurumlu RS and Killackey HP (1980) *Neuroscience*. 5: 1891–1901; Hoogland PV, Welker E, and Van der Loos H (1987) *Experimental Brain Research* 68: 73–87; Mantle-St. John LA and Tracey DJ (1987) *Journal of Comparative Neurology* 255: 259–271; Jacquin M, Barcia M, and Rhoades RW (1989) *Journal of Comparative Neurology* 282: 45–62; Killackey HP, Jacquin M, and Rhoades RW (1990) In: *Development of Sensory Systems in Mammals*, pp. 403–429. New York: Wiley; Chiaia NL, Rhoades RW, Bennett-Clark CA, Fish SE, and Killackey HP (1991) *Journal of Comparative Neurology* 314: 201–216; Benett-Clarke CA, Chiaia NL, Jacquin MF, and Rhoades RW (1992) *Journal of Comparative Neurology* 320: 323–338; Diamond ME, Armstrong-James M, Budway MJ, and Ebner FF (1992) *Journal of Comparative Neurology* 319: 66–84; Williams MN, Zahm DS, and Jacquin MF (1994) *European Journal of Neuroscience* 6: 429–453; Veinante P and Deschenes M (1999) *Journal of Neuroscience* 19: 5085–5095; Pierret T, Lavallee P, and Deschenes M (2000) *Journal of Neuroscience* 20: 7455–7462; Yu C, Derdikman D, Haidarliu S, and Ahissar E (2006) Parallel thalamic pathways for whisking and touch signals in the rat. *PLoS Biology* 4: e124; Simons DJ, Carvell GE, Kyriazi HT, and Bruno RM (2007) Thalamocortical conduction times and stimulus-evoked responses in the rat whisker-to-barrel system. *Journal of Neurophysiology* 98: 2842–2847; Masri R, Bezdudnaya T, Trageser JC, and Keller A (in press) Encoding of stimulus frequency and sensor motion in the posterior medial thalamic nucleus. *Journal of Neurophysiology*). The representation of the vibrissae forms a somatotopic map ('barreloids') in VPM thalamus (Van Der Loos H (1976) *Neuroscience Letters* 2: 1–6; Sugitani M, Yano J, Sugai T, and Ooyama H (1990) *Experimental Brain Research* 81: 346–351) and a diffuse map in PO thalamus (Nothias F, Peschanski M, and Besson J-M (1988) *Brain Research* 447: 169–174; Fabri M and Burton

Cerebellar Loops

The pontine–cerebellar system appears to function at a hindbrain level in a loop that involves direct connections from the contralateral SpVI nucleus and indirect connections between contralateral trigeminal nuclei and the ipsilateral superior colliculus (Figure 4). For the latter case, the trigeminal nuclei project to both the pons and the inferior olive, which in turn directly project to crura 1 and 2 in the cerebellum. Similar inputs, which project to the same crura in cerebellum,

H (1991) *Brain Research* 538: 351–357) and VPM-vl (Pierret T, Lavallee P, and Deschenes M (2000) *Journal of Neuroscience* 20: 7455–7462). (Trigeminal nuclei → zona incerta) Nuclei in zona incerta (ZI) consist exclusively of inhibitory projection neurons; those involved in vibrissa somatosensation receive input from SpVI (Kolmac CI, Power BD, and Mitrofanis J (1998) *Journal of Comparative Neurology* 396: 544–555). ZI forms a negative (**–**) feedback connection to PO thalamus (Trageser JC and Keller A (2004) *Journal of Neuroscience* 24: 8911–8915; Lavallee P, Urbain N, Dufresne C, Bokor H, Acsady L, and Deschenes M (2005) *Journal of Neuroscience* 25: 7489–7498) that is inactivated only by descending input from vibrissa cortex Urbain N and Deschenes M (2007) Motor cortex gates vibrissal responses in a thalamocortical projection pathway. *Neuron* 56: 714–725 (Dorsal thalamus ↔ neocortex) Thalamic regions VPM, PO, and ZI project to primary (S1), secondary (S2), and posterior ventral areas of sensory cortex, and cortex sends feedback projections to VP, PO, and the trigeminal nuclei (Wise SP and Jones EG (1977) *Journal of Comparative Neurology* 175: 129–158; Donoghue JP, Kerman KL, and Ebner FF (1979) *Journal of Comparative Neurology* 183: 647–664; Donoghue JP and Kitai ST (1981) *Journal of Comparative Neurology* 201: 1–13; Carvell GE and Simons DJ (1987) *Journal of Comparative Neurology* 265: 409–427; Hoogland PV, Welker E, and Van der Loos H (1987) *Experimental Brain Research* 68: 73–87; Koralek K, Jensen KF, and Killackey HP (1988) *Brain Research* 463: 346–351; Welker E, Hoogland PV, and van der Loos H (1988) *Experimental Brain Research* 73: 411–435; Jacquin MF, Wiegand MR, and Renehan WE (1990) *Journal of Neurophysiology* 64: 3–27; Chiaia NL, Rhoades RW, Bennett-Clark CA, Fish SE, and Killackey HP (1991) *Journal of Comparative Neurology* 314: 201–216; Chiaia NL, Rhoades RW, Fish SE, and Killackey HP (1991) *Journal of Comparative Neurology* 314: 217–236; Diamond ME, Armstrong-James M, Budway MJ, and Ebner FF (1992) *Journal of Comparative Neurology* 319: 66–84; Deschênes M, Bourassa J, and Parent A (1996) *Neuroscience* 72: 679–687; Lévesque M, Charara A, Gagnon S, Parent A, and Deschênes M (1996) *Brain Research* 709: 311–315; Shepherd GM and Svoboda K (2005) *Journal of Neuroscience* 25: 5670–5679; Landisman CE and Connors BW (2007) VPM and PoM Nuclei of the rat somatosensory thalamus: Intrinsic neuronal properties and corticothalamic feedback. *Cerebral Cortex* 17: 2853–2865, Urbain N and Deschenes M (2007) A new thalamic pathway of vibrissal information modulated by the motor cortex. *Journal of Neuroscience* 27: 12407–12412; Bokor H, Acsady L, and Deschenes M (2008) Vibrissal responses of thalamic cells that project to the septal columns of the barrel cortex and to the second somatosensory area. *Journal of Neuroscience* 28: 5169–5177); The projection from ZI thalamus to S1 cortex is unique in providing an inhibitory input (Chapin JK, Schneider JS, Nicolelis M, and Lin C-S (1990) *Science* 248: 1553–1556; Nicolelis MAL, Chapin JK, and Lin RCS (1992) *Brain Research* 577: 134–141). (Direct intercortical connections) Vibrissa S1 cortex forms reciprocal projections with other vibrissa sensory areas in neocortex (Carvell GE and Simons DJ (1987) *Journal of Comparative Neurology* 265: 409–427; Chapin JK, Sadeq M, and Guise JLU (1987) *Journal of Comparative Neurology* 263: 326–346; Welker E, Hoogland PV, and van der Loos H (1988) *Experimental Brain Research* 73: 411–435; Fabri M and Burton H (1991) *Journal of Comparative Neurology* 311: 405–424; Hoffer ZS, Hoover JE, and Alloway KD (2003) *Journal of Comparative Neurology* 466: 525–544; Chakrabarti S and Alloway KD (2006) *Journal of Comparative Neurology* 498: 624–636) and with vibrissa motor (M1) cortex (White EL and deAmicis RA (1977) *Journal of Comparative Neurology* 175: 455–482; Fabri M and Burton H (1991) *Journal of Comparative Neurology* 311: 405–424; Aroniadou VA and Keller A (1993) *Journal of Neurophysiology* 70: 1493–1553; Keller A (1993) *Cerebral Cortex* 3: 430–441; Miyashita E, Keller A, and Asanuma H (1994) *Experimental Brain Research* 99: 223–232; Izraeli R and Porter LL (1995) *Experimental Brain Research* 104: 41–54; Veinante P and Deschenes M (2003) *Journal of Comparative Neurology* 464: 98–103; Hoffer ZS, Arantes HB, Roth RL, and Alloway KD (2005) *Journal of Comparative Neurology* 488: 82–100; Chakrabarti S and Alloway KD (2006) *Journal of Comparative Neurology* 498: 624–636). The representation of the vibrissae forms a somatotopic map in S1 cortex (Woolsey TA, Welker C, and Schwartz RH (1974) *Journal of Comparative Neurology* 164: 79–94; Durham D and Woolsey TA (1977) *Brain Research* 137: 169–174)-'barrels'- and S2 (Carvell GE and Simons DJ (1986) *Somatosensory Research* 3: 213–237; Kleinfeld D and Delaney KR (1996) *Journal of Comparative Neurology* 375: 89–108). Note that M1 is taken as the parasagittal agranular medial area. (Indirect intercortical connections) Feedback from neocortex to thalamus via projections from cortical layer 6 provides a pathway for different cortical columns and regions to intact in thalamus (Deschenes M, Veinante P, and Zhang Z-W (1998) *Brain Research Reviews* 28: 286–308). This effect is enhanced by an effective intrathalamic connection mediated by thalamoreticular and recticulothalmic projections (Crabtree JW, Collingridge GL, and Isaac JT (1998) *Nature Neuroscience* 1: 289–394; Crabtree JW and Isaac JT (2002) *Journal of Neuroscience* 22: 8754–8761; Golomb D, Ahissar E, and Kleinfeld D (2005) *Journal of Neurophysiology* 95: 1735–1750). (Neocortex → superior colliculus) Both sensory and motor cortices send descending projections to the superior colliculus (Wise SP and Jones EG (1977) *Journal of Comparative Neurology* 175: 129–158; Killackey H and Erzurumlu R (1981) *Journal of Comparative Neurology* 201: 221–242; Welker E, Hoogland PV, and van der Loos H (1988) *Experimental Brain Research* 73: 411–435; Mercier BE, Legg CR, and Glickstein M (1990) *Proceedings of the National Academy of Sciences of the United States of America* 87: 4388–4392). Cellular interactions between the descending cortical M1 projection to colliculus and from the colliculus to the facial nucleus support the relay of motor commands to the facial nucleus (Miyashita E and Shigemi M (1995) *Neuroscience Letters*195: 69–71). (Motor cortex → reticular nuclei) A direct connection from vibrissa M1 cortex to nuclei in the reticular formation (Miyashita E, Keller A, and Asanuma H (1994) *Experimental Brain Research* 99: 223–232; Hattox AM, Priest CA, and Keller A (2002) *Journal of Comparative Neurology* 442: 266–276) is suggestive of a central pattern generator (CPG) by analogy with the CPG for mastication (Nozaki S, Iriki A, and Nakamura Y (1986) *Journal of Neurophysiology* 55: 806–825) and provides descending control of the vibrissae. The ambiguus and parvocellular reticular nuclei in the medulla, as well as the pontine reticular nucleus, are capable of evoking vibrissa movement and further receive input from M1 cortex (Hattox AM, Priest CA, and Keller A (2002) *Journal of Comparative Neurology* 442: 266–276). Critically, direct input from M1 terminates in the lateral facial nucleus and may directly drive the vibrissae (Grinevich V, Brecht M, and Osten P (2005) *Journal of Neuroscience* 25: 8250–8258).

Table 2 Afferent nuclei to the lateral aspect of the facial nucleus

Afferent nucleus	*VMCtx afferent*	*Evoked movement*	*Transmitter*
Myelencephalon (medulla)			
Dorsal motor nucleus of the vagus	x		
Reticular nucleus of the medulla	x		
Intermediate reticular nucleus	x		GABA, Gly
Lateral reticular nucleus	x		
Ambiguus nucleus	x	x	
Gigantocellular reticular nucleus	x		GABA, Gly, 5-HT
Parvocellular reticular nucleus	x	x	
Spinal vestibular nuclei	x		GABA, Gly
External cuneate nucleus			
Nucleus solitary tract			
Raphe magnus, pallidus, obscurus			5-HT
Paragigantocellular reticular nucleus			
Spinal trigeminal nucleus			GABA, Gly
Hypoglossal nucleus			
Metencephalon (pons)			
Pontine reticular nucleus	x	x	GABA, Gly
Ventral parabrachial nucleus	x		
Kölliker-Fuse nucleus	x		
Paralemniscal nucleus	x		GABA, Gly
Lateral parabrachial nucleus	x		
Subpedencular tegmental nucleus	x		
Intertrigeminal nucleus	x		
Subcoeruleus nucleus	x		
Ventral nucleus of the lateral lemniscus			
Motor trigeminal nucleus			
Pediculopontine tegmental			
Medial parabrachial nucleus			
Mesencephalon (midbrain)			
Deep mesencephalic nucleus	x		
Oculomotor nucleus	x		
Central gray	x		
Superior colliculus	x	x	
Red nucleus	x	x	
Edinger-Westphal nucleus	x		
Pararubral nucleus	x		
Nucleus raphe dorsalis			
Interstitial nucleus of medial longitudinal fasciculus			
Retrorubral nucleus			
Nucleus Darkschewitsch			
Substantia nigra			
Primary motor cortex (VMCtx)	–	x	Glutamate

The listings are based on anatomical studies. Neurons in the lateral facial nucleus integrate inputs from about 40 presynaptic sources (Fay RA and Norgren R (1997) *Brain Research Reviews* 25: 276–290). These include reticular motor nuclei that are potentially involved with the generation of the oscillatory drive for rhythmic whisking, such as the parvocellular nucleus (Mogoseanu D, Smith AD, and Bolam JP (1994) *Experimental Brain Research* 101: 427–438; Hattox AM, Priest CA, and Keller A (2002) *Journal of Comparative Neurology* 442: 266–276), reticular nuclei that are involved with other oromotor behaviors (Travers JB (1995) In: Paxinos G (ed.) *The Rat Nervous System*, 2nd edn., pp. 239–255. San Diego: Academic Press), such as suckling and licking, trigeminal sensory nuclei, whose input to the facial nucleus completes a feedback loop that encompasses the vibrissae; cerebellar deep nuclei, whose input also completes a feedback loop (Huerta M, Frankfurter A, and Harting J (1983) *Journal of Comparative Neurology* 220: 147–167), input from the superior colliculus (Miyashita E, Keller A, and Asanuma H (1994) *Experimental Brain Research* 99: 223–232; Miyashita E and Shigemi M (1995) *Neuroscience Letters* 195: 69–71), and direct input from the primary motor cortex (Grinevich V, Brecht M, and Osten P (2005) *Journal of Neuroscience* 25: 8250–8258). The column labeled 'VMCtx afferent' denotes that the nucleus receives a projection from primary motor cortex. VMCtx, vibrissa primary motor cortex. The column labeled 'Evoked movement' indicates that activation of this region in anesthetized animals leads to vibrissa movement.

arise from the intermediate and deep layers of the superior colliculus. The relative means by which these inputs contribute to a pronounced sensory response in crus 2, and a more restricted response in crus 1, is unknown. Finally, the cerebellar Purkinje cells form synapses on the cerebellar nuclei, which provide output projections to superior colliculus to complete this intermediary-level loop.

Figure 5 The follicle contains both superficial (SVN) and deep (DVN) nerve terminals that report both self-movement and contact of the vibrissa. The follicle sits in the mystacial pad as part of an array of five rows and roughly ten arcs of follicle/vibrissa units (Insert in lower right corner). Rows are labeled by letters and arcs by numbers. The four posterior vibrissa, referred to as straddlers, are labeled by Greek letters. In the awake and aroused animal, the sinuses (CS and RS) are engorged with blood, which stiffens the structure. Both self-movement and touch are presumed to be coded by both the superficial and deep nerves, which project to the trigeminal ganglion and have similar passive response properties (Waite PME and Jacquin MF (1992) *Journal of Comparative Neurology* 322: 233–245). The DVN ultimately projects to the PrV, SpVO, SpVI, and SpVC trigeminal nuclei (Hayashi H (1985) *Journal of Comparative Neurology* 237: 195–215; Jacquin MF, Stennett RA, Renehan WE, and Rhoades RW (1988) *Journal of Comparative Neurology* 267: 107–130), and the SVN has been reported to project only to SpVC (Martin Deschenes, unpublished observations). This illustration was adapted from Arvidsson J and Rice FL (1991) Central projections of primary sensory neurons innervating different parts of the vibrissae follicles and intervibrissal skin on the mystacial pad of the rat. *Journal of Comparative Neurology* 309: 1–16; see also Rice FL, Fundin BT, Pfaller K, and Arvidsson J (1994) *Experimental Brain Research* 99: 233–246. A mechanical model of the follicle is given by Mitchinson B, Gurney KN, Redgrave P, et al. (2004) *Proceedings of the Royal Society of London, Series B: Containing Papers of a Biological Character* 271: 2509–2516. V, vibrissa; SG, sebacceous gland; RW, ringwulst; RS, ring sinus; ORS, outer root sheath; MS, mesenchymal sheath; IRS, inner root sheath; ICB, inner conical body; F, follicle; Ep, epidermis; CS, cavernous sinus; C, follicle-sinus-complex capsule; BM, basement membrane; CGRP, calcitonin gene-related peptide; and Art, arteriole.

Thalamic-Forebrain Loop

Multiple structures in ventral and dorsal thalamus receive input from the trigeminal nuclei. Only one of these, zona incerta (ZI) in the ventral thalamus, projects directly back to the superior colliculus (Figure 4), where it forms inhibitory connections with the superior colliculus. Thus, ZI thalamus appears to function as a forebrain-level intermediary in a loop that involves the trigeminal nuclei and the colliculus. Further, inhibitory projections from ZI thalamus serve to gate afferents from PO thalamus to vibrissa SI cortex. This gate is removed by descending inputs from vibrissa M1 cortex.

Neocortical Loop

Cortex receives input from the trigeminal nuclei along four streams that pass through the thalamus (Figure 4):

1. The well-known lemniscal pathway that ascends from the PrV nucleus via the central region of the ventral posterior medial (VPM) thalamus and projects to vibrissa primary somatosensory (S1) cortex. Neurons in VPM thalamus rapidly respond to stimulation of a single vibrissa in anesthetized animals, whose receptive fields are referred to as barreloids. Similarly, neurons in the granular layer

Figure 6 Geometry, musculature, and motion of the follicles and vibrissae. (a) Drawing of extrinsic musculature in mouse; a similar pattern occurs in rat. Four extrinsic muscles invade the mystacial pad while maintaining external attachment points. The retractor *M. nasolabialis* attaches dorsal–caudal to the pad and runs superficially below the skin. A second retractor, *M. maxillolabialis*, attaches ventral–caudal to the pad and fuses with the fibers of *M. nasolabialis* as they invade the pad. *M. nasalis* attaches rostral to the pad at the nasal septum and runs deep to the follicles as it extends caudally. *M. transversus nasi* lies transverse to the snout and runs superficially through the pad. (b) Drawing of intrinsic musculature in mouse. The intrinsic muscles join adjacent follicles (insert in **Figure 5**) of a single row. Each muscle attaches medially and laterally to the superior part of the caudal follicle while forming a sling around the lower third of the rostral follicle. The skin and other connective tissue, such as the fibrous plate, provide a passive restoring force. Superficial extrinsic muscles run just below the skin. (c) A mechanical model of a row of three vibrissae, shown in the rest state, to illustrate how the extrinsic and intrinsic muscles pull on the vibrissae. The attachment points are illustrated for the springs, dampers, and muscles, which together from an active vasoelastic element. The approximate relationship between these points is conserved, but the figure is not drawn to scale. Arrows indicate the direction of muscle forces, which point away from the attachment points. (d) Average vibrissa motion and muscle activity from a head-restrained rat. Each whisk was linearly mapped from time onto the range of 0 to 2π radians and the average taken across phase. Average traces (1750 whisks) are repeated to display two cycles; only motion along the A–P axis is shown. The rectified electromyogram values were normalized by the maximum voltage of each trace. The dashed vertical lines indicate the three phases of average muscle activity. The drawings in panels (a) and (b) were adapted from Dorfl J (1982) The musculature of the mystacial vibrissae of the white mouse. *Journal of Anatomy* 135: 147–154; see also Dorfl J (1985) The innervation of the mystacial region of the white mouse: A topographical study. *Journal of Anatomy* 142: 173–184. The model and data in panels (c) and (d) from Hill DN, Bermejo R, Zeigler HP, and Kleinfeld D (2008) Biomechanics of the vibrissa motor plant in rat: Rhythmic whisking consists of triphasic neuromuscular activity. *Journal of Neuroscience* 28: 3438–3455.

of S1 cortex respond to stimulation of a single vibrissa, whose receptive fields are formed by afferents from VPM thalamus and are referred to as barrels.

2. The well-known paralemniscal pathway that ascends from the rostral part of the SpVI nucleus, passes through posterior medial (PO) thalamus, and projects down to the superior colliculus as well as up to agranular layers 1 and 5 in S1 cortex, vibrissa secondary somatosensory (S2), and vibrissa motor (M1) cortices. Neurons in PO thalamus receive inhibitory projections from ZI thalamus; this inhibitory block is relieved by projections from M1 cortex to PO thalamus.

3. A recently described extralemniscal pathway that ascends from the caudal part of the SpVI nucleus, passes through the ventrolateral border of VPM (VPM-vl) thalamus, and projects to S1 and S2 cortices. Neurons in VPM-vl thalamus rapidly respond to stimulation of multiple vibrissae in anesthetized animals.

4. A recently described extralemniscal pathway that ascends from the part of the PrV nucleus that contains large neurons with multivibrissa responses, passes through the dorsomedial border of VPM (VPM-dm) thalamus that lies next to PO thalamus, and projects to S1 cortex. Neurons in VPM-dm thalamus rapidly respond to stimulation of multiple vibrissae in anesthetized animals.

Figure 7 Dynamics of a single vibrissa. (a) Photographs of the motion of the straddler vibrissa γ (see insert, **Figure 5**) at successive resonant frequencies. The vibrissa was glued to a small voice coil that was driven by a wave generator. Note that the displacements are shifted to the finer and more distal parts of the vibrissa at progressively higher-order modes. Data was taken in the laboratory following reports by Hartmann (Hartmann MJ, Johnson NJ, Towal RB, and Assad C (2003) Mechanical characteristics of rat vibrissae: Resonant frequencies and damping in isolated whiskers and in the awake behaving animal. *Journal of Neuroscience* 23: 6510–6519) and Moore (Neimark MA, Andermann ML, Hopfield JJ, and Moore CI (2003) Vibrissa resonance as a transduction mechanism for tactile encoding. *Journal of Neuroscience* 23: 6499–6509; Ritt JT, Andermann ML, and Moore CI (2008) Emdodied information processing: Vibrissa mechanics and texture features shape micromotions in actively sensing rats. *Neuron* 57: 599–613). (b) Cartoon that shows how the drag on a vibrissa can couple to the intrinsic mechanical vibrations (modes) of the vibrissa via 'stick–slip' friction. This effect may be relevant for the encoding of texture. Adapted from Mehta SB and Kleinfeld D (2004) Frisking the whiskers: Patterned sensory input in the rat vibrissa system. *Neuron* 41: 181–184. (c) Spectral power of the vibrations measured at the base of a vibrissa artificially whisked across different textures, in support of a model in which different surfaces preferentially excite different modes of a vibrissa (Moore CI and Andermann ML (2005) In: Ebner FF (ed.) *Neural Plasticity in Adult Somatic Sensory–Motor Systems.* Boca Raton, FL: CRC Press). Adapted from Fend M, Bovet S, Yokoi H, and Pfeifer R (2003) An active artificial whisker array for texture discrimination. In: *Proceedings of the IEEE/RSJ International Conference on Intelligent Robots and Systems* (IROS), Las Vegas, NV, October.

All four thalamic areas receive feedback projections from the infragranular layers of S1 and S2 cortices. Further, VPM-dm thalamus receives feedback projections from M1 cortex.

There is evidence for the segregation of neuronal signals among the different pathways. The lemniscal pathway appears to convey a combination of touch and position signals while the extralemniscal pathway appears to convey primarily touch-based signals. The evidence for signaling along the paralemniscal pathway is inconsistent. Activation of neurons in PO thalamus in anesthetized animals occurs via feedback from S1 cortex. On the other hand, during whisking neurons in PO thalamus may be driven directly by sensory input and report vibrissa position. Independent of this segregation of information, the thalamic nuclei interact via reciprocal connections to the reticular thalamic nucleus, which may lead to a mixing of touch and position signals, among others. Further, sensory and motor cortex interact through corticocortical projections, and there is considerable feedback among thalamic-mediated connections between cortical areas (**Figure 4**). This implies that sensory and motor functions are likely to be distributed throughout these areas.

The cortical loop is closed by corticospinal-like projections from M1 cortex to the vibrissa areas of the facial nucleus, as well as by projections from both S1 and M1 cortices to the superior colliculus, which in turn sends descending projections to motor neurons in the facial nucleus. By analogy with the

anatomy of corticospinal projections in primates, there may be undiscovered projections from vibrissa S1 cortex to the facial nucleus.

Back to the Brain Stem

Two more points bear on the nested topology of the vibrissa system. The first is that a single synaptic connection from neurons in the trigeminal complex to those in the facial nucleus (* in Figure 4) is paralleled, from hindbrain to midbrain to forebrain, by connections of increasing complexity. The second and related issue is that the motor neurons in the lateral facial nucleus appear as arbitrators of activity from loops at all levels, receiving input from neurons in nearly 40 identified nuclei (Table 2). This makes the motor neurons arbitrators of motor commands to the vibrissae.

Mechanics of the Vibrissae

The vibrissae are shaped as round, tapered beams. Videographs of the vibrissae as rats whisk clearly show that the vibrissae flex as a consequence of the muscular forces that propel them forward at their base as well as the forces that act on contact (Figure 1(b)). A result of this flexibility is that, as for all extended mechanical systems, individual vibrissae exhibit a set of resonances (Figure 7(a)). The lowest-order resonance exhibits bending all along the vibrissae, while higher-order resonances exhibit bending that is localized toward the tip.

What are the potential ethological roles that vibrations of the vibrissae can play? One is that a vibrissa can twang when it contacts an object, so that touch will yield a rapid succession of taps rather than a single tap. The frequency of these taps will depend on the location of contact along the shaft of the vibrissa but will be in the order of the roughly 100 Hz resonant frequencies. This rate is sufficient to induce short-term synaptic plasticity; so mechanical resonance may contribute to the transmission probability of a contact event.

The vibrations of the vibrissae may also play a role in sensing texture. The vibrissae may alternately stick and slip as they are dragged across a rough surface (Figure 7(b)). As the vibrissa slips, the resultant vibrations of the shaft will be a superposition of the intrinsic vibrations of the vibrissa. It is natural to posit that differences between surfaces are expressed by the extent to which different modes are favored. In particular, when the tip of a vibrissa is moved across surfaces of differing roughness, the set of frequencies of the vibration is essentially the same for all surfaces, but the relative amplitude associated with each vibration will depend on the detailed properties of the surface (Figure 7(c)).

Transmission of High-Frequency Signals

The timing of neuronal signals from the initial contact of a vibrissa with an object to their representation in vibrissa S1 cortex is central to perception. This timing is heavily dependent on the state of the animal, that is, sessile versus aroused, as mediated through synaptic changes and cellular adaptation. While modulation of the timing might complicate the processing of sensory signals, simplicities appear in two limits as signals ascend the lemniscal pathway (Figure 4). For punctate signals, as might occur with a sharp initial contact, there is a high probability that the signal will successfully propagate up through cortex. In contrast, for steady-state periodic signals, the probability of transmission can be low (Figure 8). At the level of primary sensory neurons, periodic signals are faithfully transduced up to frequencies of ~1200 Hz. However, this signal begins to degrade at the level of the PrV nucleus in brain stem, such that for vibration frequencies above ~350 Hz, roughly half the spikes are dropped (* in bottom row, second column, of Figure 8). By the level of VPM thalamus, roughly half the spikes are dropped for frequencies above ~35 Hz, and by the level of S1 cortex, roughly half the spikes are dropped for frequencies above ~5 Hz. Thus the ability of individual neurons to faithfully follow rapid movements of the vibrissa degrades with higher-order structures in the sensorimotor system.

How are high-frequency events, such as vibrations, encoded in cortex? First, even the response in the primary sensory cells may be insufficient to track the finest surface detail. In particular, the maximum response frequency of 1200 Hz corresponds to the rhythmic motion of the tip of a vibrissa across a corrugated surface with a pitch of only ~200 μm, which is rather coarse. Second, while neurons in S1 cortex cannot track the phase of periodic inputs above ~35 Hz, at least in anesthetized animals the high-frequency sensory inputs are coded as an approximate Poisson process (right column in Figure 8). It is interesting that the rate of this spike process is proportional to the logarithm of the vibration frequency of the vibrissa, that is,

$$\text{Firing Rate} \propto 2 \ln \{\text{Vibration Frequency}\} + \text{Constant}$$

This is in the form of Weber's Law, but for frequencies rather than intensity. The coarseness of logarithmic coding suggests that comparisons of rhythmic inputs with slightly different frequencies will be problematic.

Figure 8 Loss in phase-locked spiking with ascending activation of vibrissa brain centers as the frequency of periodic stimulation is increased. In all cases a sinusoidal stimulus was applied to a single vibrissa in an anesthetized animal. The extracellular, single-unit responses are shown in the first and fourth columns, and intracellular responses are shown in the second and third columns. Individual units in the trigeminal ganglia respond reliably up to 1200 Hz stimulation of the vibrissa (Gottschaldt KM and Vahle-Hinz C (1981) *Science* 214: 143–186), and essentially all units respond reliably to 300 Hz. By the anatomical level of the ventral posterior medial nucleus of dorsal thalamus (VPM), the responses are phase locked to the stimulus but rather infrequent; that is, most spikes are dropped. By the level of the PrV, the responses are still phase locked to the stimulus but drop-outs (*) are significant by 350 Hz. At the level of cortex, the drop-out rate is apparently so high that phase-locked spiking is not apparent at high frequencies, yet for stimulation frequencies near 100 Hz and above, the neurons appear to fire in a largely asynchronous manner, that is, as an inhomogeneous Poisson process. Note that, at all levels, the onset of stimulation always leads to transient activation. Data in the first three columns from Deschenes M, Timofeeva E, and Lavallee P (2003) The relay of high-frequency sensory signals in the whisker-to-barreloid pathway. *Journal of Neuroscience* 23: 6778–6787, and data in the final column from Arabzadeh E, Petersen RS, and Diamond ME (2003) Encoding of whisker vibration by rat barrel cortex neurons: Implications for texture discrimination. *Journal of Neuroscience* 27: 9146–9154. The responses are different in aroused animals or anesthetized animals with activation of their cholinergic system; the responses in VPM thalamus (Castro-Alamancos MA (2002) Different temporal processing of sensory inputs in the rat thalamus during quiescent and information processing states *in vivo*. *Journal of Physiology* 539: 567–578.) extend to higher frequencies before attenuation, while the frequency dependence of the response in vibrissa S1 cortex is largely unchanged (Castro-Alamancos MA (2004) Absence of rapid sensory adaptation in neocortex during information processing states. *Neuron* 41: 455–464) and may further exhibit bursts of spikes (de Kock C and Sakmann B (in press) High frequency action potential bursts (100 Hz) in L2/3 and L5B thick tufted neurons in anaesthetized and awake rat primary somatosensory cortex. *Journal of Physiology*; Ewert TA, Vahle-Hinz C, and Engel AK (2008) High-frequency whisker vibration is encoded by phase-locked responses of neurons in the rat's barrel cortex. *Journal of Neuroscience* 14: 5359–5368).

Sensory Representation of Texture

Studies on the coding of texture typically make use of irregular surfaces of differing roughness, such as sandpapers, as stimuli. In one paradigm, artificial whisking with anesthetized animals is used to ensure a repeatable pattern of motion of individual vibrissae, whose detailed positions can be recorded with high-speed videography (Figure 9). Artificial whisking makes use of electrical stimulation of the facial nerve, with trains of pulses to induce rhythmic sweeps. Yet artificial whisking provides a practical means to study the variation in vibrissa movement across surfaces for the same muscular drive. Further, once the motion is recorded, one can use the stored waveforms to control piezoelectric manipulators that move the vibrissa in a repeatable manner. The caveats of this approach are twofold: first, the resultant motion is abnormal in that the three phases of natural motor activity (Figure 6(c)) are reduced to one and, second, sensation may be altered in that extrinsic movement of the vibrissae approximates self-induced movement.

The motion of the vibrissae across different sandpapers in the artificial whisking paradigm has been characterized in two ways. First, variations in motion were quantified in terms of the root-mean-square (RMS) speed of the shaft of individual vibrissae. The RMS speed initially increased in a progression from smooth to rough surfaces, then reached an asymptote as the size of the surface features reached ~35 μm (Figure 9(a)). Concomitant with this asymptote in

Figure 9 Evidence that vibrissa motions induced by textured surfaces are encoded by both average spike rate and temporal variations in the rate. (a) Texture coding by the average rate of neuronal firing. The spike rate is plotted for texture-induced vibrations, quantified by the root-mean-square (RMS) speed of the horizontal vibrissa motion, averaged across 100 trials of 500 ms each. The average spike count per trial was pooled from ten trigeminal ganglion neurons and 12 neurons in vibrissa S1 cortex (granular layer); note the different scales for spike counts. The insets show the surfaces. (b) Texture coding by patterns in the firing rate for three examples. The top line shows variations in velocity of a vibrissa as it moves across one of three different textures. The second line shows the peristimulus time histograms, with 0.2 ms bins, for a unit in the trigeminal ganglion. The final line shows the peristimulus time histograms for a unit in S1 cortex. Each profile is the average of 100 trials. Data adapted from Arabzadeh E, Zorzin E, and Diamond ME (2005) Neuronal encoding of texture in the whisker sensory pathway. *PLoS Biology* 3(e17): 155–165; the discrimination of different textures is discussed by von Heimendahl M, Itskov PM, Arabzadeh E, and Diamond ME (2007) Neuronal activity in rat barrel cortex underlying texture discrimination. *PLoS Biology* 5: e305.

speed, the spike rate of units in both the trigeminal ganglion and vibrissa S1 cortex also achieved an asymptotic value. This implies that average measures cannot distinguish among different coarse surfaces. In contrast, a second analysis considered the full time dependence of the velocity for motion across surfaces of different roughness. This measure exhibited clear changes as surface features doubled and tripled in size

(Figure 9(b)). Further, neurons in the trigeminal ganglion faithfully tracked these changes, with directional preference, consistent with their ability to track high-frequency vibrations (Figure 8). At the level of S1 cortex, there were repeatable differences in the spike rate for all sandpapers, although many details of the timing were not tracked (Figure 9(b)).

The data suggest that the motion of a vibrissa across a textured surface is dominated by stick–slip events (Figure 7(b)), this conclusion has been partially verified with awake animals in natural textural settings. Further, while primary sensory cells can encode different textures, the algorithm for encoding a natural ensemble of textures in terms of cortical spike rates remains an open issue, as does the issue of the fidelity of that encoding.

Sensory Representation of Object Location

Neuronal Signals of Vibrissa Position

There is a lack of evidence for spindle fibers, the transduction mechanism for proprioception, in the facial musculature, as well as a lack of evidence for descending inputs to primary sensory neurons. Nonetheless, the results of experiments with the artificial whisking paradigm report the presence of reference signals for vibrissa position in a subset of primary sensory neurons (left panel in Figure 10(a)). Different neurons preferentially spiked at different angles during the whisk cycle (right panel in Figure 10(a)), with a bias toward protraction from the retracted position. These data, together with

Figure 10 Encoding of vibrissa position in the hindbrain and forebrain. (a) Spiking output from primary sensory neurons of the trigeminal ganglion was recorded during vibrissa motion induced by 5 Hz electrical stimulation of the facial motor nerve. The left panel shows the trial-averaged response of the reference signal for one neuron; the angle $\Delta\theta_{Ref}$ is the extent of protraction, relative to the initial retracted position, at the peak of the neuronal response. The right panel summarizes the data for all cells. From Szwed M, Bagdasarian K, and Ahissar E (2003) Encoding of vibrissal active touch. *Neuron* 40: 621–630. The radial coordinate is the logarithm of the peak spike rate, and the angular coordinate is the phase within the whisk cycle. (b) Responses in vibrissa S1 cortex measured as animals whisked without contact. The data on the left show an example of the correlation between spiking and the peak of the electromyogram (EMG). The scale on top accounts for the lag between vibrissa position and the EMG (Berg RW and Kleinfeld D (2003) *Journal of Neurophysiology* 89: 104–117); the time t_{Ref} is the peak of cortical spiking relative to the fully retracted position. The panel on the right summarizes the data for all cells from these extracellular measurements, for which the radial coordinate is the modulation of the spike–EMG correlation, as well as cells from recent intracellular studies, for which the radial coordinate is the maximum intracellular depolarization. The bias in spiking as a function of phase in the whisk cycle comes slightly earlier than that for the membrane depolarization, as expected for a threshold process. Data from Fee MS, Mitra PP, and Kleinfeld D (1997) Central versus peripheral determinants of patterned spike activity in rat vibrissa cortex during whisking. *Journal of Neurophysiology* 78: 1144–1149; Mehta SB and Kleinfeld D (2004) Frisking the whiskers: Patterned sensory input in the rat vibrissa system. *Neuron* 41: 181–184; and Crochet S and Petersen CCH (2006) Correlating whisker behavior with membrane potential in barrel cortex of awake mice. *Nature Neuroscience* 9: 608–609.

Figure 11 Intracellular potential of neurons in primary vibrissa cortex of a head-fixed mouse during active touch. (a) The mouse whisked in air both without contact (left sides of top two traces) and with contact against an object (right sides) when it thrust its vibrissae forward. The intracellular potential is marked by V_m (black), the videographed vibrissa position is marked by WP (green), and contact is marked by a gray bar. Note that the rest level of the cell is relatively depolarized. The box corresponds to an expansion of one contact event, with videographs of the contact event shown below. (b) The superposition of ten consecutive contacts shows the reliability and temporal precision of the intracellular response. (c) Intracellular responses evoked by contact with an object were averaged (blue) and compared with the average response aligned with respect to the peak of the vibrissa position for whisking in air (WP in (a)). The response evoked by contact was faster and larger than that evoked by free whisking; dashed red line marks the subtraction of the two responses. Adapted from Crochet S and Petersen CCH (2006) Correlating whisker behavior with membrane potential in barrel cortex of awake mice. *Nature Neuroscience* 9: 608–609.

nerve block experiments, imply that the position signal originates from peripheral reafference.

At the level of vibrissa S1 cortex, experiments with awake animals trained to whisk in air show that the spike rates of individual cortical neurons are locked to the rhythmic motion of the vibrissae, as inferred from the electromyogram (EMG) of the intrinsic muscles (left panel of Figure 10(b)). This constitutes a reference signal of vibrissa position. The distribution of preferred angles extends over the entire whisk cycle, with a bias toward retraction from the protracted position. Further, intracellular measurements with head-fixed awake animals find a similar distribution of preferred angles for the peak of the excitatory postsynaptic potential. The bias in spiking as a function of phase in the whisk cycle comes earlier than that for the membrane depolarization, as expected for a threshold process. Collectively, these data imply that rats ascertain the position of their vibrissa at the time of contact.

Finally, the fidelity of the reference signal in cortex depends on reward. Whisking in air that is coupled to a food reward is a factor of 2 to 3 times more coherent with vibrissa position than whisking in air that is

Figure 12 Sensorimotor feedback in the hindbrain (brain stem) loop. This closed loop is formed by the vibrissae follicle → trigeminal ganglion → trigeminal nuclei → facial nuclei → follicle musculature pathway; trigeminal nucleus principalis and spinal nucleus interpolaris are likely to mediate the trigeminal pathway (**Figure 6**). (a) Data from a brain stem slice preparation of juvenile animals (postnatal days 10–15) that preserves the connectivity, except that excitation of sensory terminals is replaced by shock to the infraorbital nerve (IoN), which excites vibrissa neurons in the trigeminal ganglion, and muscle output is replaced by intracellular recording from facial motor neurons in the lateral aspect of the facial nucleus. Shown are excitatory postsynaptic potentials in a motor neuron following suprathreshold stimulation (average of 20 responses) of the IoN in a slice. (b) Trial and preparation averaged intracellular response to nerve stimulation. The responses from ten trials each of 25 motor neurons were averaged together; mean, black trace; standard error of measurement, gray band. (c) The electromyogram (EMG) responses elicited by vibrissa contact in a ketamine xylazine-anesthetized adult rat. The cartoon in the top row shows the experimental setup for the contact experiment during artificial whisking (**Figure 9(a)**), for which the facial motor nerve (buccolabialis branch, driving the retractors *M. nasolabialis* and *M. maxillolabialis*; **Figure 6(a)**) is stimulated at 8 Hz with 9 mA, 50 s pulses to make the vibrissae protract. Shown are the contact signals (top traces, with control trials on the left and contact trials on the right) and consecutive averaged rectified EMG responses recorded simultaneously in intrinsic (middle traces) and extrinsic (bottom traces) vibrissa muscles. Note that the contact-induced EMG signals adapt after a single contact. Each trace is the average of 30 sweeps. Data from Nguyen Q-T and Kleinfeld D (2005) Positive feedback in a brainstem tactile sensorimotor loop. *Neuron* 45: 447–457.

unrewarded. This shows that reward, which is likely to heighten the attentional state of the animal, can strongly bias the nature of its sensorimotor processing.

Whisking-Dependent Contact Signals

A reliable and robust response to contact is observed at the level of the trigeminal ganglion in awake animals. The spike rate of primary sensory cells increases with increasing impact, or velocity, of contact until a saturation level is reached for angular speeds on the order of $500°s^{-1}$. There is also evidence that the radial distance to the contact point is encoded independent of the velocity.

Experiments with anesthetized animals indicate that there are robust spike responses to the initial deflection of a vibrissa along the entire ascending lemniscal pathway. Yet a systematic study of spiking at

Figure 13 Real-time control of vibrissa position by primary motor cortex. (a) Intracortical microstimulation (ICMS) of vibrissa M1 cortex leads to retraction at a majority of stimulation sites (blue dots and associated traces at top; magnification of 3 by 5 mm image) but protraction in a medial region of frontal cortex (red dots and associated traces at bottom of image). The amplitude of the response as a function of the frequency of the microstimulation was greater for low vs. high-frequency stimulation (cf. 60 vs. 500 Hz). Data from

all levels in the sensorimotor hierarchy in awake animals remains to be completed, including the essential issue of spiking induced by animal-initiated contact. Nonetheless, preliminary observations of the nature of the subthreshold input to neurons in the upper layers of vibrissa S1 cortex have revealed the coexistence of whisking-related changes in subthreshold potential and changes in potential that are locked to contact (Figure 11). Contact signals that are referenced to vibrissa position could, in principle, be computed from the observed signals.

Sensory Modulation of Vibrissa Motion

The observation of changes in whisking on contact of the vibrissa with a wall (Figure 1(a)), along with changes in whisking amplitudes for whisking in air versus against a target (Figure 2(a)), provides evidence for changes in whisking strategy based on the task. How can this occur?

Brain Stem Mechanisms

Recent work shows that the brain stem loop exerts a transient positive feedback (Figure 12). At the level of *in vitro* physiology, sensory feedback from the trigeminal input to the motor neurons was measured in a brain stem slice preparation that preserves the vibrissa sensorimotor feedback pathway; see brain stem loop in Figure 4. Stimulation of the IoN leads solely to excitatory postsynaptic potentials in the motor neurons of the facial nucleus (Figure 12(a)). The latency of the response has two components, a fast Δt_1 component that presumably reflects disynaptic (IoN → trigeminal nuclei → facial nucleus) input and a slower Δt_2 component that is involved in trisynaptic or higher-order feedback in brain stem (Figure 12(b)). The critical issues are that feedback is both positive and rapid, that is, $\Delta t_1 \sim 10$ ms compared with the ~ 100 ms timescale of whisking.

At the level of *in vivo* physiology, the brain stem can be functionally isolated through the use of anesthesia. The artificial whisking paradigm is then used to drive the vibrissa muscles at physiological whisking rates. As a means to study sensorimotor feedback, a rigid contact detector is introduced in the trajectory of the vibrissae during alternate measurements to ascertain whether EMG responses could be elicited by contact of the vibrissae with the detector (Figure 12(c)). Consistent with positive feedback, contact led to a transient increase in the amplitude of the rectified EMG for both intrinsic and extrinsic muscles. This effect rapidly adapted for stimulation frequencies above 5 Hz. These data show that positive, transient feedback can lead to an increase in motor force.

Behavioral data to support transient positive sensorimotor feedback come from measurements of changes in whisking force coincident with contact. When animals whisked symmetrically yet made contact with a sensor on only one side of the face, the amplitude of the mystacial EMG on the contact side was transiently increased by 25%. These data show that the vibrissa feedback loops act to transiently increase the interval and force of contact.

Cortical Mechanisms

We conjecture that changes in whisking strategies, as opposed to transient changes in force, are regulated at the thalamocortical level. Three classes of experiments support this view. As a means to delineate the sensory representation of rhythmic input in M1 cortex, the first experimental effort made use of awake, head-fixed animals that were trained not to whisk. The observed response captured only the fundamental frequency of the input pattern for pulsatile stimuli delivered at frequencies that ranged from 5 to 20 Hz, that is, the range of exploratory whisking. This nonlinear transformation resembles the synthesis of a sinusoidal feedback signal for servocontrol of a motor.

A second class of experiments showed that vibrissa M1 cortex supports oscillations in extracellular current flow that are phase locked to whisking. These signals are preserved after lesions of the IoN to block sensory input. Further, ablation of M1 cortex leads to alteration of the whisking patterns. Thus, motor cortex generates rhythmic signals that can drive normal exploratory whisking.

Haiss F and Schwarz C (2005) Spatial segregation of different modes of movement control in the whisker representation of rat primary motor cortex. *Journal of Neuroscience* 25: 1579–1587. (b) Intracellular stimulation of a single neuron in M1 cortex with current I has little effect on the membrane potential V_m as well as on the motion of the vibrissae in the anesthetized state but leads to protraction of vibrissa E2 in the awake animal. Data from Brecht M, Schneider M, Sakmann B, and Margrie T (2004) Whisker movements evoked by stimulation of single pyramidal cells in rat motor cortex. *Nature* 427: 704–710. (c) Videographic data of vibrissa position in sessile vs. aroused animals in response to ICMS of motor cortex. Note that ICMS in the sessile case led to retraction of the muscles, whereas stimulation in the aroused case led to a whisk cycle with retraction followed by a protraction phase. Data from Berg RW and Kleinfeld D (2003) Rhythmic whisking by rat: Retraction as well as protraction of the vibrissae is under active muscular control. *Journal of Neurophysiology* 89: 104–117. Early studies also considered the direction of motion induced by ICMS to M1 cortex (Sanderson KJ, Welker W, and Shambes GM (1984) *Brain Research* 292: 251–260; Gioanni Y and Lamarche M (1985) *Brain Research* 344: 49–61).

A final class of experiments, highlighted in Figure 13, explored the motion of the vibrissa in response to activation of vibrissa M1 cortex in both anesthetized and behaving animals. From a functional perspective, there are two contiguous motor areas. For the largest region (blue dots in Figure 13(a)), activation of tissue with a brief train of extracellular current pulses, or even depolarization of a single cell, leads to retraction of the vibrissae. For a smaller region near the midline (red dots in Figure 13(a)), activation with a brief train of extracellular current pulses leads to protraction. It is interesting that stimulation of neurons in this region with a continuous train of high-frequency pulses, rather than a brief train, can induce rhythmic whisking.

The ability of M1 motor cortex to drive whisking is enhanced when rats are awake as opposed to anesthetized. Further, this enhancement is profoundly increased in the attentive, as opposed to sessile, awake state. First, stimulation of even a single projection neuron in vibrissa M1 cortex can lead to movement of one or more vibrissae. In the awake animals, this movement is dramatically increased (Figure 13(b)). Second, while stimulation of the major fraction of vibrissa M1 cortex leads to retraction when animals are anesthetized or awake but sessile, this motion is transformed into a full whisk, with protraction and retraction, when animals are in the awake and aroused state (Figure 13(c)). This effect is mimicked by cholinergic activation of cortex, a key component of attention. Collectively, these data show that M1 cortex, in principle, can subsume full control of vibrissa movement.

Epilog

The vibrissa system in rodents has a multitude of features that make it ideal for the study of sensorimotor control in a mammal. It preserves the basic architectonics of nested feedback loops (Figure 4), yet the lissencephalic cortex of rodents makes all structures of the brain very accessible. Critical for studies of active sensation, work to date has refined a number of behavioral paradigms that tax the active nature of this sensorimotor system and define strategies for processing the sense of vibrissa-based touch (Figures 2 and 3).

Electrophysiology studies with awake, behaving animals have begun to elucidate the algorithms involved in active sensing. For texture discrimination, this is likely to include the detailed timing of spikes in vibrissa S1 cortex (Figure 9). For touch in face-centered coordinates (Figure 3), this is likely to involve the merge of touch and reference signals of vibrissa position (Figures 10 and 11). Experimental progress is anticipated to be critical to a proper understanding of active sensing in two broad, open issues.

How Do Rats Map the Space about Their Vibrissa?

The main issue is whether rats maintain an abstract representation of objects that is independent of which vibrissa makes contact with an object. Or is this representation based solely on a single vibrissa (which would suggest little interaction between columnar representations)? A number of immediate issues within the realm of representation are ripe for study:

- There is evidence that rats encode texture by the time between stick–slip events. How is this used to form a perception? By analogy with flutter coding in somatosensory experiments in monkeys, do rats count the number of events in a period? Or are individual periods stored? Beyond this lies the issue of whether stick–slip events are encoded across different vibrissae.
- There is evidence that primary sensory neurons can encode the radial distance of contact. How is radial distance separated from impact on contact?
- The notion of object location depends on the presence of a neuronal response that encodes contact conditioned on vibrissa position in the whisk cycle. At what level of the sensorimotor pathways do such responses first occur?
- There is evidence that the phase of the vibrissae within a whisk cycle, rather than the absolute position, is encoded. How is this accomplished? One hypothesis is that it relies on adaptation at the level of the primary sensory neurons.
- Adaptation of the neuronal response at all levels of sensory processing, and particularly at the level of thalamocortical synapses, is strong. Thus steady state responses are much different from transient responses. How does this play into the representation of sensory signals?

How Do Rats Change Their Motor Output in Response to Vibrissa-Based Touch?

The main issue is how touch leads to changes in body position, whisking dynamics, and locomotion.

- Rhythmic whisking can occur in the absence of sensory feedback and in the absence of high-level control. Where are the pattern generators for rhythmic whisking? Further, what form of circuitry allows these generators to stabilize at a different, single frequency from bout to bout?

- The superior colliculus is capable of driving patterned, stereotyped motor behaviors. What is the role of the colliculus in transforming vibrissa sensory inputs into motor commands?
- Motor neurons can potentially receive feedback from sensory pathways at all levels of the brain. How are these inputs arbitrated?

Viral Vectors in the CNS

C N Cearley and J H Wolfe, University of Pennsylvania and Children's Hospital of Philadelphia, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Viruses have evolved to be very efficient at entering and transferring their genes into eukaryotic cells. Viral vectors have been designed to take advantage of the efficiency of viral entry while removing or reducing the associated pathological functions. Recombinant viral vectors are made by removing the genes for most viral functions while retaining the sequences necessary for the recombinant genome to be packaged into a virus particle (the virion) and the elements needed for the desired viral functions within the target cell. The deleted sequences are replaced with a foreign gene and other elements needed for function of the transferred gene, such as promoter(s), splice signals, and polyadenylation signal. To produce recombinant viral particles, the minimum number of viral genes necessary for replication and assembly of the virion is provided in trans, usually encoded on separate plasmids from the transferred gene (Figure 1). This allows the construction of a replication-incompetent recombinant virion at the final stage of vector production.

The recombinant viral vectors enter target cells where the new foreign gene either is integrated into the host cell genome or exists episomally. This is usually a single-hit process, whereby the vector genome is transferred into only the target cell and does not spread further by viral replication; therefore, the concentration of the vector needs to be very high to reach a high number of cells. The concentration of vectors (the titer) is usually measured in genome copies per milliliter or as a functional measure of target cells expressing the transferred gene. The transfer of the vector-encoded gene to the target cells is called transduction.

Applications of Viral Vectors in the CNS

Gene transfer into the central nervous system (CNS) using viral vectors usually requires a surgical procedure (Figure 2) but has several advantages over other methods of genetic manipulation. The procedure involves a stereotaxic injection into specific sites but, in most cases, only a single injection of very small amounts of the concentrated vector is needed for expression of the transgene in the appropriate group of cells. An advantage over transgenic alterations is that the vector can be injected unilaterally, leaving the contralateral side as a nontreatment control. The transgene can be targeted to specific regions of the brain or to specific cell types. There are a variety of vectors available, each with advantages and disadvantages.

The most commonly used application of viral vectors in the CNS is gene therapy, which in most cases involves delivery of a normal copy of a defective gene. Viral vectors can also be used for overexpression or knockdown of genes or proteins to study their function, for visualization of specific cell types *in vivo*, for tract tracing, and for experimental manipulations during development. There are several things that need to be considered when designing such an experiment. Some vector types only transduce dividing cells, and the cells in the CNS are mostly nondividing. Some vectors transduce cells only near the injection site, whereas others are transported to distal sites; therefore, an understanding of the extent of gene delivery needed in an experiment is required. The length of time a gene needs to be expressed is important because some vectors result in only transient gene delivery. For therapeutic applications, consideration also needs to be given to the potential for generation of replication-competent viruses, immune responses, insertional mutagenesis, and germ-line transmission.

Many studies require the level of transgene expression to be regulated. Viral vectors are currently being developed that use drug-controlled molecular switches. The most common systems use tetracycline, rapamycin, ecdysone, or progesterone. In these systems, a transactivator is expressed from a tissue-specific promoter. In the presence of the inducible drug, the drug binds to the transactivator, and this allows transcription of the downstream gene. One potential problem is that these systems can be leaky. If the gene leads to the expression of trophic factors that are potent at very low concentrations, there may be an expression of biologically active amounts of the protein even without the presence of the inducible drug. Another method of regulating gene expression is to use a promoter that is upregulated only in specific cell types. Promoters can be used that are turned on only during development in order to upregulate certain genes during a specific stage of the life cycle.

Viruses Used in CNS Studies

The major classifications of viruses are by RNA or DNA genome and whether they are enveloped or nonenveloped. The major types of viruses being used for gene transfer to the nervous system are herpes simplex virus (HSV), adenovirus (Ad), adeno-associated virus (AAV), onco-retrovirus, lentivirus,

Figure 1 Example of viral vector design and production. To make an AAV vector, a three plasmid transfection system is used, consisting of the AAV vector plasmid, an AAV packaging plasmid, and an Ad helper plasmid. The AAV vector plasmid (enlarged view on the left) contains the gene of interest flanked by the inverted terminal repeats (ITRs), which are the only elements from the wild-type AAV included in the plasmid. The AAV packaging plasmid contains the AAV genes necessary for genome replication (Rep) and capsid protein formation (Cap), but these are not flanked by ITRs and thus are not incorporated into the virion. AAV is a dependovirus, which requires functions supplied by a helper virus such as adenovirus or herpes virus. For vector production, a helper plasmid encoding the minimum gene functions needed for replication is used. The three plasmids are transfected together into a packaging cell line, such as 293T cells, and normal cellular pathways are used to express the genes and proteins leading to the assembly of viral particles. The particles are released into the media after cell lysis or budding from the cell surface, depending on the type of virus. The vector particles are isolated from the lysate by cesium chloride gradient, pelleted by centrifugation, or column purified. The vector viral particles are then quantified and can be used for experimental purposes. Production of most vector viruses is done using a similar strategy, with the functions supplied in trans on plasmids or by helper viruses varying depending on the virus type. AAV, adeno-associated virus; Ad, adenovirus; SDSA, splice donor–splice acceptor; IRES, internal ribosomal entry site; pA, poly-adenylation signal.

and alphavirus, but some studies have used John Cunningham (JC) virus, Simian virus 40 (SV40), Sendai virus, and others. The six major vector types and their advantages and disadvantages for use in the CNS are discussed next; the major features for gene transfer are listed in Table 1.

RNA Viruses

Retrovirus Retroviruses (RVs) are enveloped RNA viruses that are reverse transcribed into DNA within the target cell and that integrate as double-stranded DNA proviruses into the host-cell genome. RVs bind host cell receptors via glycoprotein envelope proteins that are on the surface of the virion. Envelope proteins from some other viruses can be incorporated into the RV particle, a process known as pseudotyping, to change the cell-type specificity of the vector. There are two major classes of retroviruses: the onco-retroviruses and the lentiviruses.

The term RV vector is used in gene transfer studies to mean RVs from the onco-retrovirus family. These viruses were historically identified by their leukemia-inducing properties and thus are termed leukemia viruses, which have been isolated from mice (murine leukemia virus (MuLV)), cats (FeLV) gibbon apes (GALV), and others. The RV vectors transduce only dividing cells, so they are not able to transduce mature neurons *in vivo*. However, RV vectors are able to transduce stem and progenitor cells either in culture or *in vivo*, allowing the expression of the transgene in the progeny of the cells. This property has been used in the developing CNS to selectively label progenitor cells at different stages of development to follow their fate and to selectively deliver

Figure 2 Gene transfer into the central nervous system (CNS) by direct injection and analysis of expression: (a) injection in mouse brain; (b) gene expression; (c) secreted protein; (d) cell-type specificity. In experiments involving the use of gene therapy vectors to treat disorders of the CNS, most vectors are directly injected into the brains of animals using a stereotaxic frame, and the brains are analyzed at a specified times postinjection. Vector analysis usually involves sectioning the brain and looking for gene expression using *in situ* hybridization and for protein expression using antibodies or functional analysis. Shown in (b–d) are sections from an animal that was injected with AAV 9 containing the gene for β-glucuronidase (GUSB) and then was sacrificed and examined 2 months postinjection. Gene expression (b) was examined using a DIG-labeled antisense riboprobe against the human GUSB gene. Protein expression (c) was examined using a histochemical reaction that allows the visualization of the enzymatic activity (red stain). In this disease, the dramatic enzyme expression beyond the gene-expressing cells is due to the ability of lysosomal enzymes to be secreted from a genetically corrected cell and to be either endocytosed by adjacent cells or transported to distal cells via axons. The neuronal specificity of the AAV 9 vector is shown in (d); fluorescent *in situ* hybridization using a Cy3-labeled riboprobe (red) is co-localized with a neuron-specific antibody, MAP2ab (green). AAV, adeno-associated virus; DIG, digoxigenin; MAP, microtubule-associated protein. (d) Reproduced from Cearley CN and Wolfe JH (2006) Transduction characteristics of adeno-associated virus vectors expressing cap serotypes 7, 8, 9, and Rh10 in the mouse brain. *Molecular Therapy* 13: 528–537, with permission from Elsevier.

toxic genes to tumor cells while sparing the nondividing normal cells.

RV vectors are most commonly used in *ex vivo* gene therapy, in which cells are modified in culture and then transplanted into the animal or patient. In the case of diseases in which the replacement of the gene leads to production of a secretable protein, this results in a source of therapeutic protein that can be secreted into the extracellular space, cerebrospinal fluid (CSF), or circulation to correct the disease at distal sites. *Ex vivo* gene therapy can also be used to genetically modify stem cells, which differentiate into more mature cells and may migrate within the CNS. Transduced hematopoietic stem cells and their progeny can circulate throughout the body, but their entry into the CNS is variable. An advantage of using *ex vivo* gene therapy is that the patient's or animal's own cells can be used, which circumvents heterologous immune responses.

Lentivirus The lentivirus (LV) is the second major subgroup of the retroviruses, and vectors have been developed from human immunodeficiency viruses (HIV-1 and-2), simian immunodeficiency virus (SIV), feline immunodeficiency virus (FIV), and equine infectious anemia virus (EIAV). The major advantage of LVs for the CNS is that they can transduce postmitotic cells such as neurons and, thus, can be injected directly into the brain. LV vectors become stably integrated into the host-cell genome and can mediate long-term expression of the transgene. Because LV vectors integrate into the host-cell

Table 1 Viral vectors commonly used for CNS applications

Virus class	*Virus currently being used for gene therapy applications*	*Serotypes/ pseudotypes used for CNS applications*	*Cells amenable to transduction*	*Foreign gene capacity*	*Stable genomic state*	*Virus type*	*Known receptor targets*
Retrovirus	MuLV	MuLV, VSV-G	Dividing cells only	6–7 kb	Integrated	RNA genome	Variable
Lentivirus	HIV-1, FIV, EIAV	VSV-G, rabies, Mokola, LCMV, Ross River, MuLV	Most cell types	7–8 kb	Integrated	Enveloped, single-stranded RNA genome	VSV-G-nonspecific membrane fusion; Ram-1/Pit-2 for MuLV; α-dystroglycan for LCMV
Alphavirus	Simliki forest virus and Sindbis virus	N/A	Neurons, but virus production in propagating cells only	7 kb	Replicon: genome amplified within cytoplasm	Enveloped, single-stranded RNA genome	Laminin and other receptors for SFV vectors, unknown for other strains
Herpes simplex virus	Amplicon, HSV-1, PRV	gD, gI variants	Neurons	150 kb for amplicon; 40 kb for replication defective HSV	Episomal	Double-stranded DNA genome	Herpes virus entry mediator A and nectin-1
Adenovirus	hAd5, cAd	Ad2, Ad5	Most CNS cell types	8 kb for replication defective; 30 kb for gutless	Episomal	Nonenveloped double-stranded DNA genome	Coxackievirus, adenovirus receptor, and integrins
Adeno-associated virus	AAV2, AAV5 ITRs	Most use serotypes 1, 2, 5, but 6, 7, 8, 9, Rh10 are promising	All serotypes transduce neurons; AAV1 also transduces oligoden-drocytes and AAV4 astrocytes	~4.5 kb	Mostly episomal, possibly integrated	Nonenveloped single stranded DNA genome	HS proteoglycans for AAV2; PDGF-R for AAV5; unknown for most

AAV, adeno-associated virus; Ad, adenovirus; cAd, canine adenovirus; CNS, central nervous system; EIAV, equine infectious anemia virus; FIV, feline immunodeficiency virus; h, human; HIV, human immunodeficiency virus; HS, heparan sulfate; HSV, herpes simplex virus; ITRs, inverted terminal repeats; LCMV, lymphocytic choriomeningitis virus; MuLV, murine leukemia virus; N/A, not applicable; PDGF-R, platelet-derived growth factor receptor; PRV, pseudo-rabies virus; Ram-1/Pit-2, amphotropic retrovirus receptor; SFV, Semliki Forest virus; VSV-G, vesicular stomatitis virus G-protein.

genome, they could potentially disrupt oncogenes, but they are not known to cause transformation by a promoter/enhancer insertion mechanism in natural infections. To further reduce this possibility, most LV vectors are designed to be self-inactivating (SIN) vectors, in which the long-terminal repeat (LTR) promoter and enhancer are deleted from the integrated provirus form. This also eliminates competition with the internal promoter in the expression cassette.

The HIV-1 vector is the most commonly used LV vector for CNS experiments. Only people with HIV-1 have circulating antibodies against this vector, making this an ideal vector to use when it comes to avoiding an immune response. The HIV-1 capsid proteins also appear to have a short half-life, reducing the time span in which the immune system can recognize the transduced cells.

Lentiviruses can transduce most cell types within the CNS, including neurons, astrocytes, stem cells, oligodendrocytes, and glioma cells. The host range can be expanded by pseudotyping LVs with surface glycoproteins from a number of other enveloped viruses, including vesicular stomatitis virus G (VSV-G,) MuLV, Mokola, lymphocytic choriomeningitis virus (LCMV), and rabies. Each pseudotyped vector transduces different subgroups of cells within regions of the CNS. The selectivity is mediated by variable expression of the cell-surface receptors to which theviral envelope protein binds. Thus, targeted transduction within the CNS can potentially be achieved using a combination of cell tropism and cell-type-specific promoters. There also is some evidence that LV vectors undergo retrograde transport, but this does not occur in all nervous system pathways.

Alphavirus The alphaviruses are enveloped and have single-stranded RNA genomes. Alphavirus vectors can be generated rapidly and simply, resulting in high-titer replication-deficient particles. The most commonly used alphavirus vectors for experiments in the CNS have been based on the Semliki Forest virus (SFV). Within the CNS, the SFV vector transduces mostly neurons at a rapid rate but with very transient transgene expression (a few days). Because of the transient expression, SFV vector use in the CNS is usually restricted to slice culture experiments. Wild-type SFV vectors give high infection rates in primary cultures of hippocampal neurons and in hippocampal slice cultures. SFV vectors can be cytopathic due to a shut off of host-cell protein synthesis, but this appears to be dependent on the cellular differentiation state of the CNS cells. Immature neurons are highly susceptible to SFV cytotoxicity, which occurs rapidly, but SFV vectors are able to persist for weeks in the highly differentiated cells of the adult mouse brain. Because alphaviruses can target a wide variety of cell types, an alternative to SFV viruses or other alphaviruses is to use the glycoproteins from the coats of these viruses to pseudotype retroviral and lentiviral vectors, although attempts to do this have resulted in very low titers thus far.

DNA Viruses

Herpes virus Herpes viruses have a large double-stranded DNA genome, and many of the genes are not required for replication: thus, herpes vectors can potentially hold large inserts. Human HSV-1 is the most commonly used herpes virus vector system for experiments involving the CNS, although porcine pseudo-rabies virus (PRV) has been used for tract tracing studies. HSV-1 vectors establish an episomal latent infection in neurons, thus insertional mutagenesis does not occur.

There are two types of HSV-1 vectors: recombinant replication-competent vectors and nonreplicating amplicons. Both types result in gene delivery to CNS cells. Recombinant HSV vectors consist of a wild-type HSV genome, selected either for loss of viral pathogenic effects or for deletion of genes necessary for replication. The deleted genes can either be supplied in trans using a plasmid system or can be expressed in a eukaryotic cell line that can be used for packaging the recombinant vectors. Recombinant HSV vectors can potentially accommodate large inserts of 30 kb or more and can be made into relatively high-titer vectors. Because HSV-1 is a naturally neurotropic virus, only low titers are needed for spread of the replicating virus in the CNS. Recombinant HSV vectors are thought to establish a persistent latent state as a non integrated nuclear element, similar to wild-type HSV. In natural infection, after latency is established, only one viral gene is expressed, the latency-associated transcript (LAT), which is expressed for the lifetime of animals. Thus, the promoter of the LAT sequence has been used to drive long-term expression of therapeutic genes in the CNS.

The HSV amplicon vector system is based on a eukaryotic expression plasmid that can be packaged either using a helper plasmid (viral genes supplied in trans) or a helper virus-free packaging method. HSV amplicons have a potential packaging capacity of up to 130 kb. Because the HSV amplicon vector can accommodate such a large insert, several copies of the transgene can be packaged into a single vector, forming concatamers, resulting in an increased transgene dose per infected cell. A disadvantage in using the amplicon-based system is that these vectors result only in relatively limited transgene expression and

expression in dividing cells is transient because vector DNA is lost during mitosis. For this reason, hybrid vectors have been developed which combine components of the HSV-1 amplicon with genetic elements from other types of viral vectors. HSV–AAV hybrid vectors have been made that combine the benefits of both vector systems, resulting in a vector that can package very large inserts, target multiple cells types, and result in high expression levels for an extended period of time.

Adenovirus Ads are nonenveloped with a double-stranded DNA genome. Ad vectors have both significant advantages and disadvantages for gene therapy experiments. Advantages include their simplicity to generate; large transgene capacity; and ability to transduce a variety of cell types, both dividing and postmitotic, including neurons, astrocytes, oligodendrocytes, ependyma, and blood vessels. Transduction using Ad vectors results in high levels of transgene expression. Another potential advantage is that Ad vectors are transported along neuronal pathways in some cases.

The main disadvantage of using Ad vectors is that they are highly immunogenic, which is the main contributor to loss of transgene expression after administration. Ad vectors target dendritic cells, which facilitates immune stimulation. Most humans carry circulating antibodies against adenoviruses, due to natural infection, which is a potential barrier to clinical use. One approach to reduce this effect is to alter the capsid protein to less-immunogenic forms. Another is to use a gutless vector, which has a genome deleted of all the Ad proteins, which are supplied in trans to form a virus. Gutless Ad vectors have mediated, stable, long-term expression of a transgene in the CNS and can accommodate an insert of approximately 30 kb, whereas replication-defective Ad vectors carry approximately 8 kb.

Adeno-associated virus AAVs were discovered as contaminates of laboratory preparations of Ads. AAVs are parvoviruses, which are nonenveloped and have a single-stranded DNA genome. AAVs are naturally replication-defective and can only replicate when co-injected with a helper virus (Ad or HSV). AAV vectors are one of the most widely used gene therapy vectors in CNS experiments. When directly injected into the brain AAV vectors transduce mostly neurons, but some serotypes can also transduce other neural cell types. AAV vectors result in a delayed-onset but persistent transgene expression. The lag in onset is due to the time it takes for the conversion of the single-stranded AAV genome into a double-stranded transcription-competent DNA molecule. AAV vectors can be concentrated and purified to very high titers, resulting in widespread and stable transduction with low toxicity.

The limitations of AAV vectors include their small cloning capacity (~4.5 kb), preventing their use for large therapeutic genes or limiting the use of many genetic regulatory elements. AAV vectors are relatively inefficient for *in vitro* experiments compared to other vectors, but they can transduce a number of neural cell types. AAV vector production is also labor intensive and time consuming. Recent studies suggest that the use of AAVs in humans may be limited by the existence of preexisting antibodies to AAV, although AAV vectors induce a minimal immune response when injected directly into the brain. When an animal's immune system is primed for a particular AAV serotype, transgene expression is severely diminished and transduction by later injections of the vector is prevented by the immune response.

There are numerous serotypes of AAV capsid genes available, each a sequence variant of the capsid protein. Each serotype has been shown to have different transduction characteristics in the CNS. The AAV-2 serotype vector has been widely for CNS applications but has relatively low transduction. This capsid protein uses heparan sulfate proteoglycan as a receptor, resulting in rapid local uptake by cells in the injection site, which restricts spread within the brain. There is growing use of several other serotypes in the CNS, especially serotypes 1, 5, 6, 7, 8, 9, and Rh10, and many new variants are being tested. Different serotypes can produce different patterns of transduction when injected into specific regions of the CNS, which can be used to selectively target certain cells. There is evidence that the AAV vector serotypes 1, 5, and 9 are transported within the CNS along some neuronal pathways.

Experimental Applications for Viral Vectors in the CNS

Viral vectors have many other CNS applications in addition to therapeutic purposes. Vectors can be used to alter genes in CNS cells in order to study the function of the particular gene. Viral vectors can also deliver fluorescent proteins to a targeted subset of cells, allowing visualization of these cells *in vivo*.

Modeling CNS Neurodegeneration in Animal Models

Modeling a human disease phenotype in a mouse brain has proven to be difficult for many diseases. Germ-cell alterations often do not show the selective pathology evident in human CNS tissue. To most

accurately model a human disease in a mouse, only the cell types affected in the human tissue should be affected in the mouse. One way to achieve this is to transduce the specific cell types with a targeted viral vector expressing the disease-causing transgene. Examples of diseases currently being modeled include Huntington disease (HD), by expressing the mutated human huntingtin protein with extended glutamine repeats in striatal neurons, and Parkinson disease (PD), by expressing α-synuclein in nigral dopamine-containing neurons.

Targeted transduction of specific cells and subregions of the CNS can be achieved by a combination of cell-surface targeting of virus entry and the use of cell-type-specific promoters. The most widely used variants for cell-surface entry are LV pseudotypes and AAV serotypes. However, tropism to specific brain structures usually cannot be predicted and must be determined empirically because the receptors for most of the envelope or capsid proteins are unknown. Once the vector is known to enter a specific cell type or cells in a specific layer or nucleus, further restriction of expression can be achieved by using a the promoter of a gene known to be expressed in the target cell and not adjacent cells. This may have high utility for experimental manipulation of specific genes (e.g., by siRNA silencing). The advantages of this approach over germ line manipulations are that the genetic modification can be done unilaterally, allowing comparison with the contralateral side, and that it is done in the mature cell, avoiding compensatory mechanisms that may be operating during development.

Viral Vectors to Understand CNS Development and Organization

Visualization of the development of the cells can be achieved by using a vector with long-term expression of a reporter gene. This has been exploited primarily to map the fate of cells transduced at the time of injection, including in the subventricular zone, hippocampus, and retina. Another use exploits the property that some viral vectors are transported along neural pathways, allowing tract tracing within the CNS or from the peripheral nervous system (PNS) to the CNS. The herpes virus PRV has been used to map neuronal pathways by immunostaining for the viral proteins, which are expressed at high levels for several days after injection, or by expression of lacZ as a reporter molecule from an acute-phase protein promoter. A replication-competent virus is required to obtain the transneuronal movement needed for tract tracing, but three to four orders of neurons can be labeled by this method.

CNS Diseases as Potential Targets for Gene Therapy

Gene therapy is currently being used to treat and study a number of neurological diseases. The most likely targets for gene therapy are diseases in which a single gene defect affects the CNS or diseases in which the presence of the corrected gene leads to a secretable protein. Gene therapy is also being investigated as a treatment for neurodegenerative diseases by augmentation of neurotransmitter receptors, restoration of neurotransmitter levels, inhibition of the neurodegenerative process, and stimulation of regeneration.

Parkinson Disease

PD is due to the loss of dopaminergic neurons of the substantia nigra. In the past, treatment of PD has involved transplantation of dopamine-expressing cells into the striatum. Problems with this method include the disturbance of striatal circuitry caused by the engraftment and the short-term survival of cellular grafts. Gene therapy represents a more long-term approach that will leave the striatal circuitry undisturbed. Current gene-therapy experiments involve the delivery of trophic factors such as glial-derived neurotropic factor (GDNF) to prolong the life of existing dopaminergic neurons, the delivery of tyrosine hydroxylase (TH) or amino acid decarboxylase (AADC) to the substantia nigra to promote dopamine production within the region, and expression of glutamate decarboxylase (GAD) to alter the neurotransmitter imbalance within the basal ganglia circuits. In the rarer cases in which PD is caused by a loss-of-function mutation, gene therapy might be used to replace the defective gene.

Alzheimer Disease

In Alzheimer disease (AD), neurons in the CNS undergo widespread degradation, especially cholinergic neurons in the basal forebrain. One approach is to use vectors expressing the gene for nerve growth factor (NGF), which can rescue cholinergic neurons from lesion-induced degeneration. However, the direct infusion of NGF into the brains of patients has caused adverse effects due to the resulting presence of NGF in nontargeted structures of the brain. For NGF to be useful therapeutically, it needs to be targeted only to the basal forebrain specifically, which can be done using gene therapy. AAV and LV vectors have been used for this purpose, and the degeneration of cholinergic neurons is prevented in animal models with this method of treatment. Viral vectors have also been used to increase the expression

of Nep (an extracellular amyloid-β-degrading enzyme) in the brain. Another approach to the treatment of AD using gene therapy is to use a viral vector expressing a functional RNAi to knock down expression of amyloid-β proteins by targeting β- and γ-secretases, which are responsible for amyloid-β production. Most studies have used LV vectors for RNAi experiments, and LV and AAV vectors for the other treatment methods.

Expanded Trinucleotide Repeat Disorders

A whole class of diseases has been discovered that are caused by variable numbers of trinucleotide repeats, usually causing a dominant negative effect. These include HD, spinocerebellar atrophies, and Kennnedy disease.

HD is caused by expanded CAG trinucleotide repeats which encode for glutamine in the huntingtin gene. This is a toxic gain-of-function mutation, which causes the loss of striatal neurons, resulting in cognitive and motor deficits. Gene therapy techniques to treat HD have included viral-vector-mediated delivery of ciliary neurotropic factor (CNTF), GDNF or brain-derived neurotropic factor (BDNF), all neuroprotective agents, with the goal of extending the life of existing striatal neurons. Another approach that is currently being attempted involves silencing the expression of the mutant allele by using a viral vector encoding an RNAi specifically against the mutant allele, leaving the normal huntingtin allele functional.

Inborn Errors of Metabolism

Genetic disorders can be the most difficult to treat in the brain because the lesions are typically globally distributed. This occurs because the mutations usually affect metabolic pathways that are common to all cells or all cells of a specific type. Diseases in which the corrected gene leads to the secretion of a therapeutic protein are potentially the most amenable to correction using viral vectors because not every cell has to be directly treated. This category includes the lysosomal storage disorders (LSDs), which have defects in structural lysosomal enzyme genes.

Each LSD results from a significant decrease or complete absence in the activity of a soluble lysosomal enzyme caused by a mutation in a single gene. Most lysosomal enzymes are ubiquitously expressed, and although most of the body can be at least partially treated using bone marrow transplants or enzyme replacement therapy, CNS treatment is more difficult because the enzyme does not easily cross the blood–brain barrier. In lysosomal storage disorders, cells have the ability to undergo cross-correction, which involves genetic correction of a group of cells that can secrete the enzyme, which can be taken up by neighboring cells, usually via endocytosis. Thus, only a subset of the cells needs to be directly corrected, and these then act as a source of normal enzyme to neighboring cells.

Many animal models of LSDs have been treated using several of the gene-therapy strategies to deliver the normal enzyme. *Ex vivo* gene therapy has been tested using RV or LV vectors to transduce neural stem cells, mesenchymal stem cells, and fibroblasts, which were then injected into the diseased brain. Many studies in mouse models have shown that variable amounts of transduction and correction of lesions can be achieved with recombinant Ad, AAV, LV, and HSV vectors. When animals are treated as neonates or fetuses, the progression of disease can be arrested before significant pathology occurs. Treatment of adult animals has shown that significant reversal of established lesions can be achieved, including improvements in behavioral tests and neurodegeneration parameters. Furthermore, studies have demonstrated that in some neural pathways, the enzyme can be transported to distal neuronal cell bodies, which can amplify the sphere of correction far beyond the injection site.

A major barrier to clinical application of these methods is in scaling up from the small rodent brain to a human brain, which is 2000–3000 times larger, depending on age. However, large animals with these diseases (cats, dogs, and monkeys) can serve as test systems because the animals have essentially the same disease as human patients, their brains are much closer in size (only 10- to 20-fold smaller), and the organization is more similar to the human brain than the rodent brain (e.g., a sulcated cerebral cortex). Clinical improvement of the neurological syndrome by gene transfer has been shown in at least one large animal model of an inherited disease (the alpha-mannosidosis cat), suggesting that human treatment for a disseminated CNS disease may be feasible.

Ocular Diseases

The eye is an attractive target for gene therapy because it is easily accessible and can be monitored postinjection using opthalmoscopy. It is also a relatively enclosed system, so when using a nontransportable vector, concerns about the transgene reaching the rest of the CNS are reduced. Most gene-therapy studies have looked at treating diseases of the retina. Retinal diseases that are currently being studied for treatment with gene therapy include several of the retinitis pigmentosas, chorioiderimea, and ocular

neovascular disorders such as age-related macular degeneration and diabetic retinopathy. Dogs with Leber congenital amaurosis have had their eyesight restored by AAV vector-mediated gene transfer, providing the basis for a clinical trial that is underway.

Tumors

One use of viral vectors in tumor therapy involves introducing a therapeutic gene that may generate anticancer compounds within the tumor. Gene-mediated drug activation can be selectively targeted to the tumor tissue alone, saving surrounding normal tissue from damage. Therapeutic genes can directly kill or block the growth of tumor cells, inhibit angiogenesis, stimulate immune responses to tumor antigens, or block tumor cell invasion. Vectors that are cytotoxic, such as Ad and HSV, can serve as selectively toxic agents and be targeted to receptors that are specifically expressed on tumor cells. Ad5 vectors have tropism for some brain tumors and so are currently being used in model systems of gene therapy to treat CNS tumors that are both primary and metastatic. Unfortunately, current gene-therapy approaches have not resulted in the delivery of the therapeutic gene to all the tumor cells. However, HSV has been used in rodent models in which it was shown to kill tumor cells while sparing adjacent normal neurons. HSV is one of the few systems that has shown some efficacy in human trials. RV vectors have also been used to deliver genes such as HSV-derived thymidine kinase that convert gancyclovir into a toxic product in dividing cells (by DNA chain termination), which is optimal in the brain, where most normal cells are nondividing.

Epilepsy

Epilepsy is due in part to an imbalance in excitatory and inhibitory neurotransmission. Gene therapy could be used to deliver agents to neurons with the potential of affecting this imbalance. Neurotransmitter receptors and ion channels are the most likely targets for gene-therapy applications. Vectors that express glutamate, γ-aminobutyric acid (GABA), neuropeptide Y, and galanin have been used to attempt to treat induced epilepsy in animal models. Results have been promising, and the attenuation of seizures and neuronal death by AAV vectors expressing galanin have been reported. Adenosine is a drug that can inhibit neuronal activity, but adenosine causes strong adverse side effects when administered in high doses. To circumvent these adverse side affects, another method to treat epilepsy has been developed using gene therapy that involves grafting *ex vivo*-modified cells expressing adenosine directly into the region with the neurotransmission imbalance. This method has been shown to suppress seizures in rodent models of epilepsy without any side effects. Recently, another approach has been to manipulate the stoichiometry of $GABA_A$ receptors, which are disrupted by experimental status epilepticus in the rat, to make the cells less susceptible to abnormal activity.

Trauma

The mammalian CNS does not spontaneously regenerate or reestablish synaptic contacts after severe traumatic injury. Trauma causes a cascade of events leading to substantial cell death long after the initial event, thus a number of strategies are being tested to block these sequele. Viral vectors have been used to express neuroprotective agents such as NGF or BDNF within the area of injury, resulting in reduced or reversed atrophy, and improved learning ability over time. *Ex vivo* therapy has also been used in which genetically modified cells expressing NGF have been engrafted into the region that suffered the trauma, which attenuated long-term cognitive dysfunction posttrauma.

Conclusion

There are numerous potential applications for viral gene transfer vectors in the CNS. The use of these vector systems in the CNS has proven to be invaluable in treating experimental disease in animal models and, despite previous setbacks in gene-therapy studies, are beginning to be used clinically. Viral vectors also have many nontherapeutic uses, including modeling human diseases in animals, studying the function of specific genes, studying developmental fate, and mapping neuronal pathways. Their usefulness in experimental manipulations of specific functions in the brain will increase as the properties of cell tropism and gene expression are more precisely understood and controlled.

Visceral Pain

G F Gebhart, University of Pittsburgh, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Individuals suffering from one of the painful disorders that affect the internal organs (e.g., irritable bowel syndrome, noncardiac chest pain, nonulcer dyspepsia, and painful bladder syndrome) fully comprehend the typical characteristics of visceral pain. Visceral pain is diffuse in character and is typically difficult to localize unless adjacent structures, such as the parietal peritoneum or pleura, are involved (e.g., appendicitis). With respect to functional disorders of the viscera, defined by chronic pain in the absence of structural, infectious, or biochemical abnormalities, hypersensitivity is the shared characteristic. This hypersensitivity is commonly not restricted to the affected organ but also associated with both an expansion of the area on the body to which visceral pain is typically referred (or transferred) and increased tenderness to cutaneous/subcutaneous probing in the area of referral.

The anatomical organization and central nervous system terminations of visceral sensory (afferent) input largely explains why visceral pain is not commonly felt at the source, is diffuse in character, and is generally associated with greater autonomic and emotional responses than is pain arising from superficial structures. Visceral hypersensitivity, particularly as it relates to functional visceral disorders, involves both peripheral and central mechanisms, neither of which is fully understood. This article briefly summarizes the major features of visceral pain and addresses visceral hypersensitivity by considering potential mechanisms and molecules that contribute to the sensitization and increase in neuron excitability that underlie hypersensitivity. It is important at the outset to appreciate that visceral pain in general and functional disorders in particular do not conform to the traditional biomedical model.

Characteristics of Visceral Pain

Unlike activation of sensory receptors in skin, muscle, and joints, activation of sensory receptors in the viscera by a wide range of physiologically relevant stimuli does not commonly result in the conscious awareness of such input. For example, mechanical activation of baroreceptors in the aortic arch, secretion of digestive enzymes and activation of gastric and small bowel motility initiated by the ingestion of food, and activation of airway receptors by inspiration rarely lead to conscious perception of such stimuli. The principal conscious sensations that do arise from the viscera include nausea, dyspnea, discomfort (e.g., bloating), and pain generated by mechanical (principally), ischemic, and inflammatory events in visceral organs. Ischemic events, such as associated with angina, often generate conscious sensation of chest pain, which is typically referred to the upper left shoulder and down the left arm. Organ inflammation, such as associated with the colon and pancreas, generates conscious, diffuse abdominal pain. Mechanical events that lead to obstruction of organ outflow (e.g., gall or kidney stones), traction on the mesentery, or organ overfilling, which increases tension of circumferential and longitudinal organ smooth muscle, similarly generate diffuse, difficult to localize sensations, including significant pain in many cases (e.g., kidney stones and intestinal obstruction). Complicating localization of the source of visceral input is referral of visceral sensation to nonvisceral structures such as skin and overlap in areas of referral from different organs. Referral reflects the convergence of visceral and nonvisceral inputs onto the same second-order spinal neuron. Virtually all spinal neurons that receive a visceral input also receive input from a cutaneous and/or subcutaneous site, whereas spinal neurons that receive a cutaneous input do not all also receive a visceral input. In addition to somatovisceral convergence in spinal cord, viscerovisceral convergence is common. For example, sensations arising from the gall bladder, lower esophagus, and heart have overlapping areas of referral on the chest. Similarly, sensations arising from the urinary bladder, large bowel, and other pelvic organs have overlapping areas of referred sensation on the abdomen. Notably, tissue-damaging stimuli, which uniformly cause pain when applied to skin, do not reliably give rise to visceral discomfort or pain. That is, stimuli adequate for activation of nociceptors are different for skin, muscle, joints, and the viscera. Cutting, crushing, or burning stimuli applied to the viscera do not generally cause discomfort. Rather, as indicated previously, mechanical, ischemic, and inflammatory stimuli are adequate for activation of visceral nociceptors.

Visceral Innervation, Central Terminations, and Projections

Distinct from all other tissues in the body, each internal organ is innervated by two different nerves. The vagus nerves, probably the most extensive sensory nerves in the body with respect to targets of innervation,

innervate all organs in the thoracic cavity and most organs in the abdominal cavity except the urinary bladder, distal colon, and pelvic organs (e.g., prostate, cervix, and uterus). Cell bodies of vagus nerves are located principally in the nodose ganglia with central terminations in the brain stem nuclei tractus solitarii (NTS). These same thoracic and abdominal organs are also innervated by nerves identified as spinal visceral nerves with cell bodies in dorsal root ganglia that are bilaterally distributed along the length of the spinal cord. Accordingly, the airways, esophagus, stomach, heart, etc. are innervated by both vagus and spinal visceral nerves with central inputs terminating in NTS and thoracic spinal cord, respectively. The urinary bladder and distal colon are innervated by the pelvic nerve and splanchnic nerves with central terminations in sacral and upper lumbar segments of spinal cord, respectively; multiple segments of lumbar spinal cord separate these inputs. Thus, all viscera send inputs to distinct and separate sites in the central nervous system, further contributing to difficulty in localization of input and to the diffuse character of such input. It has been appreciated for some time that the different innervations of the viscera are associated with distinct functions, but characterizing these functions has only recently become a research priority.

Despite the extensive reach of the vagus nerves and dual innervation from spinal nerves, the viscera are relatively sparsely innervated, particularly by the spinal visceral nerve innervation. Only approximately 5–8% of total sensory input from all tissues into the spinal cord is represented by visceral input. Visceral input into spinal cord, however, is extensive in the sense that the spinal inputs diverge into rostral (ascending) and caudal (descending) branches which arborize extensively in multiple segments both above and below the site of entry into the spinal cord. Moreover, spinal visceral input also includes fiber terminations in the side of the spinal cord contralateral to the input. This organization, again, contributes both to difficulty in localization of visceral input and to the diffuse character of visceral pain.

Supraspinal Projections

Spinal visceral input reaches supraspinal sites by two principal pathways. Primary visceral inputs terminate on second-order neurons in the spinal cord that are located principally in the superficial dorsal horn (laminae I and II), in the intermediolateral cell column/sacral parasympathetic nucleus (where they synapse onto autonomic efferent neurons), and in lamina X dorsal to the central spinal canal. One ascending pathway of visceral input arises from axons of second-order spinal neurons that cross to the contralateral side of the spinal cord and become part of the anterolateral ascending pathway en route to third-order neurons in the thalamus (Figure 1). A postsynaptic dorsal column pathway arises from axons of second-order spinal neurons located principally in lamina X. This pathway ascends the spinal cord on the side ipsilateral to the visceral input and synapses on third-order neurons in the nuclei gracilis or cuneatus (depending on the spinal level of visceral input), which then crosses to the contralateral side of the central nervous system en route to destinations generally overlapping with those receiving input from the anterolateral ascending spinal pathway. Both ascending pathways give rise to collateral axons throughout the brain stem as well as to hypothalamus, thus widely distributing visceral input throughout the brain. Visceral inputs that reach areas in the brain stem medulla and pons are associated with autonomic control and feedback functions, autonomic responses to noxious visceral stimuli, and endogenous pain control (e.g., midbrain periaqueductal gray). Beyond the thalamus, visceral inputs reach the anterior cingulate cortex, the anterior insular cortex and primary and secondary

Figure 1 Diagrammatic representation of central visceral sensory pathways. Spinal visceral nerve input from the gastrointestinal tract (and thoracic cavity organs and pelvic organs, not shown) terminates on second-order spinal neurons in the superficial dorsal horn, which conveys information rostrally after crossing the spinal cord to become part of fiber tracts ascending and terminating in the brain stem, hypothalamus, and thalamus. A second ascending pathway arises from second-order spinal neurons located principally dorsal to the central canal (spinal visceral nerve input to these neurons is not illustrated). Fibers in this second pathway ascend in the dorsal column medial lemniscal (DCML) tract to synapse on third-order neurons in the ipsilateral gracile and cuneate nuclei, the ascending axons of which cross to the contralateral side of the brain to terminate in the brain stem, hypothalamus, and thalamus. Visceral information is widely distributed to the sensory cortices, insula, prefrontal cortex, and anterior cortex. ALQ, anteriolateral quadrant ascending tract; DRG, dorsal root ganglion.

sensory cortices, as well as areas of the limbic system associated with the emotional and perceptional consequences of visceral inputs.

Intrinsic (Enteric) Nerves

In addition to the sensory (extrinsic) innervation of visceral organs described previously, the viscera are further characterized by an intrinsic innervation (sometimes referred to as intrinsic primary afferent neurons). This local or 'regional' nervous system is considered to be the third major division of the autonomic nervous system. In the gastrointestinal tract, a myenteric plexus, containing most of the enteric neurons, is located between the circumferential and longitudinal layers of organ smooth muscle and is principally associated with motility, particularly coordinating oral to aboral motility. This is achieved by descending and ascending excitatory and inhibitory reflexes within the gut. A submucosal plexus, or actually submucosal plexus layers (outer and inner), also contributes to motility but, more importantly, to vasomotor and secretomotor organ functions. The enteric nervous system can act independently of the central nervous system, and the various classes of neurons within the enteric nervous system respond to a rich variety of local stimuli, including mechanical and chemical stimuli.

The foregoing only superficially describes the enteric nervous system, which is described here primarily to emphasize the virtual absence of knowledge about how the extrinsic sensory visceral innervation, which gives rise to conscious visceral sensations, interacts with the intrinsic nervous system. Even the anatomical relationships between extrinsic sensory nerve terminals in organ muscle layers or submucosal sites and neurons intrinsic to an organ have not been resolved, thus limiting our ability to unravel functional interactions. It seems likely that functional visceral disorders, which previously were considered to represent motility or vasosecretory disorders, represent at least in part a dysfunctional interaction between the intrinsic and extrinsic nervous systems.

Visceral Sensitivity and Hypersensitivity

Among stimuli adequate for activation of visceral nociceptors, mechanical stimulation has been most widely employed for several reasons. First, balloon distension of hollow organs in humans reproduces the localization, sensation, and intensity of their visceral pain. Second, mechanical stimuli are more easily controlled experimentally than either ischemia or inflammation. Consequently, in both behavioral and electrophysiological experiments in nonhuman animals, balloon distension of hollow organs has been widely used to develop models of visceral pain and to evaluate function(s) of the visceral sensory innervation.

Mechanosensation and Nociceptors

Single-fiber studies *in vivo* have revealed the presence of two groups of mechanosensitive afferent fibers in visceral nerves. Studies in gall bladder, esophagus, stomach, urinary bladder, small bowel, colon, ureter, and uterus in different species (mouse, rat, guinea pig, cat, and opossum) have identified a proportion of afferent fibers with high thresholds for activation, principally by organ distension. These high-threshold mechanosensitive endings in the viscera first respond at distending pressures considered to be noxious ($\geq$30 mmHg) and the 20–30% of high-threshold fibers described in the literature likely function as mechanonociceptors and signal acute visceral pain. Typically, they encode distending pressures throughout the noxious range. That is, response magnitude increases as stimulus intensity (distension pressure) increases. The larger proportion of mechanosensitive afferent fibers (e.g., 70–80%) have response thresholds in the physiological range (2–5 mmHg) and also encode stimulus intensity, typically into the noxious range. Accordingly, and unlike cutaneous mechanoreceptors, both high- and low-threshold visceral mechanoreceptors are responsive to noxious intensities of visceral stimulation.

Nociceptors were proposed by Sherrington to be the sensory end organs in skin that responded to stimuli which damaged or threatened damage to skin (e.g., cutting and crushing). Thus, nociceptors are defined functionally by response to noxious stimulation. As indicated previously, adequate noxious stimuli differ between skin, muscle, joints, and viscera, and although cutting, crushing, or burning of visceral tissue do not reliably activate nociceptors, mechanical, ischemic, and inflammatory events do (although ischemic and inflammatory stimuli likely activate visceral nociceptors indirectly).

When studied, visceral mechanoreceptors also respond to chemical and/or thermal (heat or cold) stimulation, revealing that most, if not all, mechanosensitive endings in the viscera are polymodal. The converse, however, is not true; that is, there likely exist receptive endings in viscera that are selectively chemosensitive (e.g., to nutrients) and are not also thermo- or mechanosensitive. Another characteristic of visceral nociceptors, first described for cutaneous nociceptors, is their ability to sensitize. Sensitization is defined by an increase in response magnitude to a noxious intensity of stimulation and a decrease in response threshold into what was previously the range of nonnoxious stimulation; an example is

given in Figure 2. Spontaneous activity may also increase. Interestingly, both high-threshold and low-threshold visceral mechanoreceptors sensitize after experimental organ insult or even after exposure to noninjurious stimuli (e.g., intragastric instillation of a hot, 46 °C solution). These findings suggest that low-threshold visceral mechanoreceptors, unlike low-threshold cutaneous mechanoreceptors, can contribute to sensations of visceral discomfort or pain. Extrapolating this information to functional visceral disorders in humans suggests activation of sensitized low-threshold mechanoreceptors by normal physiological events in the viscera, such as ingestion of food and slow bladder filling.

In vitro preparations of organs with nerves attached reveal a further division of visceral mechanoreceptors, including the presence of mechanosensitive endings associated with organ mucosa/submucosa (or bladder urothelium), smooth muscle, mesenteric attachments, and serosa. There have also been described muscular–mucosa endings in stomach, urinary bladder, and colon which respond both to gentle stroking of the mucosal surface and to circumferential stretch of muscle. Although evidence is limited, muscular–mucosal mechanosensitive endings in the viscera seem to be more readily sensitized than muscular endings in the viscera. If these findings are correct, they may provide a mechanistic foundation for common complaints of patients with functional disorders associated with normal physiological processes that would initially access the mucosal surface of an organ. Furthermore, the proportions of muscular and muscular–mucosal endings in the different nerves innervating the same organ are not the same. For example, there is a greater proportion of stretch-responsive endings in the pelvic nerve innervation of the mouse colon relative to the lumbar splanchnic nerve innervation, and only the pelvic nerve innervation includes muscular–mucosa endings. This suggests the possibility of target-oriented therapeutic strategies because, presumably, the phenotypic expression of sensory receptors differs between the two nerves innervating an organ.

Figure 2 Example of sensitization of a mechanoreceptor in the pelvic nerve innervation of the mouse urinary bladder. Responses are plotted to 5 to 25 g stretch applied to the bladder before (pre) and after (post) application of inflammatory soup (IS; bradykinin, histamine, PGE_2, and serotonin at pH 6.0) to the receptive ending in the urinary bladder. The response to stretch 5 min after application of IS is increased, or sensitized, as illustrated by the action potential records for the response to 20 g stretch before and 5 min after application of IS.

Sensitization

The process of sensitization of visceral receptors and afferent fibers, reflecting an increase in excitability of the sensory neuron (as evidenced by changes in sodium, potassium, and calcium ion currents), has important consequences within the central nervous system. Peripheral sensitization of visceral sensory neurons leads to increased input from organs into the central nervous system, release of increased amounts of neurotransmitters and modulators from their central terminations, and a consequent increase in the excitability of the central neurons upon which the visceral sensory neurons terminate. This process is termed central sensitization and has been studied most extensively at the first central synapse, usually in the spinal cord, but it also occurs at subsequent central synapses, including in the brain stem and likely more rostral terminations of the visceral sensory pathways. Both peripheral and central processes of sensitization have been studied more extensively in nonvisceral models, in which mediators and intracellular signaling pathways have been examined and revealed. Analogous mechanisms and processes likely exist in the visceral realm, but this remains to be established. Both peripheral and central sensitizations are normally time limited and reversible. A good example is a burn (e.g., sunburn) to skin that leads first to sensitization of cutaneous nociceptors and then to central sensitization, which is commonly manifest as increased sensitivity to stimuli applied to the uninjured skin adjacent and near the burn, including stimuli that are normally not painful, as well as an expanded area (receptive field) from which discomfort and pain can be evoked. In the viscera, hypersensitivity is typically expressed as increased tenderness to palpation of the abdomen, for example, and an expanded area of referred sensation.

Although commonly reversible as tissue heals and recovers from insult, there is growing awareness that central sensitization in some cases may be sustained (by mechanisms not understood). That is, changes in the excitability of central neurons may persist, perhaps become permanent, and contribute to the development and maintenance of functional disorders. It

has been appreciated for some time that endogenous modulatory systems can be engaged in the brain stem (e.g., periaqueductal gray). Although it is now known that descending systems are neither selective nor specific modulators of spinal nociceptive (pain) transmission, they have been most widely investigated and discussed as a means of endogenous pain control (inhibition). Generally, inhibitory control does predominate, but facilitatory or excitatory influences are also engaged in the same areas of the brain stem and it is now considered that the balance between descending inhibitory and facilitatory influences may be changed in chronic pain conditions, including functional visceral disorders, and that the system is dysfunctional. Although important details and mechanisms are not currently known, brain imaging studies in humans and experimental manipulations in nonhuman animals do support the concept of central, supraspinal dysregulation of endogenous modulatory systems as contributing to maintenance of chronic, functional disorders in which discomfort and pain are prominent. It remains an open question whether central dysregulation is the result or cause of any functional disorder.

Mediators and Modulators of Visceral Hypersensitivity

Considerable evidence has accumulated during the past decade pointing at endogenous mediators and a variety of ion channels and receptors as contributing to the process of peripheral visceral neuron sensitization. Visceral sensory neurons have been shown to respond to numerous substances, including protons, serotonin, histamine, bradykinin, purines (e.g., ATP), and proteases, and all have been shown to likely contribute to visceral sensory mechanisms. It is important to appreciate that these and other putative mediators arise from a variety of sources, notably from epithelial cells lining hollow organs, including the bladder urothelium. For example, approximately 90% of the body's serotonin is contained in enteroendocrine cells located in the intestine. The number of enteroendocrine cells reportedly increases after intestinal inflammation, suggesting that the release of serotonin (5-HT) by mechanical or chemical stimulation within the intestine may be important in the pathogenesis of functional bowel disorders. Accordingly, therapeutic strategies for treatment of symptoms of irritable bowel syndrome (IBS) have targeted 5-HT receptor agonists (e.g., 5-HT4 agonists) and antagonists (e.g., 5-HT3 antagonists) and the serotonin transporter.

Mast cells are a rich source of bioactive substances and are found in close approximation to nerves within the human gastrointestinal tract. Mast cells contain and release histamine, proteases, and other potential mediators and modulators of visceral sensation. Mucosal biopsy samples from IBS patients release greater amounts of proteases than do biopsy samples from control subjects, presumably from mast cells. Also, supernatants from incubated biopsy samples have been shown to activate visceral sensory neurons, an effect that can be blocked experimentally by inactivation of serine proteases or a histamine receptor antagonist. Thus, in addition to serotonin, histamine and proteases released in greater amount from tissues of patients with functional bowel disorders suggest a role for these mediators in activation and sensitization of visceral sensory neurons.

Proteases such as tryptase activate proteinase-activated receptors (e.g., PAR_2) by releasing a tethered ligand that is part of the receptor to activate visceral sensory neurons, an effect that can be mimicked by experimental administration of a PAR_2 agonist. PARs have been hypothesized to link mast cell-derived proteases to inflammatory processes in colon and urinary bladder. In addition, PAR_2 agonists (as well as serotonin) have been shown to modulate the activity of the transient receptor potential ion channel TRPV1 found in many sensory neurons, including visceral sensory neurons. Additional chemical signals that can activate and/or sensitize visceral sensory neurons include endogenous products such as lactate, protons, and bradykinin, all of which can accumulate during ischemia (e.g., myocardial ischemia or angina), and cyclooxygenase-dependent products of arachidonic acid (e.g., prostaglandins). Moreover, gastroesophageal reflux disease, in which gastric acid reflux into the lower esophagus contributes to discomfort and pain, suggests a role for protons in visceral hypersensitivity. Bradykinin has been reported to accumulate in cardiac sinus blood during cardiac ischemic episodes and, along with lactate and protons, is believed to contribute to cardiac pain sensations. For example, experimental coronary artery occlusion leads to a prompt decrease in myocardial pH with commensurate increases in tissue proton and lactate content that accumulates during tissue hypoxia and can activate ischemia-sensitive cardiac sensory neurons in spinal visceral nerves.

Purines, including ATP and its metabolites, are ubiquitous and are released during cell injury, including from epithelial cells lining the gastrointestinal tract and urinary bladder. Ligand-gated P2X and G-protein-coupled P2Y receptors have thus been investigated for their potential roles in visceral pain mechanisms. Urinary bladder epithelium (urothelium) and colonic mucosa release ATP when these organs are experimentally distended. Following experimental organ inflammation, the amount of ATP released is

increased and can contribute to activation and/or sensitization of visceral sensory neurons. For example, bladder sensory neuron excitability is increased after experimental cystitis, as evidenced by the development of spontaneous activity, a significant reduction in rheobase (i.e., the amount of current injected into the cell that is required to generate an action potential), and changes in P2X channel kinetics of activation. Complimentary studies using P2X receptor antagonists or knockout mice have shown attenuation of responses to organ distension, revealing a potential role for ATP and its cognate receptors in mechanosensation from the viscera. It has been more generally suggested that epithelial cells which release ATP function as 'sensory intermediaries' in the signaling of organ luminal events to visceral sensory neuron terminals in submucosal tissue where luminal contents normally cannot access sensory neuron terminals.

Much of the foregoing has been supported by studies in mice in which selected gene deletions have been made (i.e., knockout mice). Thus, deleting $P2X_2$ and/or $P2X_3$ purinergic receptors alters responses in bladder and colon sensory neurons, supporting previous studies and reinforcing the notion that purinergic receptors can contribute to or modulate mechanosensory events in the viscera. Similarly, deleting ion channels that are gated by protons, such as acid sensing ion channels (ASICs) or the transient receptor potential vanilloid receptor 1 (TRPV1) also reveals contributions to visceral sensation. For example, TRPV1 knockout mice have a higher frequency of nonvoiding bladder contractions than do wild-type mice, and recordings from TRPV1 knockout mice visceral sensory nerves reveal attenuated responses to organ stretch (distension). Consistent with the importance of ischemia as a trigger of cardiac pain, in which increased protons (decreased pH) are present, and the contribution of protons to gastric and gastroesophageal pain, deletion of ASIC3 ion channels suggests their role in mediating nonmechanical events in the proximal gastrointestinal tract and heart. Supporting many of these experimental findings in nonhuman animals is evidence from human biopsy material. The expression of TRPV1, ASIC3, and $P2X_3$ has been shown to be increased in samples taken from people with gastroesophageal reflux disease, painful bladder syndrome, intestinal inflammation, and rectal urgency.

Considerable effort continues to be focused on improved understanding of peripheral events that contribute to visceral hypersensitivity and the central consequences of such altered visceral input. Therapeutic strategies are currently directed toward attenuating sensitized input from the viscera into the central nervous system. However, given that persistent visceral pain such as is characteristic of functional disorders likely involves changes in the central nervous system, acquisition of new knowledge about central contributions is critical to the development of visceral pain management strategies based on mechanism.

Viscero-Sensory Functions: Capsaicin

Capsaicin as a Tool in Studies of Viscerosensory Function

Capsaicin is the pungent substance found in spicy chili peppers (Figure 1). It has been used extensively as a tool in sensory research in three different ways, depending on the concentrations and manner in which it is employed.

Capsaicin as a Selective Stimulating Agent

At moderate concentrations, capsaicin acutely and intensely excites nociceptive afferent fibers without causing frank tissue damage and thus can be used as a very selective stimulating agent. Responses to capsaicin are often used to characterize visceral neurons and visceral pathways in physiological experiments.

Exposure of visceral afferents to capsaicin leads to their activation and sensitization; thus, application of capsaicin to visceral mucosa is used as a means to evoke controlled responses both in animals and in humans. For example, application of capsaicin to the colon in the mouse has been developed as a model of visceral pain and is used to explore the behavioral pharmacology of visceral pain responses. Intracolonic capsaicin evokes short-lived dose-dependent spontaneous pain responses and longer-lasting enhanced responses to external stimuli applied to the abdomen, hind paws, and tail (referred hyperalgesia). In human subjects, hot pepper sauce (which contains capsaicin) or capsaicin solutions delivered orally have often been used to evoke reactions in the gastrointestinal tract and the sensory and/or motor responses recorded. The sensations produced by direct application of capsaicin to the mucosa of the ileum have been described in patients with ileostomies. Perfusion of the duodenum with capsaicin solution has even been proposed as a diagnostic test for dyspepsia.

Capsaicin as a Selective Desensitizing Agent

In higher concentrations or with more prolonged exposure, capsaicin causes a functional elimination (desensitization) of a subpopulation of afferents. In visceral systems, this technique is often used for topical application to a mucosa.

Capsaicin may produce acute activation followed by desensitization, but afferents that do not generate action potentials in response to capsaicin exposure may also be cross-desensitized to other stimuli. Both spinal afferents originating in the dorsal root ganglia (DRG) and vagal afferents are affected. Approximately 40% of vagal afferents can be acutely desensitized on capsaicin exposure.

Topical application of capsaicin and other vanilloids, notably resiniferatoxin, to the bladder is used therapeutically in patients with overactive bladder. The positive results obtained have been shown to be due to capsaicin-induced desensitization of fine unmyelinated afferents innervating the bladder.

Capsaicin as a Selective Neurotoxin

When delivered in high systemic doses in neonatal rodents, capsaicin acts as a neurotoxin and kills a subpopulation of afferent sensory neurons. Animals treated as neonates with high systemic doses of capsaicin develop relatively normally and can be used in a wide variety of studies as adults. After neonatal capsaicin, stimulation of unmyelinated efferent fibers in autonomic nerves produces normal functional effects. This observation led to the conclusion that neonatal treatment with capsaicin selectively destroys unmyelinated afferent fibers without any effects on the unmyelinated efferents of the autonomic nervous system. Anatomical methods show that this technique eliminates a subpopulation of DRG and vagal afferent neurons, preferentially those with unmyelinated afferents along with a small number with thinly myelinated fibers. The proportion of dorsal root afferents innervating the viscera affected by neonatal capsaicin is larger than those in the somatic population. Also, since the viscera are much less densely innervated than cutaneous structures, the functional effects are more marked. However, the effect is not complete, and a proportion of visceral unmyelinated afferent fibers survive. Also, the neurotoxic effect is not uniform. For example, examining the vagal innervation of the gastrointestinal tract using anatomical tracing methods following capsaicin treatment, vagal afferents innervating the small intestine, the cecum, and colon are almost all eliminated. However, up to 90% of the esophageal and 60–90% of gastric vagal endings survive capsaicin treatment. There are some adaptive changes in the central nervous system (CNS) in neonatal capsaicin-treated animals, so the deficits observed in these animals probably do not reflect the full range of functions that the ablated afferents subserved.

Figure 1 Structures of capsaicin and other TrpV1 agonists.

Molecular Mechanism by which Capsaicin Affects Viscerosensory Functions

A long series of classical pharmacological experiments carried out by many laboratories, including the development of synthetic agonists that mimicked the effects of capsaicin and antagonists that blocked its actions, led to general agreement that capsaicin exerted its effects on sensory neurons via a specific membrane receptor. The capsaicin receptor was finally isolated using an innovative expression cloning strategy and called the vanilloid receptor 1 (VR1) by Caterina and colleagues. The receptor is a member of the transient receptor potential (Trp) family and is now known as the TrpV1 receptor. The identification of the capsaicin receptor generated considerable interest and new work in this area because TrpV1 was the first transduction protein for noxious stimuli to be discovered.

TrpV1 is a nonselective cation channel that is very effectively gated by capsaicin in most mammals. The endogenous 'ligands' for TrpV1 include noxious heat (42–53 °C), protons (pH 5–6), and various lipid derivatives, including lipoxygenase metabolites of arachadonic acid, endogenous cannabinoids such as anandamide, and endogenous vanilloids such as *N*-arachidonoyl-dopamine (Figure 1). Which of these ligands is responsible for TrpV1 activation depends on the tissue and the physiological or pathophysiological circumstances, but they may also interact and potentiate the effects of each other (Figure 2).

Several natural products derived from plants, including capsaicin, also gate TrpV1. Capsaicin is

Figure 2 TrpV1 channel activation.

found in plants of the genus *Capsicum*, and it is a specialized metabolite produced in the fruits as a deterrent to seed predators. The production of capsaicin was presumably selected for during evolution because its stimulatory effects on the gastrointestinal tract of mammals is adversive, although capsaicin-producing *Capsicum* species have been cultivated by humans for more than 6000 years. Other plants cultivated for culinary or medicinal use produce TrpV1 agonists such as piperine, the pungent ingredient of black pepper corns, and resiniferatoxin, a very potent TrpV1 agonist secreted in the sap of the succulent plant *Euphorbia resinifera* commonly found in Morocco and used as a purgative (Figure 1).

Mechanism by which Capsaicin Excites and Sensitizes Visceral Afferent Neurons

TrpV1 gating (opening of the channel pore) results in an influx of cations and thus an excitatory effect on terminals of primary sensory neurons with a subsequent depolarization of the nerve fiber and the initiation of action potential propagation. Conduction of action potentials toward the CNS triggers reflex responses such as cough, voiding of the urinary bladder, or motor responses of the gut. The action potential traffic may also lead to conscious sensations, particularly of pain. In addition, calcium influx into the nerve endings, driven either by antidromic conduction of action potentials or directly by TrpV1 gating, causes the local release of neuropeptides from the terminal, including calcitonin gene-related peptide (CGRP) and the tachykinins, substance P, and neurokinin A. Activation of CGRP and tachykinin receptors on effector cells causes a series of responses, collectively referred to as neurogenic inflammation. Neurogenic inflammation is characterized by vasodilation of small arterioles, producing an increase in blood flow, and leakiness of capillary walls, resulting in plasma extravasation into the tissues, and swelling.

In addition to the wide range of potential adequate stimuli that gate TrpV1 channels, the TrpV1 receptor has another very important characteristic, which is that a large range of factors can sensitize the channel to activating stimuli. This sensitization is manifested both as a decrease in the threshold for activation and as an increase in the channel open time in the presence of normally suprathreshold stimuli. Sensitizing factors include direct phosphorylation of TrpV1 by protein kinase C (PKC) or protein kinase A and release of PtdIns(4,5)P2-mediated inhibition by activation of phospholipase C (PLC). Thus, the TrpV1 receptor may be activated by inflammatory mediators such as lipoxygenase products and low pH, but it can also be sensitized to heat, acidic stimuli, anandamide, or vanilloids by a range of inflammatory mediators which act on their own membrane receptors on the same cell and generate PKC and/or PLC, such as ATP via purinergic receptors, bradykinin via B2 receptors, or nerve growth factor via Trk A receptors.

This molecular sensitization of TrpV1 likely underlies the sensitization of visceral afferent terminals

to endogenous chemical and even heat stimuli, especially under inflammatory or ischemic conditions. For example, application of ATP can reduce the heat threshold of native TrpV1 channels from 43 to 35 °C, below normal body temperature, such that the channel would be activated continuously at core body temperature. Mild acidification (pH < 7.6) and low concentrations of capsaicin can also sensitize the response of TrpV1 to heat by a mechanism distinct from the direct activation of the channel by lower pH.

Mechanism by which Capsaicin Desensitizes or Kills Visceral Afferent Neurons

In the skin, topical application of capsaicin both in experimental animals and in humans has been shown to produce a rapid decrease in the number of epidermal fine nerve fibers, such that after 3 days there is a nearly complete disappearance of neuronal profiles as identified using a pan-neuronal marker, PGP9.5. The neurons do not die; capsaicin produces a dieback or retraction of the terminal portion of the nerve fiber arbors. On cessation of capsaicin treatment, the epidermal nerve fibers take 2 or 3 weeks to recover and reinnervate the epidermis. In the bladder, intravesical instillation of resiniferatoxin results in a long-lasting reduction in detrusor hyperactivity. Biopsies from patients in which the treatment was effective show a substantial decrease in the number of suburothelial fibers as determined by immunohistochemical labeling for PGP9.5. Studies also show a decrease in the TrpV1 immunoreactivity in both neuronal profiles and urothelial cells. The process of desensitization occurring in other visceral tissues after exposure to capsaicin or other exogenous TrpV1 agonists such as resiniferatoxin is likely very similar.

One important feature of the use of capsaicin as a desensitizing tool is that although capsaicin desensitization results from the action of capsaicin as a specific and selective TrpV1 agonist, it produces a defunctionalization of the entire nerve terminal (or even its physical disappearance). Thus, the affected afferents no longer respond to TrpV1 agonists (protons, lipid derivatives, capsaicin, etc.) and also do not respond to all the other stimuli that act on the different channels and receptors expressed on the nerve terminal. TrpV1 is therefore required for any capsaicin effect, but the results observed do not allow firm conclusions on the role of TrpV1 in the physiological function or pathological condition under investigation.

The precise mechanism triggering dieback of the afferent terminals on exposure to TrpV1 ligands such as capsaicin is unknown; however, it seems likely that it parallels the mechanism by which capsaicin has been shown to produce cell death in cultured, TrpV1-expressing neurons or cell lines. As described above, TrpV1 is a nonspecific cation channel. In neuronal cells, TrpV1 is expressed largely on the plasma membrane (although when heterologously expressed in other cell types, it is also expressed intracellularly). Exposure to capsaicin or other TrpV1 ligands gate the TrpV1 channel, allowing large influxes of calcium and thus very large increases in intracellular calcium concentration, which induce cytotoxicity. Cell death is dependent on extracellular calcium and appears to be mediated by activation of calcium-sensitive proteases such as calpain.

Expression of Capsaicin-Sensitive TrpV1 Receptors in Viscerosensory Pathways

TrpV1 was initially described as being expressed exclusively in primary sensory neurons (DRG and nodose ganglia). There is a very intense expression in these neuronal cells, but it is now clear that TrpV1 is also expressed in some populations of epithelial cells, such as the urothelium, where it plays an important role in sensory functioning. There are also some reports of weak TrpV1 expression in the myenteric plexus in the muscularis layer of the duodenum or intestine. It has been amply demonstrated using TrpV1 knockout (KO) mice that TrpV1 expression is responsible for capsaicin sensitivity both in *ex vivo* preparations and *in vivo*.

TrpV1 Receptors in Extrinsic Visceral Afferent Pathways

TrpV1 receptors are preferentially expressed in visceral afferents compared to somatic afferents and are present in the majority of spinal afferents innervating the gastrointestinal tract and the urinary system in rodents. TrpV1 immunoreactivity is lower in the nodose ganglion compared to the DRG. Approximately 40% of cells in the nodose ganglion in rodents express TrpV1-like immunoreactivity. Slightly less than half of the vagal afferents innervating the gastrointestinal tract express TrpV1-IR, but its presence in many of the peripheral terminal structures is below the immunohistochemical detection threshold. In contrast, two-thirds of rat DRG neurons innervating the urinary bladder expressed the TrpV1 receptor when examined using immunohistochemistry. Very similar proportions of TrpV1-positive afferent cell bodies are observed in colonic afferents in rats and mice. A smaller proportion of spinal afferents innervating the lung and pleura in the rat are immunoreactive for TrpV1 (33% and 49%, respectively). However, immunohistochemical detection methods may underestimate the proportion of neurons that express functional TrpV1 receptors and are thus

capsaicin sensitive. For example, more than 95% of DRG cell bodies of afferents innervating the urinary bladder in the rat respond to capsaicin, compared to 69% showing clear TrpV1-like immunoreactivity. Likewise, capsaicin activates between 50% and 90% of bronchopulmonary vagal unmyelinated afferent fibers in mice, whereas immunohistochemical data suggest that approximately 40% of vagal afferents innervating the lungs are TrpV1 positive.

TrpV1 Receptors Expressed in Visceral Epithelium Cells

TrpV1 receptors are highly expressed in the mucosa and muscle layers of the lower urinary tract. Some of this expression is attributable to unmyelinated afferent fibers that also express substance P and CGRP. However, TrpV1 is expressed not only by the afferent fibers located close to the urothelium but also by the urothelial cells. This expression has been extensively studied and shown to be functional.

There are also observations of TrpV1 immunoreactivity in subpopulations of epithelial cells in the small intestine in guinea pigs and in the gastric epithelium in rats. Functional TrpV1 receptors have been demonstrated in cultured human pulmonary epithelial cells. Whereas TrpV1 receptors in the urothelium have an established role in bladder functioning, and in lung epithelial cells appear to be important in the release of inflammatory cytokines, the role of TrpV1 receptors expressed in other epithelia is more speculative. Nonetheless, the presence of TrpV1 receptors in this cell type means that responses to capsaicin and other TrpV1 ligands throughout the viscera should not be interpreted only in terms of neuronal function. Likewise, results from experiments in which capsaicin was used as a desensitizing agent have usually been attributed to loss of afferent terminals; it is possible that modulation of the functions of epithelial cells may also play a role in the results obtained.

Physiological and Pathophysiological Role of Capsaicin-Sensitive TrpV1 Receptors in Viscerosensory Functions

Although the role of capsaicin-sensitive afferents has been extensively studied, the information obtained is difficult to link to specific molecular pathways for the reasons discussed previously. The use of TrpV1 knockout mice and newly described small-molecule antagonists of TrpV1 have shed some light on the potential physiological and pathophysiological role of TrpV1 receptors and on the promise for novel therapeutic approaches.

Functions of TrpV1 Receptors in the Gastrointestinal Tract

TrpV1 receptors in the gut contribute to the sensing of acidosis, a very important feature of gastrointestinal physiology given both the production of strong acids as part of the physiological functions of digestion and the appreciable drop in pH that can be produced by inflammation or ischemia in visceral tissues in general. TrpV1 KO mice show reduced behavioral responses to acid injected intraperitoneally, and jejunal and colonic afferents recorded in these mice are only weakly activated by intraluminal acid. Both jejunal and colonic afferents in TrpV1 KO mice are less mechanically sensitive, particularly to distensions in the noxious range. The TrpV1 channel is not, as far as is known, mechanically gated, so this observation is likely also explained by a response to acidosis. Intense distensions produce ischemia and thus lower muscle pH, thereby activating TrpV1.

TrpV1 receptors are strong candidates for a key role in the sensitization of visceral afferents after tissue injury or inflammation since they are activated and sensitized by a range of inflammatory mediators. However, there is relatively little information on the pathophysiological role of TrpV1 receptors in gastrointestinal pain from animal or human studies. Application of capsaicin to the mucosa of the gut in the mouse produces a short-lived visceral pain response and a very marked, long-lasting hyperalgesia that is referred to the body surface, showing that activation of TrpV1 receptors is sufficient to produce gastrointestinal pain and their sensitization evokes visceral sensitization. However, are TrpV1 receptors necessary for gastrointestinal pain and sensitization during ischemia and inflammation?

In colon primary sensory neurons cultured from TrpV1 KO mice, sensitization to acid, capsaicin, and heat induced by serotonin is absent. Likewise, although the initial response to an inflammatory 'soup' or mixture of inflammatory mediators instilled into the colon was intact in colonic afferents from KO mice, the pronounced sensitization to colonic distension seen in wild-type mice failed to develop. Small-molecule antagonists of the TrpV1 receptor also reduce the severity of dextran-induced colitis in mice, and preliminary data suggest that TrpV1 antagonists reduce pain responses to distension of the inflamed colon in rats.

Taken together, these results suggest that TrpV1 likely contributes to pain from the gastrointestinal tract associated with sensitization of visceral afferents. This conclusion is further supported by observations of increased expression of TrpV1 in biopsies from humans suffering from painful gastrointestinal

disorders. TrpV1 receptor expression is upregulated in tissue samples from patients with esophagitis, painful inflammatory bowel disease, or Crohn's disease and also patients with rectal hypersensitivity. In the latter case, TrpV1 expression was positively correlated with the degree of sensitivity.

Capsaicin-sensitive afferents and TrpV1 also appear to have some protective functions in the gastrointestinal tract. Capsaicin-sensitive afferent fibers protect the gastrointestinal mucosa from acid-induced injury by increasing mucosal blood flow and mucus secretion in the presence of impending acid damage. Activation of the afferents also attracts mucosal inflammatory cells and increases their release of transforming growth factor-α. Furthermore, their presence is required to promote the proliferation of epithelial cells to repair damaged tissue. This role is in part subserved by TrpV1 receptors acting as a sensor of luminal pH, for example, in the duodenum. However, the pH at the epithelial surface is kept neutral by the mucus layer, so the pH level is signaled across the epithelial barrier. This occurs when luminal H^+ combines with secreted HCO_3^- to generate CO_2 (and H_2O). The CO_2 diffuses across the membrane, is hydrated to H^+ and HCO_3^-, and acidifies the epithelial cell, which extrudes H^+ into the interstitial space via anion exchange. Here, it is detected as lowered interstitial pH by TrpV1 receptors on sensory terminals.

Surprisingly, activation of TrpV1 receptors also has some protective functions in inflammation of the colon. Topical application of capsaicin protects against trinitobenzenesulfonic acid-induced colitis in mice, whereas it is enhanced in mice lacking TrpV1 receptors, which contrasts with the previous description of TrpV1 antagonists and genetic ablation of TrpV1 reducing the severity of colitis in mice. The role of TrpV1 in the gastrointestinal tract is complex and likely varies depending on the pathophysiological circumstances.

Role of TrpV1 in Bladder Function

Sensations ranging from fullness to intense pain can be perceived from the urinary bladder and ureters. The signaling of all these sensory events was previously attributed to direct activation of the afferents that innervate the urinary tract, but recent evidence suggests that the bladder epithelial cells, the urothelium, are key players in the transduction of sensory information. The lower urinary tract is lined with a multilayer transitional epithelium that acts as a barrier but that also has dynamic properties, including viscerosensory functions.

Urothelial cells release ATP on stretch and other sensory stimuli. ATP acts on $P2X_3$ receptors located in unmyelinated primary afferents to trigger both normal reflex bladder activity and pain behavior evoked by bladder irritation. Birder and coworkers further investigated the role of urothelial cells in the signaling of sensory stimuli. They found that exogenously applied capsaicin increased intracellular calcium and evoked nitric oxide release from cultured urothelium cells by a process that required TrpV1 receptors. Moreover, mice lacking TrpV1 receptors showed a reduction of ATP release by urothelial cells and a number of alterations in the expression of the micturition reflex indicative of a critical role of urothelial TrpV1 receptors in response to bladder distension.

These studies revealed a novel mechanism for the transduction of sensory stimuli, including those that may evoke pain, by the lower urinary tract. TrpV1 agonists can activate urothelial cells, and this results in the release of ATP into the subepithelial space. Likewise, the same stimuli will also activate the TrpV1 receptors located in the endings of afferent fibers and, additionally, the ATP released by the urothelium will stimulate $P2X_3$ receptors in these afferents, which in turn will evoke sensory events, such as fullness or pain, and reflex activation of bladder activity. The data also suggest a permissive role of TrpV1 receptors in the distension-evoked release of ATP by the urothelium and in the mechanical activation of bladder afferents via intermediate mechanisms not yet identified.

These observations have an immediate clinical relevance regarding the pathophysiology of bladder hypersensitivity. Urothelial cells from cats suffering from a feline equivalent of interstitial cystitis release significantly more ATP; this may account for the enhanced bladder sensitivity characteristic of this condition. Patients suffering from interstitial cystitis also show an increased level of TrpV1 immunoreactivity in the urothelium compared to normal controls. Furthermore, reduction of TrpV1 immunoreactivity after intravesical desensitization with resiniferatoxin is correlated with the degree of functional relief from overactive bladder symptoms in patients.

Role of TrpV1 in the Respiratory Tract

Activation of TrpV1 by capsaicin or other agonists directly evokes cough. A small-molecule TrpV1 receptor antagonist (BCTC) inhibits both capsaicin-induced cough and cough mediated by antigen in sensitized guinea pigs. TrpV1 is increasingly proposed as the mediator, along with other acid sensors such as acid sensing ion channels (ASIC) of acid-induced cough. Thus, TrpV1 seems to play a key role in the generation of the cough response. This is supported by the increase in expression of TrpV1 observed in airway nerves of patients with chronic cough and also

the lowered threshold to capsaicin-induced cough seen in patients with asthma and chronic obstructive pulmonary disease. Likewise, cough is a well-known adverse effect of angiotensin-converting enzyme inhibitors, which prevent the breakdown of bradykinin. Bradykinin sensitizes TrpV1 receptors via phosphorylation as described above.

Capsaicin aerosol application to the lungs also evokes bronchoconstriction, microvascular leakage, and hypersecretion. In humans and several other species, these responses are mediated directly via release of neuropeptides, particularly the tachykinins, from TrpV1-expressing afferents in a process known as neurogenic inflammation. A number of agents implicated in provoking respiratory symptoms are known to sensitize or modulate the TrpV1 receptor, which may thus have a key role in the etiology of these conditions. For example, ethanol-induced asthma is poorly understood, but ethanol sensitizes the TrpV1 receptor such that it can be activated at body temperature. Likewise, there is evidence that the afferent response to reactive oxygen species, important in smoke-induced lung injury, is mediated in part via TrpV1 receptors.

TrpV1 receptors expressed both on afferent nerve terminals and on lung epithelial cells may subserve particulate matter-induced airway inflammation. Activation of bronchial epithelial cells by capsaicin promotes proinflammatory cytokine production and cell death, whereas TrpV1 antagonists or reduction of extracellular calcium attenuate calcium flux and cytokine secretion. Exposure of these cells to particulate matter also evokes calcium fluxes and apoptosis, and these responses seem to be associated with the TrpV1-mediated response since they were abolished in cells treated with antagonists or obtained from TrpV1 KO mice.

TrpV1 receptors are likely responsible for the responses of lung irritant receptors to acidic, chemical, and even particulate matter stimuli. The sensitization and upregulation of TrpV1 receptors may also contribute to their importance during chronic inflammation of the lungs and underlie some of the symptoms which characterize this condition, particularly cough, but also perhaps irritation, discomfort, and chest tightness.

Concluding Remarks

Capsaicin and capsaicin analogs derived from natural products have been extremely valuable tools in dissecting the physiology and pathophysiology of the somatosensory system and in particular viscero-sensory functions. The discovery of the molecular mechanism by which capsaicin exerts its effects with the cloning and description of the TrpV1 receptor and the availability of TrpV1 KO mice has refined our understanding considerably in the past decade. The recent availability of selective small-molecule TrpV1 receptor antagonists which can be used as specific tools in animal studies and which are being assessed in the clinic as potential therapies for multiple disorders will no doubt lead to even greater insights during the next decade.

Vision for Action and Perception

M A Goodale, University of Western Ontario, London, ON, Canada

Introduction

Humans are supremely visual creatures. We depend on vision, more than on any other sense, to perceive the world of objects and events beyond our bodies. At the same time, we also use vision to move around that world and to guide our goal-directed actions. During the past two decades, it has become increasingly clear that the visual pathways that mediate our perception of the world are quite distinct from those that mediate the control of our actions. Indeed, this distinction between 'vision for perception' and 'vision for action' has emerged as one of the major organizing principles of the visual brain, particularly with respect to the visual pathways in the cerebral cortex.

Functional Models of the Two Visual Streams

Our reliance on vision is reflected in the large amount of brain tissue in humans (and in our primate cousins) that is devoted to visual processing. Beyond primary visual cortex, the ascending visual pathways convey information to a complex mosaic of visual areas in the primate cerebral cortex. Despite the complexity of the interconnections between these different areas, two broad 'streams' of projections arising from primary visual cortex in the macaque monkey have been identified: a ventral stream projecting eventually to the inferotemporal cortex and a dorsal stream projecting to the posterior parietal cortex. These streams also receive inputs from a number of subcortical visual structures, including the superior colliculus, which sends prominent projections to the dorsal stream (via the pulvinar). A schematic diagram of these pathways is shown in Figure 1. Although some caution must be exercised in generalizing from monkey to human, a decade or more of neuroimaging evidence suggests that the visual projections from primary visual cortex to the temporal and parietal lobes in the human brain involve a separation into ventral and dorsal streams similar to that seen in the monkey.

Although it is clear that the two streams play different but complementary roles in our visual life, theories regarding the exact nature of the division of labor have changed considerably in recent years. Traditionally, it was thought that the ventral stream plays the critical role in the identification and recognition of objects, whereas the dorsal stream mediates the localization in space of those same objects. This distinction, which has a long history in neurology and neuropsychology, is often referred to as the 'what versus where' hypothesis. Although the evidence that the two streams process different kinds of visual information (object features vs. object location) initially seemed quite compelling, subsequent findings from a broad range of studies in both humans and monkeys have forced a reinterpretation. Recent accounts emphasize differences in the outputs, rather than the inputs, of the two streams. In fact, the consensus now is that both streams process information about object features and about their spatial relations, but each stream transforms this information in different ways for different purposes.

The Perception and Action Model

According to the current understanding, processing in the ventral stream helps to construct the rich and detailed representations of the world that serve as a perceptual foundation for cognitive operations, allowing us to identify objects and events, attach meaning and significance to them, and establish their causal relations. Such operations are essential for accumulating and accessing a visual knowledge base about the world. In contrast, it is believed that the dorsal stream carries out transformations on moment-to-moment information about the location and disposition of objects with respect to the effectors being used in visually guided actions, such as manual prehension, directed at those objects. Thus, the dorsal stream can be regarded as a cortical extension of the dedicated visuomotor modules in the midbrain and brain stem that mediate visually guided movements in all vertebrates. However, although the two streams have different functions and operating principles, in everyday life they have to work together. The perceptual networks of the ventral stream interact with various high-level cognitive mechanisms and enable an organism to select a goal and a particular course of action while the visuomotor networks in the dorsal stream (and their associated cortical and subcortical pathways) are responsible for the programming and on-line control of the particular movements that the chosen action entails.

Studies of Neurological Patients

This division of labor between the two streams is clearly evident in the pattern of deficits and spared

Figure 1 The two streams of visual processing in human cerebral cortex. The retina sends projections to the dorsal part of the lateral geniculate nucleus (LGNd), which projects in turn to primary visual cortex. Within the cerebral cortex, the ventral stream (blue arrow) arises from early visual areas and projects to the inferotemporal cortex. The dorsal stream (red arrow) also arises from early visual areas but projects instead to the posterior parietal cortex. The posterior parietal cortex also receives visual input from the superior colliculus via the pulvinar. The approximate locations of the pathways are shown on a three-dimensional reconstruction of the pial surface of the brain. The two streams, which involve a series of complex interconnections, are marked in blue (ventral stream) and red (dorsal stream). Adapted from Goodale MA and Westwood DA (2004) An evolving view of duplex vision: Separate but interacting cortical pathways for perception and action. *Current Opinion in Neurobiology* 14: 203–211.

visual abilities seen in neurological patients with selective damage to the dorsal or ventral stream. Thus, patients with lesions in the superior regions of the posterior parietal cortex, the major terminus of the dorsal stream, typically have problems using vision to direct a grasp or aiming movement toward the correct location of a visual target placed in different positions in the visual field, particularly the peripheral visual field. This particular deficit is often termed optic ataxia. However, the failure of these patients to locate an object with the hand cannot be construed as a problem in spatial vision: many of them, for example, can describe the relative position of the object in space quite accurately, even though they cannot direct the affected hand toward it. Optic ataxia patients also typically have no difficulty using input from other sensory systems, such as proprioception or audition, to guide their movements. Other research has shown that many of them not only show visual misreaching but also are unable to use visual information to rotate their hand, scale their grip, or configure their fingers properly when reaching out to pick up objects, even though they have no difficulty describing the orientation, size, or shape of those objects. In addition, they do not take into account the positions of potential obstacles when they are attempting to reach out toward goal objects. All of this confirms the critical role that the dorsal stream plays in the visual control of skilled actions. The patients exhibit neither a purely visual nor a purely motor deficit but instead a specific deficit in visuomotor control.

The opposite pattern of deficits and spared abilities has been described in patients with damage to the ventral stream. The best documented case is patient D.F., a young woman who developed a profound visual form agnosia following carbon monoxide poisoning. Structural magnetic resonance imaging showed evidence of diffuse damage consistent with hypoxia but with specific lesions in ventrolateral regions of the occipital cortex, with primary visual cortex remaining largely spared (Figure 2). Even though D.F.'s contrast sensitivity and other low-level visual abilities remain reasonably intact, she can no longer recognize everyday objects or the faces of her friends and relatives, nor can she identify or copy line drawings of common objects or even simple geometric shapes. (If an object is placed in her hand, of course, she has no trouble identifying it by touch.) Remarkably, however, D.F. shows strikingly accurate guidance of her hand and finger movements when she attempts to pick up the very objects she cannot identify (Figure 3). Thus, when she reaches out to grasp objects, her hand opens wider midflight for larger objects than it does for smaller ones, just as is the case in people with normal vision. She also takes into account the position of potential obstacles in the immediate vicinity of a goal object to which she is reaching. Similarly, she rotates her hand and wrist quite normally when she reaches out to grasp objects in different orientations, and she places her fingers optimally around the edges of objects of different shape. At the same time, she is quite unable to distinguish between any of these objects when they are presented to her in simple discrimination tests. She even fails in manual 'matching' tasks in which she is asked to show how wide an object is by opening her index finger and thumb a corresponding amount. D.F.'s spared visuomotor skills are not limited to grasping. She can step

Figure 2 Area LO, a ventral stream area implicated in object recognition (particularly object form), has been localized on the brain of a healthy control subject by comparing fMRI activation to intact versus scrambled line drawings. Note that the lesion (marked in blue) on patient D.F.'s right cerebral hemisphere encompasses all of area LO. Area LO in D.F.'s left hemisphere is also completely damaged. Adapted from Goodale MA and Milner AD (2005) *Sight Unseen: An Exploration of Conscious and Unconscious Vision*. Oxford: Oxford University Press.

Figure 3 Graph showing the size of the aperture between D.F.'s index finger and thumb during object-directed grasping and manual estimates of object width. Her maximum grip aperture in flight (individual trials shown in red) was sensitive to the size of the target object, opening wider for the 50 mm-wide object than for the 25 mm-wide object. However, her manual estimates of the width of the two objects (individual trials shown in blue) were grossly inaccurate and show enormous variability from trial to trial.

over obstacles during locomotion as efficiently as controls, even though her perceptual judgments about the height of these obstacles are far from normal. In short, a profound loss of form perception coexists in D.F. with a preserved ability to use information about the form of objects to guide a broad range of actions. The contrast between what D.F. can and cannot do is exactly what one would expect in someone with a damaged ventral 'perception' stream but a functionally intact dorsal 'action' stream.

Studies in Nonhuman Primates

Lesion studies in the monkey paint a remarkably similar picture to that seen in neurological patients. For example, monkeys with lesions of inferotemporal cortex (ITC) can orient their fingers in a precision grip to grasp morsels of food embedded in small slots placed at different orientations, even though their ability to discriminate between different orientations is profoundly impaired. In short, such monkeys behave rather like patient D.F.; they have spared visuomotor abilities in the face of a profound visual agnosia. In contrast, monkeys with lesions to the posterior parietal cortex (PPC) show the opposite pattern, behaving like patients with optic ataxia.

In addition to the lesion studies, there is a long history of single-unit work in monkeys showing that cells in ITC and neighboring regions of the superior temporal sulcus are tuned to specific objects and object features – with some cells maintaining their selectivity irrespective of viewpoint, retinal image size, and even color. Moreover, the responses of these cells are not affected by the animal's motor behavior but are instead sensitive to the reinforcement history and significance of the visual stimuli that drive them. It has been suggested that cells in this region might play a role in comparing current visual inputs with internal representations of recalled images, which are themselves presumably stored in other regions, such as the medial temporal lobe, related limbic areas, and the prefrontal cortex, with which the ITC is reciprocally connected. In fact, sensitivity to particular objects can be created in ensembles of ITC cells simply by training the animals to discriminate between different objects. There is also evidence for a specialization within separate regions of the monkey's ventral stream for the coding of certain categories of objects, such as faces and hands,

which are of particular social significance to the monkey. Finally, studies using a binocular rivalry paradigm, in which competing images are presented at the same time to the two eyes, have shown that cells in ITC are tuned to what the monkey reports seeing on a particular trial and not simply to what is present on the two eyes (which remains invariant). However, neurons earlier in the visual system, such as those in area V1, do not show these correlations, instead responding equally strongly no matter which of the competing stimuli dominates the monkey's current perception. Taken together, these results provide support for the claim that the ventral stream plays a critical role in delivering the contents of our conscious percepts. These and other studies also suggest that 'object-based' descriptions are created in the ventral stream – that is, ones that can generalize across different viewpoints. These descriptions then form the basic raw material for visual perception, recognition memory, and long-term representations of the visual world.

In sharp contrast to the activity of cells in the ventral stream, the responses of cells in the dorsal stream are greatly dependent on the concurrent motor behavior of the animal. Thus, separate subsets of visual cells in the PPC have been shown to be implicated in visual fixation, pursuit and saccadic eye movements, visually guided reaching, and the manipulation of objects. Moreover, this motor involvement is quite specific. Thus, neurons in the lateral bank of the intraparietal sulcus (LIP) code the location of a target for a saccadic eye movement, whereas neurons in more medial regions of the intraparietal sulcus extending into the superior regions of the PPC code the location for a manual aiming movement to the same target (the parietal reach region (PRR)). Neurons in the anterior intraparietal sulcus (area AIP), which fire when the monkey manipulates an object, have been shown to be sensitive to the visual features of the object, such as its size and orientation, that determine the posture of the hand and fingers during a grasping movement. The PPC is also intimately linked with premotor cortex, the superior colliculus, the pontine nuclei, and other brain stem areas – structures that have been implicated in various aspects of the visual control of eye, limb, and body movements. In summary, the networks in the dorsal stream have the functional properties and interconnections that one might expect to see in a system concerned with the moment-to-moment control of visually guided actions.

Human Neuroimaging

With the advent of neuroimaging, particularly functional magnetic resonance imaging (fMRI), it has been possible to map the ventral and dorsal streams in the human brain. These studies have revealed an organization of visual areas in the human brain that is remarkably similar to that seen in the macaque. Although clear differences in the topography of some of the areas emerge as one moves from monkey to human, the functional separation into a ventral and a dorsal pathway is clearly preserved. Thus, different areas in the inferior occipitotemporal region appear to be specialized for the processing of the color, texture, and form of objects. Also, as in the monkey, activation studies have identified regions in the ventral pathway for the processing of faces that are distinct from those involved in the processing of other objects. In the dorsal stream, regions have been found that are activated when subjects engage in visually guided movements such as saccades, reaching movements, and grasping, corresponding respectively to areas LIP, PRR, and AIP, as described in the monkey. Thus, the neuroimaging data confirm that the human cerebral cortex includes both dorsal and ventral visual streams very much like those of the monkey, and that these streams have functional characteristics resembling those first identified in the monkey. In other words, areas in the posterior parietal cortex are involved in the visual control of action, whereas areas in the occipitotemporal region play a critical role in object recognition.

The Operating Principles of the Dorsal and Ventral Streams

The existence of two separate cortical visual pathways reflects the fact that perception and action each require their own particular transformations to be carried out on the incoming visual information. To be able to grasp an object successfully, for example, it is essential that the brain (specifically the dorsal stream) compute the actual (absolute) size of the object and its orientation and position with respect to the observer. Moreover, the information about the orientation and position of the object must be computed in egocentric frames of reference – in other words, in frames of reference that take into account the orientation and position of the object with respect to the effector that is to be used to perform the action. However, the time at which these computations are performed is also critical. Observers and goal objects rarely stay in a static relationship with one another and, as a consequence, the egocentric coordinates of a target object can often change dramatically from moment to moment. For this reason, it is essential that the required coordinates for action be computed immediately before the movements are initiated. For the same reason, it would be counterproductive for

these coordinates (or the resulting motor programs) to be stored in memory. In summary, the vision-for-action systems in the dorsal stream need to work in an on-line mode.

The situation is quite different for perception, in terms of both the frames of reference used to construct the percept and the time period during which that percept (or the information it provides) can be accessed. Vision for perception appears not to rely on computations about the absolute size of objects or their egocentric locations. Instead, the perceptual system in the ventral stream computes the size, location, shape, and orientation of an object primarily in relation to other objects and surfaces in the scene. Encoding an object in a scene-based frame of reference permits a perceptual representation of the object that preserves the relations between the object and its surroundings without requiring precise information about its absolute size or its exact position with respect to the observer. Indeed, if our perceptual machinery attempted to deliver the real size and distance of all the objects in the visual array, the computational load on the system would be astronomical.

The products of perception also need to be available over a much longer time scale than the visual information used in the control of action. We may need to recognize objects that we have seen minutes, hours, days, or even years ago. To achieve this, the coding of the visual information has to be somewhat abstract – transcending particular viewpoint and viewing conditions. By working with perceptual representations that are object or scene based, we are able to maintain the constancies of size, shape, color, lightness, and relative location over time and across different viewing conditions. There is much debate in the object recognition literature about how this is accomplished. Some of the mechanisms underlying object perception might use a network of viewer-centered representations of the same object, others might use an array of canonical representations, and still others might be truly 'object-centered.' However, whatever the nature of the coding might be, it is the identity of the object and its location within the scene, not its disposition with respect to the observer, that is of primary concern to the perceptual system. In other words, we can recognize objects that we have seen before, even though the position of those objects with respect to our body might have changed considerably since the last time we saw them. Of course, this stored information is not only available for mediating recognition of previously encountered objects but can also potentially contribute to the control of our movements when we are working in off-line mode.

The contribution of the ventral stream to the off-line control of object-directed actions, such as grasping, can be seen in the differential effect that delaying such actions has on the behavior of patients with lesions of the ventral or dorsal stream. Patient D.F., for example, who is able to grasp an object accurately in real time, shows no scaling of her grasp to the size of the target object when the object is removed after an initial viewing period and she is asked to 'pantomime' how she would have picked it up (Figure 4). Evidently, she has no working memory of the object – not because her memory system is impaired but, rather, because her ventral stream lesion prevents her from perceiving the dimensions

Figure 4 Graph showing the maximum grip aperture for real-time and pantomimed grasping movements performed by patient D.F. When D.F. picked up an object in real time, her grip aperture was correlated with the width of the target object (left). When she was shown one of the objects and then 2 s later was asked to pantomime how she would pick it up (the object had been removed), her grip aperture showed no relation to the size of the object (right). Adapted from Goodale MA, Jakobson LS, and Keillor JM (1994) Differences in the visual control of pantomimed and natural grasping movements. *Neuropsychologia* 32: 1159–1178.

of the object in the first place. Optic ataxic patients have exactly the converse problem (Figure 5). Because of the damage to their dorsal stream, they show no sign of scaling their grasp to the size of objects in real time. However, in the pantomime task, they perform just like healthy subjects – presumably because they are no longer activating the visuomotor mechanisms in their damaged dorsal stream but are engaging instead their intact ventral stream. These results illustrate what may be the most important single task of the ventral stream: it allows us to use vision off-line, providing a bridge from the past to the present.

Although the dorsal stream does not appear to have a visual memory, the visuomotor activities to which it contributes clearly do benefit from experience. In fact, most of our visually guided actions are as skilled as they are precisely because they are well honed by practice. It seems likely that as our initially slow and painstaking efforts become more automatic, the contribution of the ventral stream to visual control retreats and is replaced by more streamlined circuitry involving the dorsal stream, related frontal cortical areas, and subcortical structures in the brain stem and cerebellum.

The differences in the spatial metrics and frames of reference used by the dorsal and ventral streams, mentioned previously, can be seen in the way in which normal observers respond to stimuli that are distorted by pictorial illusions. For example, the opening of a grasping hand is typically insensitive to the Ebbinghaus illusion, in which a target disk surrounded by smaller circles appears to be larger than the same disk surrounded by larger circles, despite the fact that grip opening is exquisitely sensitive to real changes in the size of the target disk (Figure 6). In fact, grip aperture is not affected by the illusion even when the hand and target are occluded from view during the performance of the action, indicating that on-line visual feedback during grasping is not required to 'correct' an initial perceptual bias induced by the illusion.

Of course, the perception–action model does not predict that actions must be immune to all visual illusions. Some illusions, after all, arise so early in visual processing that they would be expected to affect both perception and action. Illusions that depend on 'top-down' knowledge of the world, however, would certainly be predicted to leave actions unaffected. One particularly striking example of such an illusion is the 'hollow face' illusion, in which knowledge of what faces look like impels observers to see the inside of a hollow mask as if it were a normal protruding face (Figure 7). Despite the fact that observers cannot resist this compelling illusion, rapid actions that they direct at the face are immune to it. Thus, when observers are asked to flick off a small 'buglike' target stuck on the face, they unhesitatingly reach out to the correct point in space, even if this means that their hand goes inside the hollow mask. This striking dissociation between what one sees and what one does provides a dramatic demonstration of the simultaneous engagement of two parallel visual systems – each constructing its own version of reality.

Conclusion

Although similar (but not identical) visual information about object shape, size, orientation, and

Figure 5 Graph showing the maximum grip aperture for real-time and pantomimed grasping movements performed by optic ataxia patient I.G. When I.G. picked up objects in real time, her grip apertures were uncorrelated with the widths of the target objects (left). However, when she was shown one of the objects and 5 s later was asked to pantomime how she would pick it up (the object had been removed), the correlation between her pantomimed grip apertures and the widths of the objects became highly significant (right). Figure 6 The effect of a size-contrast illusion on perception and action. (a) The traditional Ebbinghaus illusion in which the central circle in the annulus of larger circles is typically seen as smaller than the central circle in the annulus of smaller circles, even though both central circles are actually the same size. (b) The same display, except that the central circle in the annulus of larger circles has been made slightly larger. As a consequence, the two central circles now appear to be the same size. (c) A three-dimensional version of the Ebbinghaus illusion. Participants are instructed to pick up one of the two three-dimensional disks placed either on the display shown in panel a or the display shown in panel b. (d) Two trials with the display shown in panel b, in which the participant picked up the small disk on one trial and the large disk on another. Although the two central disks were perceived as being the same size, the grip aperture in flight reflected the real, and not the apparent, size of the disks. Adapted from Aglioti S, DeSouza J, and Goodale MA (1995) Size-contrast illusions deceive the eyes but not the hand. *Current Biology* 5: 679–685.

Figure 7 Perceptual judgments and visuomotor control with the hollow-face illusion. (a) A small magnet was placed on either the cheek or the forehead of the normal face (left) or the hollow mask (right). Participants were required either to flick the magnet from the normal or illusory (actually hollow) face or to estimate its distance psychophysically. The inset shows a photograph of bottom-lit hollow face, in which the illusion of a normal convex face is evident. (b) (Left) The mean psychophysical (perceptual) judgments of the apparent position of the magnets on the illusory and normal face with respect to the reference plate from which the two displays either protruded or receded. Note that participants perceived the hollow face as protruding forward like the normal face. (Right) The mean distance of the hand at the moment the participant attempted to flick the target off the cheek or forehead of the illusory (actually hollow) or the normal face. In the case of the illusory face, the end points of the flicking movements corresponded to the actual distances of the targets, and not to consciously seen distances. Error bars indicate the standard error of the mean. Adapted from Kroliczak G, Heard P, Goodale MA, and Gregory RL (2006) Dissociation of perception and action unmasked by the hollow-face illusion. *Brain Research* 1080: 9–16.

location is processed by both cortical visual systems, the transformational algorithms that are applied to these inputs are uniquely tailored to the function of each system. It is the nature of the functional requirements of perception and action that lies at the root of the division of labor that has emerged in the ventral and dorsal visual projection systems of the cerebral cortex during primate evolution.

Vision: Light and Dark Adaptation

A Reeves, Northeastern University, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

The visual system works effectively over an enormous range of light intensities, from starlight to bright sunlight. This is made possible by the system's remarkable ability to adjust its operating level to match the ambient illumination. Light adaptation is the adjustment of the eye to higher levels of illumination; dark adaptation is the reverse. The study of adaptation is important for a variety of practical reasons, as well as for an understanding of basic visual function. Adaptation is mediated by a combination of actions. Narrowing the pupil aperture in bright light is one of these. In species like ours, with round rather than slit pupils, constriction of the pupil reduces retinal illumination by about a decade (10 times), a small part of the entire adaptive range (14 decades). The main mechanisms of adaptation in the human eye lie within the receptors and neural structures of the retina. The human retina, like that of many species, is duplex; it possesses both a photopic system that works at the high levels of illumination provided by daylight, and a scotopic system that works at the low levels provided by starlight and moonlight. There is also an intermediate, or mesopic, range in twilight, in which both systems function. The photopic system employs cone receptors; the scotopic, rods. The large range of adaptation seen in the human eye is achieved by a change from one system to the other, as well as by adjustments of sensitivity within each system. In other species, pigment and/or receptor migration may also reduce the impact of high levels of illumination.

Regimes of Adaptation

The two adaptive regimes, scotopic and photopic, operate quite differently. In starlight there are few ambient photons, and so the ability of the dark-adapted visual system to detect individual photons becomes critical. Rod photopigments can respond to individual photons, and a massive amplification in the main rod pathway permits such minute events to initiate neural activity. Indeed, the efficiency of this scotopic system in starlight approaches the ideal level set by physical optics. Moonlight provides more ambient photons than does starlight, and at light levels over about 300 photons/rod/second, the massive amplification saturates the main rod pathway and the rod signals must now travel through a second rod pathway to initiate vision, one with considerably less amplification. In twilight, both cones and rods are active; the transition from scotopic to photopic vision is indicated by the term 'mesopic.' During this transition, cones still act like rods in that they respond to small numbers of photons. In sunlight, the entire scotopic system saturates – the rods no longer provide any useful information at all – and the photopic system takes over. At these higher light levels, the photopic system is protected by a progressive light adaptation of the cones from the saturation that effectively turns off the scotopic system. The photopic system now begins to differ fundamentally from the main rod pathway in that it no longer attempts to record every photon – there are so many that this is pointless – but rather it encodes the contrasts which specify the visible surfaces in the world as darker or lighter than their surrounds. Encoding contrast implies discounting the ambient illumination level (the space-averaged number of photons); so long as there is enough light for the world to be visible everywhere, just how brightly it is illuminated is of no great consequence. At ever higher light levels, sensitivity to contrast is maintained – one can see details on a bright beach, or in snow illuminated by the midday sun, as long as the cones are sufficiently light adapted.

Dark Adaptation

The time course of dark adaptation can be illustrated by the solid circles in Figure 1, which show thresholds obtained by first exposing the eye to a very bright light, and then plunging it into total darkness. The detection threshold, which is the intensity of light just needed for an observer to detect a brief test flash, was determined at regular intervals as dark adaptation progressed, as shown by the successive solid circles (open circles are discussed later). The plot reveals a descending curve, as decreasing amounts of light are needed to see the test flash as time goes by. Intensities below the threshold are invisible; those above it, visible. The curve has two limbs. In the first 2 min, detection thresholds drop rapidly and then taper off on a plateau. After a few more minutes, the curve again drops rapidly, reaching a final level, the 'absolute' threshold, after about 25 min. The vertical scale is logarithmic: the entire decrease in threshold of 3.3 $\log_{10}$ units from start to end corresponds to a change in test intensity of 2000 times. These progressive drops in threshold correspond to increases in visual sensitivity, first of the photopic system and then of the scotopic system. The change from one system to the other is called the rod–cone break, which occurs at about 7 min in Figure 1. There is a corresponding shift, known as the Purkinje shift, in the peak spectral

Figure 1 Dark adaptation. The solid black circles show the threshold for detection (in log units) against the length of time the eye has been in darkness (in minutes). The dashed line is an extrapolation of the upper or photopic limb of the implied curve. The lower limb is scotopic. The open circles show a specific threshold, that for just noticing hue; this threshold rises above the extrapolated line once the rods have begun to recover. Flashes were green and presented parafoveally (6° from the fovea). The observer initially adapted to a large white 4 lumens per cm^2). Adapted Lie I (1963) Dark adaptation and the photochromatic interval. *Documenta Ophthalmologica* 17: 411–510.

sensitivity of the eye from 555 nm (the photopic maximum) before the break, to 500 nm, the maximum sensitivity of rhodopsin (the rod photosensitive pigment), after it. Test lights with intensities just above detection threshold appear colored if flashed before the break, indicating cone function, and colorless after it, indicating rod function. The solid circles in Figure 1 show a dark adaptation curve produced by a middle-wavelength test flash delivered to the parafovea – that is, a retinal position outside the fovea, where both rods and cones are numerous. When the dark adaptation curve is measured with long-wavelength tests invisible to the rods, or with test flashes restricted to the rod-free fovea, there is only a photopic limb, as indicated by the dashed line. The two limbs of the dark adaptation curves can be translated vertically (on a logarithmic scale of intensity) by altering the preadaptation light in wavelength composition or in level, and by altering the test flash in wavelength, size, location on the retina, and duration. These are all factors governing visual sensitivity; for example, a larger test flash will lower thresholds due to spatial summation in the retina. However, if the two limbs do appear, their time courses will be as shown. This invariance in recovery provides behavioral evidence that the temporal recovery of each class of photoreceptor is independent of the adaptive states of the other classes of photoreceptor.

Given that the recovery of each class of photoreceptor can be followed independently, it becomes easier to study the biochemical and physiological processes which account for such recovery. Vision begins with phototransduction – that is, with the capture of an individual photon by a visual pigment molecule (rhodopsin) in a photoreceptor. Capture has two effects. First, it causes the isomerization (change of shape) of a small component of the molecule, retinal, from its 11-*cis* to its all-*trans* form. This generates various forms of metarhodopsin and a G-protein enzyme cascade which massively amplifies the minute photon-capture event, permitting signaling molecules to modify the cell membrane potential and indicate the presence of light to other retinal neurons. Hence after extended dark adaptation, individual photons of light can be detected. Second, capture will also bleach the photopigment molecule, which becomes transparent. Only unbleached photopigment molecules respond to light. As dark adaptation progresses, more and more of the photopigment molecules recover from the bleached state and again become available for capturing photons. It might seem that this effect could account for the recovery of the detection threshold seen in Figure 1. However, threshold elevation is out of all proportion to any loss due to bleaching; for example, a bleach of only 20% of the pigment can raise rod thresholds more than 1000 times, and thresholds remain considerably elevated even when nearly all of the photopigment has recovered from bleaching. Therefore the photon-catching ability of the photoreceptors alone does not regulate visual threshold. It is thought instead that the various photoproducts of bleaching – the various metarhodopsins and free opsin – which remain in the receptors when the eye is plunged into darkness act to 'veil' the incoming test flash and thus elevate threshold. It is their progressive removal which permits threshold to recover in the dark. The term 'veil' is used by analogy, as thresholds for foveal test flashes can also be elevated by glare sources such as automobile headlamps, which, when placed in the periphery of the visual field, generate a veil of real light across the eye. In 1933, WH Stiles and BH Crawford (see Wyszecki and Stiles in 1982) showed psychophysically that, following bleaches, the human visual system behaves as though it experienced a veil equivalent to real light. Unlike the real light with which it can be equated, equivalent light is usually not visible (one sees darkness, not an afterimage, during the course of dark adaptation), but this is no paradox, as real lights also become invisible if, like equivalent light, they are retinally stabilized. Equivalent light is generated in the receptors in at least two different ways. The photoproducts of bleaching may either occasionally revert to activated rhodopsin and generate false

alarms (reports of light where none exists), or they may act directly on the phototransduction mechanism itself. At the start of dark adaptation, the scotopic threshold is primarily controlled by this second mechanism, which is initially dominant but which recovers relatively quickly, thus accounting for the relatively fast initial drop of threshold following the rod–cone break in Figure 1. The subsequent slow recovery of scotopic vision to its final absolute threshold is primarily due to a slow reduction in the frequency of the photonlike events contributed by the first mechanism.

The classic recovery curve shown by solid circles in Figure 1, the curve obtained when each photoreceptor class is effectively isolated, applies if the observer 'detects' the presence of the test flash. Detection can be based on any visual sensation at all; the observer is not required to classify the sensation. However, dark adaptation may be measured with test flashes whose thresholds are determined by a specific sensation. For example, the specific threshold for seeing color, which achieves its minimum after 2 min, may rise by up to a decade after several more minutes in the dark (Figure 1, open circles). This, the Lie effect, does not occur in the rod-free fovea. It illustrates a so-called rod–cone interaction in which recovering rod vision interferes with the perception of hue mediated by the cones. This interaction must occur at some postreceptoral neural site, not in the receptors themselves, since rod and cone detection thresholds recover independently of one another.

The classic recovery curve shown by solid circles in Figure 1 can be violated in other ways as well. For example, thresholds mediated by the pathways encoding rapid luminance flicker and hue may be elevated by 10 to 100 times when the adaptation light is turned off, and remain elevated for the first minute or so of dark adaptation. A case of especial interest is that of transient tritanopia, the temporary blue blindness which can occur after turning off a long-wavelength adapting field, because in this case the field light-adapts the long- and middle-wave sensitive cones but not the short-wave cones responsible for detecting the test flash. The normal course of dark adaptation is therefore reversed at a postreceptoral neural site, not by processes in the receptors. These dramatic violations of the usual course of dark adaptation depend strongly on the wavelength composition and luminance of the adaptation light. They have not yet received detailed explanation at the physiological level, although some of the data are compatible with an opponent-process account. Summarizing, the continual recovery of vision shown by the solid symbols in Figure 1, though taken as the standard, is not always representative.

Light Adaptation

One measure of the extent of light adaptation is provided by the incremental threshold. This is the threshold for detecting a test flash against a steady, uniformly lit background to which the observer has been adapted for several minutes. Some typical results are shown in Figure 2(a). Figure 2(a) shows a plot of the incremental threshold as it depends on the luminance of the background. At low levels, the background has no effect, but as the background is raised, the threshold rises, at first gradually and then more rapidly. At higher levels, there is a second plateau followed by a second rise. As in dark adaptation curves, the two limbs of the plot can be attributed to the participation of the rod and cone systems. When the eye is adapted to low levels, the rod system is the most sensitive, but at higher levels of light adaptation, scotopic sensitivity drops below that of the cones.

As in the case of the dark adaptation curve, the limbs of the increment threshold curve depend on the testing conditions, such as the size of the stimuli, their location on the retina, and their spectral composition. The example just examined is typical of orange–yellow stimuli presented against a blue–green background. Other conditions result in a less conspicuous separation of the two retinal systems. A blue stimulus, which favors the scotopic system, presented against a red adaptation, which is effective in reducing the sensitivity of the photopic system, can produce an increment threshold curve in which the scotopic system is completely uncovered, as shown in Figure 2(b).

Different sectors of the curve shown in Figure 2(b) may be distinguished for theoretical as well as descriptive purposes. Throughout the middle of the range the curve slope is nearly 1.0 on logarithmic axes, and therefore approximates Weber's law, that the ratio of increment threshold to background intensity is constant. At the upper end the curve swings steeply upward; this is known as the saturation region (if saturation were complete, threshold could never be reached, no matter how bright the test light). At the lower end the curve bends and becomes horizontal, thus marking the region where the background is too weak to have an effect. The inset shows the stimulus arrangement in which a small test is flashed on a large, steady, adapting field to which the eye is continuously exposed; if the test and field have the same size, other color mechanisms are revealed. Several theoretical accounts of the incremental threshold curve have invoked Fechner's original concept of an intrinsic activity or noise within the receptor systems (I_0) that combines with the excitation produced by

Figure 2 The log incremental threshold (ΔI) is plotted against the intensity of the background field (I) (units are arbitrary, but on a $\log_{10}$ scale). Zero on the abscissa represents no background. The lower branch describes the sensitivity of the scotopic system; the upper, that of the photopic. (b) The scotopic increment threshold is plotted against the intensity of the field or background, expressed relative to the 'dark light' (I_0) appropriate for the receptor class (rods) being studied. The dark light and Weber's law portions apply to rods and cones equally. Conditions favored detection by rods over a very wide range. The upper section illustrates saturation in rods, with cones just starting to take over at the very top. (Saturation is absent in cones.) The smooth curve is a theoretical prediction (see text). Axes are in $\log_{10}$ units. (c) Increment threshold for a 475 nm test flash superimposed on a steady, 550 nm field of the intensity shown (in arbitrary units) on the abscissa. Curves obey $\Delta I = K(I + I_0) = k(1 + I/I_0)$. (a–c) From Wyszecki G and Stiles WS.

the background (I) to raise the threshold (ΔI). The smooth curve in Figure 2(b) is of this form, $\Delta I = K(I + I_0) = k(1 + I/I_0)$, and it accounts for all but the saturating portion of the data with an appropriate choice of the constant $K = k/I_0$. In the same vein, dark adaptation and incremental threshold curves have been related to one another with some success by postulating that I_0 characterizes the dark light or equivalent light described previously (see the section titled 'Dark adaptation'). It is important to emphasize that the curve shown in Figure 2(b) plots the effect of light adaptation on threshold for detection, but not necessarily on other aspects of visual function. For example, the central section of a curve plotted on the same logarithmic coordinate system which expresses the effects of field intensity on perceived brightness has a slope near 0.5 rather than one of 1.0, as shown by LG Brown and ME Rudd; these authors take the slower growth of brightness (as compared to threshold) to be evidence for an adaptive gain control. Our

knowledge of light adaptation as presented by detection thresholds is fairly complete, but this is not so for all aspects of visual function.

The procedures of light and dark adaptation are useful for investigating color vision. If, for example, incremental thresholds are measured with monochromatic test flashes presented against monochromatic backgrounds, the photopic sector shown in Figure 2(a) may break up, depending upon the particular wavelengths used, into two or more constituent limbs. By measuring the incremental threshold function systematically for a wide range of test and adaptation wavelengths, it is possible to determine the spectral sensitivities of these limbs and thus to define the color processes they represent, as demonstrated by WS Stiles and illustrated in Figure 2(c) for the blue- and green-sensitive mechanisms isolated with a 475 nm test flash exposed on a 550 nm field. Color processes may also be inferred from dark adaptation curves measured with monochromatic test stimuli following preexposure to monochromatic backgrounds.

The time course of chromatic light adaptation depends not only upon stimulus wavelength and intensity, as just discussed, but also, although to a lesser extent, on the spatial configuration of the stimuli. For example, adaptation to a green field, but not a blue field, is hastened when the spatial frequencies and orientations of the test and the field match. These data suggest that the neural processes subserving spatial vision integrate over the hue pathways in a manner which depends on their states of adaptation.

Rapid Adaptation Change

The initial changes in visual sensitivity, those that accompany the very onset of light and dark adaptation, are also of considerable interest. These have been measured by superimposing a small, brief test flash upon a large adaptation background that is switched on and off periodically. The timing between the test flash and the adaptation light is under experimental control. The detection threshold measured when the adaptation background is on is an incremental threshold, while that measured with it off is an absolute threshold (i.e., a threshold in darkness). This type of experiment, therefore, helps to define the transition from one type of threshold measure to the other. Thresholds (Figure 3) for detecting the test flash begin to rise shortly before the onset of the adaptation light, reach a maximum at onset, drop, and then climb to a second but lower maximum at the time of offset. Sensitivity then returns fairly quickly. The fact that the detection threshold starts to rise before the onset of the adaptation stimulus was attributed by its discoverer, Brian Crawford, to the speed with which

Figure 3 Incremental threshold as measured against a slowly flashing background. The 0.5 s epoch that the background is on is indicated. From Crawford BH (1947) Visual adaptation in relation to brief conditioning stimuli. *Proceedings of Royal Society of (London)* B134: 283.

information travels through the visual system. The relatively weak test flash gives rise to signals that travel more slowly to the level of the visual system where the threshold decision is made than do those of the stronger adaptation stimulus. This explanation does not account for the second maximum at field offset. Another hypothesis points to the large visual responses at field offset and onset seen in the electroretinogram; such responses may momentarily saturate the visual pathway responsible for detection. Yet further theoretical explanations have been developed over the years and are categorized under the heading of visual masking; none are definitive.

Electrophysiological Evidence

The phenomena of dark and light adaptation have been investigated electrophysiologically, using single-unit recording, single-cell recording, and electroretinography in various animal species, or just electroretinography in humans, with the goal of explaining the changes that occur with extended exposure to light or darkness. Retinal potentials often show a progressive increase in responsiveness that advances with dark adaptation. They are thus useful because they provide objective information regarding the visual process away from the threshold conditions to which psychophysics is limited. Although the changes seen with light and dark adaptation resemble those seen psychophysically, exact comparisons between data provided by the two methods are difficult because conditions are rarely comparable: retinal electrophysiology is typically conducted with large, bright stimuli to obtain measurable responses, whereas psychophysics is usually conducted with localized near-threshold test flashes. This is not necessarily the case, however. Experiments with suitable procedures have effected such comparisons and thus have helped to clarify

understanding of the adaptation process. Even the reduction of blue sensitivity found psychophysically at the start of dark adaptation (transient tritanopia) has been seen in the electroretinogram by D van Norren. Thus although a complete description of light and dark adaptation remains some way off, various aspects of these processes have yielded to intense scrutiny at both the electrophysiological and the behavioral levels.

Primary Visual Cortex

Primary visual cortex is the site of a remarkable transformation in the neural representation of the visual world. The afferent neurons of the retina and the primary visual thalamus, which relays the retinal signals to the primary visual cortex, have circularly symmetric receptive fields and respond to almost any stimulus, as long as the stimulus falls within a broad range of sizes. In sharp contrast, the neurons of primary visual cortex are exquisitely sensitive to several complex stimulus attributes, including orientation of a contour, direction of motion, size, and binocular disparity. In many cases, selectivity is absolute: cortical neurons will not respond at all unless the stimulus matches the neuron's preferences for each of these attributes.

Primary visual cortex has become a model system for neuronal processing by the circuitry of the cerebral cortex. Ultimately, we would like to understand how the higher cortical areas give rise to our recognition of sensory stimuli, decision making, and language comprehension. But, we barely have a way of defining what tasks are performed in these areas, let alone how they are performed. By comparison, the transformations performed by the primary visual cortex on its thalamic inputs – the extraction of orientation and direction information, for example – are complex enough to be interesting, but simple enough to be tractable. The neuronal mechanisms by which cortical receptive properties emerge have therefore become the subject of intense scrutiny and debate.

Orientation Tuning

The basic phenomenon of orientation selectivity is very simple and striking. As Hubel and Wiesel originally demonstrated in their Nobel Prize-winning work of 1962, when a bar or contrast edge is flashed in or moved across a cortical neuron's receptive field at the neuron's preferred orientation, the neuron responds vigorously with a barrage of action potentials. When the stimulus is presented within the same region of visual space but at the orthogonal orientation, the neuron, in most cases, does not respond at all. In cat visual cortex, a vast majority of neurons are orientation selective. In primate visual cortex, all neurons outside layer 4c (the thalamic recipient zone) are orientation selective. Different neurons have different preferred orientations, so that some subset of cortical neurons will respond to a stimulus of any orientation and position. The selectivity of each neuron is roughly Gaussian in shape. That is, a graph of response against stimulus orientation forms an approximately Gaussian-shaped curve, with a half-width at half-height in the range of 10–30°. For cells that give a nonzero response at the nonpreferred orientation, the Gaussian rides on top of an offset the size of the nonpreferred response.

Hubel and Wiesel also showed that orientation-selective cells can be divided into two distinct groups, labeled simple and complex. The receptive fields of simple cells are identified by the presence of two or three (or occasionally more) distinct subregions (or subfields) of their receptive fields. The subregions are defined on the basis of their response to flashing stimuli. ON subregions are defined by the responses evoked at the onset of a stimulus brighter than the background light, or the offset of a stimulus darker than background. OFF subregions are defined by the responses evoked by the onset of dark stimulus, or the offset of a bright stimulus. The subfields are elongated in the direction parallel to the preferred orientation of the cell and are positioned side by side, in the direction perpendicular to the preferred orientation (**Figure 1(a)**). They are also mutually antagonistic: a bright stimulus in an OFF region will diminish the response to a simultaneously presented bright stimulus in an ON region, and vice versa. Complex cells, by definition, lack these distinct subfields and instead respond to flashed stimuli more or less uniformly throughout the receptive field, either with ON responses, OFF responses, or both (**Figure 1(d)**). Since Hubel and Wiesel's first description of simple and complex cells, it has been shown quantitatively that they form two distinct populations, rather than the tails of a single population, when defined through the spike responses. When measured from their synaptic inputs, however, cortical cells form a continuum in which simple cells with highly segregated receptive field subregions lie at one end, and complex cells lie at the other. The transformation between synaptic input and spike output by spike threshold therefore helps to segregate simple and complex cells into distinct groups. In the cat, simple cells predominate in layers 4 and 6, the layers of the cortex that receive direct input from the visual thalamus (lateral geniculate nucleus, or LGN). Complex cells predominate in layers 2, 3, and 5, which predominantly receive input from other cortical cells instead of the LGN.

Figure 1 The emergence of orientation selectivity in primary visual cortex. The feed-forward model proposed by Hubel and Wiesel contains two stages, one that creates simple cell responses (top row) and a second that creates complex cell responses (bottom row). (a) In the first stage of the model, thalamic relay cells with circularly symmetric receptive fields converge on a simple cell. The spatial offsets of the relay cell receptive fields create the elongations observed in simple cell receptive fields. Blue indicates locations where a dark stimulus elicits a depolarization; red indicates locations where a light stimulus elicits a depolarization. (b) Elongated receptive fields then give simple cells the orientation selectivity observed in both the membrane potential and the spiking responses to drifting gratings, which elicit a modulated responses. (c) Orientation tuning is narrower for firing rate (top) than for membrane potential (bottom). Values plotted represent the peak (first Fourier component + mean) components of response. (d) In the second stage of the feed-forward model, multiple simple cells with similar orientation tuning but different spatial selectivity converge to create complex cell receptive fields. Complex cells respond to either a dark or a light stimulus placed in the receptive field, as long as the stimulus has the correct orientation. (e) Complex cells respond with a sustained depolarization to a drifting grating, but maintain orientation tuning. (f) Tuning curves for firing rate narrower than those for membrane potential.

Functional Architecture

At the same time that they first demonstrated orientation selectivity, Hubel and Wiesel also laid out what they termed the functional architecture of the cortex, or the way in which neurons with similar receptive field properties are physically arranged within the cortex. Specifically, they showed that all of the neurons in a cortical column – the cells arrayed vertically beneath one point on the cortical surface – have nearly identical preferred orientations. The columns preferring different orientations, in turn, arranged in an orderly fashion. Specifically, Hubel and Wiesel found that an electrode that is advanced in a direction perpendicular to the cortical surface encounters cells with the same preferred orientation. Conversely, as an electrode is advanced in a direction roughly tangential to the cortical surface, each cell encountered has a slightly different orientation from the previous cell. A large sequence of cells shows a smooth progression of orientation, with occasional jumps in orientation or reversals in the direction of the sequence (clockwise to counterclockwise, or vice versa). On average, a full range of orientations is covered by the neurons within a distance of about 1 mm of the cortical surface, which Hubel and Wiesel referred to as an orientation hypercolumn.

Subsequent to these observations from physiological experiments, the exact pattern or map of orientations within a hypercolumn was the subject of considerable theoretical and experimental work. The complete pattern of orientation columns was first revealed in detail by the advent of techniques for imaging neuronal activity *in vivo*. The images are based on almost imperceptible changes in the color of the cortical tissue that occur when active neurons take up oxygen, changing both the color of hemoglobin and the amount of blood flow in the local vasculature. The activity-evoked changes in reflectance of the cortical surface are less than 1/1000th of the total reflectance, but can be detected with an appropriate camera. Alternatively, the cortex can be stained with dyes that dissolve into the neuronal membranes and change their absorption as a function of the local electric field (voltage-sensitive dyes). Here again the optical signals are extremely small, but are much faster than the intrinsic, hemoglobin-based signals. Both types of imaging yield a map of orientations on the cortical surface, showing in both monkey and cat the formation of pinwheel structures, such that neurons lying within the vanes of the pinwheel each have a slightly different orientation preference (Figure 2). In a circular track around a single pinwheel, neurons of all preferred orientations would be found, arranged in order of orientation. Pinwheel centers are spaced at roughly 1 mm intervals across the cortical surface, and the vanes of adjacent pinwheels blend into one another. Note that at the centers of the pinwheels the vanes narrow down to essentially zero width, so that cells with very different orientation would lie very close to one another. The optical signals show relatively weak orientation tuning at the pinwheel centers, but because the techniques have spatial resolution somewhat larger than a single cortical cell, there are two possible explanations: the cells at the pinwheel centers could all have weak orientation preference, or the cells at the center could all be well-tuned for orientation but have different orientation preferences. Recent experiments with two-photon Ca^{2+} imaging *in vivo* have achieved single-cell resolution of neuronal activity, and indicate that cells within the pinwheel centers and cells outside the pinwheel are equally selective for orientation. The vanes of the pinwheels narrow, but are sharply defined down to the level of single cells, all the way into the centers.

Cortical Circuitry Underlying Orientation Selectivity

Nearly all discussions about the cortical circuitry underlying orientation selectivity begin with the simple and elegant model that Hubel and Wiesel proposed when they first described orientation selectivity. They noted that the ON and OFF subfields of simple cells are similar to the ON and OFF structures of LGN relay cell centers, which provide the main visual input to the cortex. Simple cell subfields, unlike the centers of relay cell receptive field, are elongated, however, which prompted Hubel and Wiesel to suggest that each simple cell's ON region is constructed from the input from a number of ON-center relay cells that have receptive fields aligned in a row. Similarly, the OFF subfield would be built from input from a set of OFF-center relay cells that have receptive fields overlapping the subregion. According to the model, orientation selectivity in the simple cell arises directly

Figure 2 Orientation maps on the surface of primary visual cortex measured with optical imaging of intrinsic signals. Gray-scale images (a–d, f–i) show responses (through both eyes) to stimulation at the orientation indicated by the colored bar inset. Dark regions are areas of strong neuronal response. Angle map (e) shows preferred stimulus orientation (scale at right). Scale bar = 500 μm; medial, up; anterior, to the right. Reproduced from Crair MC, Ruthazer ES, Gillespie DC, and Stryker MP (1997) Ocular dominance peaks at pinwheel center singularities of the orientation map in cat visual cortex. *Journal of Neurophysiology* 77: 3381–3385, used with permission.

from the spatial arrangement of the receptive fields of the presynaptic relay cells (**Figure 1(a)**). When a stimulus is parallel to the subfields, it simultaneously encounters the receptive fields of all of the constituent relay cells. The relay cells therefore synchronously excite the simple cell, bringing it to threshold. Conversely, when a stimulus is perpendicular to the subfield, it can only excite a fraction of the presynaptic relay cells at one time. The stimulus therefore generates some asynchronous excitation in the simple cell, but the excitation is too weak to reach threshold. The spatial organization of the input therefore generates the initial orientation bias in the synaptic input to the simple cell, and spike threshold amplifies the bias into an absolute selectivity in the cell's spike output.

Hubel and Wiesel's model of the relay cell input to simple cells is most likely correct. Recordings from connected pairs of LGN relay cells and simple cells demonstrate that a relay cell makes excitatory contact with a simple cell only if the relay cell receptive field center overlaps the subfeild of the target simple cell with the same response polarity (ON or OFF). In addition, intracellular recordings from simple cells, even with the cortical circuit inactivated so that the only remaining inputs are from relay cells, show strong orientation selectivity. Few would dispute, then, that the spatial organization of the relay cell input generates an initial orientation bias in the input to cortical cells.

There has, however, been dispute over whether the spatial organization of the relay cell input is sufficient to explain all of the simple cell response properties. For example, in several experiments it has been observed that the spatial organization of the receptive field overestimates the width of orientation tuning. From Hubel and Wiesel's model, one would expect that the longer and narrower a cell's receptive field subregions are, the more sensitive the cell will be to orientation. With a long, narrow subfield, a small shift in orientation will create a large mismatch between the stimulus and the receptive field, and therefore strongly reduce the evoked response. In most cells, however, tuning is even narrower than expected.

One proposal for the origin of this narrowing is lateral inhibition in the orientation domain (also called cross-orientation inhibition), in which cells with different preferred orientations inhibit one another. Alternatively, cells with similar preferred orientations and different tuning widths could inhibit one another. Cross-orientation inhibition could also explain two other strongly nonlinear properties of cortical cells: cross-orientation suppression, in which the responses to stimuli of the preferred orientation are antagonized by superimposed stimuli of the orthogonal orientation, and contrast-invariance of orientation tuning, in which the width of orientation tuning does not change with the strength (contrast) of the stimulus. Even more suggestive is the observation that antagonists of γ-aminobutyric acid ($GABA_A$)-mediated inhibition degrades orientation tuning when applied to the cortex.

Despite these strong indications that lateral inhibition among cells with different orientation preference is critical for generating orientation selectivity, direct evidence of lateral inhibition has been hard to find. Many (though not all) intracellular recordings from simple cells show only modest inhibition evoked by stimuli of nonpreferred orientation. Recent work suggests, as an alternative to lateral inhibition, that nonlinear properties of the feed-forward pathway from the LGN to the cortex can account for most of the aforementioned properties of simple cells. Spike threshold, by way of the so-called iceberg effect, for example, can explain why simple cells have such narrow orientation tuning relative to what is predicted by their receptive field maps. In this view, the input from geniculate relay cells determines the aspect ratio of the subfields, and therefore the width of orientation tuning for the synaptic input to the simple cell. Because of the iceberg effect, these inputs are suprathreshold only for a narrow range of orientations near the preferred orientation. Thus, the orientation tuning for the spike output of the cell is much narrower than that predicted by the spatial organization of the receptive field. Similar arguments, based on nonlinearities such as contrast saturation and spike rectification in relay cells, or response variability in cortical cells, can, in turn, can account for cross-orientation suppression and contrast invariance of orientation tuning.

Direction Selectivity

In addition to being selective for orientation, many cortical cells are also selective for the direction of stimulus motion. For a large fraction of both simple and complex cells in primary visual cortex, response strength depends on stimulus direction, with direction being perpendicular to the preferred orientation. Some cells are completely directional and do not respond at all to stimuli of the nonpreferred direction. As with orientation selectivity, direction selectivity is mapped onto the surface of the cortex: within a single orientation column, neurons with different preferred directions are segregated into direction-specific subcolumns. Recent Ca^{2+} imaging of neuronal activity using two-photon laser scanning microscopy has shown that the borders between direction-specific regions of the cortex are extremely precise, with neurons on either side of a sharp border having opposite

preferred directions. In primates, direction-selective neurons are also segregated by layers, tending to be located in the lower portion of layer 4 and in layer 6, which then project preferentially to extrastriate cortical areas in the dorsal processing stream.

Cortical Circuitry Underlying Direction Selectivity

As with orientation selectivity, direction selectivity is not represented in the relay cell input to primary visual cortex, and therefore must be computed within the cortex. Because motion in its essence requires a comparison over time and space (Where is the stimulus now? Where was it before?), computing direction requires that the responses of different inputs differ in both time and space. The origin of direction selectivity is still not fully understood, but in simple cells it clearly depends the heterogeneity of response timing within receptive field subregions. Specifically, it has been observed that in direction-selective cells, the latency of the response to a flashed stimulus differs by several tens of milliseconds between one side of the subfield and the other (along the axis perpendicular to the preferred orientation) (Figure 3(a)). The cell invariably prefers motion in the direction starting-from the long-latency regions of the receptive field and moving toward the short-latency region (Figure 3 (b)). When the stimulus moves in the nonpreferred direction, it encounters the short-latency part of the receptive field first, and the long-latency part later. The inputs from the two parts of the receptive field arrive at the cell at two different times, separated by the sum of the latency difference between the two regions and the time it takes the stimulus to travel from one region to the other. Conversely, when the stimulus moves in the preferred direction, it encounters the long-latency part of the receptive field first and the short-latency part later. If the stimulus travel time is approximately equal to the latency difference, then the inputs from the two parts of the receptive field will sum. The preferred stimulus therefore evokes a larger, though shorter-duration, input, compared to the nonpreferred stimulus.

This mechanism is strongly akin to orientation tuning, but with the orientation in the space–time domain rather than in the purely spatial domain. That is, a two-dimensional (2-D) plot of response latency against stimulus position is tilted for direction-selective cells (those without a gradient of latency across the receptive field), and is vertical for non-direction-selective cells (those with a gradient). Only stimuli with the correct spatiotemporal tilt (which move in the preferred direction) will evoke responses.

Although the preferred direction of motion is well predicted by the tilt of the spatiotemporal receptive field, the degree of selectivity in simple cells is often much greater than that predicted by the spatiotemporal receptive field map, much the same way that the spatial receptive field map underestimates the degree of orientation tuning. And similar to orientation tuning, one proposed explanation is lateral inhibition, in this case in the direction domain, such that direction-selective cells of opposite preferred direction inhibit one another. Once again, however, intracellular recordings from simple cells show little evidence for lateral inhibition. Excitation and inhibition in most cells share the same preferred direction. The apparent mismatch between the predictions of the spatiotemporal maps and recorded direction selectivity can be explained by the nonlinearity inherent in spike threshold. Because spike threshold disproportionately suppresses smaller synaptic inputs relative to larger ones, the direction selectivity of the spike output of cells is much larger than the direction selectivity of their synaptic inputs (Figure 3(c)).

The origin of the difference in response latency between different synaptic inputs is not known. Different relay cells could have different visual latencies (e.g., lagged and nonlagged relay cells), or long- and short-latency inputs could originate in different regions (such as the LGN and cortex).

The Aperture Problem

The processing of motion information at the level of primary visual cortex is incomplete. Neurons in primary visual cortex respond to the retinal image through a small aperture, defined by their receptive fields. They are only sensitive to the component of motion perpendicular to their preferred orientation within that restricted area. A cortical cell, then, cannot detect the difference between an optimally oriented stimulus moving in the preferred direction and an indentical stimulus moving at a different angle but higher speed (Figure 4). As long as the stimuli are much longer than the receptive field, such that their ends do not cross the receptive field, the stimuli appear identical to the cell and evoke the same response. Disambiguating such stimuli can only occur by integrating information from across the visual field and assembling the small components of the image into larger patterns. For motion, the extrastriate cortical medial temporal (MT) area is thought to be critical to this process.

Disparity Tuning

Information from the right and left eyes converges onto single cells for the first time in primary visual cortex. Throughout the cortex the balance of input from the two eyes (ocular dominance) covers the full

Figure 3 The emergence of direction selectivity in primary visual cortex. (a) Direction selectivity in primary visual cortex emerges due to the convergence of nondirectional responses that differ in both spatial preference and response timing (compare the latency and spatial preference of the two input neurons). The resulting spatiotemporal receptive field is tilted in space and time, a hallmark of direction-selective simple cells. Blue indicates an increase in response to a dark stimulus; red indicates an increase in response to a light stimulus. (b) Tilt in the spatiotemporal receptive field creates direction-selective responses to bars drifting across the receptive field. As a moving bar is sequentially flashed across the receptive field, a response is evoked at location (colored traces, locations indicated by the arrows in (a). For a leftward bar, moving from the purple arrow toward the red arrow, the response peaks at each location synchronously (indicated by the asterisk for each trace). The synchronous responses sum to create a large response to the leftward bar (bottom trace). The peak responses to a rightward bar are asynchronous and the summed response is therefore small. (c) Direction selectivity observed in cortical simple cells is evident both in the membrane potential and in spiking responses. The direction selectivity measured from membrane potential is modest relative to the selectivity observed in firing rate: direction index $= (R_p - R_n)/(R_p + R_n)$, where R_p and R_n are the responses in the preferred and nonpreferred (null) directions; for this example neuron, membrane potential $= 0.36$; firing rate $= 0.80$.

Figure 4 The aperture problem. (a–c) The direction of a drifting grating, moving behind the aperture, is ambiguous. All three conditions have the same apparent motion within the aperture. When information from multiple cells with different orientation preferences is available, the correct direction and speed of a moving diamond can be computed (right panel). By converting the motion components into velocity space (where direction is indicated by angle, and speed is indicated by vector length), each edge gives rise to a family of possible motions (indicated by the line orthogonal to each edge velocity vector). The intersection of these two lines indicates the correct solution to the object's velocity. Reproduced from Adelson EH and Movshon JA (1983) The perception of coherent motion in two-dimensional patterns. *Proceedings of the ACM SIGGRAPH/SIGART Interdisciplinary Workshop on Motion Representation and Perception*, pp. 11–16. © 1983 ACM, Inc. Reprinted by Permission.

range, with some cells receiving excitatory input only from one eye, some receiving predominant but not exclusive input from one eye, and others receiving equal input from the two eyes. Like orientation, ocular dominance is organized into columns, in this case alternating bands of about 0.5 mm thickness, with completely monocular cells near the center of the bands and more binocular cells near the edges.

In most cases, the receptive field of a binocular cortical cell mapped through one eye is identical in all respects to the field mapped through the other eye. Orientation and direction preference are the same, as are receptive field type (simple or complex), size, and position, even if the strength of the responses is different for the two eyes. By position, here, we refer to the relative positions of the receptive fields in the two retinas. That is, the receptive fields are located at the same direction and distance relative to the point of central vision (fovea in primates, area centralis in cats). Thus, the receptive fields are located at correspondent points in the retina, such that images falling on those points would appear to originate from the same point in visual space.

Of course, the images generated by many objects do not fall on correspondent points of the retina, specifically those objects that lie in front of or behind the plane of fixation. As one can easily demonstrate for oneself, for an object in front of the fixation plane the image in the left eye appears to lie to the right of the image in the right eye (and vice versa for objects beyond the fixation plane) (Figure 5). This depth-dependent lateral displacement of the two retinal images of an object is called binocular disparity and forms the basis for binocular depth vision.

Many neurons in the primary visual cortex are highly sensitive to binocular disparity. Tuned excitatory cells respond to stimulation in either eye, and tend to respond most strongly to simultaneous stimulation of correspondent points on the retinas – that is retinal disparities at or near 0°. Tuned inhibitory cells respond most weakly at 0 disparity and respond more strongly at disparities on either side of 0. Near cells respond only to crossed disparities, which are generated by objects closer than the fixation plane; far cells respond to uncrossed disparities.

Although their function is still under debate, together, these different types of cells could encode enough information to support depth perception. It has been noted that since the eyes are separated laterally, only horizontal disparities are generated by stimuli out of the fixation plane. If disparity-sensitive cells in the visual cortex feed into the circuitry for depth perception, the reasoning goes, they would be preferentially sensitive to horizontal disparities. Data on this point are equivocal, however.

Much like the aperture problem for direction selectivity, accurately reconstructing the three-dimensional visual world from the signals provided by disparity-sensitive cells presents a formidable computational problem. At the heart of the problem lies the existence of a large number of what are called false stereo matches in the two retinal images, also referred to as the stereo correspondence problem. When looking at a repeating pattern, such as a picket fence, for example, the brain must decide which slats of the fence in the right eye's image match with the slats in the left eye. If the slats lie in the plane of fixation and are spaced at 0.25° intervals, then

Figure 5 Retinal disparity. The retinal representations of objects at different depths differ in relative position between the right and left eyes. The red and blue arrows are placed at near and far depths, respectively, and their representations occupy different portions of the retinal representations. The retinal images for the red arrow fall on the temporal portion of the retinas, while the blue arrow images lie on the nasal retinas.

disparity-tuned cells that prefer 0°, ±0.25°, ±0.5°, and so forth will all be active. The ±0.25° cells, however, will be falsely matching a slat in one eye, and the adjacent one in the other eye. Only the 0° cells are responding correctly in the sense that a real object exists in the fixation plane. There are number of models as to how the brain suppresses false matches and arrives at a reasonably accurate perception of the three-dimensional stimulus. If the disparity-sensitive cells of primary visual cortex contribute to this process, however, their raw responses to disparity matches are likely further processed in higher cortical areas, such as visual areas V2, MT, and beyond.

Conclusion

The discovery of the response selectivity of cortical neurons by David Hubel and Torsten Wiesel in the early 1960s has raised a variety of questions, all of which have received considerable attention. How

does the cortical circuit extract information about orientation, direction, and size from the nonselective signals coming from the retina and thalamus? Why is the visual image parsed into these particular parameters? What advantages do orientation and direction selectivity confer on the animal, and how do they facilitate object detection and recognition at higher cortical levels? How does the circuitry of the cortex develop, and does development require visual experience?

Vision: Surface Segmentation

H S Scholte and V A F Lamme, University of Amsterdam, Amsterdam, The Netherlands

© 2009 Published by Elsevier Ltd.

Introduction

In midlevel vision, attributes such as orientation, motion, depth, and luminance are combined to form boundaries and surfaces. Boundary detection consists of detecting local continuities and discontinuities in the visual image on the basis of these attributes. Surface segmentation consists of grouping parts of the visual scene that share these attributes. Together, these processes result in a surface representation of the visual image in which some surfaces of the visual scene are assigned as figure and other surfaces are assigned as ground, and as such contribute to the perceptual interpretation of a scene. This figure–ground relation is characterized by three aspects: (1) the figure appears to be located in front of the ground, (2) the local discontinuity between figure and ground is perceived as belonging to the figure (the figure has ownership of the border), and (3) the ground appears to continue behind the figure.

Behavioral experiments suggest that boundary detection precedes surface segmentation. The perception of brightness of a white patch, presented on a dark background, seems to evolve from the edge inward. A similar observation has been made for the process of texture segregation. Moreover, it seems that boundaries are more important in texture segregation than is similarity of the features within the segregated surface, suggesting that the boundaries determine where the surfaces are located.

Boundary Detection

Neurons in the earliest cortical visual area, V1, respond preferentially to a particular orientation of luminance contrast and respond to stimuli in a restricted part of visual space that extends from 1 to 2°. This area is called the classical receptive field (cRF; see Figure 1(a)), area enclosed by the inner dotted line) and its size is the result of input from neurons in lower tier areas (i.e., it is purely determined by means of feed-forward connections). The RF is 'tuned' to particular features – that is, it only responds to stimuli that meet particular requirements. There is also an area beyond the cRF in which stimuli do not elicit a response on their own but can modulate a cRF-driven response. This is called the surround receptive field (sRF; see Figure 1(b), area inside the outer dotted line).

The total size of the receptive field in V1 (cRF + sRF) is at least two to five times larger than the cRF area. The most typical type of sRF effect is response suppression. Approximately 72% of cells in monkey V1 show this behavior when a central grating is presented that is successively increased in diameter. A similar pattern is observed when a line element is presented in the cRF and randomly oriented line elements are presented in the sRF (see Figure 1(b)). This inhibition is stronger when adjacent receptive fields, with a similar feature preference, receive the same type of input.

This situation changes drastically when the presented visual information contains local structure. Compared with the random surround, the firing rate of the neuron will be higher if the line element is surrounded by line elements with an orientation orthogonal to that of the center stimulus, or when the saliency of the line segment is enhanced by adding similarly oriented line segments along its principal axis (see Figure 1(c)). The behavior of neurons in these latter situations correlates with the anatomical structure and physiological properties of the horizontal connections – that is, long-range projections that originate from pyramidal cells, between cortical columns in early visual cortex. These horizontal connections preferentially link orientation columns with a similar orientation tuning, and these connections between similarly oriented cells are even stronger when these cells have RFs along a collinear axis. Behaviorally, these increases in firing rate coincide with an increase in the sensitivity of humans and monkeys to detect these stimuli. It is important to note that these effects are modulatory and only occur when the cRF is stimulated. When a stimulus is presented into the cRF of a neuron in one eye, and a context is presented into the sRF of the other eye, the sRF effects do not disappear (dichoptic presentation). sRF properties in V1 are therefore not determined by means of pure feed-forward processing but rather are cortical in origin (be it via horizontal connections within the cortical area or feedback processing from higher tier areas).

In summary, we see that neurons with their receptive field on a boundary of areas with dissimilar features have the strongest responses because they are less inhibited by their neighbors. This results in a response enhancement in areas where oriented texture boundaries are present, which appears between 40 and 80 ms after stimulus presentation, depending

Figure 1 (a) The classical receptive field (cRF) and surround receptive field (sRF) of a neuron in area V1 which is optimally stimulated by a line element. (b) Example of a scene in which random line elements are presented in the sRF of the neuron. This results in response suppression. (c) The presence of a collinear line in the sRF of the receptive field results in a relative response enhancement. (d) The feed-forward model of surface segregation. Neurons in V1 are involved in the detection of line elements. Extrastriate areas receive this V1 input, detect boundaries and border ownership, and perform surface segmentation. Areas in temporal cortex use this information for object recognition.

on how the boundary is defined. These signals can be relayed from area V1 to extrastriate areas with larger receptive fields. These higher tier areas have a coarser representation of visual space, and computational models have shown that boundary information can be integrated over space in this fashion. Debate remains whether contextual modulation signals in V1 related to boundary detection and contour integration are influenced by horizontal connections or feedback processing, and in different situations (depending on factors such as distance between elements in the visual scene) the mixture of these influences will differ. Functional magnetic resonance imaging studies further show that areas V2, V3, V3a, and V4 are also involved in boundary detection.

The Feed-Forward Model of Surface Segmentation

The most simple and elegant neural model of boundary detection and surface segmentation perceives these processes as being implemented by a series of temporal hierarchical processing steps that are implemented by spatially hierarchical organized brain areas, going from V1 via extrastriate areas to temporal cortex (see Figure 1(d)) via pure feed-forward connections. The region of space over which information has to be analyzed to achieve surface segmentation is typically much larger than the cRF of a neuron in V1 or V2. Areas in higher tier regions do have cRF sizes that are large enough to encapsulate the region of a particular surface, and the feed-forward model of surface segregation presumes that these cells are successful in integrating this information into surfaces.

Support for this model comes from experiments that show that there is an increase in the complexity of surface segmentation-related signals going from lower tier to higher tier areas. As discussed in the preceding section, areas V1, V2, V3, V3a, and V4 are involved in the process of boundary detection. A more complex level of representation is border ownership. Neurons that are sensitive for border ownership signal the presence of a border, but only if this border belongs to a figure on a specific side of the receptive field. More than 50% of the neurons in areas V2 and V4 and a smaller percentage of neurons in V1 signal border ownership. Border-ownership-related signals appear to be available in these areas at the same time (69–73 ms; luminance-defined figures). Neurons in V4 are tuned to elementary shapes, making them well suited for the integration of edgelike information from lower tier areas.

Higher in the hierarchy, the lateral occipital (LO) area responds to different shapes regardless of how

they are defined (cue invariant). This area also shows an adaptation response for stimuli that were identical in perceived shape but differed in contour organization, but not when contours were identical but perceived shape differed. This shows that area LO represents higher level shape information. Finally, neurons in areas such as the inferior temporal (IT) region, using input from lower tier areas, respond to specific objects, such as faces.

In summary, the feed-forward model of boundary detection and surface segmentation is both simple and elegant. It conforms to the main features of the visual system (increase in cRF size, increase in the specificity of the tuning of the cRF). Boundary detection precedes surface segmentation and occurs in early visual cortex. Surface segmentation occurs in extrastriate cortex, feeding its resulting output to higher tier areas where object perception takes place (see Figure 1(d)).

Surface Segmentation in Area V1

Recent findings have made it clear that the relationship between surface segmentation and boundary detection is more complicated than the feed-forward model suggests. Studies have shown that area V1 is sensitive for a large range of contextual influences that are spatially well beyond what could be expected on the basis of feed-forward processing (e.g., beyond the extent of the cRF).

Lamme found that a V1 neuron responds more strongly when its cRF is on the inside of a figure than when it is stimulated by identical background elements, even though its cRF is smaller than the figure (see Figure 2(a)). The black circle in the adjacent texture represents the cRF of this neuron. One result from this study is presented in Figure 2(b); the upper graph depicting the single-unit response from a neuron in V1 was obtained by presenting a texture with homogeneously oriented line elements. Overlaid on this is the response toward a texture where a figure can be perceived. After approximately 80 ms the response of this neuron is influenced by the context in which the line elements within the receptive field of the neuron are presented. Neurons with their receptive field on the boundary between figure and ground show an increase in firing rate at this interval. Subsequently, neurons within the boundaries show an increase in firing rate (compared to the condition in which only a homogeneous texture is presented) that starts after ~100 ms. This is shown in Figure 2(c), in which the activity evoked by a figure texture is plotted over time, for different positions of the cRF relative to the figure and the figure–ground boundary. This 'contextual' modulation, as measured in the center of a figure, is large for smaller figures and declines as figures grow larger. More importantly, there is an asymmetry, also visible in Figure 2(c), of modulation across the figure–ground boundary. As soon as the cRF is outside the figure, the sRF modulation is absent. This sharp decline in enhanced activity correlates with the observation that boundaries belong to the figure (and not the background). Other experiments have shown that this 'late' enhancement not only occurs for texture-defined figures but also for figures that are defined by color, motion, and depth, indicating that contextual modulation is cue invariant. Finally, border manipulations that alter the perceptual interpretation of a scene co-vary with the amount of contextual modulation.

The correlation between neuronal activity in V1 and the perceptual interpretation of the surface is further strengthened by a study that shows that masking the stimulus in such a way that a monkey is not capable of detecting the stimulus anymore coincides with an abolishment of the sRF effects. When a figure is masked by a stimulus that follows the presentation of a figure immediately (16 ms), the monkey is incapable of detecting this figure. With an increase in time between the presentation of the figure and the presentation of the mask, the capability of the monkey to detect the figure also increases and the size of the sRF effect that can be measured at these different masking intervals correlates with the reported visibility of the monkey. Finally, when the figure stimulus is followed by a blank screen mask, the figure is much easier to detect. The sRF effect again correlates with the visibility of the stimulus and this indicates that this effect is not a result of the presentation duration of the figure stimulus but rather of the perceived presence of the figure.

On the basis of these observations we can link contextual modulation signals measured in area V1, from 100 ms onward, to the process surface segmentation (at least for texture-defined figures), a view that is also supported by results from studies with humans. Event-related potential (ERP) studies have revealed that when the evoked response from occipital channels, obtained by presenting homogeneous textures, is subtracted from the response obtained by presenting figure textures (like the one in Figure 1(a)), a signal with peak latencies between 140 and 219 ms in occipital channels remains. The systematic manipulation of the visibility of the figure has indicated that the latter part of this response, around 200 ms, is more related to surface segmentation, while the earlier part of this response appears to be more related to boundary detection.

Figure 2 General phenomenology of contextual modulation. (a) The responses of a neuron in V1 (single unit, smoothed) when the classical receptive field (cRF) falls on a texture with homogeneously oriented line elements (top) and additional activity (bottom right, in gray) that can be measured when the line elements that fall in the cRF are part of a figure. (b) The neural activity (*z*-axis, smoothed spiking activity) evoked by a figure texture plotted over time (more vertical axis) and across a line circumcising a figure (more horizontal axis) measured in V1 of a macaque monkey. Notice that the neurons start to fire vigorously after 40 ms (visual response); 40 ms later, is possible to see a difference in activity between the neurons with their classical receptive field on the edge and the other neurons. After this, is becomes possible to see 'filling-in' in the area between the boundaries. (c, d) When the peristriate areas are removed, isolating V1 and V2 from the rest of the brain, activity related to the 'filling-in' disappears while the activity related to boundary detection remains visible. (e) The recurrent model of surface segmentation. Boundary detection and border ownership are established during the initial feed-forward sweep. This results in coarse object detection, after which recurrent processing starts, which results in a surface segmentation representation in early visual cortex. Over time, this results in a more specific, object identity-related response and disambiguation of the visual scene.

Influence of Recurrent Processing

Apart from connections running from lower tier areas to higher tier areas there are also connections running from higher tier areas to lower tier areas, and horizontal connections that provide connectivity within an area (see Figure 2(e)). After the initial feed-forward sweep of activity, these horizontal and feedback connections start to contribute to neural processing, and this is called recurrent processing. Contextual modulation is a result of recurrent processing, involving both horizontal connections and feedback processing.

Lesion Studies

When a peristriate cortex lesion is made in visual cortex, isolating areas V1 and V2 from the rest of the cortex, responses to the presence of the boundaries between figure and ground remain. This indicates that boundary detection is completed within areas V1 and V2. However, the subsequent response toward the figure, which signals surface segmentation, is abolished by this lesion (see Figure 2(d)). This implicates the involvement of recurrent or feedback processing – that is to say, the influence from higher tier areas on lower tier areas in surface segmentation. Likewise, it was shown, by using reversible inactivation of the medial temporal (MT) area, that feedback connections serve to amplify the response of neurons in area V1 and enhance suppression evoked by the background.

Speed of Processing in the Visual System

Feed-forward and feedback corticocortical connections conduct information at an extremely high speed, approximately 2–3.5 m s^{-1}, activating neurons in area V1 between 35 and 72 ms, neurons in the gyrus part of the inferior temporal cortex (area TE) between 60 and 120 ms, and neurons in the temporal pole between 100 and 160 ms. Taken that the synaptic relays add only an additional 5–20 ms to the relay time per cortical area and that there are long-distance corticocortical projections from, for instance, V1 to MT, it is no surprise that all visually responsive areas in the macaque cortex are activated approximately 115 ms after stimulus onset, including regions in motor and frontal cortex.

This rapid speed of the corticocortical projections contrasts with the lower conduction velocity of horizontal connections that are in the order of 0.1–0.33 ms^{-1}. This tenfold difference in conduction speed is caused by a difference in myelination and diameter between horizontal and interareal corticocortical connections.

Contextual effects of scene elements at a distance up to 3–10° influence the measured spiking activity 100 ms after stimulus presentation. At a range of 3°, eccentricity span horizontal connections are such that they can influence processing in this time interval in the range of 4°. However, because of the cortical magnification factor, this influence should be slower for more centrally presented stimuli and faster for more peripherally presented stimuli. Since there is only a modest dependency on cortical distance, the most consistent interpretation is that contextual modulation at some distance from the cRF is mainly caused by recurrent processing.

The Need for Recurrent Processing in Surface Segregation: Disambiguation

Neural network models of surface segregation suggest that recurrent processing is necessary to accurately perceive complex aspects of an object shape because higher-tier visual areas lack the spatial resolution of early visual cortex. If we consider a feed-forward model of perception in which neurons in higher-tier areas look at the output of lower-tier areas, it is difficult to see how a neuron in a higher tier area can differentiate between a filled figure, on the one hand, and a figure with a hole in the center, on the other hand. Adding recurrent processing to such a model does allow the system to differentiate between different geometric shapes. From this perspective, one of the purposes of recurrent processing in surface segregation is the disambiguation of information in the feed-forward sweep.

The Need for Recurrent Processing in Surface Segregation: Object Identification

Historically it has been presumed that surface segmentation is subservient to object recognition, assuming that object representations are only selected for regions selected by prior surface segmentation. However, neurons in area IT show object specific activation within 80 ms after stimulus onset. This is before surface-segregation-related activity appears in area V1 (100 ms and onward) and this indicates that object-related activity can precede surface segregation signals in V1. Furthermore, experiments have shown that object-based responses in area IT develop over time from categorical responses to exemplar-related responses between approximately 100 and 200 ms.

These observations have found behavioral support in experiments that show that object categorization does not require a longer stimulus presentation or a longer response time than does detecting the presence of an object. Since figure–ground segmentation should

be sufficient for accurate performance in object detection (i.e., detecting the presence of an object, regardless of its identity), this indicates that figure–ground segmentation does not precede object categorization in all circumstances, since detection and categorization take an identical amount of processing. The same experiments have shown that object identification takes a longer stimulus duration and processing time than does categorization. Together, these results suggest that recurrent processing, visible in area V1 after 100 ms, is necessary for the identification, but not detection\categorization, of visual stimuli, and that the activity that is measured in area V1 after 100 ms represents the ongoing perceptual interpretation of the visual scene in a high spatial resolution.

Surface Segregation Is Part of a Dynamic Process

Surface segregation is not a neural computation that takes place in one area of the brain in a limited window of time, but rather is a dynamic process that evolves over time and space. First, in a feed-forward sweep of activation, initial boundaries and border ownership of these boundaries are established. A recent magnetoencephalographic (MEG) study looking at the time course of illusionary shape-related activity showed that area LO was activated at 155 ms, after which activity propagated to early visual cortex and higher tier areas. If we take the response properties of area LO into account, it could very well be that this area is a necessary relay station between early visual cortex and object-selective areas in the temporal lobe (see Figure 2(e), black arrows). Recurrent processing between these areas results in a surface representation in area V1 and an increase in the tuning of neurons in object-related areas. Furthermore, it seems likely that the brain tries to solve ambiguities present in the visual image during these later stages of processing.

Associative Memory in Vision: An Elementary Model for Declarative Memory Networks

A significant aspect of high-level cognitive function in humans is our ability to categorize and memorize declarative knowledge and experiences in associative networks that can be reactivated on demand by both internal and external cues. In seeking to better understand the neuronal mechanisms underlying these processes, visual associative memory offers an attractive model that is readily accessible to empirical neurophysiological approaches.

The primate visual system is divided into two functionally and anatomically distinct streams: the dorsal stream and the ventral stream. The dorsal stream, which conveys information from early visual areas to the posterior parietal cortex, is involved in processing the location and motion of visual objects (i.e., where); interruption of this stream disrupts the perception of the spatial relations among objects. On the other hand, the ventral stream conveys information from early visual areas to the inferior temporal (IT) cortex and is involved in processing color and shape (i.e., what); interruption of this stream affects the ability to recognize objects and discriminate among them. In monkeys, bilateral excision of the anterior IT cortex causes severe deficits in visual object recognition and impairs visual pattern discrimination, whereas more posterior, temporal-occipital lesions produce more severe perceptual deficits. Similarly, patients who have undergone right anterior temporal lobectomy show mild impairment in perceptual tasks such as the Mooney Closure Faces Test (in which subjects are asked to visually organize a percept of a face from degraded images), but show markedly impaired recognition memory of complex visual patterns which cannot be verbalized. These deficits are unrelated to the extent of hippocampal removal during the temporal lobectomy. Moreover, electrical stimulation of the temporal lobes of conscious epileptic patients during brain surgery induces vivid, almost hallucinatory memories (i.e., faces of friends and sounds of music), suggesting that electrical input to the putative memory storehouse reactivates the memory records.

These findings suggest that the IT cortex contributes to the representation and storage of visual memories. If this is so, then how are visual associative links represented within the IT cortex? This article focuses on the neuronal substrates and mechanisms underlying visual associative long-term memory (LTM), mainly revealed by single-unit recordings from the brains of monkeys performing memory tasks. We first introduce neurophysiological evidence for neuronal representations of visual associative memories in the monkey IT cortex. We then present single-unit recordings indicating that neural activity within the monkey IT cortex also contains the retrieval signal of visual associative memories. Finally, we discuss how the visual association is recalled from memory by reactivation of the neuronal representation, focusing on two different processes mediating memory retrieval: automatic memory retrieval signaling, which is conveyed backwardly from the limbic cortex to the temporal neocortex, and active retrieval signaling, which is conveyed as top-down signaling from the prefrontal cortex (PFC) to the IT cortex.

Neuronal Correlates of Associative Memory in the Monkey Inferior Temporal Cortex

Inferior Temporal Neurons Establishing Visual Associative Links

The neuronal correlates of visual associative LTM were first identified by Miyashita and Sakai in the monkey IT cortex. They recorded from single neurons while the subjects performed a pair-association (PA) task, which is a well-known neuropsychological test widely used in humans to assess dysfunction of the medial temporal lobe system. In the PA task, the monkeys were trained to memorize associations between computer-generated paired pictures that had no apparent geometric similarity (Figures 1(a) and 1(b)). At the start of each trial, one of the pictures was presented as a cue (i.e., 1 in Figure 1(b)). After a delay interval, during which no stimulus was presented, the subject was presented with a choice between the paired associate of the cue (i.e., 1′) and a stimulus from another pair. Using this approach, two classes of task-related neuronal activities were identified in the IT cortex. In one class of neurons, the strongest and second strongest responses during the cue period were ascribed to particular paired pictures (pair-coding neurons; Figures 1(c) and 1(d)). The other type of neurons not only responded to an optimal stimulus during the cue period, but also was active during the blank delay period after the paired associate of the optimal picture was presented as a cue. This delay activity gradually increased until

Figure 1 Pair-association (PA) task for monkeys used by Sakai and Miyashita: (a) sequence of events within a trial; (b) examples of paired associates used in the task (the monkeys learned to retrieve the other member of the associated pair for each cue picture); (c) rastergrams of neural discharges in each trial (upper) and spike density functions (SDF, lower) obtained from a single neuron; (d) mean discharge rates during the cue period (60–320 ms from the cue onset). As shown in (a), after a lever press by the monkey initiating a new trial, there is a warning, a green square (1 s); then a cue, one of the Fourier descriptors that serves as the cue stimulus (1 s); then a delay, a green square (4 s); and then a choice of two stimuli, the paired associate of the cue and one from a different pair. Fruit juice was given as a reward for correctly touching the paired associate. In (c), the optimal trial (the strongest response) is shown as the thick black line and optimal-pair trial (the second strongest response) is shown as the thick gray line. The trials are aligned at the cue onset. The thin black line denotes the averaged responses in the other trials. The duration of the cue period was 320 ms. In (d), 12 pairs of stimuli are labeled on the abscissa. The open and filled bars in pair 1, for example, refer to the responses to stimulus 1 and 1′, respectively. Error bars denote SEM. PCI, pair-coding index. (c, d) Reproduced from Naya Y, Yoshida M, and Miyashita Y (2003) Forward processing of long-term associative memory in monkey inferotemporal cortex. *Journal of Neuroscience* 23: 2861–2871. the choice stimuli appeared (target-recall activity; see the section titled 'Two types of sustained activities in the delay period'). This pattern of activity includes the ability of IT neurons to acquire selectivity for visual patterns through associative learning and to establish links between neuronal representations of different stimuli that have a semantic association but no geometrical relationship. Neurophysiological studies of monkeys by other groups lend additional support to this notion of the properties of the IT cortex. For instance, the Logothetis and Tanaka research groups reported that the visual stimulus selectivity of neurons in TE showed a training effect – the proportion of neurons responsive to trained stimuli was significantly greater in trained monkeys than in control untrained monkeys. In addition, Erickson and Desimone recorded single neurons in the perirhinal area of the IT cortex while monkeys performed a visual cue-choice association task and found that the correlation relating responses to a familiar cue and a choice stimulus is highly significant.

Forward Processing of Long-Term Associative Memory

The IT cortex comprises two cytoarchitectonically distinct but mutually interconnected areas: TE and A36 (Figure 2). TE is a unimodal neocortical area located at the final stage of the ventral visual stream devoted to object vision. By contrast, A36 is a limbic polymodal association area and a component of the medial temporal-lobe memory system, which is involved in the formation of declarative memory. The respective roles played by these two areas in the neuronal representation of associative memory were analyzed in terms of the pair-coding responses of neurons. A correlation coefficient was calculated for each neuron between the mean firing rate during the cue period to one stimulus and the mean firing rate during the cue period to the paired associate of that stimulus (pair-coding index (PCI)). If a single neuron in a population showed a pattern of stimulus selectivity that was independent of the stimulus pairs, the

mean value of the PCIs would be expected to approach 0 as the number of neurons in the population increased. This analysis showed that the PCI values for A36 neurons were significantly higher ($P < 0.001$) than those for TE neurons (Figure 3(a)) and that the percentage of neurons which showed significantly positive PCIs at the single-neuron level (pair-coding neurons) was also much higher in A36 (33%) than TE (4.9%). However, the general stimulus selectivities of the cue-selective neurons (as measured by R^2 and kurtosis in Figures 3(b) and 3(c)) did not differ between the two areas, indicating that the associative memory is represented in a highly specific change of neuronal stimulus selectivity (as measured by the PCI).

Figure 2 Macaque brain: (a) lateral view; (b) coronal cross section. A36, area 36 (green); TE, area TE(red); TEO, area TEO; V4, visual area 4; D, dorsal; V, ventral; A, anterior; P, Posterior. Reprinted from Naya Y, Yoshida M, and Miyashita (2001) Backward spreading of memory-retrieval signal in the primate temporal cortex. *Science* 291: 616–664, with permission from American Association for the Advancement of Science.

Next, the time courses of the responses of TE and A36 pair-coding neurons were compared, and it was observed that most of the pair-coding neurons in A36 began to encode the association between paired stimuli as soon as they exhibited stimulus selectivity (called type 1 neurons); the remaining pair-coding neurons in A36 began to encode the association 20–30 ms after they began to show stimulus selectivity (type 2 neurons). This suggests that type 1 neurons encode the associative memory by directly combining the feed-forward input from TE, whereas type 2 neurons more likely encode the association memory using feedback input from other higher areas (see the section titled 'Active retrieval: Top-down signal from the prefrontal cortex in executive control of memory retrieval') or intrinsic input from other A36 neurons.

Collectively then, the findings presented so far indicate that the association between the representations of paired-associates proceeds forward through the anatomical hierarchy of the IT cortex and suggest

Figure 3 Response correlation to paired associates and general response properties of cue-selective neurons in A36 (green) and TE (red): (a) cumulative frequency histogram of PCIs for A36 ($n = 76$) and TE ($n = 347$) neurons; (b) cumulative frequency histogram of R^2; (c) cumulative frequency histogram of kurtosis. In (a), the PCIs for A36 neurons were significantly higher than those for TE neurons ($P < 0.001$; Kolmogorov-Smirnov test). In (b), R^2 provides an estimate of how much of the variance in firing rate can be accounted for by the factor of stimulus. In (c), kurtosis provides a measure of the sharpness of the stimulus selectivity. Neither the R^2 ($P < 0.99$) nor kurtosis ($P = 0.41$) significantly differs between A36 and TE neurons. The equations used are:

- In (a), $\mathrm{PCI} = \sum[(x_i - \mu)(x_i - \mu')]/\{\sum[(x_i - \mu)^2]\sum[(x_i - \mu)^2]\}^{1/2}$, $(i = 1, \ldots, 12)$; where x_i is the mean cue response for the ith stimulus (the ith and i'th pictures belong to a pair), and μ and μ' are the average of x_i and $x_{i'}$., respectively.
- In (b), $R^2 = \sum m_j(x_j - \mu_{\mathrm{tot}})^2/\sum(x_{j,k} - \mu_{\mathrm{tot}})^2 (j = 1, \ldots, 12, 1', \ldots, 12'; k = 1 - m_j)$;
- In (c), kurtosis $= \sum(x_j - \mu_{\mathrm{tot}})^4/\{\sum(x_j - \mu_{\mathrm{tot}})^2\}^2 (j = 1, \ldots, 12, 1', \ldots, 12'; k = 1 - m_j)$, where in the last two equations, $x_{j,k}$ is the cue response in the kth trial for the jth stimulus; x_j is the mean cue response for the jth stimulus; m_j is the total number of the trials for the jth stimulus; and μ_{tot} is the average of the cue responses across the total trials.

selective convergence onto a single A36 neuron from two groups of TE neurons that separately encode each paired picture.

Retrieval Signaling in Visual Association Memory

Two Types of Sustained Activities in the Delay Period

In the IT cortex, two types of sustained activities were found in the delay period when the subject retrieved and maintained the target stimulus from LTM. One population of IT neurons exhibits a stimulus selectivity pattern during the delay period that was similar to that during the cue period. That is to say, this sustained activity in optimal trials (i.e., the trials in which the optimal stimulus was presented as a cue stimulus) related to the cue stimulus itself – cue-holding activity (Figures 4(a) and 4(b)). On the other hand, another population of neurons exhibits target-recall activities, which was elicited by the paired associate of the cue stimulus rather than by the cue stimulus itself as previously discussed (Figures 4(c) and 4(d)). This sustained activity in optimal-pair trials (i.e., the trials in which the paired associate of the optimal stimulus was presented as a cue stimulus) is induced only when the subject retrieves and maintains the optimal stimulus in mind and thus reflects the memory of the optimal stimulus. To further characterize the cue-holding and target-recall activities, the responses to all of the cue stimuli were considered. The partial correlation coefficients relating delay activity to the responses to a particular cue stimulus (cue-holding index (CHI)) and to its paired associate (pair-recall index (PRI)) were calculated for each neuron. CHI and PRI values are bounded by −1 and 1; a large CHI implies cue-holding activity as shown in Figures 4(a) and 4(b) (CHI = 0.95, PRI = −0.47), whereas a large PRI implies target-recall activity as shown in Figures 4(c) and 4(d) (CHI = −0.01, PRI = 0.64).

Then, how are these two types of delay activities, cue-holding and target-recall, represented in TE and A36? The comparison of the delay activities between individual TE and A36 neurons during a PA task in terms of their signal content provided the answer to this question. A comparison of the CHI and PRI values for TE and A36 neurons revealed that in TE the PRIs for the delay-selective neurons were significantly higher than the CHIs. In A36, by contrast, the

Figure 4 Examples of delay-selective neurons: (a) A36 raster displays and spike density functions; (b) A36 polar plots of mean discharge rates; (c) TE raster displays and spike density functions; (d) TE polar plots of mean discharge rates. In (a,c) , trials using the cue-optimal stimulus as the cue (optimal trials, green) and those using the paired associate as the cue (optimal-pair trials, red) were aligned at the cue onset. In (b) and (d), mean discharge rates during the cue and delay periods (60–320 ms and 1320–2320 ms; gray boxes in (a) and (c), respectively) are shown in polar plots for each cue presentation. The responses to stimuli and to their paired associates are indicated by radial lines. The discharge rates were normalized based on the maximum values for each period ((b) cue period, 44.0 Hz at stimulus 4′; delay period, 18.6 Hz at stimulus 4′; (d) cue period, 48.7 Hz at stimulus 4; delay period, 18.7 Hz at stimulus 4′). A36, area 36; TE, area TE. Reproduced from Naya Y, Yoshida M, Takeda M, Fujimichi R, and Miyashita Y (2003) Delay-period activities in two subdivisions of monkey inferotemporal cortex during pair association memory task. *European Journal of Neuroscience* 18: 2915–2918. Copyright 2003, with permission from Blackwell Publishing Ltd.

PRIs for the delay-selective neurons were not different from the CHIs. Moreover, the CHIs were significantly lower in TE than in A36, whereas the PRIs did not significantly differ in the two areas. This suggests that the delay activity of TE neurons preferentially represents the paired associate that is retrieved from LTM, not the cue stimulus itself, whereas the delay activity of A36 neurons retained not only the paired associate but also the cue stimulus.

Active Maintenance of Associative Mnemonic Signaling in the Monkey Inferior Temporal Cortex

In another study focusing on delay activity with the aim of determining the contribution made by IT neurons to the persistence of internal representations, single units were recorded from neurons in the IT cortex while monkeys performed a sequential type of PA task in which distractor stimuli interrupted the delay period between a cue stimulus and the target stimulus (the paired associate of the cue stimulus) (Figure 5(a)). Some delay-selective neurons exhibited, in optimal trials, cue-holding activity during the first delay period. This sustained discharge was attenuated when the distractor stimulus was presented (compare the two light-gray shaded areas in Figure 5(b)). During optimal-pair trials, the neuronal discharge of the same cell was weak throughout the trial (Figure 5(c)). However, during optimal-pair trials another type of neuron exhibited target-recall activity during the first delay period, and the significant activity was still sustained during the second delay period (compare the two light-gray shaded areas in Figure 5(e)). During optimal trials, by contrast, the neuronal discharge of the same cell was weak both during the first and the second delay periods (Figure 5(d)). These results mean that the cue-holding activity tends to be attenuated by the subsequent distractor stimulus (in fact, this activity is replaced by that elicited by the distractor stimulus) during the second delay period (i.e., after the presentation of the distractor stimulus); on the other hand, the target-recall activity continues to signal the target stimulus information, even after an intervening distractor.

A population analysis of all the delay-selective neurons recorded is shown in Figures 5(f) and 5(g). Partial regression coefficients (β) were used to relate the neuronal discharge during the first delay period and second delay periods to the discharge elicited by the cue and target. A larger value of β means that the delay activities convey more information about the cue or target.

The scatterplots relates the β values for the cue (Figure 5(f)) and target (Figure 5(g)) stimuli during the first and second delay periods. Note that the values for the cue stimulus lie below the orthogonal line, whereas those for the target stimulus lie around it. This indicates that the target stimulus information signaled by delay activity is more resistant to the distractor stimulus than the cue stimulus information and suggests that, whereas LTM-derived information required for upcoming behavior (i.e., target stimulus) is actively maintained in IT neurons, visually derived information tends to be updated irrespective of behavioral relevance (i.e., cue stimulus and distractor stimulus).

Global Network of Memory Retrieval

Thus far, we have provided evidence as to how visual associative memory is stored and represented in the IT cortex. We next discuss how these mnemonic representations are reactivated during memory retrieval. The evidence summarized shows that memory retrieval can be processed either within the IT cortex or via an interaction between the PFC and the IT cortex.

Everyone knows from experience that sometimes recollection is effortless but that at other times one must make an effort to recall successfully. Here, we refer to the former as automatic retrieval and to the latter as active retrieval. Visual associative memories can be retrieved from the IT cortex by either of these two processes.

Automatic Retrieval: Backward Spreading of the Memory-Retrieval Signal in the Temporal Cortex

During a PA task, groups of neurons in both TE and A36 show target-recall activity. The responses of representative A36 neuron and TE neuron are shown in Figures 6(a) and 6(c). One stimulus elicited the strongest response during the cue period (perceptual signal), and the latencies of the response in TE neurons were significantly shorter than those in A36 neurons (TE, median 77 ms; A36, median 89 ms; Kolmogorov–Smirnov test, $P < 0.05$). Moreover, the paired-associate stimulus of a cue stimulus elicits the highest delay activity in A36 and TE neurons, although the onset of the target-recall tonic activity was later in TE than in A36 (Figures 6(a) and 6(c)).

To compare the properties of the target-recall activities between TE and A36 neurons, the time courses were analyzed. In this analysis, an instantaneous PRI at time plot t (PRI(t)) was defined as partial correlation coefficients relating instantaneous firing rates at time t in the response to each cue stimulus to the responses to its paired associate. Then the time courses of the average PRI(t) across the population of stimulus-selective neurons in A36 and TE were determined. The average PRI(t) for the A36 neurons began to increase within the cue period and developed over a

Figure 5 (Continued)

comparatively rapid time course (Figure 6(b)). On the other hand, the PRI(t) for the TE neurons increased slowly, reaching a plateau in the middle of the delay period (Figure 6(d)). Apparently, even though the visual signal reaches TE before it reaches A36, the memory retrieval signal emerges first in A36 and then TE neurons are gradually recruited to represent the sought target. The implication of this finding is that backward projections from A36 to TE may underlie the activation of TE neurons that represent mnemonic information retrieved from LTM.

Active Retrieval: Top-Down Signal from the Prefrontal Cortex in Executive Control of Memory Retrieval

Memory retrieval can be regulated by top-down processes that have been implicated in executive functions, such as planning. For instance, examination of an epileptic patient with a selective posterior callosotomy revealed that although sensory stimuli confined to the nondominant right hemisphere could not be transferred to the left hemisphere for naming, semantic features of those stimuli could be described using the expressive language system of the left hemisphere. This observation suggests that top-down processes originating in the PFC can regulate the retrieval of LTM from the modality-specific posterior association cortex, even in the absence of direct sensory input.

To test that idea, the posterior corpus callosum (CC) and the anterior commissure were transected in monkey subjects (the posterior split-brain paradigm), after which the monkeys' performances on a PA task were evaluated. The critical question was whether the PFC of these monkeys could instruct the contralateral hemisphere, via the intact anterior CC, to retrieve LTM when sensory interaction between posterior cortical areas was prevented. In the posterior-split-brain monkey, each hemisphere receives bottom-up visual information only from the contralateral visual hemifield, and LTM acquired through learning pair association does not transfer interhemispherically via the anterior CC. Nonetheless, information about the cue stimulus presented to one hemisphere was transmitted through the anterior CC, enabling the target stimulus specified by the cue to be retrieved from the other hemisphere. Thus, we can conclude that, although visual LTM is stored in the temporal cortex, memory retrieval is under the executive control of the PFC.

The existence of top-down signaling from the PFC to the temporal cortex and its contribution to the active retrieval process have been demonstrated using single-unit recordings from the IT cortex of posterior-split-brain monkeys. In these animals, IT neurons in one hemisphere were activated by bottom-up visual inputs when an object was presented in the visual hemifield contralateral to the recording site (Figure 7(a)). When the object was presented in the ipsilateral hemifield, however, these neurons did not receive the bottom-up visual inputs (Figure 7(b)), so any neural activation should reflect top-down inputs from the PFC. And, in fact, a considerable number of IT neurons received top-down signals from the PFC (Figure 7(c)). The neurons were activated not only by contralateral presentation of stimuli but also by ipsilateral presentation of stimuli. The stimulus selectivity of the bottom-up response was similar to that of the top-down response. The onset latency of neuronal responses was significantly longer under the top-down than the bottom-up condition, and top-down responses were abolished after transection of the remaining anterior CC (full-split).

The memory retrieval is a complicated process; it is not just the process of cueing and interrogation of the memory store (a narrow sense of memory retrieval), but it is also bound up with the updating of memory information in working memory and evaluation or monitoring of this information. Recent positron

Figure 5 Sequential-type paired-association task. (a) The procedure; (b,c) rastergrams and SDFs of the optimal trials and optimal-pair trials showing representative neurons exhibiting cue-holding activity; (d,e) rastergrams and SDFs of the optimal trials and optimal-pair trials showing representative neurons exhibiting target-recall activity; (f) scatterplot of the effect of the cue stimulus on neuronal activity during the delay epoch; (g) scatterplot of the effects of the target stimulus on neuronal activity during the delay epoch. As shown in (a), after the fixation spot, one of the pictures was presented as the cue stimulus. During the delay epoch that followed the cue stimulus, one, two, or three test stimuli were presented. After each delay period, the paired associate of the cue stimulus (target stimulus) or a distractor stimulus was presented as the test stimulus. In (b–e), gray lines indicate average SDFs in trials in which the other pictures were presented as cue stimuli. Data from correct trials are aligned on the onset of the cue, first-test, and second-test stimuli. Light-gray shading indicates the first and second delay periods for analysis. In the optimal trials, neuronal discharge (cue-holding activity) declined from the first to the second delay period (b). In the optimal-pair trials, strong neuronal discharge (target-recall activity) was observed during both the first and second delay periods (e). In (f), the scatterplot relates the changes in the β values for the cue stimulus from the first delay (x axis) to the second delay (y axis) period across the population of delay-selective neurons ($n = 59$). The regression slope is significantly positive ($t = 8.58$, $p < 0.01$). In (g), the regression slope for the β values for the target stimulus is significantly positive ($t = 9.95$, $p < 0.01$) and steeper than that for β values for the cue stimulus ($F = 11.57$, $p < 0.01$). The open triangles in (f, g) represent the data from the neurons in (b,c) and the open squares represent the data from the neurons in (d,e). SDF, spike density function. Reproduced from Takeda M, Naya Y, Fujimichi R, Takeuchi D, and Miyashita Y (2005) Active maintenance of associative mnemonic signal in monkey inferior temporal cortex. *Neuron* 48: 839–848. Copyright 2005, with permission from Elsevier.

Figure 6 Neuronal activity related to memory retrieval during the paired-association task: (a) activity of a representative A36 neuron; (b) temporal dynamics of average PRI(t) for the population of stimulus-selective A36 neurons ($n = 45$); (c) activity of a representative TE neuron; (d) temporal dynamics of average PRI(t) for the population of stimulus-selective TE neurons ($n = 69$). In (a) and (c), SDFs are aligned at the cue onset in trials where the cue-optimal stimulus served as the cue (top) and in trials where its paired associate served as the cue (bottom). Black lines indicate responses to the cue-optimal stimulus (top) or its paired associate (bottom); gray lines indicate mean responses to all stimuli. In (b) and (d), mean values of PRI(t) are plotted every 100 ms (solid circle, total; diamond, monkey 1; open square, monkey 2; open triangle, monkey 3). Thick lines (green and red, respectively) indicate the best-fit Weibull functions for the population-averaged PRI(t) in the two areas. Thin lines indicate this for the neurons whose PRI(t) increased above the 5% significance level. PRI, paired-recall index; SDF, spike density function. Reprinted from Naya Y, Yoshida M, and Miyashita Y (2001) Backward spreading of memory-retrieval signal in the primate temporal cortex. *Science* 291: 661–664, with permission from American Association for the Advancement of Science.

emissions tomography (PET) and functional magnetic resonance imaging (fMRI) studies carried out in humans while they performed a memory retrieval task confirmed that the PFC is involved in these component processes. In that context, Fletcher and Henson investigated the roles of three regions of the lateral frontal cortex: the ventrolateral frontal cortex (VLFC; Brodmann's area (BA) 44, 45, 47), the dorsolateral frontal cortex (DLFC; BA 9, 46), and the anterior frontal cortex (AFC; BA 8, 10). In paired associate-cued retrieval tasks, activation of the VLFC contributed to updating and maintaining working memory (WM), within which the cue must be maintained along with possible responses retrieved from LTM. The DLFC, on the other hand, was involved in selecting, manipulating, and monitoring information already active in WM. Because efficient interaction between the VLFC and DLFC is necessary to meet the demands of the task, a meta-level of control is needed to coordinate them. Such control was attributed to the AFC, which optimally selects between the processes or goals of the VLFC and DLFC in order to maximize task performance. Earlier anatomical studies showed that BA 47/12 (an area within the VLFC) is strongly connected with the IT cortical region, which suggests that the top-down retrieval signaling from the PFC to the IT cortex seen in the single-unit study previously summarized may have originated from the homolog of BA 47/12 in the monkey PFC.

The actual retrieval processes are even more complicated than we mentioned in the preceding paragraph; they may entail encoding processes (i.e., when we remember something, we inevitably encode it again at the same time, and vice versa). Consequently, it is important to reevaluate the previous neuroimaging studies from the viewpoints that the memory retrieval process can be seen at different levels of the definition. Questions that remain include, are there the prefrontal regions which are specifically involved in retrieval processes in the narrowest definition? If yes, what signals are exchanged between these areas and the areas related to monitoring or selection or encoding? And which prefrontal area controls these complicated processes of across-areal communication?

Figure 7 Experimental design measuring neuronal activity in monkeys: (a) bottom-up condition; (b) top-down condition; (c) activity of a single IT neuron under the top-down condition (top-down, blue; bottom-up, black). As shown in (a), in the bottom-up condition visual stimuli (cue and choice pictures) were presented in the hemifield contralateral to the recording site (electrode) in the IT cortex. The monkey was required to make the correct choice specified by the cue. Fixation was required throughout each trial ($< 0.6°$). Bottom-up sensory signals (black arrow) were detected in this condition. As shown in (b), in the top-down condition, the cue was presented in the hemifield ipsilateral to the recording site, but the choice was presented contralaterally. In posterior-split-brain monkeys, sensory signals do not reach the visual areas in the opposite hemisphere. In this condition, only top-down signals (blue arrow) can activate IT neurons through top-down connections from the prefrontal cortex. In (c), the raster displays and SDFs are aligned at the cue onset. In the SDFs, the thick lines show responses to the optimal cue; the thin lines show responses to a null cue. The onset of the top-down response (arrowhead) was later than the onset of the bottom-up response (doubled arrowhead). CC, corpus callosum; IT, inferior temporal; SDF, spike density function. Future research should provide answers to these and other questions, enabling a fuller understanding and appreciation of the neuronal mechanisms responsible for the management of semantic memories in primate brains.

The visual system of humans and other primates is an evolutionary success story. It has developed an elaborate peripheral sensor system, the retina, in which the information picked up by more than 100 million receptors is compressed in a highly efficient manner and sent to the central nervous system by 1.5 million axons leaving the eyes. The complexity and level of sophistication of the retina is matched by a dedicated cortical processing hierarchy that encompasses more than 30 anatomically and/or functionally distinct areas covering approximately 50% of cerebral cortex in macaques and 20–30% in humans.

Although such a system picks up a plethora of information, even the highly developed visual cortex of primates would not be sufficient to process it all optimally and equally. Essentially, two interacting systems have evolved to counteract this limitation. A bottom-up system substantially compresses the information picked up by the retinal photoreceptors, and a top-down system dynamically allocates central processing resources for the visual information deemed most relevant in the current situation. The latter system, selective attention, is the focus of this article, but the two systems work hand-in-hand to provide an organism with the information most likely to be of relevance for its survival.

This article concentrates on our understanding of the neural basis of visual attention, emphasizing the most direct methodological approaches, namely single cell recordings from the visual cortex of behaving monkeys and, to a lesser degree, brain imaging measurements in human subjects. The central task for studies aimed at elucidating the neural correlates of attention is to evaluate linking hypotheses – that is, proposals of how the activity of neurons (in visual cortex or elsewhere) could account for the features and perceptual consequences of visual attention. More directly, such studies need to document effects that show the three characteristic features of attention that have been established in psychophysical studies: (1) attention selects relevant information – that is, some sensory signals receive preferential treatment; (2) the processing of selected and unselected information is differentially modulated – that is, attention changes how sensory information is processed; and (3) this selective modulation has perceptual consequences – that is, it changes the weighting or salience of different aspects of the visual environment as a function of their behavioral relevance, creating a representation that enhances some aspects at the expense of others. These three aspects serve as a framework for this article.

Selectivity

Spatial Attention

Directing attention into versus out of the receptive field Early attention research demonstrated that visual attention can be directed to selected locations in the visual field, even covertly (i.e., in the absence of eye movements). Behavioral measurements have shown that stimuli at attended locations are processed faster and more accurate compared to stimuli at unattended locations. Modern imaging studies of attention have measured brain activity during spatial attention tasks and have documented an enhanced activity in retinotopic cortical areas representing the location of the focus of attention.

This spatial allocation of attention has often been likened to a spotlight, suggesting as a neural correlate an enhanced response of a sensory cell and an increased synchrony in the activity of cell populations when spatial attention overlaps a neuron's receptive field. Indeed, studies report modulated responses when attention is directed into the receptive field of neurons from almost every area in visual cortex tested. However, an attentional mechanism that would modulate responses solely depending on whether the 'attentional spotlight' is inside versus outside the receptive field would have very poor spatial resolution beyond striate cortex as receptive fields grow with increasing levels of hierarchy in visual cortex, covering large portions of the visual field in higher areas. Instead, our visual system seems to be able to allocate spatial attention at a finer spatial scale than implied by the large receptive fields in higher areas of visual cortex.

Differential attentional effects inside the receptive field To examine the resolution of the neural mechanisms of spatial attention, several studies have trained monkeys to direct their attention to one of two stimuli inside the receptive field. In most of these studies, one stimulus was matched to the sensory preferences of a cell, whereas the other was not. Responses are generally substantially higher in trials in which the animals are attending to the preferred stimulus. Thus, attention can modulate responses even when it is only switched between two stimuli

that are both inside the receptive field, demonstrating that attentional modulation has a better spatial resolution than the size of the receptive fields in these areas (Figure 1).

For middle temporal area (MT) neurons the neuronal correlate of the attentional selection of one of two stimuli inside a receptive field has been investigated by carefully mapping the receptive fields while the animal was directing its spatial attention to one of the two stimuli inside the receptive field. Under these conditions, the center of the receptive field shifts toward the attended location with a concomitant slight decrease in receptive field size (Figure 2). A similar distortion of receptive field profiles has been observed in area V4 when spatial attention is directed to various positions just outside the receptive field.

Figure 1 Effect of directing attention to either of two moving stimuli presented inside the receptive field of direction-selective neurons in macaque visual cortex. The inset illustrates the experimental conditions. Two stationary, semicircular apertures containing moving random dots are presented inside the receptive field. One of the dot fields is moving in the preferred direction (red semicircle; upward motion in this example) the other one in the null direction (green semicircle) of the neuron under study. At the beginning of each trial, the animal was instructed to covertly direct attention either to one of the two dot fields or to the fixation point (blue square) while maintaining its gaze on the fixation point. The curves represent firing rates, normalized to the level of sustained activity with attention on the preferred direction semicircle, and averaged across a population of neurons from the middle temporal and the medial superior temporal area. The *x*-axis represents time, with time zero indicating the onset of the visual stimulus. As can be seen, attending to the preferred direction stimulus inside the receptive field increases firing rates (red trace) compared to a condition in which attention is directed to the luminance of the fixation point (blue trace). In contrast, attending to the null-direction stimulus inside the receptive field reduces firing rates (green trace) relative to the fixation point condition. Modified from Treue S (2001) Neural correlates of attention in primate visual cortex. *Trends in Neurosciences* 24(5): 295–300, with permission.

As a consequence of such receptive field shifts, more neuronal processing resources are devoted to attended stimuli. Assuming that neuronal responses provide evidence of the presence of a stimulus at their original receptive field locations, attentional shifts of receptive fields could be the basis of the perceptual overestimation of an attended stimulus' size observed psychophysically.

Although the consequence of the observed shifts in receptive fields is fine-grained changes in visual information processing caused by spatial attention, it should be emphasized that the observed modulation need not be created in the large receptive fields in extrastriate cortex where it has been observed but, rather, could be the consequence of effects on the matrix of small receptive fields in area V1 that together form the large receptive fields in higher areas.

Attention can suppress responses The response modulations that are demonstrated when switching attention from outside to inside the receptive field suggest that directing attention into the receptive field always enhances responses. To investigate this conjecture, a 'neutral' or 'sensory' condition can be used in which attention is directed outside the receptive field, with two (behaviorally irrelevant) stimuli inside the receptive field. Usually, one of the two stimuli is matched to the neuron's preference (e.g., aligned to the preferred orientation), whereas the other is a nonpreferred stimulus. In such a paradigm, the response of the neuron is increased when directing attention toward the preferred stimulus inside the receptive field. However, the response of the neuron will usually drop below the neutral response when attention is directed to the nonpreferred stimulus. Switching attention between two stimuli inside the receptive field combines the suppressive effect of attending to the nonpreferred stimulus with the enhancing effect of attending to the preferred stimulus (Figure 1). This push–pull interaction may be one of the reasons why the attentional modulation is typically stronger in experimental paradigms that juxtapose two stimuli inside the receptive field. As a consequence of such attentional effects, the neural representation of attended stimuli is enhanced at the expense of unattended stimuli.

Nonspatial Attention

Feature-based attention The spotlight metaphor suggests a special role for spatial location as the basis for attentional selection, but several studies have demonstrated nonspatial, feature-based attentional modulation as well. Responses in inferior temporal cortex are enhanced, even before the onset of the preferred shape of a neuron, if its appearance was

Figure 2 Modulation of receptive field structure by spatial attention. The gray panels at the top represent a computer monitor and illustrate the sequence of events in a single trial of the experiment. After the monkey fixates the small black square, a cue is briefly presented indicating the spatial location of one stimulus (target) that will appear together with two others (distractors). After the cue disappears, three stationary apertures containing moving random dots are presented on the screen, two of which are placed inside the receptive field of the recorded neuron (dashed circle) and the other one is placed outside. While the monkey is attending to the target, trying to detect a subtle change in the direction of motion, an additional small moving pattern is briefly presented at spatially random locations marked with the black dots. Plotting the neuron's response to this pattern as a function of its position describes the spatial structure of the receptive field. The bottom of the figure shows such a receptive field obtained from a single neuron in the middle temporal area. The strength of the response is coded in color, with white indicating the strongest excitation and blue indicating inhibition. The top right panel represents conditions in which attention was directed to the stimulus outside the receptive field. The top left panel and the bottom left panel represent conditions in which attention was directed to the stimulus marked with the green square or to the stimulus marked with the blue circle, respectively. Finally, the bottom right panel represents the difference between the latter two conditions, showing the push–pull effect of spatial attention across the receptive field that underlies the shift of the receptive field center between the conditions. Modified from Treue S, Womelsdorf T, and Martinez-Trujillo JC (2007) Visuelle Aufmerksamkeit: Von Orten, Eigenschaften und Kontrasten. *NeuroForum* 13: 55–60, with permission from NeuroForum.

expected and behaviorally relevant. Similarly, when monkeys are discriminating the orientation of a bar that matches the color of a cue, enhanced responses are observed in area V4 compared to situations in which the color of the bar is different from the color of the cue.

Feature-based attentional modulation that reaches far beyond the confines of the spatial receptive field of a sensory cell has been reported in the dorsal cortical pathway. The activity of MT neurons is higher when the animal is attending to a stimulus moving in their preferred versus nonpreferred direction, even when the attended stimulus is far from the classical receptive field. Thus, attending to a feature, such as a particular direction of motion, enhances the responsiveness of all neurons that prefer this particular stimulus feature, not just those whose receptive field includes the attended stimulus. This global spread of feature-based attention has been confirmed in behavioral and functional brain imaging studies.

Feature-based attentional modulation is comparable in strength to spatial attentional modulation, and the two influences combine additively in appropriate experimental paradigms. The similarity in strength of spatial and nonspatial attention and the additivity of the two modulations have also been observed in the ventral pathway, suggesting a unified system in which the spatial location is just another stimulus feature.

These observations have led to the formulation of the feature similarity gain model of Treue and Martinez-Trujillo. In essence, this model predicts the sign and magnitude of attentional gain modulation based on the similarity between the currently attended feature and the preferences of the neuron under study. Attending to the preferred feature of a given neuron (e.g., its preferred direction) increases neuronal responses, whereas attention to nonpreferred features (e.g., the nonpreferred direction) decreases neuronal responses. Note that the feature similarity gain model also accounts for spatial attentional modulations, interpreting the response reduction when spatial attention is shifted outside the receptive field as a situation of low feature similarity since the attended location is not matched to the preference of the neurons (i.e., its receptive field).

Object-based attention In addition to spatial and feature-based attention, the perceptual grouping of individual stimulus features into visual objects can also strongly influence the allocation of attention. Traditionally, investigations of object-based attention have played a more prominent role in psychophysical and functional magnetic resonance imaging experiments. Typically, two or more visual objects are superimposed such that spatial attention cannot be used to guide the allocation of attention. In such paradigms, features belonging to the same object are generally processed faster and more accurately than features belonging to different objects. Strong evidence for the existence of object-based attentional mechanisms has also been provided by imaging studies comparing activity in functionally defined regions of interest. The visual features of superimposed objects are carefully chosen to differentially activate well-defined cortical regions. Attending to a particular feature can result not only in enhanced activity within the cortical region processing the attended feature but also in enhanced activity within regions processing other, task-irrelevant features of the same object. Therefore, in contrast to feature-based attention, object-based attention is characterized by a transfer of attention from attended to unattended features of the same object. In physiological experiments, it has been difficult to distinguish feature-based attention from object-based attention. A notable exception is a series of experiments in primary visual cortex involving a task in which the animal was trained to mentally trace a curved line while keeping fixation on one of its ending points. Multiunit activity of V1 recording sites overlapping with different segments of the line was simultaneously enhanced if the curve crossing the receptive fields was behaviorally relevant as opposed to when it was not. Such findings indicate that responses of neurons in area V1 depend on whether the stimulus inside their receptive field is part of an attended object.

In summary, different experimental paradigms have revealed apparently distinct forms of attention, depending on whether spatial locations, nonspatial stimulus features, or visual objects are relevant in terms of current behavioral goals. Additional physiological examinations of these phenomena will help to assess the validity of such a strict separation by investigating the basic neuronal mechanisms leading to an enhanced representation of relevant visual information.

Modulation

Multiplicative Modulation of Tuning Curves

The ability of a given neuron in visual cortex to encode a particular stimulus feature is captured by the neuron's tuning curve, the bell-shaped response profile which plots the response of a neuron as a function of some continuous stimulus property, such as orientation or direction of motion. Investigating the neural basis of attentional modulation of information processing therefore requires examining attentional influences on tuning properties. Studies of orientation-tuned cells in area V4 (i.e., the temporal visual pathway) as well as of direction-tuned neurons in MT and medial superior temporal (MST) areas (i.e., the dorsal pathway) have documented that switching spatial attention from outside to inside the receptive field of a given neuron enhances the neuron's responses in a multiplicative manner. Thus, the tuning curves in these two attentional conditions are scaled versions of each other, not differing in their tuning width but only in their amplitude (**Figure 3**). This shows that the allocation of spatial attention into the receptive field of a neuron enhances the neuron's response gain independently of the particular stimulus that drives its response. Moreover, the temporal dynamics of direction tuning in MT neurons show multiplicative modulation by attention in the absence of shifts or changes in shape of the temporal profile. Collectively, these studies show that the highly specific modulation of the response gain of sensory neurons in visual cortex is a central mechanism of attentional influence.

Nonmultiplicative Consequences of Attention

Although both spatial and feature-based attention have been shown to create gain changes (i.e., exert a multiplicative influence on neurons in visual cortex), it is important to note that multiplicative effects can be combined to create nonmultiplicative modulations. One example of such nonmultiplicative modulations is the change in receptive field profiles created

Figure 3 Multiplicative effects of spatial attention on neuronal tuning curves. The red curve in both panels represents the response when attention was directed toward the stimulus inside the receptive field, whereas the green curve gives the response to the same stimulus when attention was directed out of the receptive field. For both pairs, the attentional modulation did not significantly change the width of the tuning curve. The left panel shows firing rates, averaged across a population of neurons from the medial superior temporal area (MST), in response to the direction of a high-contrast moving random dot pattern. The right panel shows the average tuning curve across V4 cells to the orientation of a grating. The dashed lines represent the background firing rates (i.e., the responses of the cells in the absence of a stimulus). Modified from Treue S (2001) Neural correlates of attention in primate visual cortex. *Trends in Neurosciences* 24(5): 295–300, with permission.

when shifting spatial attention within a receptive field or between locations inside and outside the receptive field (Figure 2). Nevertheless, this modulation can also be caused by gain changes, if one assumes that spatial attention differentially enhances and reduces the gain of those V1 neurons providing the input to MT neurons and covering the attended and unattended portions, respectively, of the MT receptive field.

Similarly, switching attention from a fixation point to a stimulus moving in various directions inside an MT receptive field creates a systematic but nonmultiplicative change of the direction-tuning curve between the two attentional conditions (Figure 4). Note that although even purely multiplicative effects of attention have been shown to improve the signal-to-noise ratio of attended stimuli, this selective modulation is even higher in the case of nonmultiplicative modulations based on gain changes. As such, they usually exert a push–pull influence that cannot be achieved directly through a gain change, suppressing sensory responses to unattended stimuli and enhancing responses to attended stimuli.

Saliency

Comparing Response Modulation by Contrast and Attention

The multiplicative modulation of responses by attention is very reminiscent of the modulatory influence of a number of well-studied stimulus parameters on sensory responses, such as contrast, speed, and motion coherence. This similarity suggests a common neural mechanism that would allow attention to modulate the strength of a stimulus representation by changing its 'effective contrast' or saliency. Alternatively, this similarity in terms of effects might simply reflect the existence of two independent multiplicative systems.

A few studies have addressed this issue by testing whether the effects of stimulus contrast interact with the effects of attention. These studies have measured contrast response functions under different attentional conditions. If the two systems were truly independent, the multiplicative effects of attention should be independent of the level of contrast, and the contrast response function should be scaled by a constant factor along the vertical dimension (Figure 5(a)), in the same way as the tuning curves shown in Figure 2. If, on the other hand, these two systems share a common mechanism, directing attention should have the same effect as changing contrast and should therefore become evident in a horizontal shift of the contrast response function between attentional conditions. As a consequence, the strongest attentional effects would then be expected for stimuli of intermediate luminance or contrast (Figure 5(b)).

Recordings from area V4 have revealed a horizontal shift of the contrast response function, consistent with the notion that contrast modulation and attentional effects share a common mechanism. Studies in MT and MST have also reported such a horizontal shift and have documented the strongest attentional effects for intermediate levels of stimulus luminance (i.e., for levels corresponding to the steepest part of the sigmoidal contrast response function). Altogether, the studies further support the notion of a close coupling between these mechanisms. They could thus underlie the attentional effects on perceived stimulus saliency observed in psychophysical studies (Figure 5(c)). Moreover, the

Figure 4 Feature-based attention in the middle temporal area (MT). (a) Schematic representation of tasks used to assess the effects of attention to direction of motion. Two stationary apertures containing moving random dots were presented on the computer monitor. One of them was placed inside the receptive field (dashed white line) of the neuron under study, and the other one was placed outside. The dot patterns always moved in the same direction (white arrows), but different directions of motion were presented on different trials. On some trials (bottom row), the attention of the animal (gray arrows) was directed to the fixation spot to detect a change in luminance. On other trials (top row), a cue at the beginning instructed the animal to pay attention to the motion of the pattern outside the receptive field to detect a subtle change in that motion. (b) Responses of a representative MT neuron to different directions of motion, separately for each attentional condition. Attention to the preferred direction of motion increased the response of the neuron, but attention to the null direction of motion decreased its response. Thus, attention to a particular direction of motion does not increase responses across all neurons. Rather, it has a push–pull effect that increases responses only for neurons that prefer motion close to the attended direction. Modified from Maunsell JHR and Treue S (2006) Feature-based attention in visual cortex. *Trends in Neurosciences* 29(6): 317–322, with permission.

influence of stimulus contrast on the magnitude of the attentional effects might account for the variability in the magnitude of attentional modulation reported in the literature. However, a related study, also recording from area V4, reported a mixture of effects, including multiplicative scaling of the contrast response function by spatial attention, leaving open the possibility of a less direct and more complex relationship between attentional and contrast modulation. Further research is necessary to reconcile these findings.

Forming an Integrated Saliency Map by Spatial and Feature-Based Attention

Our visual environment is represented as the neuronal activity across a population of neurons, with various receptive field positions and preferred feature values. The insights into the neuronal mechanisms of attentional modulation gained from the studies mentioned previously permit inference on the attentional modulation of this population activity, caused by directing attention to a particular feature at a particular location in a complex visual scene. Conceivable could be a scenario in which the visual input creates a fairly homogeneous level of activation across the neuronal population. Spatial attention will increase the gain of all neurons whose receptive field overlaps the current attentional focus, creating an enhanced representation at that location that is akin to a local increase in contrast and that creates a corresponding perceptual effect (Figure 5(c)).

Since similarity in terms of features can also be based on spatial location, the feature similarity hypothesis predicts that the attentional modulation within this retinotopic population should vary considerably. Specifically, neurons whose receptive fields only partially overlap the focus of attention will experience less of a gain increase than those centered on the focus – a prediction that has not been tested experimentally.

In addition to this spatially confined modulation of the retinotopic representation, the contribution of the attended nonspatial feature must also be considered. Feature-based attention will cause a differential gain change across the whole retinotopic representation with a particularly strong gain increase for neurons preferring the attended feature and a corresponding gain decrease for those of opposite preference. The total effect will be a population response that is no longer homogeneous but has its highest activity in the group of neurons preferring the attended location and feature, intermediate enhancements at retinotopic locations where the visual input only matches the attended nonspatial feature (i.e., potential targets in a visual search situation), and suppressed responses everywhere else. Combining such modulated population responses across cortical areas could create an integrated saliency map – that is, a topographic representation of relative stimulus strength and behavioral relevance across visual space.

Figure 5 Depiction of the similarity between attentional effects and changes in luminance contrast. (a and b) Possible attentional effects on contrast response functions of visual cortical neurons. According to the response gain model (a), attention modulates the neuronal response to every level of contrast by a constant factor, effectively scaling the contrast response function along the vertical dimension. According to the contrast gain model (b), directing attention is equivalent to changing contrast, resulting in a shift of the contrast response function along the horizontal dimension. A number of studies have provided evidence for the contrast gain model, suggesting that an unattended stimulus of a given contrast will have the same effect as an attended stimulus of lower contrast. An increase in the perceived contrast by attention has been demonstrated in behavioral experiments with human observers and is illustrated in (c). The two stimuli, shown to the left and right of the fixation square, are judged to be equal in contrast if attention is directed to the left stimulus only. Modified from Treue S, Womelsdorf T, and Martinez-Trujillo JC (2007) Visuelle Aufmerksamkeit: Von Orten, Eigenschaften und Kontrasten. *NeuroForum* 13: 55–60, with permission from NeuroForum.

Top-Down and Bottom-Up Response Modulation

The previously outlined attentional modulations of neural activity in visual cortex all result in an enhancement in the activity or the synchrony of cell populations preferring attended stimulus attributes and a simultaneous suppression in the activity of cell populations preferring nonattended attributes. This will create an enhanced representation of attended relative to unattended stimuli, an effect reminiscent of the selective enhancement of particular aspects of the visual input by the hardwired bottom-up coding mechanisms mentioned in the introduction. The similarity of the two systems suggests their combination into the integrated saliency map, in which the visual input is represented not by an individual stimulus' physical strength (e.g., its luminance) but by its saliency (i.e., its difference in features compared to the spatially surrounding visual input). The integrated saliency map combines the bottom-up saliency with the modulatory influence of attention, strengthening or weakening it according to the behavioral relevance of a particular location, feature, or object.

This interaction provides an account for a central function of attention in enhancing the representation of stimuli of intermediate strength while particularly salient stimuli will be well represented even in the absence of attention. This is in good agreement with results from a large body of psychophysical studies demonstrating that highly salient stimuli (known as 'pop-out' stimuli in visual search tasks) need little attentional resource allocation, whereas the same stimuli embedded among similar distractors will only be perceived when attention is directed toward them.

Conclusion

The understanding of attentional influences has advanced considerably beyond the view that attention is a separable influence providing only a late modulation of an otherwise stimulus-driven sensory information processing system. Instead, attention influences the processing of visual information even in the earliest areas of primate visual cortex. This influence seems to shape an integrated saliency map – that is, a representation of the environment that weighs every input by its local feature contrast and its current behavioral relevance. This map enables the visual system to integrate large amounts

of bottom-up and top-down information because it provides an efficient coding scheme for the potentially most relevant information in the sensory input. However, by completely integrating bottom-up sensory information and top-down attentional influences, it equates the absence of attention with low stimulus power. This provides a possible explanation for the observation that highly salient stimuli will be processed even in the absence of attention, whereas low inherent salience will often prevent the perceptual representation of unattended parts of complex natural scenes, although exceptions seem to exist for the categorization of the gist of natural scenes.

The brain areas providing the guidance for the top-down attentional effects seem to be tightly linked to those areas responsible for the planning and execution of eye movements in agreement with the frequent need for foveating salient regions of the visual environment for a more detailed analysis.

Although many questions remain, the rapid development of functional imaging techniques and the development of sophisticated paradigms and recording techniques in monkeys trained to perform complex attentional tasks provide the basis for the recent growth in understanding. By bringing together bottom-up stimulus aspects that are often responsible for automatic attentional allocation and top-down influences reflecting voluntary attention, a global map representing stimulus saliency modulated by the current behavioral state of the organism can provide a unified framework for interpreting future findings on attentional effects and their close integration with sensory information processing.

Visual Cortex in Humans

B A Wandell, S O Dumoulin, and A A Brewer, Stanford University, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Human visual cortex comprises 4–6 billion neurons that are organized into more than a dozen distinct functional areas. These areas include the gray matter in the occipital lobe and extend into the temporal and parietal lobes. The locations of these areas in the intact human cortex can be identified by measuring visual field maps. The neurons within these areas have a variety of different stimulus response properties. We describe how to measure these visual field maps, their locations, and their overall organization. We then consider how information about patterns, objects, colors, and motion is analyzed and represented in these maps.

Regions of cortex that respond powerfully to retinal stimulation are called visual cortex. In the human brain, the visual cortex is located in the occipital lobe and extends into the temporal and parietal lobes (Figure 1). In many mammalian species, visual cortex spans as much as half of the entire cortical surface area; in humans, the fraction is smaller – approximately 20%.

A key problem in visual neuroscience is to understand how information about patterns, objects, colors, and motion is analyzed and represented within visual cortex. One of the great advances of the past 50 years in our understanding of the processing of visual information has been the discovery of a basic functional architecture. In many species, visual cortex is divided into more than 12 distinct functional areas. The neurons within these areas differ in their stimulus response properties.

New developments in the past 15 years have allowed a multiplicity of distinct areas to be identified using functional magnetic resonance imaging (fMRI) in the intact human brain. The areas within human visual cortex are identified by measuring visual field maps. These are cortical regions that contain a topographic representation of the visual field; stimuli adjacent in the visual field evoke responses that are adjacent in visual cortex. Visual field maps can be identified in individual subjects with fMRI experiments that last approximately 1 h. Measurement of these maps is the most reliable approach to identifying a functional area within human visual cortex.

In this article, we first introduce the reader to the largest and best studied visual field map, primary visual cortex (V1). We describe how this map is measured using fMRI, and we discuss the main features of the V1 map. We then summarize the positions and properties of ten additional visual field maps. This represents our current understanding of human visual field maps, although this remains an active field of investigation, with more maps likely to be discovered. Finally, we describe theories about the functional purpose and organizing principles of these maps.

The Size and Location of Human Visual Cortex

The entirety of human cortex occupies a surface area on the order of 1000 cm^2 and ranges between 2 and 4 mm in thickness. Each cubic millimeter of cortex contains approximately 50 000 neurons so that neocortex in the two hemispheres contain on the order of 30 billion neurons. Human visual cortex includes the entire occipital lobe and extends significantly into the temporal and parietal lobes (Figure 1). Visual cortex contains on the order of 4–6 billion neurons.

The number of neurons in human visual cortex far exceeds the number in many other species that depend on vision. For example, the surface area of macaque monkey visual cortex is probably no more than 20% that of human visual cortex, although the cortical neuronal density is similar. This species difference in the number of cells in visual cortex cannot be explained by how these species encode the visual world. The monkey samples the retinal image at a higher resolution. There are 1.5 million optic nerve fibers from each eye in macaque and only 1 million such fibers in humans. The large size of human visual cortex is likely not a result of an increase in the supply of information but, rather, due to an increase in visual processing and the organization and delivery of information to other parts of cortex, such as those devoted to language and reading. Given these differences in visual cortex size, it would not be surprising that many features of human visual cortex are not present in closely related primate systems.

The Location of Primary Visual Cortex

The largest input to visual cortex projects from the retina via the optic nerve to the lateral geniculate nucleus (LGN) of the thalamus and then to primary visual cortex, commonly called V1. V1 is located in and around the calcarine sulcus, which can be found on the medial surface of both hemispheres (Figure 2(a)). The portions of left and right V1 that respond to signals near the vertical meridian are

connected; the axons mediating these connections pass through the posterior aspect of the corpus callosum (the splenium).

The position of V1 can be identified on histological grounds. There is a stripe of heavy myelinated tissue in calcarine cortex that is apparent to the naked eye. This stripe was discovered by an Italian medical student, Francesco Gennari, in 1782, and the stripe is now called the stria of Gennari. Consequently, V1 is also referred to as the striate cortex, whereas other parts of visual cortex are collectively referred to as extrastriate cortex. Figure 2(b) is a cross section through the calcarine cortex stained to reveal the myelination; note that the white matter is also strongly stained. The myelination runs through one of the cortical layers. The stria of Gennari terminates at the border of V1.

The discovery of the stria of Gennari was one of the first indications that cortex could be differentiated into distinct regions. The association between this stripe and the projection zone of the LGN was not known at first. One hundred years after the discovery of the stria of Gennari, the Swedish neuropathologist Henschen showed that it is coextensive with the LGN projection zone.

Figure 1 Human visual cortex. The extent of human visual cortex is indicated by the purple overlay shown on the medial and lateral views of a right hemisphere. Visual cortex occupies approximately 20% of the surface area of neocortex. Measuring Visual Field Maps

Anatomical

Until recently, researchers have had almost no access to measuring functional signals in the human brain. The development of fMRI resulted in an enormous outpouring of new data about the human brain. One of the first applications of this technology was to define the architecture of signals in human visual cortex. From extensive work in animal models, particularly macaque, it was known that visual cortex could be partitioned into a set of distinct visual field maps. Hence, an early focus in humans was to define the locations and properties of human visual field maps.

The organization of visual cortex is easily discernible on a flattened representation of the cortical surface. However, in humans, the cortex is highly convoluted, masking this topographic organization. In order to trace the borders of visual field maps, it is useful to create a representation that plainly exposes the signals in the sulci. This process is initiated by acquiring a set of anatomical images that have high contrast between the gray and white matter of the brain (Figure 3(a)). These data are processed to determine the location of the white matter (axon bundles) and the gray matter sheet that surrounds the white

Figure 2 V1 and the stria of Gennari. (a) The location of right calcarine cortex and the splenium of the corpus callosum are shown. Primary visual cortex falls in and around the calcarine sulcus. Portions of right and left primary visual cortex are connected by axons that pass through the splenium. (b) Photograph of a coronal slice through the calcarine sulcus. This slice is stained for myelin (dark regions). Primary visual cortex (V1) is also called striate cortex because it is coextensive with the densely stained stripe that is the stria of Gennari. Reproduced from Andrews TJ, Halpern SD, and Purves D (1997) Correlated size variations in human visual cortex, lateral geniculate nucleus, and optic tract. *Journal of Neuroscience* 17(8): 2859–2868, with permission.

Figure 3 Cortical surface reconstruction and visualization. (a) A coronal slice of an anatomical MRI image is shown. Regions within the right hemisphere are colored to identify white matter (purple) and gray matter (green). (b) The white and gray matter segmentation identified in multiple slices defines a surface that can be reconstructed. (c) The cortical surface is 'inflated' or 'unfolded' to provide a convenient visualization of the cortical sheet within both sulci (dark) and gyri (light).

matter. Although there are several automated methods that achieve a good first approximation for this segmentation, careful work usually requires hand editing.

Once the gray matter voxels are identified, many automated tools are available to create a three-dimensional rendering of the boundary between the gray matter and the white matter (Figure 3(b)). Smoothing algorithms create a new 'inflated' representation of the surface (Figure 3(c)). In this format, the sulci are exposed so activation patterns can be tracked along the gyri (shown as light shading) and within sulci (shown as dark shading).

Functional

Visual field maps represent visual space in a unified, organized arrangement. These maps are often called retinotopic maps because their organization reflects the organization of the retinal image. Visual field maps can be identified by measuring which stimulus position in visual space produces the largest response in a particular section of visual cortex. There are many reasonable ways to perform this experiment, but the most widely used method is to divide the measurements into two parts: measurements of eccentricity and angle with respect to the point of fixation. In one experimental session, one measures cortical responses

Figure 4 Traveling wave measurements using contrast rings. The functional activation elicited by a contrast ring surrounding fixation (red dot) is shown on an inflated representation of cortex. The peak response shifts smoothly from posterior to anterior calcarine as the ring grows from a small central ring to a large peripheral ring.

to a series of contrast rings, which measures the eccentricity component of the map (Figure 4); in a second session, one measures with a series of contrast wedges at different polar angles, which measures the angular component of the map.

This approach produces strong responses in human visual cortex. For example, a set of contrast rings of increasing size produce peak fMRI signals at a series of locations from posterior to anterior calcarine cortex (Figure 4). The peak response shifts smoothly from posterior to anterior calcarine as the ring grows from a small central ring to a large peripheral ring.

By analyzing the timing of the peaks and troughs in the data, one can identify the visual field eccentricity that most powerfully stimulates each location in visual cortex. The information is commonly color coded to show the eccentricity that most effectively drives the response at each cortical location (Figure 5(b)). In a second experiment, using the rotating wedge stimulus, one can identify the angular direction that most effectively stimulates each cortical location (Figure 5(c)). Taken together, these two measurements define a visual field map, expressed in polar coordinates of eccentricity and angle. These measurements are combined into a single visual field map. The first three maps, V1–V3, are shown in Figure 5(d).

The Human V1 Map

There are a few important characteristics to note about the V1 measurements(Figure 6). First, in the right calcarine sulcus, the most effective wedges are always located in the left part of the visual field. This confirms a well-known anatomical projection: signals from the left visual field project to V1 in the right hemisphere. Second, stimuli in the upper visual field are

most effective for neurons on the lower bank of the calcarine (lingual gyrus), whereas stimuli in the lower visual field produce the greatest response on the upper bank of the calcarine (cuneus). Stimuli near the horizontal midline are most effective at stimulating cortex near the depth of the calcarine sulcus. Thus, the V1 map is inverted with respect to the visual field but consistent with the retinal image. Finally, the central portion of the visual field stimulates posterior calcarine, whereas the more peripheral visual field stimulates anterior calcarine.

Figure 5 Polar angle and eccentricity measurements define visual field maps on the cortical surface. (a) The cortical surface of the right hemisphere is displayed from a ventroposterior view, emphasizing the occipital lobe. The position maps are displayed on the enlarged part of the occipital lobe, as indicated by the large black square. The maps for eccentricity (b) and polar angle (c) are shown. The insets indicate the color code that defines the part of the visual field that most effectively stimulates each cortical location. Visual field maps V1–V3 are identified from these eccentricity and polar angle measurements (d).

Note that that there is considerably more cortical territory in V1 responding preferentially to stimuli within 2° or 3° of visual angle than responding preferentially to stimuli in the periphery. The visual field map in V1 is a distorted version of the visual field; this magnified foreal representation is called cortical magnification. The term is unfortunate because the magnification is not introduced in cortex. Rather, the magnification begins at the level of the foveal cone photoreceptors in the retina, which are smaller and more tightly packed than peripheral cones. The number of retinal ganglion cells carrying information to the LGN and the number of V1 neurons transmitting the cone signals mirror the uneven cone density. Since the density of cortical neurons is approximately uniform, the differential number of neurons needed to process foveal and peripheral signals is manifest by an expanded surface area for foveal compared to peripheral representations in V1.

Extrastriate Visual Field Maps

The orderly representation of eccentricity and angular responses continues beyond the V1 map. The eccentricity representation in the surrounding cortex parallels that in V1 (Figure 5(b)). The polar angle representation in surrounding cortex is regular, but it reverses direction. At the boundary of V1, the angular representation turns from the vertical meridian of the upper or lower visual field and progresses toward the horizontal representation (Figure 5(c)).

Figure 6 Schematic representation of the V1 visual field map. When one looks at the fixation point (red dot), the left part of the visual field evokes a response in right V1. Both the visual field and the V1 representation of this visual field are schematically illustrated. The V1 map preserves visual field topography, but relatively more cortical area is devoted to the central part of the visual field; this is called cortical magnification. Also, note that the lower visual field evokes activity on the upper bank of the calcarine, whereas the stimulus in the upper visual field evokes activity on the lower bank.

The angular map reversal line is the functional signal used to define the boundary between the V1 and V2 maps.

The V2 map surrounds V1 (Figures 5(d) and 7). One section is located on the cuneus; this section is most effectively driven by signals in the lower visual field. The other section of V2 falls on the lingual gyrus; this section is most effectively driven by signals in the upper visual field. The V2 map is surrounded by a third map, V3. At the V2/V3 boundary, the angular representation reaches the horizontal and then reverses again into V3.

Careful mapping reveals the presence of at least 10 visual field maps (Figure 7). In many cases, these visual field maps are small maps which contain foveal representations distinct from the foveal confluence of the V1–V3 maps. The maps shown here are largely agreed upon, although there is some debate concerning the specific organization of certain maps. It can be difficult to measure these maps for several reasons. Some of the maps are much smaller than the V1–V3 maps and thus are at the spatial resolution limit of conventional fMRI. Also, the size of neuronal receptive fields can be quite large in many of these areas, which makes measurements of the internal structure of these maps more difficult. As resolution and experimental methods improve, new maps will be identified, and our understanding of the known maps will be refined.

The presence of so many distinct visual field maps suggests that the map itself serves a functional purpose. The spatial organization of the maps may facilitate certain types of cortical computations. The internal structure of the visual field maps may simplify the connectivity needed for spatially localized visual computations between neurons specialized for carrying such information as stimulus orientation, color, or motion. The simplification of axonal wiring is an

Figure 7 Visual field maps on a cortical surface. Currently identified visual field maps are shown on several views of a right hemisphere (see color legend). Fovea and upper/lower visual fields are indicated by the asterisk, plus, and minus symbols, respectively. The first visual maps are termed V for visual and a number, such as V1, V2, V3, and V3A, following the naming of apparent homologs in monkey. Doubts about the homology of the fourth visual map between monkey and human caused this map to be identified as hV4 (for human V4), and similarly for hLIP, a putative homolog to monkey lateral intraparietal sulcus. Historically, V5 is also referred to as medial temporal. Maps in lateral occipital cortex are numbered as LO-*x*, maps in ventral occipital are numbered as VO-*x*, and maps in the intraparietal sulcus are numbered IPS-*x*.

important aspect of visual field map organization, given the remarkable observation that the axons in 1 mm^3 of cortex would extend over a length of more than 3 km.

Visual Field Maps and Perception

How information is processed within visual field maps and the significance of this processing in terms of visual perception are central questions in visual neuroscience. The presence of multiple maps supports a view of visual cortex based on functional specializations. This view contrasts with the classic null hypothesis that cortex is equipotential or the theory that there is a canonical cortical circuit.

The dominant thinking for the past 30 years assumes that each extrastriate map represents a computational specialization. Furthermore, it is frequently asserted that these computations are associated with specific perceptual experiences. For example, a map on the lateral surface (V5/MT) is often described as a 'motion center,' and a set of maps on the ventral surface are often described as a 'color center.' The principle of associating maps with a perceptual experience is a form of the cortical specialization hypothesis. This framework has provided a scheme for scientists to discuss the significance of these maps, although this framework is far short of a computational theory.

The basis for the relationship between functional specialization and perceptual experience originated in neurological findings: damage to specific extrastriate regions in ventral cortex leads to specific visual disabilities. Four cortical regions in which damage can produce a specific perceptual deficit are illustrated in Figure 8. The neurological deficits illustrated here are inability to recognize faces and interpret facial expressions (prosopagnosia or face blindness), loss of color vision of cerebral origin (cerebral achromatopsia), loss of motion perception (akinetopsia), and loss of the ability to read whole words (alexia). The neurological literature has focused on acquired forms of these deficits, but prosopagnosia also exists in a congenital (developmental) form; it is possible that the other dysfunctions may be discovered in developmental form as well.

The specificity of localized brain damage and perceptual deficits supports the functional specialization hypothesis for extrastriate maps. In contrast, the behavioral consequences of V1/V2 lesions are not usually functionally specialized. Damage to small (<5 mm) regions of V1 degrades vision generally within the corresponding portion of the visual field. This suggests that the visual signals necessary for motion, color, recognition, and so forth are intermixed in neural signals in V1. Extrastriate regions, either innately or through learning, are specialized to interpret visual information needed in certain tasks. Hence, the architecture of visual cortex supports a mixed model in which certain cortical zones support a mixture of functions, whereas others are highly specialized.

Figure 8 Regions of ventral visual cortex associated with specific neurological deficits. Regions implicated in specific visual impairments are indicated: the inability to recognize faces (prosopagnosia; red), to detect motion (akinetopsia; blue), to read words (alexia), and color blindness (achromatiopsia; green). fMRI measurements aimed at isolating these functions typically yield strong activations at these corresponding cortical regions.

Visual Field Map Clusters

Although the relationship between visual field maps and perceptual experience is an important scale to understand, the association between a map and perceptual experience does not provide a full model of visual processing, and it is unlikely that functional segregation by maps constitutes the only perceptual principle in visual cortex. For example, the dominant model of visual processing in retina, LGN, and V1 consists of several specialized and interleaved neural pathways within each structure. Starting in the retina, there are multiple parallel pathways specialized for conveying specific information about different aspects of the visual signal. Each pathway contains neurons that form a sampling mosaic covering the entire visual field. The neurons within these pathways are located near one another in retina and project to adjacent locations in the LGN and then V1. The retina, LGN, and V1 can thus each be thought of as containing multiple, functionally distinct, superimposed visual field submaps.

Figure 9 Visual field map clusters. (a) Schematic diagram of the organization of eccentricity representations in visual cortex. This diagram is based on measurements of these visual field map clusters, as shown on flattened cortex (b) and on a three-dimensional rendering of the inflated cortical surface (c). Each cluster contains several visual field maps that can be delineated based on the polar angle maps. VO, ventral–occipital; LO, lateral–occipital.

This architecture is not likely to be completely abandoned in extrastriate cortex. In fact, there are already examples in which a single visual map contains distinct neural circuits that measure different aspects of the visual signal. An early and important example of functional heterogeneity can be found in motion-selective cortex (V5/MT), in which there is an orderly representation of both motion direction and binocular depth.

Just as functional specializations exist at a resolution finer than the map, specializations may also exist at a coarser scale. It was previously noted that the V1–V3 maps share a parallel eccentricity representation and are functionally divided by reversals in the angular representation. This same map architecture is present in several other clusters of maps, located in the ventral, dorsal, and lateral regions of visual cortex (Figure 9). Such organization of the individual maps into visual field map clusters may reflect a coarse-level organization that follows specific functional capabilities; visual field maps may be arranged in clusters when the neural mosaics within these maps serve similar computational goals.

Conclusions

The visual system is a valuable model system for neuroscience research because of the extensive information we have about the retinal encoding of light, the multiple pathways that communicate retinal information to cortex, and the distribution of the information from these pathways into maps in visual cortex. This information makes the visual system an excellent target for study beyond the core of vision science, including the neuroscience of development, plasticity, and consciousness.

The organization of visual pathways, maps, and clusters also may have application as an architectural model of general cortical processing. The parallels for other sensory systems are obvious and in many ways appear to be valid. For example, several distinct auditory maps with tonotopic organization have been demonstrated. It also may be that cognitive functions, such as decision making or the distribution of affective functions, are organized using a mixed architectural model in which certain regions contain general and others more specialized processing. To the extent that the cortical architecture of visual cortex matches that in other parts of cortex, we become more confident in results from both fields. Functional neuroimaging, which operates at a relatively coarse resolution of several millimeters to multiple centimeters, is well suited to uncovering structures at the scale of these visual maps or groups of maps.

In the near future, there will be many opportunities to link the functional neuroimaging measurements in quantitative ways to measurements at other resolutions – down to small (a few thousand) populations of cortical neurons. Advances in functional neuroimaging methods have already provided new information about the white matter pathways and long-distance connections between cortical zones. There will be substantial improvements in measurements of the molecular constituents of these cortical regions and in tracking changes in the molecular composition throughout development or following damage. Our current understanding of the architecture of visual cortex makes it a good system for developing these new methods and learning about cortical function broadly.

Visual Cortex: Mapping of Functional Architecture Using Optical Imaging

Introduction

Neurons with similar stimulus response properties are clustered together in vertical columns in cortex, giving rise to what has come to be known as functional architecture – the mapping of various stimulus feature dimensions onto the cortical sheet. At the level of cortical columns ranging from tens of micrometers to a few millimeters, no other technique offers the combination of high spatial resolution and noninvasiveness as optical imaging. This article reviews the properties of optical imaging, the sources of intrinsic signals, and the studies conducted using it, often combined with other techniques, to reveal functional architecture of visual cortex in striking detail.

Properties of Optical Imaging of Intrinsic Signals

Optical imaging of intrinsic signals has a unique set of properties that has made it the method of choice in research of visual cortex where the goal is to study functional architecture of several millimeters of cortex at a resolution corresponding to cortical columns, often over long periods of time and for several visual features.

Resolution

The spatial resolution of optical imaging of intrinsic signals depends on the spatial scale at which hemodynamic signals are regulated in response to neural activation and on the sampling frequency and signal-to-noise ratio of the data. In practice, this has resulted in spatial resolution as good as 20 μm and typically 50 μm. This is ample resolution to image cortical columns, which are typically a few hundred micrometers across.

The temporal resolution of optical imaging of intrinsic signals is constrained by the slow hemodynamic recruitment in response to neural activation. Hemodynamic activation typically follows neural activation by 300–500 ms and lasts for more than 10 s for even very short neural responses. Thus, the temporal envelope of the optical signal is much wider than that of the neural response, and optical imaging of intrinsic signals is thus not considered to allow visualization of neural dynamics. One could attempt to alleviate this shortcoming by deconvolving the intrinsic signal with a hemodynamic impulse function as suggested for functional magnetic resonance imaging (fMRI); however, this has not been attempted for optical imaging yet, and it would strongly rely on the assumed hemodynamic response function. In practice, when neural dynamics need to be imaged at a spatial resolution of a few tens of micrometers, optical imaging using voltage-sensitive dyes is employed. However, for studies of functional architecture, where static maps are explored or maps change at a scale of days or minutes at most, the temporal resolution offered by optical imaging of intrinsic signals is more than adequate.

It should be noted that the light scattering signal is both faster and more tightly co-localized with neural activity than the hemodynamic signal; however, it is weaker in most preparations.

Mapping of Multiple Visual Features

Another important mapping method that has been extensively used in visual cortex, and which has similar spatial resolution to that of optical imaging of intrinsic signals, is the 2-deoxyglucose technique, in which a radioactive sugar analog is uptaken and trapped within active cells, which can then be imaged postmortem. This technique can be used to map responses to up to two stimulus conditions. In contrast, optical imaging of intrinsic signals is performed *in vivo* without invasive extrinsic probes and can therefore be performed repeatedly and, theoretically, to any number of stimulus conditions. This allows mapping of multiple visual features, such as orientation and ocular dominance within the same cortex, and has resulted in detailed studies of the spatial relations between functional maps of various visual attributes.

Chronic Imaging: Development

The relative noninvasiveness of optical imaging of intrinsic signals allows chronic implantation of the imaging chamber for repeated imaging sessions within the same animal and over extended periods of time. An important consequence is that it is ideal for studies of the development of the visual system, in which young animals undergo multiple imaging sessions. The changes in functional architecture between different developmental stages can therefore be followed from before eye opening in species born with eyes closed until adulthood.

Chronic Imaging: Awake Preparation

Chronic imaging also enables studies of functional architecture in awake animals, especially monkeys. This is important for two reasons. First, one wants to verify that the functional architecture revealed in anesthetized animals is an intact representation of the properties of cortex in the awake animal. Second, using unanesthetized monkeys, it is possible to study higher level visual functions that are more cognitive and require the animal's behavior. Optical imaging of intrinsic signals has been repeatedly performed in monkeys for periods of more than 1 year. The orientation and ocular dominance maps obtained throughout this period are stable and constant.

Combination with Other Methods

Optical imaging of intrinsic signals naturally lends itself to combination with other neurobiological techniques because it offers a large exposed patch of several millimeters of cortex within a sealed chamber. Electrodes can straightforwardly be introduced into the preparation, allowing electrophysiological recording targeted to specific loci of interest (e.g., the center of an orientation pinwheel) identified during an imaging session. Anatomical tracers can also be injected to study the structural relationship of horizontal connections to a feature map of interest.

These properties of optical imaging of intrinsic signals have been exploited in extensive studies of the visual cortex, which are reviewed later. In order to understand these results, one also needs an understanding of the underlying sources of these signals, which are discussed next.

Sources of Intrinsic Signals

The intrinsic signal has different components, originating from different sources, as detailed here; however, functional maps obtained at different wavelengths are very similar. Therefore, all of these components can be used for functional mapping. Using optical imaging, imaging spectroscopy, oxygen-dependent phosphorescence quenching, and fluorescent blood plasma tracing, the following changes appear to give rise to different components of the intrinsic signal:

- activity-dependent oxygen consumption affecting hemoglobin saturation;
- changes in blood volume affecting the tissue light absorption;
- changes in blood volume affecting the tissue light scattering;
- changes in blood flow affecting hemoglobin saturation;
- activity-dependent changes in tissue light scattering.

The first component of the intrinsic signal originates from activity-dependent changes in the oxygen saturation level of hemoglobin. This change in oxygenation contains two different components. The onset of the first component is an early one: an increase in the deoxyhemoglobin concentration, resulting from elevated oxygen consumption of the neurons due to their metabolic activity. This causes a darkening of the cortex due to increased absorption by deoxyhemoglobin molecules. This early phase was referred to as the 'initial dip' in the fMRI and related optical imaging literature. The second component of the intrinsic signal originates from an activity-dependent increase in cortical blood volume, increasing the amount of light absorbed by activated cortical regions in a wavelength-dependent fashion, following the absorption spectrum of oxyhemoglobin. Co-localization of blood volume changes with the electrically active columns is much weaker than for the deoxyhemoglobin increase during the initial dip. This poorer co-localization is revealed by a lower signal-to-noise ratio in spatial maps of activation calculated from the cortical blood volume component relative to those from the initial dip. This is especially true for maps in which the response to a single stimulus condition is normalized by the response to a blank ('single-condition' maps). For 'differential' imaging, where the response to a stimulus condition is normalized by or subtracted from the response to an 'orthogonal' stimulus condition, high-quality maps have been obtained, although they are still somewhat poorer than those from the initial dip. The differential procedure removes much of the blood volume noise because it nearly eliminates the contribution of the nonstimulus-specific part of the vascular response.

The third component is a delayed activity-related increase in blood flow, causing a decrease in the deoxyhemoglobin concentration. This happens because the blood rushing into the activated tissue contains higher levels of oxyhemoglobin. Another signal component originates from changes in blood volume, which are probably due to local capillary recruitment or a rapid filling of capillaries and dilation of venules in an area containing electrically active neurons. These blood-related components dominate the signal at wavelengths between 400 and 630 nm. However, blood volume changes in capillaries compress the cortical tissue, giving rise to a change in light scattering that exists at all wavelengths and exhibits a time course typical of blood volume changes rather than that of light scattering changes that originated from electrical activity *per se*. This last significant component of the intrinsic signal arises from changes in light scattering that accompany cortical activation. These changes are caused by ion and water movement, expansion and contraction of

extracellular spaces, capillary expansion, or neurotransmitter release. Light scattering components become a significant source of intrinsic signals above 630 nm and probably dominate the intrinsic signals in the near infrared region above 800 nm.

Functional Architecture of Visual Cortex

Optical imaging of intrinsic signals has been extensively employed in visual cortex of monkey, cat, ferret, tree shrew, rat, and mice to explore functional architecture at high spatial resolution. Most of these studies used the increase in deoxyhemoglobin concentration occurring early in the hemodynamic response due to elevated oxygen consumption by active neurons. This signal is imaged as darkening of the cortex, especially at a wavelength of 605 nm. Imaging at longer wavelengths, emphasizing the light scattering component, has also proven useful. Many of these studies combined optical imaging with electrophysiological or anatomical tracing methods to either confirm the optical imaging results or characterize the relationship between physiological or structural properties of neurons and the functional maps within which they are embedded.

Orientation Map

The orientation selectivity of visual cortical neurons has been well-known since the pioneering studies of David Hubel and Torsten Wiesel in cat and monkey in the 1960s and 1970s. These studies also revealed that in visual cortex, similar to somatosensory cortex as discovered by Vernon Mountcastle, neurons are arranged in vertical columns such that the orientation preference of all neurons in a column is similar. This led to the idea of a map of orientation preference across visual cortex, and Hubel and Wiesel suggested a smooth and orderly shift of preferred orientation as one moves along the cortical surface. However, a direct method to visualize this map was not available at the time. With the advent of optical imaging of intrinsic signals, the technique was first applied in visual cortex to study the orientation map in cat area 18. Direct visualization of the map revealed a different pattern than expected: rather than elongated bands of slowly changing orientation preference, iso-orientation domains are highly ordered patches organized in pinwheels around centers where orientation preference changes quickly (Figure 1). In ferret visual area 17, the two cardinal axes (horizontal and vertical orientations) are somewhat overrepresented, in terms of their area in the orientation map, than the obliques. This result mirrors the behavioral advantage that the cardinal axes have over obliques in some tasks, such as orientation discrimination.

The pinwheels and pinwheel centers are a prominent architectural feature of areas 17 and 18 in cat and V1 in monkey. To study the properties of neurons in pinwheel centers, extracellular recording using tetrodes, which improve the ability to record from single neurons, was targeted to centers imaged with optical imaging. Neurons near pinwheel centers have very different preferred orientations within a distance of a few tens of micrometers. However, their spiking responses are just as orientation selective as those of neurons in orientation domains distant from pinwheel centers (Figure 2). In contrast, the subthreshold input to neurons reflects their neighboring environment – the orientation tuning of the membrane potential response, measured with intracellular electrodes, of pinwheel cells is much broader than that of orientation domains (Figures 2(b) and 2(c)).

Direction Selectivity

Neurons often have a preferred direction of motion that is orthogonal to their preferred orientation. Cells in early visual cortex are clustered according to this property, allowing its mapping using optical imaging. Direction preference shifts, mostly smoothly, along the cortical surface. The discontinuities that occur in the direction map are different from those in the orientation map. Rather than pointlike pinwheel centers, the discontinuities here are fracture lines, and they subdivide iso-orientation domains into areas preferring the two opposite directions orthogonal to the preferred orientation. Direction fracture lines run between orientation pinwheel centers (Figure 3).

Spatial Frequency

Another visual feature for which early cortical visual neurons have long been suggested to be clustered for is spatial frequency. Whereas earlier reports from cat area 17 indicated that the spatial frequency map is binary (i.e., includes regions of high and low preferred spatial frequency that can be mixed in different proportions), other work suggests that continuous values of preferred spatial frequency are mapped, ranging from approximately 0.1 to 1.2 cycles per degree.

Spatial frequency mapping is often used in optical imaging experiments to image the border between area 17 and area 18, exploiting the well-known difference between population preferred spatial frequency in the two areas. By stimulating with oriented gratings at two frequencies, typically 0.2 and 0.6 cycles per degree, and imaging the differential activity, one can quickly and easily detect the 17/18 border as a band of <1 mm across which preference shifts from predominantly higher preferred spatial frequency to predominantly lower preferred spatial frequency.

Figure 1 Orientation mapping – cat areas 17 and 18. (a) An activity map for one orientation is obtained straightforwardly by dividing the image captured during presentation of this orientation by the average of the images captured during presentation of all orientations. (Top) The image of the cortical surface is illuminated with green light to emphasize the vasculature. (Bottom) Activity maps evoked by visual stimulation with horizontal and vertical gratings. (b) The full orientation map presents the preferred orientation for each imaged pixel using a color code (center right). Preferred orientation is calculated from a set of at least four single-condition maps (a) by vector averaging. The orientation map is organized in pinwheels, where iso-orientation domains of all orientation preferences meet. Adapted from Bonhoeffer T and Grinvald A (1991) Iso-orientation domains in cat visual cortex are arranged in pinwheel-like patterns. *Nature* 353: 429–431.

Relationships between Maps

Multiple features are mapped in early visual cortex, including orientation, direction, spatial frequency, ocular dominance, retinotopy, and cytochrome oxidase blobs. Since these maps are superimposed on a two-dimensional cortical surface, an important question arises as to the geometrical relationships between them. These relationships should presumably ensure full coverage of all possible combinations of the multiple visual features so that functional blind spots for particular feature combinations are avoided. Indeed, in monkey V1 the following detailed relationships have been found using optical imaging and cytochrome oxidase staining:

1. Orientation preference is organized radially.
2. Orientation domains are continuous and have fuzzy boundaries.
3. Iso-orientation lines tend to cross ocular dominance borders at 90°.
4. Orientation pinwheels are centered on ocular dominance columns.
5. Blobs are centered on ocular dominance columns.
6. The centers of the blobs and the centers of the orientation pinwheels are segregated.
7. There is a regular mosaic-like organization for each type of functional domain without there being an overall pattern of repeating hypercolumns, each of which contains all types of functional domains. See Figure 4.

Similar results were found in cat area 17, in which many iso-orientation lines intersect the borders between ocular dominance borders at right angles, and orientation singularities are concentrated in the center regions of the ocular dominance columns. Pinwheels are frequently centered on centers of high and low spatial frequency preference patches. Low spatial frequency domains tend to co-localize with peaks of ocular dominance and with cytochrome oxidase blobs.

Optimal Coverage

An especially important issue for full coverage of all possible feature combinations is the relationship of the different maps with retinotopy, the map of visual space onto a cortical area, because any stimulus should be possible in each region of visual space. Retinotopy is considered the primary map in visual cortex because it exists in species in which even an orientation map does not exist, such as the rat, and because it is the smoothest map, demonstrating, perhaps with orientation, the strongest clustering of neurons. Whereas for other maps many cycles of all values of a feature exist in primary visual cortex, repeating at approximately 1 or 2 mm, retinotopy is the only map for which a single period exists. Therefore, it is critical whether other

Figure 2 Properties of neurons in pinwheel centers – cat areas 17 and 18. (a) Extracellular recording using tetrodes. (Left) Orientation map with two targeted electrode penetrations, an iso-orientation domain and a pinwheel center. The orientation tuning curves of neurons from the iso-orientation domain (middle) and from the pinwheel center (right) show similar tuning widths, although for the latter the preferred orientation has a larger scatter. Thus, neurons at the pinwheel center prefer a variety of orientations, but the selectivity of each neuron's spiking response to its preferred orientation is similar to that of neurons in iso-orientation domains. (b) Intracellular recording. Similarly to extracellular recordings, the spiking responses (red curves) of a simple cell in an iso-orientation domain (left) and of a simple cell in a pinwheel center (right) have similar tuning width. However, the subthreshold membrane responses (blue curves) exhibit a distinct difference. Whereas the iso-orientation domain cell exhibits a well-tuned membrane potential response, the pinwheel center cell's membrane potential response is much less selective. This low selectivity likely results from the cell's local input, which arises from cells with a wide range of preferred orientation. (c) Averaging over a population of intracellularly recorded cells, similar spike tuning width for pinwheel centers and iso-orientation domains is observed concurrently with a less selective subthreshold membrane potential response for pinwheel centers versus iso-orientation domains. (a) Adapted from Maldonado PE, Godecke I, Gray CM, and Bonhoeffer T (1997) Orientation selectivity in pinwheel centers in cat striate cortex. *Science* 276: 1551–1555. Figure 3 Direction-selectivity mapping. (a) A direction-selectivity map from cat area 18 shown with the orientation map in the same cortical surface. The red lines represent the preferred orientation and the magnitude of preference by their angle and length, respectively. Superimposed are green arrows, representing the local preferred direction. At the background, in gray-level presentation, is the map of magnitude for direction preference (dark represents low magnitude). Locations coded in yellow exhibited a high rate of change of preferred orientation angle (orientation singularities, computed using the gradient transform). (b) Zoom into a window in (a), showing a direction fracture line (gray) running between two pinwheel centers (yellow) and dividing an iso-orientation domain (red bars at ~135 °) into two areas preferring opposite motion directions (green arrows pointing to ~45 ° in the upper left portion of the image and to ~225 ° in the lower right). Scale bar = 1 mm (a). Adapted from Shmuel A and Grinvald A (1996) Functional organization for direction of motion and its relationship to orientation maps in cat area 18. *Journal of Neuroscience* 16: 6945–6964.

Figure 4 Revised ice cube model of monkey V1, schematically illustrating the relationships between orientation columns, ocular dominance columns, and cytochrome oxidase blobs. Black lines mark the borders between columns of neurons that receive signals from different eyes. This segregation is partially responsible for depth perception. White ovals represent groups of neurons responsible for color perception (CO blobs). The 'pinwheels' are formed by neurons involved in the perception of shape, with each color marking a column of neurons responding selectively to a particular orientation in space. Note that both the blobs and the centers of the pinwheels lie at the centers of R or L columns. The iso-orientation lines (appearing as a border between two colors) tend to cross borders of ocular dominance columns (black lines) at right angles. The top 'slice' above the ice cube model depicts two adjacent fundamental modules ($400 \times 800\,\mu m$). Each module contains a complete set of approximately 60 000 neurons, processing all three features of orientation, depth, and color. This scheme is oversimplified in various aspects, and the mosaic formed by hypercolumns is not as orderly as depicted here. Adapted from Bartfeld E and Grinvald A (1992) Relationships between orientation-preference pinwheels, cytochrome oxidase blobs, and ocular-dominance columns in primate striate cortex. *Proceedings of the National Academy of Sciences of the United States of America* 89: 11905–11909.

maps conform to it such that optimal coverage is achieved. Early modeling, in which map continuity and coverage were optimized for retinotopy and orientation, predicted distorted retinotopy and a negative correlation between the gradient of the retinotopic map and that of the orientation map.

In cat areas 17 and 18, conflicting results were obtained in studies using optical imaging to map orientation and extracellular electrophysiology to map retinotopy. An earlier study found distorted retinotopy exhibiting positive correlation of its gradient to the orientation map gradient, whereas a later study found smooth retinotopy with no local correlation to the orientation map. In V1 of tree shrew, as well as in ferret, the retinotopic map was found to be smooth and without local correlation to the orientation map (Figure 5). Detailed modeling, optimizing continuity and coverage, shows that this should be the case when feature maps additional to orientation, such as spatial frequency and ocular dominance, are superimposed on the retinotopic map. Further studies are required to resolve this issue.

Optimal coverage seems to be achieved by two general principles. First, whenever possible, the gradients of each pair of maps are negatively correlated, such that fast changes in one stimulus feature occur while the other changes slowly. This principle is manifest in the previously mentioned findings of pinwheel centers (i.e., areas of high orientation gradient), coinciding with the center of ocular dominance columns and spatial frequency domains, where these features change slowly. It implies an orthogonal intersection angle between contour lines of the two maps, which has been observed, for example, in the relationship between orientation and ocular dominance.

Second, when it is impossible to maintain orthogonal intersection angles between two maps, the strongest orthogonality is maintained in places where the two maps have the highest gradients. For example, in ferret V1 the contour lines of orientation, ocular dominance, and spatial frequency maps have a weak tendency to cross retinotopic contour lines at 90°. For each of these three maps, this tendency is stronger in the pixels with high gradient values. Given an anisotropic retinotopic map, such as that in ferret V1, orthogonal intersection angles between the contours of each pair of the three maps cannot be maintained throughout the cortical surface (under the continuity and coverage constraint) and are kept more strongly for those places where pairs of maps have overlapping high gradients, as shown in Figure 6.

Lateral Connections

The properties of connections between subdomains of cortical visual areas are a major feature of functional architecture and have been studied using anatomical tracing. Classical studies have shown that axon collaterals in V1 are distributed in clustered patches that can reach several millimeters away from the soma. These projections have been proposed to connect sites with neurons that have similar orientation preference. However, some quantitative studies combining anatomical tracing with electrophysiological orientation mapping have suggested that the overall bias favoring long-range iso-orientation projection sites is weak, perhaps due to significant, although diffuse, intercluster projections, which have no iso-orientation preference. Optical imaging has been combined with tracer injection to study this

Figure 5 The retinotopic map is locally smooth and independent of the orientation map – tree-shrew V1. (a) Orientation map (color) superimposed with a position preference map with isoazimuth lines at 1° intervals (black lines). At this scale, the retinotopic map is smooth and bears no relationship to the orientation map. (b) Extracellular recordings (white circles) and optical imaging (solid squares) at the 14 locations marked in a show that even at this finer scale, a few hundred micrometers, graded progression over the cortical surface is accompanied by smooth progression in visual space. Scale bar = 1 mm (a). Adapted from Bosking WH, Crowley JC, and Fitzpatrick D (2002) Spatial coding of position and orientation in primary visual cortex. *Nature Neuroscience* 5: 874–882.

Figure 6 Intersection angles of pairs of maps – ferret V1. Orthogonal intersection angles between a pair of maps are kept more for areas where both maps have high gradients than over the whole cortical surface. (a) Orientation and ocular dominance maps. (Left) Colored orientation contour lines are superimposed on black ocular dominance contour lines. Gray regions indicate overlap of high-gradient regions of orientation and ocular dominance (30th percentile). (Right) Distribution of intersection angles between the orientation gradient and the ocular dominance gradient over all pixels (red) and for the pixels with overlapping high gradients (blue). The former exhibit all values, whereas the latter tend to exhibit high values closer to orthogonal. (b) The same as (a), but for the orientation and spatial frequency maps. Adapted from Yu H, Farley BJ, Jin DZ, and Sur M (2005) The coordinated mapping of visual space and response features in visual cortex. *Neuron* 47: 267–280.

question. For example, in cat area 17, layer 3 injections near pinwheel centers result in projections that have no orientation bias, in agreement with the subthreshold membrane responses mentioned previously. Iso-orientation domains of layer 4 in area 18 likewise send overall smooth projections, without orientation preference. Individually labeled inhibitory basket cells showed a slight preference toward projecting to iso-oriented patches. In view of the complexity of the neocortical circuit, additional studies are required to shed light on these apparently contradicting results.

Lateral connections have also been studied physiologically, by assessing the cross-correlation in spiking activity between laterally displaced neurons, in conjunction with optical imaging. Neurons are strongly interconnected locally, irrespective of their relative orientation. Furthermore, correlation decreases with distance between the neurons, similarly for same orientation pairs and for orthogonally oriented pairs.

Development

Since the earliest days of modern research of visual cortex by Hubel and Wiesel, the development of its functional features over the course of an individual's maturation has been explored. This field has seen a surge of works employing optical imaging of intrinsic signals to study how the formation and stabilization of orientation preference, ocular dominance, and retinotopy are molded by visual experience, neural activity, and molecular and genetic factors. Such studies often require longitudinal experiments to determine changes in the cortical functional architecture over long periods of time. Optical imaging is particularly appropriate for these studies since it offers both

the required spatial resolution and the ability to perform prolonged, comparative studies. The results of these studies are reviewed extensively elsewhere in the encyclopedia.

V2

Cytochrome oxidase staining in primate V2 produces three sets of repeating modules: thin dark, thick dark,

Figure 7 Feedback projections from V2 to V1 show orientation bias and exhibit retinotopic axis specificity. (a) Cytochrome oxidase-stained tangential section at ~570 μm depth, showing cytochrome oxidase blobs in V1 (right of dotted yellow line) and thick, thin, and pale stripes in V2 (left of border). The injection site in V2 is delineated in red and the clusters of feedback projections to V1 in orange and brown, with darker color denoting denser clusters. (b) Orientation map of the same cortical surface, aligned using the superficial blood vessel pattern. Separate local alignments between the histological slices and optical imaging data were performed around the V2 injection point and the V1 clusters. Dark regions correspond to locations with weak orientation preference (e.g., the darker regions in V2 which correspond to the thin stripes). Both the injection site and the feedback projection clusters demonstrate preference for a near-vertical orientation. Note the overall elongated structure of the feedback clusters. (c) Distribution of preferred orientation at the injection site and feedback projection clusters for the population of six cases in the study, with zero denoting the mode orientation at the injection site. The injection site and the feedback clusters peak at a similar orientation, but the distribution for the feedback clusters is broader and less selective. (d) Retinotopy in V1, showing the mapping of horizontal and vertical strips in visual space (left and right, respectively). These data are from a typical hemisphere in a different monkey. (e) Retinotopic axis specificity of the feedback projections. (Top) Preferred orientation values within the injection site – distribution of values (black line) and vector sum (red bar). (Bottom) Injection site and feedback clusters, overlaid with a coordinate system of the local retinotopic axes at the clusters' center of gravity (dashed lines correspond to horizontal and vertical axes in visual space). The spatial distribution of the feedback projections is anisotropic, with the major axis of anisotropy (open double-arrowed bar) approximately parallel to a retinotopic axis that corresponds to the preferred orientation at the injection site in V2 (red bar). Adapted from Shmuel A, Korman M, Sterkin A, et al. (2005). Retinotopic axis specificity and selective clustering of feedback projections from V2 to V1 in the owl monkey. *Journal of Neuroscience* 23: 2117–2131.

and pale stripes. The neurons within each of these modules have specialized functional properties. Optical imaging has helped characterize the modular organization of primate V2. Early optical imaging studies in V2 showed that it is possible to image stripes that correspond to the thin and thick cytochrome oxidase stripes by contrasting the response to monocular stimulation with that to a blank screen. In fact, the thin and thick stripes are discernible by calculating the difference in response between any stimulated condition and a blank (single-condition map). Selectively visualizing the thin stripes is done by contrasting color with luminance gratings since thin stripes contain regions of neurons that prefer color over luminance gratings. Within the color-preferring regions of the thin stripes, optical imaging has revealed an orderly map of hue preference. The thin stripes contain additional areas of luminance-preferring neurons clustered together; however, orientation mapping is absent from both subcompartments of the thin stripes. Clustering according to preferred orientation is predominant in both pale and thick stripes, with the iso-orientation domains about twice as wide there as in V1 (4 times the area). Thick stripes contain clustering of disparity-selective cells.

Feedback projections from the pale and thick V2 stripes to V1 in owl monkey show weak orientation bias, such that the sites receiving input in V1 exhibit a slight tendency to have the same preferred orientation as the site sending it, as shown in **Figures 7(a)–7(c)**. Interestingly, however, the spatial distribution of the feedback projections is anisotropic, with the major axis parallel to a retinotopic axis in V1 that corresponds to the preferred orientation of cells in the V2 injection site (**Figures 7(d) and 7(e)**). This suggests that feedback from V2 to V1 facilitates the response to collinear contour elements, which has been shown to be perceptually enhanced relative to noncollinear configurations. Other evidence suggests that intrinsic lateral connections within V1 are involved in contour integration, and the relative contributions of intrinsic and feedback connections to extraclassical receptive field modulation are currently an active research area.

Beyond V1/V2

Although the majority of imaging studies in visual cortex were performed in primary visual cortex, optical imaging of intrinsic signals has been successfully implemented in a variety of other visual areas. Examples include retinotopy in V3 (dorsal) of owl monkey, showing that this region has a representation of the lower visual field, smaller than and mirror-imaging that in V2 (dorsal). Orientation and size preference were mapped in V4 of macaque, showing an orientation map in central visual field with iso-orientation domains comparable in size to those in V2 and revealing size-sensitive regions suppressed by large stimuli. In owl monkey area MT, which is involved with motion processing, direction and orientation were both mapped, suggesting, since the orientation map is even stronger than the direction map, that shape processing is important in MT functioning. In inferotemporal cortex of macaque, the highest strictly visual area, where single neurons respond selectively to moderately complex object features, optical imaging has shown that neurons with similar selectivity are clustered together. Furthermore, the neural coding for object features in this area seems to be distributed because a single object activates multiple patches, and a single cortical location is activated by different objects.

Conclusion

Optical imaging of intrinsic signals has been instrumental in the discovery and characterization of the plethora of functional maps in visual cortex, their development, and the relationships between them. There is a growing body of information arising from optical imaging combined with other techniques about connections between modules of visual processing and about the particular physiology of cells within these modules.

Visual Cortical Models of Orientation Tuning

R Shapley, New York University, New York, NY, USA

Introduction

The primary visual cortex V1 is a nonlinear dynamical system, and one of its tasks is to find local stimulus features in the neural image of the visual scene relayed to V1 from the eye through the lateral geniculate nucleus (LGN). Different sources of intracortical inhibition contribute to the selectivity of V1 neurons: local-circuit inhibition, inhibition mediated by signals from long-distance intrinsic V1 horizontal connections, and feedback from extrastriate cortex that drives inhibitory interneurons in the local circuit. Different sources of excitation drive the activity in V1 cells: local thalamocortical projections, local circuit corticocortical excitation, long-distance horizontal V1 axons, and also feedback. Models of V1 cortex seek to explain the visual functions of V1 in terms of its architecture and connections.

Orientation Selectivity

One of the key questions neuroscientists have studied is how orientation selectivity is generated in V1. In V1 there is a transformation to orientation-tuned elements. Prior to V1, in the retina and LGN, there is weak or no orientation selectivity in single cells. It has been thought from the time of its discovery that orientation tuning, as an emergent property in visual cortex, must be an important clue to how the cortex works and why it is built the way it is. That is why it continues to inspire a volume of research. Much has been learned about basic principles of cortical neurophysiology on account of the intense investigation of orientation selectivity, particularly in the area of theories of the cortex to explain orientation selectivity.

The main problem V1 needs to solve, in order to generate orientation selectivity, is the reduction of responses to nonpreferred orientations. While the original feed-forward model provided by Hubel and Wiesel is supported by several studies, it does not account for the considerable evidence that has accumulated about the cortex's suppression of nonpreferred responses and the presence of powerful inhibitory conductance increases with visual stimulation in V1 cells. The feed-forward model is not wrong, but it is incomplete. The feed-forward model can be used to account for the pattern of orientation preferences, but it does not explain the distribution of orientation selectivity across the population. That is where corticocortical inhibition comes in.

Feed-Forward Models

There are two poles of the theory of orientation selectivity: feed-forward filtering on one hand and attractor states on the other. There are also investigators with views somewhere in the middle – perhaps a good label for their view would be recurrent network filtering. However, first chronologically, and first discussed here, is the feed-forward view, descended from Hubel and Wiesel. Hubel and Wiesel's feed-forward model (the HW model) has been a dominant idea in this field. It involves the addition of signals from LGN cells that are aligned in a row along the long axis of the receptive field of the orientation-selective neuron. For example, in the often encountered edge-sensitive orientation-tuned cells, Hubel and Wiesel postulated that a row of ON cells from the LGN would provide excitatory input and an adjacent parallel row of OFF cells would provide excitation for the opposite sign of contrast. There is some direct support for this kind of neural architecture in the ferret visual cortex from Chapman and Stryker, and from dual recordings in LGN and cortex in the cat from the work of Reid and Alonso. The experiment on cooling of cat V1 by Ferster's group was interpreted to mean that there is substantial orientation tuning of the collective thalamic input to a cortical neuron, consistent with the HW model. Chung and Ferster reached similar conclusions based on different experiments. In spite of all this evidence, several authors have shown that the HW model predicts rather little orientation selectivity by direct computation of the predicted synaptic current of the HW model.

The reason for the shortfall of orientation selectivity in the HW model, compared with experiments, has been discussed before. LGN cells have a low spontaneous rate but are quite responsive to visual stimuli, so their firing rate during visual stimulation clips at 0 spikes s^{-1}, even at fairly low stimulus contrast. Under these conditions LGN cells act like nonlinear excitatory subunits as inputs to their cortical targets, as originally suggested by Palmer and then by Tolhurst. Since the HW model simply adds up the LGN sources, its summation of the clipped LGN inputs would cause it to have a nonzero response at 90° from the optimal orientation. Computational simulations by Sompolinsky's group and by Miller and colleagues of the HW model have demonstrated

that this analysis is correct. An example is given in Figure 1, which shows a computation of the peak excitatory synaptic input (as a function of orientation) from an HW model onto a cortical cell. Such a model produces a substantial LGN input to a cortical cell at 90° from the preferred orientation, as seen in the figure. But many cortical cells respond little or not at all at 90° from peak orientation, so the HW convergence mechanism must be only a part of the story of cortical orientation selectivity.

One may wonder why the experiments of Ferster et al. and Chapman et al. are not decisive pieces of evidence for a large amount of orientation selectivity as a consequence of LGN convergence. The cooling experiments of Ferster et al. measured the first-order Fourier component (F1) in the intracellular voltage response to a drifting grating from a neuron in a cooled cortex and found it to be as tuned for orientation as in the warm cortex. But this does not account for the tuning of the mean spike rate, which is tuned as much as the F1 component of the spike rate. So to account for the orientation selectivity that is observed in the mean spike rate, it would have been necessary for Ferster et al. to measure also the orientation selectivity of the mean intracellular voltage response in the cooled cortex. They did not do this in the cooling experiments reported in 1996, probably for technical reasons. But if they had measured the DC response in the cooled cortex, and if the HW model does describe the LGN input to V1 neurons, then we can predict that Ferster et al. should have found the mean (or DC) intracellular voltage response to be only weakly selective for orientation (based on the analysis of the HW model in the previous paragraph). One can go further and analyze why Ferster et al. found so much orientation tuning for the F1 component. The only mechanism for orientation-selective response for an F1 response in the HW model is different spatial frequency resolution along the two axes of the elliptical receptive field. The reason is that the HW model has no inhibition; it is a purely excitatory model. Thus, Ferster et al. probably observed orientation selectivity in the cooled cortex only because the spatial frequency of the grating they used was too high for the elliptical LGN array to resolve it along the long axis, but spatial frequency was not too high for the summed LGN input to resolve it along the minor axis. The conclusion of all these considerations of the cooling experiment is that it is not decisive evidence for a feed-forward explanation of orientation selectivity. Next, the Chapman et al. results about rows of LGN terminals found in layer 4 of ferret V1 cortex, after cortical inactivation with muscimol, was offered as evidence that the HW model could explain orientation selectivity in ferret layer 4. But later it was learned that layer 4 neurons in ferret V1 are very broadly tuned for orientation – about half the neurons in layer 4 are almost completely nonselective. Therefore, the results of Chapman et al. are completely consistent with the conclusions of the analysis by Sompolinsky and Shapley and by Troyer et al. that the HW convergence mechanism would make neurons only very weakly selective for orientation.

Figure 1 Orientation tuning curve of the synaptic current evoked by the lateral geniculate nucleus (LGN) input to a V1 cortical cell, calculated from a feed-forward model. In this model, the LGN afferents formed an ON-OFF-ON receptive field. Each subregion had an aspect ratio of 2. A total of 24 OFF-center cells comprised the central OFF subfield, while 12 ON cells comprised each ON subregion in the model in an attempt to emulate the pattern of LGN inputs to cortex as indicated from experiments. Redrawn from Sompolinsky H and Shapley R (1997) New perspectives on the mechanisms for orientation selectivity. *Current Opinion in Neurobiology* 7: 514–522.

Cortical Inhibition

One possible addendum to the HW model, to increase the orientation selectivity greatly, has been known for a long time. One can obtain increased orientation selectivity by adding inhibition: either push–pull inhibition or some other kind of cross-orientation inhibition. Given what is known about V1 connections, this inhibition must come through cortical interneurons rather than directly from the thalamic afferents. Experiments on intracortical inhibition in V1 have given mixed results. Initially, Sillito's experiments with bicuculline suggested that intracortical inhibition might be necessary for orientation tuning. The role of intracortical inhibition was supported by the work of Bonds and collaborators on cat V1 cortex. They studied interactions between stimuli at different orientations, the effects of blocking activity in infragranular layers, and the effects of γ-aminobutyric acid on orientation selectivity. Sato and colleagues, in their study of macaque V1, found that neuronal orientation selectivity was reduced when very broadly tuned cortical inhibition was weakened by pharmacological blockade by bicuculline; response to off-peak orientations grew stronger relative to the

response to the preferred orientation. Eysel and his collaborators also found evidence in cat cortex for the important role of inhibition in causing a sharpening of orientation selectivity.

Feed-Forward Inhibition Model

A theory of orientation tuning in cat cortex has been offered by Troyer et al. and attempts to explain orientation tuning in terms of specific feed-forward 'push–pull' inhibition previously pushed by Palmer and then later by Tolhurst. However, the main mechanism for sharpening of orientation tuning in the Troyer et al. model is corticocortical inhibition that is broadly tuned for orientation. This is not the feature of inhibition emphasized by the authors. They instead emphasize that the inhibition is phase-sensitive, but the phase sensitivity is irrelevant for the sharpening of orientation tuning. In the Troyer et al. model, there is moderately tuned LGN convergent excitation from an HW mechanism, and then more broadly tuned inhibition that cancels out the wide angle responses but that leaves the tuning curve around the peak orientation relatively unchanged. Therefore, this model in some ways resembles other corticocortical interaction models for orientation selectivity. Like the Ben-Yishai et al. model discussed in the section titled 'Cortical excitation and attractor models,' it achieves contrast-invariant orientation selectivity.

Cortical Excitation and Attractor Models

The idea that corticocortical recurrent excitation within V1 plays a crucial role in orientation tuning has been advanced by theorists of brain function. There are three well-known papers that make the case for this corticocortical recurrent excitation. Somers and his colleagues presented an elaborate computational model for orientation tuning that involved recurrent excitation and inhibition. Douglas and his colleagues argued for the importance of recurrent excitation in cortical circuits and its role in orientation tuning as an example. They proposed there was a 'canonical microcircuit' of V1 cortex, which described a cortical circuit with a large amount of recurrent excitation. Third, Ben-Yishai et al. offered an analytical model from which they made several predictions. One of their important theoretical results is that one cannot predict the observed contrast invariance of orientation tuning with feed-forward models, but their model with recurrent excitation and inhibition does exhibit contrast invariance. Another of the Ben-Yishai et al. results is that if recurrent feedback is strong enough, one will observe the 'marginal phase' state in which V1 behaves like a set of attractors for orientation.

Tsodyks and his colleagues also considered attractor states of recurrent excitatory models. The concept is that very weakly orientation-tuned feed-forward signals can be massively sharpened by strong recurrent excitatory feedback causing the cortex to respond to any visual signal by relaxing into a state of activity governed by the pattern of corticocortical feedback.

NYU Models

McLaughlin, Shelley, Wielaard, and Shapley developed a large-scale model, referred to as the Version 1 NYU model, of four hypercolumns in layer 4cα of macaque V1. Inspired by the ring models in the work of Somers et al. and Ben-Yishai et al. it seeks to account for the same set of phenomena as these models but with more biological realism. Version 1 incorporates known facts about the physiology and anatomy of V1. One novelty in this model is that the spatial strength of connections between neurons is taken to be the spatial density of synaptic connections revealed by anatomical investigations of cortex. The model places the 'footprints' of synaptic excitation and inhibition on the pinwheel latticework that is revealed by cortical optical imaging. The Version 1 model causes significant sharpening and also diversity of orientation selectivity compared with the LGN inputs to cortex, and it also produces simple cells.

One big difference between the Version 1 NYU model and the push–pull model of Troyer et al. mentioned above is that in Version 1 the inhibitory conductance input to a cell is phase-insensitive (the opposite of push–pull). This happens because inhibition onto a model cell is a sum from many neural sources. Each of these sources is a cortical inhibitory cell with a fixed phase preference that is different from those of neighboring neurons. This view of the nonselective nature of local corticocortical inhibitory interactions is consistent with the measured phase insensitivity of measured inhibition.

Building Version 1 presented the challenge of obtaining simple cells in a nonlinear network model of V1 and of obtaining orientation selectivity. One basic principle established by this modeling work is that there is a need for strong lateral inhibition for any of these cortical models to behave like V1 cortex. Strong cortical inhibition was needed just to produce simple cells. The strong inhibitory synaptic coupling makes the model neurons' membranes shunted, and as a result the neurons act like coincidence detectors as calculated by Shelley. This could explain the observed increased efficacy for nearby spikes from retinal ganglion cells to cause excitation of cortical

cells better than widely spaced spikes, as shown in the experiments of Kara and Reid. The high-conductance state also means that membrane potential fluctuations are what produce model neuron spiking. With realistic dendritic and axonal spread of excitation and inhibition within the input layer, corticocortical recurrent excitation carries a 'complex' signal. Thus the more a model cell is excited by corticocortical recurrent excitation, the more it is like a complex cell. This is an idea similar to the proposals of Chance and her colleagues about the role of recurrent excitation in building complex cells.

Then a model was proposed that will produce simple and complex cortical cells, Version 2: a recurrent cortical model, also called the 'egalitarian' model, to distinguish it from hierarchical models of V1. Figure 2 illustrates some of the components of Version 2. The model is a large-scale computational model of a 1 mm patch of layer. This network consists of approximately 4000 neurons, 75% excitatory and 25% inhibitory integrate-and-fire, conductance-based point neurons. The network is comprised of cells within four orientation hypercolumns. Distinctive features of Version 2 are that the local lateral connectivities, as set by the specification of the coupling kernels (plotted in Figure 2, lower left), are nonspecific and isotropic (unlike phase- or orientation-specific architectures as in models like that of Troyer et al.) and not hierarchical. The orientation and spatial phase preferences of individual model neurons are influenced by the convergent LGN excitatory drive resulting from the summed output of segregated sets of on- and off-center LGN cells, as in the HW model. In the model cortex, orientation preference is laid out in pinwheel patterns based on the experimental results of Bonhoeffer and Grinvald. Preferred spatial phase varies randomly from neuron to neuron, as dictated by some experimental results. However, orientation selectivity and response time course are generated by intracortical inhibition (as in the Version 1 model).

Figure 2 Diagram of the Version 2 egalitarian model. Each V1 cell 'sees' a collection of lateral geniculate nucleus (LGN) cells that is sampled from a 2D Gabor function. Orientation preference is laid out in pinwheels (the color orientation map). Spatial phase preference is random for nearby cells. The number of LGN cells (*Ni*) providing afferents varies from cell to cell (shown for three sample neurons). *Ni* distributed uniformly between 0 and 30. Lower left, corticocortical couplings are isotropic with interaction profiles Gaussian in shape (excitation in red; inhibition in blue), with the length scale of excitation = 200 μm and that of inhibition = 100 μm. 4Cα refers to the macaque primary visual cortex. Exc, excitatory; Inh, inhibitory.

The main achievement of the egalitarian model is simple and complex cells coexisting in the same network. The egalitarian architecture may be a possible explanation of the earlier finding by Ghose that excitatory cross-correlation could be observed between complex and simple cells, a result that seems counterintuitive based on the feed-forward model. The basic idea of the egalitarianism in the Version 2 model is that there is not a strict hierarchy of connections; rather, cells' properties come from the balance of their synaptic connections. In such a model, cells could be shifted from simple to complex by, say, weakening inhibition. This had been observed experimentally, but there was no explanation offered before the Version 2 model. The opposite effect, namely, transferring a cell from the complex to simple group by increasing inhibition, was reported in 2006 by Bardy and colleagues, so this could be viewed as experimental confirmation of a prediction of the egalitarian model.

NYU model Version 3 is a refinement of the egalitarian model and includes the concept of sparse corticocortical connections. The orientation tunings of average responses to drifting sine gratings obtained with Version 3 are plotted for a few model neurons in Figure 3. The upper row, labeled *m*, is the spike rate, and below are shown intracellular membrane potentials (V) and the synaptic conductances – g_{lgn}, g_E, and g_I – that control the cells' firing. Each column in Figure 3 is for a different cell. Note that the inhibitory conductance (bottom row) is mostly very broadly tuned or flat, consistent with measurements of untuned suppression in orientation dynamics experiments. Untuned or broadly tuned inhibition arises naturally in network models like the egalitarian model that take into account the measured spatial spread of inhibitory connections in V1.

One important feature of the pure feed-forward model is that it does not predict different dynamics of responses to different orientations. The egalitarian models (like other recurrent inhibition models) predict there ought to be a difference because of the somewhat slower time course of inhibition. This

Figure 3 Four sample excitatory cells (two simple cells on the left, two complex cells on the right) from the Version 3 egalitarian V1 model. Plots of orientation tuning (from top to bottom rows) for cells' firing rates (spikes s^{-1}; labeled *m*), for medium contrast (solid lines) and low contrast (dot-dashed lines); membrane potential (labeled *V*); excitatory conductances from LGN inputs (g_{lgn}); corticocortical excitatory conductances (g_E); and corticocortical inhibitory conductances (g_I; in units of 1 s^{-1}). Dashed curves in rows 2–5 show the mean ± SD for potentials and conductances. All quantities are time-averaged.

effect was observed in reverse correlation experiments. In more recent work on the dynamics of orientation selectivity, a baseline of response has been established through the use of blank stimuli as well as oriented grating patterns, and deviations above and below the baseline have been measured. This has yielded the observation that responses to preferred and orthogonal-to-preferred orientations had different dynamics. The result is shown in Figure 4.

Figure 4 shows population average responses from many (140) macaque V1 neurons. The time course of the orthogonal-to-preferred response (blue) is more biphasic than the preferred response (red, and scaled down in black-dashed). Different dynamics of responses to nonpreferred and preferred orientations are seen also with voltage-sensitive dyes in cat V1 and with intracellular recording in cat V1.

Untuned Suppression

Untuned suppression, estimated from the orientation dynamics experiments, was approximately the same for large and optimal-size stimuli in rhese experiments, implying that it was generated mainly by local circuitry, as predicted in the recurrent cortical models (see Figure 3 for example). Previously, Ben-Yishai et al. had proposed untuned inhibition (they called it 'global inhibition') as one possible mechanism for enhancing orientation selectivity. Direct intracellular measurements in cat V1 prove the existence of broadly tuned cortical inhibition in some neurons.

Figure 4 Time courses of the averaged response at the preferred orientation (R_{pref}; red curve) and at the orthogonal-to-preferred orientation (R_{orth}; blue curve). These are experimental data from the population-averaged dynamics of orientation tuning, based on observations in reverse correlation experiments on macaque V1 by Xing, Shapley, and Hawken. Both R_{orth} and R_{pref} have positive responses at early time. At early time (prior to 50 ms after stimulus onset), R_{orth} has a time course similar to R_{pref} but is rescaled by a factor $\alpha = 0.27$ (dashed curve). At later times, the blue and dashed curves are different because of the time development of untuned suppression caused by local circuit inhibition.

Spatial Phase in Models and in Experiments, and the Simple/Complex Dichotomy

Since the pioneering work of Maffei and Fiorentini in 1973, many scientists have grouped cells into simple and complex classes by means of their responses to

drifting gratings. Simple cells, being more tied to the visual image, modulate their firing rate at the same temporal frequency as that of the drifting grating stimulus. Complex cells fire more impulses when a grating drifts by, but their firing rate is not modulated in time. The ratio of the modulated to the unmodulated components of the response (the modulation ratio, or F1/F0) has been used to classify cells as simple or complex. The F1/F0 ratio is closely related to spatial phase dependence because the modulation of response in simple cells is a consequence of their high sensitivity to spatial phase, while the spatial phase insensitivity of complex cells is related to their elevation of discharge when a drifting grating moves over their receptive fields. This is because a drifting grating is a grating whose spatial phase ϕ is changing continually with time; $\phi = 2\pi ft$, where f is the temporal frequency of drift.

Hubel and Wiesel in 1962 proposed that there are distinct simple and complex cell classes that are steps along a functional hierarchy. Mechler and Ringach reexamined this issue 40 years later by showing that the bimodal distribution of F1/F0 in the firing rate of V1 neurons could be the result of the nonlinear voltage-to-spike rate transduction in V1 neurons. The bimodality of the F1/F0 ratio had been taken previously as an indication of the functional distinctness of simple and complex classes. Then Priebe, with Ferster and Carnadini, using intracellular recording in cat V1, showed that a bimodal distribution of F1/F0 in the firing rate could be generated by the spike–threshold nonlinearity from an underlying unimodal distribution of F1/F0 in the membrane potential. Supporting this result, Shapley and colleagues reported that Priebe et al.'s results are what the Version 2 model predicts.

The way in which spatial phase is handled is very different in different models of V1 cortex. The Version 2 egalitarian model was designed so that spatial phase preferences of neurons were random even very locally. But Troyer et al.'s push–pull model introduced spatial phase specificity into local connections so that excitatory and inhibitory neurons near each other formed antiphase pairs. Intracellular data in fact suggest a somewhat intermediate situation: there is a spatial phase-specific component to the membrane potential but also a large phase-nonspecific component.

Gamma Frequency Oscillations in the Local Field Potential and V1 as Dynamical System

Analysis of the activity of the Version 2 model in responses to drifting grating stimuli revealed γ-band peaks in the spectrum of the population spike rate. Temporally structured network activity in the form of oscillations is a hallmark of the steady state dynamics of highly recurrent neural networks even when single units are firing irregularly. Therefore, ensemble oscillations when the V1 network is activated are expected if one hypothesizes that V1 is dominated by recurrent activity. This led to experiments to record the local field potential (LFP) simultaneously with single cell spikes and to analyze the spectral changes in the LFP with stimulation by drifting gratings. Henrie and Shapley found that visual stimuli caused an increase both in the variance and in the temporal structure of the LFP; power became more concentrated in the γ-band with increasing contrast.

Gamma-band oscillations have been interpreted as an important mechanism for feature integration, but instead, the LFP may simply be the reflection of local network activity. This notion is based on experimental observations and theory. Confirming earlier studies, Henrie found that the γ-band of the LFP could be fairly sharply tuned to orientation or spatial frequency and has contrast–response functions very similar to those of single V1 neurons recorded nearby when drifting grating stimuli were used that were of optimal size for the neurons. These results are consistent with the view that the γ-band peak in V1 is a natural consequence (i.e., theoretically predicted) of high levels of recurrent network activity recruited by stimulating the system with an effective stimulus (in agreement with earlier cortical theories).

Conclusions

Theories of V1 cortex have led to the view that cortical inhibition plays a very large role in the visual function of V1. Strong inhibition allows the cortex to have simple cells that are faithful to the image. Inhibition provides the mechanism for sharpening the selectivity for orientation and also for spatial frequency and other stimulus features. The high-conductance state caused by large inhibitory conductances makes most cortical cells act like coincidence detectors and therefore makes them very sensitive to temporal patterns in incoming spike trains and in network activity. The recurrent excitatory–inhibitory network of V1 determines the visual properties of the neurons in V1. But the network architecture is flexible and may serve also to allow other cortical areas to combine V1 responses to the immediate visual stimulus with stored memories of visual objects. Theories of higher-level vision may be able to make use of models of the V1 recurrent excitatory–inhibitory network to account for the way feed-forward and feedback signals are combined for perception.

Historical Perspective

Of the primary senses, vision is arguably the most important for higher level mammalian species. It is not surprising, then, that there is a long history of rumination and experimental investigation of the consequences of missing or deficient or altered vision. The earliest considerations of these issues were at a philosophical level since experimental procedures had not been developed. An early question, described by John Locke in the seventeenth century, concerned the nature of visual perception of individuals who regain their sight after long periods of blindness. Could a spherical object be discriminated as different from a cuboidal one without the addition of tactile sensation? Locke's speculation was that this kind of visual discrimination would not be possible. Subsequent related philosophical ideas were put forward with views divided into two major categories, nativism and empiricism. Nativism implied that sensory systems were hard-wired at birth and that visual skills were developed early and independently of experience. Empiricism connotes the opposite, suggesting that mature visual behavior is dependent on the nature of postnatal visual experience. This idea therefore implies that there is considerable plasticity in postnatal periods. These concepts form the basis of nature versus nurture issues that could be considered using empirical science once suitable methodology was developed.

In addition to its primary importance, the visual system is very accessible and therefore amenable to experimental study. Physiological and behavioral exploration is relatively straightforward. For the study of deprivation, it is generally possible to control the degree and type of visual stimulation during a rearing procedure. This permits a wide variety of investigations. Some studies provide ample evidence of clear differences regarding the susceptibility to visual deprivation of different species. In addition, locations along the visual pathway vary in the degree of vulnerability to abnormal vision. These observations are considered later in some of the descriptions of experimental work.

Normal Development

In order to consider the effects of visual deprivation, it is first necessary to outline the main elements of normal development. Both neural and behavioral processes are considered. The relevant investigations in the normal system, as well as those concerning deprivation effects, are almost entirely limited to the central visual pathways from retina through lateral geniculate nucleus to primary visual cortex. Nearly all experimental work has been undertaken in these areas. By far the most common species studied is the cat, but the ferret has also been used because of its relative immaturity at birth. Neural changes that occur postnatally are easier to study than those that occur prenatally. The monkey is also of interest because, as a primate, it shares many close similarities with human sensory systems. Human infant work has largely been limited to behavior and gross electrophysiological approaches.

Before considering specific postnatal developmental findings, it is worth noting that the complexity of the prenatal process is considerable. Projections from neurons take specific and sometimes tortuous pathways to reach specific portions of nuclei. Inputs are received through dendritic trees and outputs are propagated through axons which project to specific targets. Control of this activity must be largely genetic and is carried out via molecular and chemical processes. Prenatal events have been studied in the visual system, in which it has been shown, for example, that cell generation in the retina occurs over a relatively long period of time and in a peripheral-to-central location sequence. The visual cortex develops in a multistage sequence. These processes involve cell migration, cell loss, dendritic prunings, terminal sprouting, synaptic realignments, and axon terminal retraction. These topics are beyond the scope of this article.

Many details of anatomical and physiological organization of the retina are immature at birth and this varies with species. In the kitten, physiologically, retinal ganglion cells are somewhat sluggish at the youngest ages at which they may be reliably studied (approximately 2 weeks postnatally). Receptive fields are also generally relatively large. During subsequent weeks, cells become more responsive and receptive fields shrink in overall size, suggesting that spatial resolution correspondingly increases. There are two standard, physiological categories of retinal ganglion cells in cats – X and Y types. For X types, linear spatial summation can be demonstrated. Relatively high spatial resolution and medium axonal conduction velocities are also reported for X cells. For Y types, summation is nonlinear, spatial resolution is low, and axonal conduction velocity is high. There are also anatomical differences in these cell types. Developmentally, these categories are difficult to distinguish until approximately 4 weeks postnatally.

In the lateral geniculate nucleus, lamination and segregation according to eye dominance appears in early postnatal stages of the kitten (1 or 2 weeks postnatally). However, response properties of cells are immature. They are generally unresponsive and have low spontaneous rates. When responsive, they have long response latencies and adapt quickly to repeated visual stimulation. Receptive fields are large and often lack center–surround organization. Maturity of these factors occurs rapidly during several postnatal weeks. Resolution changes have also been measured in monkey lateral geniculate nucleus (LGN) cells as a function of early postnatal age. LGN neurons near the fovea exhibit relatively low acuity at birth which improves markedly during the first few postnatal months. These types of measurements are important because they should establish neural limits to behaviorally determined acuities. Only limited data are available for primates and more are required for firm conclusions.

Primary visual cortex is the first location in the central pathway from the retina at which signals from left and right eyes are integrated. In addition to binocular vision, major differentiations are observed in response properties in visual cortex. Some developmental studies have been aimed at determining the status of neuronal maturity at early postnatal ages. This information is directly relevant to the nature–nurture question referred to previously. Most research has been undertaken with kittens, but monkeys have also been studied. Published reports vary considerably regarding the extent of maturity of the visual cortex at early postnatal periods. One of the problems in addressing this question, especially in the case of kittens, is the practical difficulty of obtaining reliable electrophysiological recordings in very young animals. In addition, there is a vascular tunic surrounding the lens that remains for approximately the first postnatal week. This experimental problem could confound conclusions regarding relative maturity. It appears that fundamental response characteristics are present to some extent as early as one can effectively measure them. This applies also to tests of binocular interaction. Tuning characteristics become stronger and more specific during early postnatal periods and more neurons become responsive. This process appears to level off at approximately 5 or 6 weeks in kittens. In monkeys, physiological maturity is probably more rapid.

Anatomically, there are additional indications of postnatal maturation in visual cortex. Lateral geniculate afferents in layer IV are segregated into ocular dominance bands in mature cats. This organization is not apparent until a few weeks postnatally. However, electrophysiological recordings show clear slabs of cortex that are controlled alternately by left and then right eyes. These findings apply to supragranular and infragranular cortical layers, indicating differential laminar effects. It should also be noted that during early postnatal weeks, there is a considerable increase in synaptic density in kittens and in dendritic spines in monkeys. This indicates that neural infrastructure and physiological response characteristics mature in parallel.

Abnormal Development

Binocular Deprivation

There are two main reasons why binocular deprivation has been studied. First, since postnatal visual development appears in general to be a gradual process, an obvious question concerns the requirements for normal maturation. Specifically, is normal visual input a requirement for development of the system? If so, then by preventing visual exposure in postnatal periods, developmental processes should be abnormal. Second, there are rare clinical disorders in which normal binocular exposure is not possible. To understand the physiological and anatomical consequences of these conditions, it is necessary to study animal models in which binocular vision is prevented. For these reasons, a number of studies have been conducted on the consequences of binocular deprivation.

In early work, effects of binocular deprivation were studied in a variety of animals with a focus on the retina and optic nerve. Deprivation was by dark-rearing or eyelid closure. Generally, in most studies, minimal effects were reported. In one study, however, severe degeneration was observed in the retinal ganglion cell layer and the optic nerve of a chimpanzee. In addition, light deprivation appears to interfere with metabolic processes in cell maintenance.

In experimental studies that followed this early work, effects of binocular deprivation were examined for both dark-rearing and bilateral lid suture. For both conditions of binocular deprivation, physiological deterioration can be pronounced. In kittens, effects become apparent after approximately 2 weeks postnatally. Approximately half of the cortical cells in bilaterally lid-sutured cats are unresponsive or respond weakly, nonselectively, or in an irregular manner. Orientation selectivity is severely diminished. In monkeys, these effects may be accentuated. Newborn monkeys seem to exhibit relatively mature neuronal response characteristics which are compromised extensively during binocular lid suture of relatively short periods.

Consistent with the physiological data, behavioral tests show clear abnormalities in animals reared with binocular deprivation. Clearly, peak levels of visual performance require adequate sensory input during

postnatal development. The potential for recovery may be tested by bringing dark-reared animals into a normal lighted environment. Some recovery is observed, the degree of which is approximately inversely proportional to the initial length of deprivation. The monkeys studied recovered more quickly and completely than cats, but they had initial normal visual experience before deprivation. Recovery is not uniform for all visual functions that may be assessed. For example, dark-rearing does not substantially affect the proportions of cortical cells that may be driven through either eye. However, behavioral tests show that stereopsis is completely deficient in these animals even after periods of recovery. Stereopsis requires a precise coordination in the processing of images from left and right eyes. The neural basis for this appears to be irreversibly incapacitated if coordinated active postnatal binocular input is prevented.

The two forms of imposing binocular deprivation, bilateral lid suture and dark-rearing, are not necessarily equivalent. Although the literature does not generally distinguish between these methods, direct comparisons have been made. In pure dark-rearing, there is a complete absence of visual input and, in principle, any developmental changes must be genetically controlled. As an aside, there is a practical problem in maintaining complete darkness during rearing. In the case of bilateral lid suture, depending on the pigmentation of the animal, diffuse light reaches the retina. There are two opposing views regarding the consequence of this diffuse exposure. In one, the unfocused or diffuse light exposure causes developmental abnormalities. The opposite view is that even unfocused images can allow some elements of quasi-normal development. This apparently establishes the visual pathway so that it is not subsequently modifiable. There is evidence that dark-rearing freezes development so that the visual pathways are left in a nonspecified condition. In this case, subsequent normal visual exposure and recovery are more likely. Given these observations, the method of choice for the study of binocular deprivation depends on the class of question one wishes to address.

Monocular Deprivation

By far the most widely studied form of visual deprivation is the restriction of visual input through one eye. There are several procedures by which this may be accomplished. The eyelids of one eye may be sutured closed. This blocks patterned vision but allows exposure to low levels of diffuse light. To eliminate the light, an opaque contact lens occluder may be used under the sutured lids, but this is potentially problematic. Another option is to use an opaque contact lens occluder alone. This allows manipulation of the duration of exposure or the combination of monocular with other forms of exposure. An example of this is the imposition of alternating monocular deprivation. The period of exposure for each eye may be varied and may be combined with other procedures. In the kitten, it is possible to suture the nictitating membrane of one eye in order to degrade pattern vision with only a minimal reduction of light level. Another procedure is to use a defocusing contact lens in one eye. This mimics a clinical condition by creating a deficient image in one eye. All of these methods have been used.

The central findings of monocular deprivation are as follows. Early reports of degenerative effects in the retina from dark-rearing do not apply in the case of monocular deprivation. There are no obvious consequences, either physiological or anatomical, at the retinal level. At the next stage in the central visual pathway, the LGN, there are clear anatomical effects. Cells in layers from the deprived eye are clearly shrunken. This shrinkage may be more pronounced in binocular regions of the visual field where there could be competitive interaction between deprived and nondeprived areas. There may also be physiological effects in deprived LGN cells, but they appear to be limited.

In the main input layer of the visual cortex, layer 4, effects of monocular deprivation are substantial as determined physiologically. There is a clear reduction of cells that can be driven through the deprived eye, although the effect is not as extensive as those in other layers. This difference is more pronounced in the monkey compared to the cat. Approximately 15–20% of neurons in layer 4 retain input from the deprived eye. A standard explanation is that input from LGN to cortex is normally segregated into alternating sections where it terminates in layer 4. The alternating sections are composed of ocular dominance columns that extend through the cortex approximately perpendicular to the surface representing input from each eye. Since there is segregation of inputs from the left and right eyes, there is a minimum of competitive interaction. In other cortical layers, which in the normal condition provide nearly full integration of input from both eyes, it is assumed that the deprived eye in the case of monocular deprivation must compete for functional connections. The nondeprived eye takes over in this situation, and for long periods of deprivation initiated at early postnatal stages, there is nearly complete dominance of neurons in supragranular and infragranular layers. It is important to note that there is a combination of both expansion and contraction of cortical space controlled by the nondeprived and deprived eyes, respectively. This has been demonstrated physiologically and anatomically. Therefore, the effects of monocular deprivation involve active processes and not just passive deterioration of neural connections.

A very broad range of investigations have been conducted on monocular deprivation. An enormous number of parameters have been examined. Examples include postnatal age of induction, length of deprivation, minimal periods required for effects, interactions with other specialized rearing procedures, effects of different ways to cause monocular deprivation, pharmacological effects, recovery, enhancement of vision in the nondeprived eye, effects of visual experience prior to monocular deprivation, and genetic and molecular manipulations.

The main assay for most of this work has been physiological estimates of the degree to which left and right eyes control studied populations of neurons in the visual cortex. The data that are generated from this assay are presented as ocular dominance histograms. They are determined from separate tests of each eye, and they represent the states of binocularity of animals reared with various conditions of monocular deprivation. Most of the histograms presented in the literature were obtained by use of subjective tests. The fundamental problem with this technique is that the state of binocularity may not be accurately determined by use of monocular tests. Direct quantitative assays of ocular dominance using both monoptic and dichoptic tests show clearly that input to a given eye is underestimated in the former case. This may not be a problem for large effects. However, for subtle differences between rearing conditions, inaccurate conclusions may result.

Monocular deprivation effects are caused by a spatially deficient image in one eye. The deficiency has to do specifically with spatial detail. For example, reduced light level causes minimal effects, but suturing of the nictitating membrane or use of a translucent occluder causes extensive consequences. In general, the earlier the initiation of monocular deprivation, and the longer it lasts, the greater the consequences.

Normal postnatal binocular experience prior to deprivation may increase substantially the extent of recovery. Some recovery is observed if binocular vision is instituted following monocular deprivation. Recovery is facilitated if the nondeprived eye is closed when the deprived eye is opened. There appear to be some species differences between cats, monkeys, and humans.

Orientation Selectivity

The two main properties of neurons in the normal visual cortex that are different from those of early pathways are binocularity and orientation selectivity. The deprivation studies described so far deal only with interference with binocular function. There have also been efforts to manipulate the orientation domain. Kittens reared with limited ranges of orientation (e.g., only vertical stripes) have been reported to have very few cortical neurons selective to orthogonal edges. This result has been challenged and is somewhat controversial. In the original work, estimates of this effect were made from populations of single neurons. Optical imaging of intrinsic signals shows that the visual cortex of stripe-reared kittens responds to all orientations. However, considerably more cortical space is devoted to the experienced orientation. A simple interpretation of this result is that the orientation preferences of some cells are shifted toward the rearing orientation. This implies an active process rather than a passive selective deterioration.

Clinical Conditions

The driving force for the study of visual deprivation stems from questions concerning nature–nurture and plasticity of the nervous system. A direct application of these issues arises from clinical disorders. A large number of the deprivation protocols that have been studied in animals have analogous clinical syndromes in human patients. The most obvious conditions are amblyopia, strabismus, and anisometropia. Amblyopia is a developmental visual malfunction in which resolution for spatial detail is reduced without any apparent organic disorder. It is generally associated with anisometropia (unequal refractive powers in left and right eyes) or strabismus (misalignment of left and right visual axes) or both. It may also occur following a clinical condition such as a tumor that blocks spatial vision in an early postnatal period. Textbook categories of amblyopia often refer to a strabismic or an anisometropic type. However, clinicians generally believe there is always some degree of strabismus associated with anisometropia. In any case, it is important to differentiate causation from correlation. Conditions of anisometropia and strabismus can result in amblyopia, but the reverse is also possible. Because of variable conditions in many cases of amblyopia, it is helpful to examine large populations of subjects. For example, this approach suggests that wide differences in behavioral performance may be based on the degree of remnant binocular function in amblyopic subjects.

Animal models of these clinical abnormalities have been investigated in cats and monkeys. These include studies of monocular deprivation by eyelid closure or opaque occluders or by defocusing lenses to mimic anisometropia. Artificial strabismus has also been studied by surgical resection of extraocular muscles and by use of optical prisms to dissociate the visual axes in left and right eyes. In general, results of clinical model studies are consistent with predictions that can be made from basic investigations. Electrophysiological and behavioral tests show deficits that are

commensurate with conditions of rearing. These studies also allow direct comparisons with human populations that have analogous clinical disorders. One difference that emerges from these comparisons is that human subjects appear to have more potential for degrees of recovery than animal models might suggest.

Studies of orientation selectivity also have a clinical analog in the form of ocular astigmatism. In these cases, there are sometimes substantial differences in focal planes corresponding to vertical and horizontal orientations. Assuming a congenital basis for the astigmatism, these are conditions in which a specific range of orientations in object space may be habitually defocused. This is analogous to selective orientation rearing. In these cases, there are clear differences in visual resolution between focused and unfocused orientations. The clinical condition is meridional amblyopia.

Mechanisms

Critical Period

Although most of the experimental work on visual deprivation has been of a phenomenological nature, there have been attempts to address underlying mechanisms. A few examples are considered here. Perhaps the most global issue is the establishment of critical or sensitive periods during which the visual system is most vulnerable to deprivation. Critical periods have been observed for many different sensory systems. They represent windows of time during which the brain is especially sensitive to specific types of input. This susceptibility alters neuronal properties that are modified by direct sensory experience. It is generally assumed that the genome cannot encode requirements of individual animals. The critical period provides a mechanism for a matching of neuronal circuits to individual requirements.

In the original studies of the critical period in kittens for the effects of monocular deprivation, two variables were confounded. Age at which deprivation was initiated and length of monocular closure were both varied. To obtain an accurate profile, one variable should be eliminated. This has been done by imposing a fixed period of monocular closure at successively increasing postnatal ages. The resulting profile shows that sensitivity is initiated as early as one can effectively measure neuronal responses (approximately 2 weeks postnatally) and reaches a peak at approximately 4 weeks. At the peak of sensitivity, a very short period of monocular closure can alter the ocular dominance histogram. As little as 8 h may be sufficient for an observable alteration, but this change can be rapidly reversed by subsequent binocular exposure. The period of susceptibility extends for several months and can be extended further by prior dark-rearing.

There are no comparable data for monkeys. The available data indicate that the critical period for the main input layer (layer 4) is very short compared to that for other layers. For the other layers, the peak is probably similar to that of kittens, approximately 4 weeks postnatally, and the period of vulnerability gradually tapers over an extended time course to 1 year or more.

In humans, of course, there is considerable interest in parallel data. One complicating problem is that there are generally multiple variables in human amblyopia. Clinical observations have placed amblyopia susceptibility to within the first 6 or 7 years of life. One attempt to define this period has been made with a relatively homogeneous population. Subjects with traumatically caused unilateral cataracts that occurred at different ages were studied to determine the extent of recovery following surgery. In general, cataracts in the first 3 postnatal years had devastating effects. Later deprivation had milder consequences, and at approximately 9 years there was complete recovery of visual resolution. In studies of both animals and humans, it is clear that the more normal binocular vision prior to deprivation, the more likely the chance for recovery.

Finally, it should be noted that the critical period for susceptibility to amblyopia is not equivalent to one for treatment. The main treatment regimes are pharmacologically or behaviorally based or a combination is used. There are cases in which very substantial recovery is reported even for severe forms of amblyopia. There is clearly some degree of plasticity in the adult nervous system and it is of clear interest to explore its limits.

Competition

There are several lines of evidence suggesting that the processes active during monocular visual deprivation involve competitive interaction between the pathways from each eye. The main observation is that monocular occlusion causes extreme effects compared to those of binocular deprivation. For example, visual recovery is clearly greater in dark-reared compared to monocularly deprived animals. A standard explanation is that afferent pathways from left and right eyes compete for control of cortical neurons. As noted previously, anatomical studies in the lateral geniculate body suggest that cell shrinkage is maximal for monocular deprivation in binocular segments. This result has been supported by behavioral and physiological determinations. Other studies are consistent with the notion that competition is a primary factor in developmental processes.

Suppression

The competition notions noted previously apply to the cortical input layers in which afferents from left and right eyes converge. However, there is considerable intracortical processing beyond the input stage. It is possible that the competitive advantage of the nondeprived eye in monocular deprivations is heightened by a suppressive mechanism in intracortical connections. In this case, activity from the nondeprived eye would suppress that from the deprived pathway. A direct test of this idea is to surgically remove the nondeprived eye. Cortical extracellular recordings may be made before and after enucleation so that activity can be observed in a given animal before and after the procedure. Although there is some inconsistency in the results, there appears to be both physiological and behavioral evidence consistent with the notion that suppression is one of the mechanisms in monocular deprivation. Attempts have also been made to neutralize suppression pharmacologically by iontophoretic or systemic use of bicuculline, an antagonist of the inhibitory neurotransmitter γ-aminobutyric acid. Results are not definitive, but there is evidence consistent with the suppression notion.

Sensitivity of Nondeprived Eye

A natural question that arises in the case of monocular deprivation concerns the nondeprived eye. Evidence demonstrates that the cortical space available to the deprived eye can be substantially reduced while that for the nondeprived eye is expanded. It is of interest to know if the expanded territory devoted to the nondeprived eye provides heightened visual sensitivity. This is a difficult question to address in humans since the clinical conditions resulting in monocular vision are broadly variable. It is further complicated by the fact that visual resolution may operate at a limit of what is possible based on anatomical and physiological features. Measurements of vernier acuity and contrast sensitivity for gratings over a range of spatial frequencies show generally higher levels for monocular subjects compared to values for normal viewers tested through one eye. There are also some conflicting results. Studies of mice and rats show clear evidence of enhanced visual performance through the nondeprived eye. Visual-evoked potentials, behaviorally measured visual acuity, and optokinetic responses are all enhanced in the nondeprived eye of monocularly occluded animals compared to monocular values of normal binocular subjects. More data are required to establish the basis and limits of enhanced visual performance in monocular subjects.

Visual Development

L M Chalupa and B Chapman, University of California at Davis, Davis, CA, USA

For much of the last century, and continuing to the present time, the visual system has served as the premier model for studying the development and plasticity of the brain. Experiments dealing with development have been concerned primarily with which factors regulate the formation of specific features of the mature visual system, whereas those focused on plasticity have sought to assess how the normal course of events could be modified by various interventions at different developmental stages. An underlying unifying theme of this vast literature has been the role of neuronal activity in the normal development and plasticity of the visual system. Given the prevalent role of activity in these processes, we focus this article on this major issue. In particular, we consider the relevant historical background and underscore what is known and what remains to be resolved in this dynamic field.

Most neuroscientists agree that both activity-dependent and activity-independent mechanisms are responsible for the formation of neuronal connections in the developing brain. What is far less certain is how these factors interact to establish the exquisite patterns of specific connections that characterize neuronal systems at maturity. It is still an open question how neuronal connections are regulated by activity and which connectional features are shaped by activity-mediated events. Perhaps the most convincing evidence for the paramount importance of activity in the wiring of neuronal circuits comes from studies dealing with the development of ocular dominance, whereby the projections of the two eyes become segregated from one another. Indeed, the often-cited phrase "neurons that fire together, wire together" originated in this field. In the last few years, however, new observations have called into question the widely accepted role of activity in the development of the mammalian visual system. As a consequence, this field now appears to be in a state of unexpected flux.

The modern era of activity-dependent regulation of neural connections can be traced to Wiesel and Hubel's findings that monocular visual deprivation caused a marked loss in the ability of the deprived eye to activate cells in the kitten visual cortex, whereas only subtle visual deficits resulted from binocular deprivation. Subsequently, it was discovered that the geniculocortical projections of the two eyes in the monkey and cat appear to be initially intermingled before gradually segregating into left- and right-eye ocular dominance columns. After early monocular deprivation, the cortical territory innervated by the deprived eye became much more restricted than normal, whereas the projections of the nondeprived eye became substantially expanded. This neatly explained why the deprived eye was so deficient in driving cortical neurons. To account for the changes in ocular dominance columns observed after visual deprivation, Hubel and Wiesel suggested that during development "the maintenance of a synapse depends not only on the amount of incoming impulse activity but also on a normal interrelationship between activity in the different afferents" (Hubel and Wiesel, 1965: 1057). This idea is reminiscent of the model proposed some years earlier by Donald Hebb to account for reverberating cortical circuits.

With the introduction of *in utero* surgical methods in combination with axoplasmic transport anatomical tracing methods by Rakic, it became feasible to examine the prenatal development of the visual system. This revealed that in the embryonic macaque monkey the projections of the two eyes are initially overlapped in the dorsal lateral geniculate nucleus (dLGN) before segregating into eye-specific layers and that ocular dominance columns begin to form in the striate cortex more than a month before birth. Ocular dominance columns have also been found by Stryker to form in the neonatal cat prior to the onset of visual experience. Rakic also showed that fetal monocular enucleation (removal of one eye) resulted in the maintenance of a widespread projection from the remaining eye to the dLGN, demonstrating the importance of prenatal binocular interactions in this process. Similar results have been obtained following monocular enucleation in the fetal cat by the Chalupa lab.

Collectively, these studies demonstrated that, although visual experience can alter ocular dominance columns after birth, it is not required for the initial segregation of left- and right-eye projections. Binocular interactions, however, play an important role in the segregation of initially overlapped binocular projections even before birth. Whether such interactions are mediated by activity is still an open question. It is important to point out that the studies discussed so far did not directly address the issue of whether the formation of left- and right-eye segregated projections is mediated by activity-dependent or activity-independent events.

The role of activity in the formation of eye-specific projections was first assessed directly by blocking

retinal action potentials during the developmental period when the connections serving the two eyes are overlapping. This approach was employed by Stryker and Harris, who made binocular intravitreal injections of tetrodotoxin (TTX) in kittens to study the effects of retinal activity blockade on the development of ocular dominance columns, and by Shatz and Stryker, who infused this Na-voltage-gated channel blocker directly into the brain of fetal cats to study the effects of complete activity blockade on the development of eye-specific segregation in the LGN. In both cases, essentially equivalent outcomes were obtained. In the former study, it was found that retinal blockade prevented the formation of cortical ocular dominance columns; in the latter, retinal projections from the two eyes to the dLGN were found to remain widespread and overlapping. These findings have been interpreted to show that retinal discharges are essential for the establishment of left- and right-eye segregated projections in the dLGN and in the visual cortex.

One implication of these experiments is that retinal ganglion cells are capable of discharging action potentials very early in development, even before these cells can be activated by light. The presence of such activity was soon established by recordings from retinal ganglion cells of embryonic rats by Maffei. By means of multielectrode array recordings and imaging of Ca^{2+} transients using isolated retinas, the Shatz lab showed that spontaneous bursts of activity propagate across the retina in a wavelike manner. It has been suggested that such patterned activity is essential for the establishment of left- and right-eye inputs, the segregation of on and off projections to dLGN sublaminae, and the establishment of topographically appropriate projections. The overriding message of these studies is that during development activity-mediated events are required to refine initially diffuse projection patterns. This notion is in line with the concept of the Hebbian synapse, and it has led to many theoretical models explaining how activity-mediated events could regulate the formation of eye-specific projection patterns.

Perhaps the most convincing evidence for the role of patterned activity in forming segregated binocular inputs comes from studies in Carla Shatz's laboratory in which patterns of retinal activity were perturbed. One study used intravitreal injections of epibatidine, a cholinergic agonist which was found to block retinal ganglion cell firing *in vitro*. Binocular injections of this drug prevented eye-specific segregation, whereas monocular treatment with this drug caused the treated eye to occupy a smaller than normal territory within the dLGN while the projections of the treated eye were found to be expanded. The latter finding, reminiscent of the effects of early monocular enucleation, suggest that activity-mediated binocular competition underlies the formation of eye-specific retino-dLGN projections. In a subsequent study from the Shatz lab, monocular intravitreal injections of forskolin, a drug that increases the intracellular levels of cyclic adenosine monophosphate (cAMP) were used to increase the frequency of waves in the retina. This resulted in the treated eye's innervating a greater than normal amount of territory in the dLGN. The results of this study extended the concept of activity-mediated binocular competition by showing that the more active eye captured more territory in the target nucleus.

A limitation of the foregoing studies is that they did not differentiate between retinal waves (i.e., correlated discharges of spatially adjacent retinal ganglion cells) and retinal activity *per se*, in that all manipulations designed to block or increase retinal waves also affected the overall discharge levels of retinal ganglion cells. For this reason, a role for correlated retinal activity in the formation of eye-specific retinogeniculate projections remained to be tested.

One approach to resolve this issue is to attempt to perturb correlated activity without affecting the overall discharge levels of developing retinal ganglion cells. During the time that eye-specific projections are being established, retinal waves in the ferret are driven by acetylcholine released by starburst amacrine cells. Chalupa reasoned that partial depletion of these cholinergic interneurons from the developing ferret retina might disrupt the correlated discharge patterns of retinal ganglion cells without changing overall firings levels. A novel immunotoxin was used to deplete a majority of the cholinergic amacrine cells in newborn ferrets, and this treatment did decorrelate the firing patterns of adjacent ganglion cells during the time when eye-specific projections are normally formed (**Figures 1 and 2**). Significantly, the overall discharge rates of ganglion cells in the immunotoxin-treated retinas were not significantly different than normal. **Figure 3** shows the normal development of the retinogenciulate projection, where the left- and right-eye inputs are extensively overlapping at birth and completely segregated by P10. **Figure 4(a)** shows that, surprisingly, the projection patterns in the immunotoxin-treated animal are identical to those seen in the normal animal. This means that decorrelating the discharges of the developing retinal ganglion cells did not affect the normal segregation of retinogeniculate projections. By contrast, in the case of the animal that received binocular injections of epibatadine to block retinal activity (**Figure 4(b)**), it is obvious that segregated

Figure 1 Correlated ganglion cell activity in control newborn ferret retina. (a) Top shows two neighboring ganglion cells recorded with patch-clamp technique and then filled with red and green dyes. Below are shown recordings from two such pairs of cells, in each case the two cells in the pair show correlated bursts of activity. (b) Cross-corelation analyses of 15 pairs of cells recorded in young ferret retinae from postnatal day (P) 2–9 shown in blue and summary data shown in red. In each case, strong correlations are seen in the membrane potentials of neighboring cells indicating correlated activity. Reproduced from Huberman AD, Wang GY, Liets LC, Collins OA, Chapman B, and Chalupa LM (2003) Eye-specific retinogeniculate segregation independent of normal neuronal activity. *Science* 300: 994–998. Reprinted with permission from AAAS.

eye-specific projections failed to form. Therefore, although retinal activity clearly plays a role in eye-specific segregation, normal retinal activity (i.e., retinal waves) is not required.

Another attempt to dissociate retinal waves and the formation of segregated retinogeniculate projections involved studies of the prenatal macaque monkey by the Chalupa lab. In the species commonly used for studies of the developing visual system, such as the ferret and the mouse, the time period during which connections in the visual system are made and refined is relatively brief. Many developmental events occur concurrently in these species, and as a consequence it is difficult to dissociate the links between them. For instance, refinements in retinotopy and formation of eye-specific projections are overlapping developmental events during which retinal activity may play a role in both. By contrast, the developmental period when brain connections become established is much more protracted in the macaque monkey, so it seems reasonable to think that the salient features of visual system development could be more dispersed; that makes it more likely that key events can be dissociated temporally from one another.

Modern neuroanatomical methods were employed to accurately delimit the time period during which eye-specific retino-dLGN projections are established in the fetal macaque monkey. To determine the temporal relationship between the developmental period when eye-specific projections are formed and when correlated discharge patterns are evident in the fetal macaque retina, multielectrode arrays were used to record the activity from isolated retinas of fetal monkeys at known gestational ages. Before embryonic day 55 (E55), the fetal monkey retina was found to be essentially silent, with only a few cells

Figure 2 Correlated ganglion cell activity is abolished in immunotoxin-treated newborn ferret retinae. Conventions as in **Figure 1**. Note that recordings from the two pairs of cells shown in the lower part of (a) do not show correlated bursts of activity, and that no significant correlations are seen in the correlation analyses from the 15 cell pairs recorded between postnatal day (P) 2–9 illustrated in (b). Reproduced from Huberman AD, Wang GY, Liets LC, Collins OA, Chapman B, and Chalupa LM (2003) Eye-specific retinogeniculate segregation independent of normal neuronal activity. *Science* 300: 994–998. manifesting occasional discharges. Retinal waves of activity were found to be prevalent at E60, which is more than a week before segregation of retinogeniculate projections is first observed. Moreover, the incidence of retinal waves decreased progressively during the period when eye-specific projections become established (E69–E76). These findings in the fetal macaque monkey differ from the results obtained in other species in which retinal wave activity has been reported to be robust throughout the period when segregated retinogeniculate projections are formed, with such activity declining after this developmental event becomes established. Thus, although the multiarray recordings from fetal monkey retina do not rule out the possibility that retinal activity plays a role in the formation of segregated retinogeniculate projections, they do indicate that retinal waves are most prominent at an earlier time in development than the period when eye-specific inputs are being established. We could still argue, however, that the limited correlated discharges observed during the segregation period are sufficient to trigger this process.

Despite the long history of studies showing the importance of activity in the development of eye-specific segregation in both the LGN and the cortex, there are also many experiments that question the role of activity. The initial experiments of Stryker and Harris showing that intravitreal TTX injections block the initial formation of ocular dominance columns have had to be re-interpreted following imaging studies from the Stryker lab that showed that ocular dominance columns have already formed by the age at which the TTX injections were begun. Therefore, the original experiment did not in fact show that retinal activity blockade prevents the development of ocular dominance columns but, rather, that activity is needed to maintain columns that have already formed. A similar result was found in the dLGN by Chapman, who showed that activity blockade can desegregate eye-specific projections to the dLGN after the layers have initially formed.

Figure 3 Normal development of retinogeniculate projection in ferret. Retinogeniculate fibers from the each eye are labeled with red or green dye. (a) Left- and right-eye inputs to the LGN are extensively overlapping on postnatal day (P) 1 in a normal ferret. (b) Left- and right-eye inputs are completely segregated by postnatal day (P) 10 in a control ferret treated with intraocular saline injections. A, A1, and C laminae have all developed normally in this control. Top panels in (a) and (b) show contralateral projections, middle panels show ipsilateral projections, bottom panels show merged images of the two. Reproduced from Huberman AD, Wang GY, Liets LC, Collins OA, Chapman B, and Chalupa LM (2003) Eye-specific retinogeniculate segregation independent of normal neuronal activity. *Science* 300: 994–998. Reprinted with permission from AAAS.

The result from the Shatz lab using epibatidine to silence activity in the developing ferret retina (leading to maintained overlap in retinogeniculate projections) may also need reinterpretation following reports from the Stryker lab that (at least in mouse) epibatidine decorrelates activity but does not block action potential firing. In addition, the role of spontaneous activity in the segregation of initially intermingled retinal projections shown in the fetal cat by Shatz and Stryker was readdressed by the Ramoa lab. These investigators placed slow-release polymer Elvax embedded with TTX into the vitreous chambers of one or both eyes of neonatal ferrets. Their main finding was that eye-specific projections are formed in spite of monocular or binocular blockade of retinal activity. The authors concluded "that spontaneous retinal activity modulates the time course of binocular segregation but does not alone account for the segregation of retinogeniculate terminals" (Cook, et al., 1999: 491). A potential shortcoming of the use of TTX to block activity is that it may induce aberrant growth of axon terminals and that this factor, rather than the disruption of activity *per se*, might account for its effects. Indeed, tracings of single retinogeniculate and geniculocortical fibers by the Shatz and Stryker labs have revealed aberrant morphological properties in TTX-treated animals not observed during normal development. Such aberrant growth patterns might be less likely to occur with the gradual and more confined release of the TTX by Elvax, and this might account for the differences between the findings of the two studies.

The binocular competitive interactions regulating the formation of eye-specific projections in the embryonic monkey could reflect diverse cellular events, including the restructuring of initially exuberant retinogeniculate fibers, as has been shown to be the case in the fetal cat by Shatz. In the fetal monkey,

Figure 4 Projection patterns in immunotoxin-treated and epibatidine-treated animals. (a) Projection patterns in immunotoxin-treated animal are identical to those in a control animal (see **Figure 3**); (b) binocular injections of epibatidine used to block retinal waves prevented segregation of eye-specific inputs to the LGN. Conventions as in **Figure 3**. Reproduced from Huberman AD, Wang GY, Liets LC, Collins OA, Chapman B, and Chalupa LM (2003) Eye-specific retinogeniculate segregation independent of normal neuronal activity. *Science* 300: 994–998. Reprinted with permission from AAAS.

however, retinogeniculate arbors have been shown by Chalupa to undergo continuous growth and elaboration from the time when binocular overlap has been reported to be maximum until the segregation of left- and right-eye projections is largely completed. Moreover, the normal growth and elaboration of monkey retinogeniculate fibers is unchanged by prenatal monocular enucleation. This shows that binocular competition does not regulate the size of retinogeniculate arbors in the embryonic monkey. These observations lend support to the hypothesis suggested by Rakic and Chalupa that overlapping binocular projections in the fetal monkey are due to supernumerary retinal ganglion cells which innervate inappropriate regions of the dLGN and that the subsequent segregation of ocular inputs reflects the loss of such retinal fibers. The lack of restructuring observed in individual retinogenculate fibers in the fetal monkey seem more in line with an activity-independent than an activity-dependent model, but this remains to be determined by future studies.

In carnivores and in the monkey, retinal projections to the dLGN are not only segregated by eye, but are also organized in a stereotypic laminar pattern. With the exception of certain mutants, these eye-specific laminar patterns are invariant across all members of a given species. Such an organization cannot be explained solely on the basis of activity-mediated events. Rather, it argues for the early expression of molecular cues guiding the development of eye-specific layers of the dLGN. Such putative molecular cues could preferentially guide axons to a given layer of the dLGN or provide the fibers stemming from one eye or the other an advantage in the competition for postsynaptic cells. Although molecules specific for ipsilateral or contralateral layers have not been identified, recent studies from the Chapman and Feldheim labs revealed that the expression of gradients of ephrins in the dLGN and their receptors in the retina are important for the formation of eye-specific retinogeniculate projections.

An expression of other laminar-specific cues can be inferred from the finding that retinal ganglion cells

in the monkey embryo diverge into M and P subtypes soon after their last mitotic division and selectively innervate either the prospective M or P layers of the developing dLGN. This occurs prior to the time when the Chalupa lab has shown that retinal ganglion cells in the fetal monkey are capable of firing spontaneous discharges, Thus, the formation of segregated M and P functional channels in the primate visual system does not appear to involve activity-mediated events. Rather, this specific ingrowth pattern suggests that M and P classes of retinal ganglion cells in the primate embryo express distinct molecular markers that allow their axons to react differentially to putative laminar-specific cues. This is in accord with earlier reports from Rakic and others showing that monocular and binocular enucleations in the fetal monkey do not perturb formation of M and P layers in the dLGN and in layer 4 of the striate cortex. Unlike the formation of eye-specific projections, the establishment of M and P functional channels in the primate embryo does not appear to be regulated by binocular interactions.

Recent studies from the Katz lab have also challenged the purported role of neuronal activity in the establishment of ocular dominance columns in the visual cortex. These investigators noted that the apparently initially overlapping geniculocortical projections seen in young animals using transneuronal tracing could have been due to an artifact. They therefore employed anterograde tracers injected directly into specific layers of the LGN to examine the organization of genioculocortical projections in normal ferrets during development and in ferrets that were binocularly enucleated very early in life, before there was any possibility of retinal activity influencing inputs to the cortex. In normal ferrets, they found that an injection of tracer into one LGN layer resulted in patchy labeled projections to the cortex reminiscent of ocular dominance columns. They did not see the continuous label in the cortex that would be expected if there was complete overlap of the projections from the two eyes early in development. Unfortunately, they were not able to use two different labels in contralateral and ipsilateral eye layers of the dLGN to show interdigitation of the projections from the two eyes to prove beyond doubt that the patchy connections really are ocular dominance columns. In enucleated animals studied at maturity, there was also evidence for the presence of what appear to be normal ocular dominance columns. The authors concluded that formation of ocular dominance columns "relies primarily on activity-independent cues, rather than on specific patterns of correlated activity" (Crowley and Katz, 1999: 1125). However, it is possible that there are still correlated signals within dLGN layers following enucleation. Therefore, these experiments are still controversial. In addition, no molecular cues distinguishing between cells in the ipsilateral and contralateral dLGN layers have yet been identified despite major efforts to find such molecules that could underlie an activity-independent mechanism of ocular dominance column development.

A recent study from the Chapman lab, on the other hand, showed that early disruption of retinal activity by intravitreal injections of epibatidine has profound effects on the layout of ocular dominance columns visualized with transneuronal labeling. The overall pattern of the columns was altered, and there was an expansion of the contralateral input, resulting in less segregated columns than normal (Figure 5). In addition, cortical cell receptive-field properties were dramatically altered in the treated animals. It is not clear whether the differences between this study and the enucleation study of Crowley and Katz, already described, are due to the different techniques used to label the columns in the two studies or whether altering retinal activity really causes changes in ocular dominance columns whereas enucleation has no effect on columns. Taken together, these finding on the developing visual system raise questions about the prominence of activity-regulated events in the formation of eye-specific projection patterns at the level of the dLGN and in the visual cortex.

What then is the role of retinal waves in the development of the visual system? Refinements in the early projection pattern of retinal axons occur at several levels, from the elimination of gross topographic errors to the reduction of multiple retinal inputs onto single dLGN neurons, and retinal waves could

Figure 5 Ocular dominance columns in contralateral primary visual cortex of control (a) and epibatidine-treated ferret (b). Note the expansion of the projection in the epibatidine-treated compared to the control animal.

clearly play a role in one or more of such developmental events. Still another possibility is that retinal waves provide an efficient means for increasing intracellular levels of Ca^{2+} into developing retinal ganglion cells essential for the expression of genes controlling normal axon growth and proliferation, cellular events that are clearly required for retinal segregation. These alternatives are, of course, not mutually exclusive. The challenge for future studies is to establish how different types of neuronal activities interact with a cascade of molecular factors to form the exquisite patterns of connections that characterize the mature visual system.

Visual Motion Detection

B K Dellen, University of Goettingen, Goettingen, Germany

Visual motion is essential for many behaviorally important functions such as camouflage breaking, detecting looming objects, and depth perception. Camouflage, in which an animal adapts the color and texture patterns on its skin to match those of its habitat, thereby reducing the risk of being detected by preys or predators, is a very effective survival tool. This tactic, however, only works as long as the animal stays still. Once it moves relative to the background that it is hiding in, other animals can use their visual motion detecting apparatus to break the camouflage. Looming visual patterns are produced by a fast-approaching object, and must therefore be detected reliably and well in advance of the expected collision in order to provide the animal with enough time to execute its escape behavior. Translational self-motion perpendicular to the line of sight produces apparent motion of stationary objects on the retina. The magnitude of this motion is related to the depth of the object. Therefore, estimating the apparent motion of different parts of the visual image can aid the brain in constructing the three-dimensional structure of the world. Such knowledge is important, for example, for navigational purposes.

In summary, having access to motion information is instrumental to an animal's chances of survival. However, motion information is not explicitly encoded at the level of the retinal input. Rather, motion has to be computed from the spatiotemporal intensity changes in the retinal image as sensed by the two-dimensional array of photoreceptors. Given the importance of visual motion for biological function, it is perhaps not surprising that all animals with vision have mechanisms for motion processing.

Local Motion Processing

There are basically two local strategies in which a moving intensity pattern can be distinguished from both static intensity patterns and random spatiotemporal intensity fluctuations. (1) The intensity at a particular location and at a given instant of time is compared with the intensity value at a neighboring location measured some time later (Figure 1). (2) The intensity change in time at one location is divided by the intensity change in space at the same location. In the literature the two algorithmic strategies are referred to as the (1) correlation and (2) gradient detectors. Multiple versions of the correlation detector have become popular in the neurobiological literature. The gradient detector has found more acceptance in the computer vision literature.

Objects in our visual environment are normally distinguishable by a number of cues such as luminance, shape, color, and texture, yet the percept of motion is qualitatively independent of the different cues. This cue independence of motion perception is paralleled by a similar cue independence of the responses of many motion-sensitive neurons in the primate visual cortex and avian tectum. Cue independence of motion perception may be a useful operational principle. To perform optimally in a variable environment, a motion analyzer should generalize across stimulus cues, thus encoding the motion of a stimulus regardless of the cue that enables it to be seen. In avian tectum, cue independence of motion computation is mediated by phasic signal transfer at the retinotectal synapse of tectal wide-field neurons. For this wide-field neuron the distinction between static stationary stimuli and dynamic spatiotemporal stimuli, such as motion, is independent of the details of the stimulus.

Our understanding of the cellular mechanisms of direction selectivity is most advanced in the vertebrate retina, where directional selective retinal ganglion cells were first discovered in the 1960s. We now know that a myriad mechanisms, including dendritic and synaptic dynamics and structure, together provide the neural substrate to potentiate the responses of retinal ganglion cells to motion in certain directions.

Global Motion Processing

A comprehensive understanding of visual processing of motion requires one to go beyond local processing of information and to consider the important effect of context. A neuron responds to visual stimuli presented within an area in the visual field, which traditionally is referred to as the 'classical' receptive field. The neuron does not respond to visual stimuli presented outside this area, which is referred to as the 'surround.' Importantly, however, the response to stimuli presented in the classical receptive field may change when additional stimuli are presented in the surround; that is, the response depends on the stimulus context. Efforts to clarify the psychophysics and physiology of contextual effects in visual motion analysis are collectively referred to as studies of global motion processing.

An important current area of research in global motion processing is transparent motion analysis (Figure 2). Motion transparency is a situation in which two overlapping surfaces move past each other, and as a result the same – or very close – retinal locations may contain two different local motion parameters. In order to estimate the motion properties of the two surfaces, local motion signals have to be first segmented, that is, assigned to either surface. Due to the spatial overlap of the surfaces, however, this segmentation process is nontrivial. While in many natural settings nonmotion cues such as contrast, color, and texture can aid the brain with the segmentation task, there are important scenarios, such as camouflage, in which the brain has to rely solely on motion information to partition the visual image into regions representing independently moving surfaces.

Figure 1 Schematic representation of the correlation-based motion detection. The snapshot of an intensity edge moving with a constant velocity in the *x*-direction is shown. The intensity pattern within a small window of the image is compared with the intensity pattern within another window at a neighboring location some time τ later. If the intensity patterns are sufficiently similar, or ideally identical, the measured velocity is equal to the distance δx between the two windows divided by the time delay τ. The similarity of the intensity pattern may be evaluated via the correlation coefficient.

Figure 2 An example of transparent motion. Two overlapping transparent random dot patterns are moving on top of each other in different directions. Hence, the location of a dot does not predict its group identity, and a single point in space might contain two different velocities.

In laboratories, such conditions can be simulated using transparent random-dot patterns, in which small dots distributed randomly across the visual space move in one of two possible directions, thereby constituting two groups. The location of a dot, however, does not predict its group identity. Further, the brain has only a noisy version of each direction of motion available. Thus, statistical methods have to be employed for this unsupervised classification problem. For instance, accurate estimation of the background motion from an image velocity field can be accomplished through an iterative cooperation between two modules: one that specializes in calculating a weighted average velocity and another that calculates a velocity contrast map. Interestingly, this approach finds an analogy in the vertebrate tectum–pretectum system and suggests that the optic tectum is in charge of calculating a motion contrast map, while the pretectum computes background motion, that is, the weighted average velocity.

'Motion repulsion' is a visual illusion that occurs during the perception of transparent motion. Motion repulsion is the perceived enlargement of the angle between the directions of motion of two transparently moving patterns. It has been hypothesized that this illusion is mediated by lateral inhibition between directionally selective units. An alternative explanation, however, relies on the statistical properties of the motion transparency problem alone. Formulating the problem as an unsupervised clustering problem reproduces motion repulsion.

Another important example of global motion processing by neurons is their sensitivity to motion contrast or relative motion between different parts of the visual image (Figure 3). For example, some cells in the deep layers of the avian optic tectum show suppression of response to a moving stimulus in their excitatory receptive field when it is accompanied by a second stimulus that is moving in the same direction, as long as the latter is within the inhibitory surround. Some neurons in the middle temporal cortex of primates show similar properties. The underlying computation requires spatial comparison of visual signals, presumably mediated by lateral and/or feedback connections.

An algorithm of motion contrast computation without motion sensors has been proposed. The algorithm classifies the visual scene into coherent and incoherent motion and determines the relative velocity of the moving parts of the visual scene. Remarkably, the algorithm predicts the measured response to

Figure 3 An example of relative motion or motion contrast. An opaque random dot square is moving to the right in front of a random dot background, which is moving to the left. Thus, the random dot square is defined only by its motion relative to the background.

motion contrast as a function of the relative angle of object motion from avian tectum and primate middle temporal area (area MT).

Neural Structure and Motion Processing

It has long been hypothesized that structure and function are correlated in neural systems. The avian retino-tecto-rotundal pathway plays a central role in motion analysis and features complex connectivity. While the retinal ganglion cells report local image contrast, the tectal wide-field neurons fire more vigorously when facing small moving stimuli. Postsynaptic neurons in the thalamic nucleus rotundus are selective for the direction of motion of an object as well as looming patterns.

These differences in representations of visual stimuli are paralleled by qualitative structural differences of the neuronal elements in the three stages (Figure 4). A dense array of retinal ganglion cell axon terminals form a topographic map and synapse onto dendritic endings of tectal wide-field neurons. In contrast, tectal wide-field neurons have large circular dendritic fields with sparsely distributed dendritic endings. Interestingly, the point-to-point topography of the retino-tectal projection is replaced by a more abstract topography in the tecto-rotundal projection that appears to be 'interdigitating,' that is, a specific locus in the nucleus rotundus receives input from a sparse population of tectal wide-field neurons throughout the entire tectum.

Figure 4 A schematic of the avian retino-tecto-rotundal connectivity pattern. Retinal ganglion cell (RGC) axons project to the dendritic endings of tectal (OT) wide-field neurons. The tectal wide-field neurons in turn project with an interdigitating topography to the nucleus rotundus (Rt).

A computational investigation revealed that the tectal wide-field neuron's structural properties enhance the neuron's sensitivity to change, a behaviorally important stimulus attribute, while preserving information about the stimulus location in the tectal wide-field neuron population activity. The computational investigation showed further that the subsequent interdigitating tectal projection to rotundal neurons allows the decoding of the direction of motion from the sparsely sampled population of tectal wide-field neurons in a two-stage process. However, the study could not address why the tecto-rotundal projection evolved toward sparse sampling, as opposed to a one-stage projection with dense sampling, which produces similar computational properties. Interestingly, however, a wiring efficiency argument provides a plausible constraint to bias the evolution toward the sparse tecto-rotundal projection approach for motion estimation.

It is tempting to speculate that a computational rationale for sparse connectivity similar to the one hypothesized for the retino-tecto-rotundal pathway will be found for other prominent computational pathways, such as the mammalian cerebral cortex, where only a small fraction of all possible connections between neurons physically exists, even within a local area.

Motion Processing in Visual Cortex

The geniculo-cortical pathway of the mammalian brain plays an important role in the processing and extraction of visual motion. The majority of retinal ganglion cells ascend via the dorsal part of the two lateral geniculate nuclei (LGN) of the thalamus to the primary visual cortex (V1). Then the processing stream continues to higher visual areas, including area MT. Many neurons in V1 and MT are sensitive to motion, and lesions of these areas severely reduce the ability of the animal to detect motion. These observations suggest that the geniculo-cortical pathway is highly involved in visual motion analysis.

Figure 5 Schematic of the receptive-field structure of a cortical simple and complex cell. Each simple cell filters the visual input by means of an oriented spatiotemporal sine function multiplied with a Gaussian envelope. Then the output of the filters is rectified to ensure positive-valued responses. The responses of two simple cells whose sine functions are phase shifted by $\pi/2$ are first squared and then added to create the complex cell response.

Traditionally, neuroscientists have attempted to classify V1 neurons into two types (Figure 5). In this classification scheme, one type, the so-called 'simple cell,' possesses periodically arranged and oriented excitatory and inhibitory areas, which make them sensitive to the spatial phase, spatial frequency, and orientation of a drifting grating. The other type, the so-called 'complex cell,' is largely insensitive to the spatial phase of a drifting grating. To date, much research has been based on the working hypothesis that visual cortical neurons are hierarchically organized with simple cells feeding into complex cells. It is important to note, however, that the experimental evidence for or against distinct simple and complex cell classes and its hierarchical arrangement has been substantial but not conclusive.

The product of an oriented sine function with a Gaussian envelope provides a useful model to reproduce the directionally selective receptive field of simple cells. In the next step, model simple cell responses are nonlinearly combined to give complex cell responses. These responses represent the projections of the stimulus velocity vector on different axes and need to be combined to obtain meaningful estimates of the full stimulus velocity. The latter computation may take place in area MT. Neurons in area MT show a strong directional selectivity and are possibly involved in the processing of global motion patterns and figure/ground segregation.

Interestingly, a mathematical analysis showed that local relative motion computation is inherent in the nonlinear transformation from simple to complex cell responses. Simulations that quantitatively reproduce measured complex cell responses in both cat and monkey to a variety of relative motion stimuli support the mathematical inference. Importantly, this computation of relative motion does not require an intermediate neural representation of local velocities and does not require lateral or feedback interactions within a network.

The hierarchical model of visual cortical motion processing is in good agreement with a large body of experimental data. However, it is a local model. Velocities are extracted from a small area of the visual field only. For the simultaneous presentation of multiple stimuli, the hierarchical model loses most of its predictability. Already in V1, neurons exhibit sensitivity to orientation and motion contrast between a stimulus in the classical receptive field and the surround, potentially contributing to perceptual pop out and image segmentation. Furthermore, recent studies suggest that cortical processing is less local than previously thought. These properties of the visual cortex might be attributed to the abundant lateral and feedback connections, which innervate the cortical layers. Less than 5% of excitatory synapses on V1 neurons originate from the LGN, while over 95% of the excitatory synapses, even in the geniculo-recipient layer in area V1, come from other cortical neurons and other nuclei. For instance, feedback from higher visual areas may be a prime candidate to mediate contextual effects.

Contextual influences from outside the classical receptive field may fundamentally change our view of visual cortical motion processing. The challenge ahead is to design global theories of the brain, in which locality is compatible with global processing strategies.

Visual Motion Models

A Borst, Max-Planck-Institute of Neurobiology, Martinsried, Germany

Whenever an animal is moving in its environment, the images of the environment shift on the animal's retina. The resulting spatial distribution of motion vectors across the visual field is called 'optic flow.' Since the optic flow depends on the animal's own movement as well as on the structure of the environment, it is widely used for visual navigation and course control. However, motion information is not explicitly represented in the two-dimensional (2-D) brightness pattern of the retinal image as sensed by the array of photoreceptors. Instead, motion has to be computed from the brightness changes in the retinal image, as one of the first and most basic processing steps in the visual system. Understanding this primary process of motion detection is important because the performance of all subsequent processing steps depends on the representation of optic flow information at their input stages.

Algorithmic Models of Motion Detection

The velocity of a moving object is defined as the object's spatial displacement over time, dx/dt. For the visual system, this results in a brightness distribution at one time, which is displaced at some time later. There are basically two ways in which motion can be detected visually. First, the brightness at a particular location and at a given instant in time is correlated with the brightness value at a neighboring location measured some time later. Second, the brightness change in time observed at one location is related to the brightness change in space at the same location. These two strategies of motion detection form the basis of two classes of model mechanisms, the so-called correlation and the gradient detectors. Various versions of correlation and gradient detectors have been proposed in the past to underlie motion detection in biological systems.

The correlation detector was first proposed on the basis of experimental studies on the optomotor behavior of insects by Reichardt and Hassenstein. According to common usage, this correlation detector will be referred to here as the Reichardt detector. In subsequent studies, the Reichardt detector has also been applied to explain motion detection in different vertebrate species including humans. Such a detector consists of two mirror-symmetrical subunits (Figure 1(a)). In each subunit, the signals derived from two neighboring inputs are multiplied with each other after one of them has been shifted in time with respect to the other by a delay line or some sort of temporal low-pass filter. The final detector response is given by the difference of the output signals of both subunits. Although each detector subunit is directionally selective on its own, it responds also to correlated input signals which are independent of the direction of motion, such as to the background brightness or its temporal changes. Since these direction-independent signals are the same in both mirror-symmetrical subunits of the complete detector, they are eliminated by subtracting the two subunit outputs from each other. The subtraction stage, therefore, increases the direction selectivity of the movement detector. Various elaborations of the basic Reichardt model have been proposed to accommodate this motion detection scheme to the particular performance of different biological systems. For instance, the retinal input signals may pass linear spatial and/or temporal filter or nonlinear processing stages, such as saturation, full-wave, or half-wave rectifier.

In biology, a popular variant of the correlation-type movement detector has been proposed by Barlow and Levick to explain their experimental findings on directionally selective ganglion cells in the rabbit retina. With respect to its layout, the Barlow–Levick model is almost identical to one subunit of the basic Reichardt model. It consists of two input lines carrying the brightness signals which are compared after one of the signals has been delayed. In contrast to the Reichardt model, this comparison is accomplished by a special logical gate, an 'and-not' or 'veto' gate. This means that the detector's activity is suppressed when both input signals arrive simultaneously at the and-not gate. The corresponding direction of motion is therefore the detector's null direction. For motion in the detector's preferred direction, the veto signal arrives too late to have an effect.

Another type of correlation detector is the so-called motion energy model. This model was inspired by the fact that visual motion corresponds to an orientation in the space–time domain. Constructing sensors with oriented spatiotemporal receptive fields, squaring their output and combining elements such that their responses to grating patterns are 90° out of phase ('quadrature pair'), their summed output shows a steady amplitude during motion with a constant velocity. Since the output of such a squared quadrature pair extracts a measure of the motion energy, these models are called motion energy models. If the Reichardt model as shown in Figure 1(a) is equipped

Figure 1 Algorithmic models. (a) Reichardt model. The detector consists of two mirror-symmetrical subunits. In each of the subunits, the detector input signals are multiplied (M) after one of them has been delayed (τ) with respect to the other by some sort of temporal filter. Both subunit outputs are subtracted to give the final detector output signal. (b) Gradient model. This detector computes the ratio of the temporal and spatial change of the pattern brightness. In the model shown here, the temporal gradient is approximated by a temporal high-pass filter and the spatial gradient is approximated by the difference between the two input signals. The mean of both high-pass filtered input signals is used in the numerator of the division operation. Note that the performance of this simple hardware-implemented gradient scheme differs substantially from the ideal mathematical one.

with the same spatial and temporal filters in its input channels, it assumes the same specific functional characteristics as the energy model and becomes completely equivalent. This identity, however, only holds for the final, fully opponent output signal of both detectors. The responses of the more peripheral processing stages may differ considerably.

With $F = F(x, t)$ designating the brightness of a stimulus pattern as a function of one spatial coordinate x and time t, gradient detectors calculate a motion estimate by relating the spatial change of brightness ($\partial F/\partial x = F_x$) to the temporal change ($\partial F/\partial t = F_t$) at a given location of the image (**Figure 1(b)**). These changes are physically related to each other by the velocity. The temporal brightness change F_t induced by a moving object at point x is proportional to the spatial brightness change F_x as well as to the velocity $v = \mathrm{d}x/\mathrm{d}t$ (note: leftward and rightward motion are conventionally defined as negative and positive velocities, respectively):

$$-F_t = F_x \cdot v \qquad [1]$$

The velocity can thus be formally recovered at least for motion in one spatial dimension by dividing the temporal brightness change by the spatial gradient:

$$v = \mathrm{d}x/\mathrm{d}t = -F_t/F_x \qquad [2]$$

This formalism relates the spatial and temporal brightness changes induced by a moving object but does not specify how the temporal and spatial change of the image brightness should be measured. There are various ways in which this can be done. The spatial pattern gradient may be approximated in the simplest way by the difference between the brightness at two adjacent image points and the temporal derivative by the temporally high-pass filtered brightness signal (**Figure 1(b)**). The response properties of this simple type of hardware-implemented gradient detector differ considerably from the ones of the 'ideal' mathematical scheme. However, more sophisticated approaches are available in computer vision to approximate spatial and temporal brightness changes. The performance of gradient models based on such approximations may then come much closer to the properties of the formalism given by eqn [2] and, thus, to an ideal gradient scheme.

As a consequence of the divisive nonlinearity which is characteristic of gradient detectors, the velocity estimate may become indefinite. This can happen when the denominator in eqn [2] becomes zero (e.g., when the pattern is locally homogeneous). Appropriate means have been proposed to overcome this problem, including the addition of a small constant in the denominator of the ratio between the approximations of the temporal and spatial brightness gradients.

The Marr–Ullman model circumvents this problem by using an 'and' gate rather than a division to relate an estimate of the temporal and spatial brightness changes. Hence, in this respect it is similar to the Barlow–Levick model and, thus, to a correlation detector. The Marr–Ullman model is based on two processing steps. In the first step, it determines the location of edges (i.e., the steepest local brightness changes) in the retinal image. By relating their polarity to the corresponding temporal brightness change, in a second processing step the direction of pattern motion can be determined.

Cellular Models

The motion detection models described so far belong to the group of so-called algorithmic models. They describe the different processing steps by formal operations such as convolutions, subtractions, and multiplications without referring to the specific properties of the biological substrate by which these computations are realized in the nervous system. In contrast, cellular models start with the physiological properties of neurons, synapses, etc. and try to build from these a neuronal machinery for motion vision. Of course, physiological models are still models and, for this reason, have a formal character: When

describing the action, for instance, of a synapse, they make use of electrical circuits as an equivalent for the neuronal membrane. Hence, 'physiological models' are formal models in the same way as algorithmic models are formal models: they are settled just one step closer to the biological substrate.

Many components of the algorithmic motion detection models can be implemented quite easily in neuronal terms. Some of them have even been inspired by the properties of different types of visual interneurons. This is true, most notably, for the different types of spatial and temporal filters that were proposed in the input channels of various versions of correlation detectors or the Marr–Ullman model. It is more demanding to account for the nonlinear interaction between the input signals of the movement detector in neuronal terms. Mainly two types of proposals have been made regarding how this processing step might be realized in biological movement detectors.

The shunting inhibition model (**Figure 2(a)**) has been considered as a physiological means to account for the and-not gate of the Barlow–Levick model. In this model, signals of the two input lines of the movement detector are thought to alter in a postsynaptic neuron the conductances of different ions, an excitatory and an inhibitory one. During motion in the preferred direction, signals are transmitted by the excitatory channel, whereas during motion in the null direction the action of the excitatory synapse is shunted by the simultaneous activation of the inhibitory synapse. A multiplication, the nonlinear interaction of the Reichardt model, is approximated by the mechanism of shunting inhibition if two conditions are met: (1) the reversal potential of the inhibitory ion is close or equal to the resting potential of the postsynaptic cell, and (2) the input signals are small compared with the leak conductance of the postsynaptic cell. If these conditions are not satisfied, considerable deviations from a quadratic nonlinearity may appear.

The threshold model is another cellular possibility to account for the nonlinear interaction between the detector input signals (**Figure 2(b)**). A threshold operation is performed by any neuron which transmits information along its axon by means of action potentials. The threshold model proposes that both input lines of the detector induce excitatory postsynaptic potentials in a common follower neuron which may superimpose in a linear way. If the resulting membrane potential exceeds a given threshold, a spike will be triggered. Since the probability of coincidence of two events is the product of the probabilities of each single event alone, the output of this type of threshold model is equivalent, on average, to a multiplication – the core of the Reichardt model.

Both of these cellular models rely on the most common properties of neurons, such as on changes

Figure 2 Cellular models. (a) Shunting inhibition model. The input signals derived from adjacent image points are assumed to change the conductances of different ion channels of a postsynaptic cell after one of the input signals is delayed with respect to the other. The postsynaptic potential can be quantitatively determined according to the electrical equivalent circuit:

$$V = \frac{E_{leak}g_{leak} + E_{exc}g_{exc} + E_{inh}g_{inh}}{g_{leak} + g_{exc} + g_{inh}}$$

where E_{leak} is the leak potential; E_{exc} and E_{inh} are the reversal potential of the excitatory and inhibitory ion, respectively; g_{leak} is the lumped leak conductances; and g_{exc} and g_{inh} are the conductances of the excitatory and inhibitory ion, respectively. As can be seen by a Taylor expansion of this expression, the resulting postsynaptic potential approximates a multiplication of the input signals g_{exc} and g_{inh} if these are small compared with the leak conductance g_{leak} and if the reversal potential of the inhibitory ion E_{inh} is close to the leak potential E_{leak}. (b) Threshold model. The action potentials of two cells induce excitatory potentials in a postsynaptic cell. When arriving alone, the excitatory postsynaptic potentials (EPSPs) are too small to trigger an action potential. Only when two spikes arrive simultaneously are the EPSPs superimposed, exceed the threshold (Thr., dashed line), and give rise to an action potential. Note that the width of the temporal window within which the superposition of the two EPSPs causes an action potential is set by the time course of the EPSPs.

in their input resistance or on spike thresholds. A number of more complex nonlinear synaptic interactions have been characterized electrophysiologically in various systems which may potentially qualify for the nonlinear interaction in biological movement detectors. Most progress has been made in the rabbit retina, where directionally selective calcium accumulation has been visualized in the dendrites of so-called 'starburst amacrine cells.' The authors observed that only motion from the cell body out to the distal ends of the dendrites leads to an increase in dendritic calcium, whereas inward motion failed to do so. Further studies in these cells provided a biophysical model which can account for this phenomenon. The model is based on voltage-gated calcium channels and a tonic voltage gradient in the dendrite, which provides the spatial asymmetry necessary for direction discrimination.

Common Properties of Motion Detector Models

Despite the apparent differences among the movement detector models discussed previously, all of them satisfy three requirements which any motion detection mechanism has to meet in order to signal motion in a directionally selective way. First, they have at least two input channels. A single input channel could not distinguish, for instance, a dark bar crossing its receptive field in one direction from a dark bar moving in the opposite direction or from a transient dimming of the light. For the correlation method, in its basic form two spatially separate measurements form the signals which are correlated; for the gradient method, at least two spatially separate measurements have to be used to approximate the spatial gradient. Second, the processing of the movement detector input signals has to be asymmetrical in some way. If it were symmetrical, the detector input channels could be interchanged without affecting the output. In this case, the detector would no longer be directionally selective. In the different versions of correlation detectors, the asymmetry is due to the fact that the detector input signals which are correlated are temporally filtered in a different way. In gradient detectors, the asymmetry is inherent in the determination of the spatial brightness gradient. Third, to compute motion, the input channels of a detector have to be related to each other in a nonlinear way. Otherwise, the mean output of a detector would be equal to the detector's response to its averaged input signals; in the averaged input signals, however, all information about the temporal sequence is lost. Thus, the result of a linear interaction cannot be directionally selective. The logical gates used by the Barlow–Levick and Marr–Ullman models, as well as the different analog operations such as the multiplication in the Reichardt model, the squaring operation in the energy model, and the division used by the gradient detector, represent such nonlinear interactions.

Performance of Motion Detectors

An ideal motion sensor should monitor the velocity, for instance, like the speedometer of a car: within its operating range, the higher the velocity, the higher should be the output signal. Yet, the Reichardt detector behaves differently. Many of the response features summarized in the following discussion were also found in motion-sensitive neurons, making the Reichardt detector one of the most successful models in computational neuroscience.

Since periodic stimuli have played a dominant role in the study of biological motion vision, we consider the steady-state response of the Reichardt to a traveling sine wave first. Denoting the wavelength of the sine wave λ, its contrast ΔI, its velocity v (°/s), the spacing of the inputs to the Reichardt detector (its sampling base) $\Delta\varphi$, and the amplitude and phase response of the temporal filter A and Φ, respectively, we obtain the following expression of the time-averaged detector response:

$$R = \Delta I^2 \cdot A(2\pi v/\lambda) \cdot \sin(-\Phi(2\pi v/\lambda)) \cdot \sin(2\pi\Delta\Phi/\lambda) \quad [3]$$

If we assume the temporal filter to be a low-pass of first order, we obtain

$$R = \Delta I^2 \cdot \frac{\tau 2\pi v/\lambda}{1+\tau^2(2\pi v/\lambda)^2} \cdot \sin(2\pi\Delta\Phi/\lambda) \quad [4]$$

The steady-state response of a motion detector can thus be seen, in general, not to be proportional to stimulus velocity. In addition, the response depends on many stimulus parameters in a nontrivial way.

Let us first consider its velocity dependence, which is shown in Figure 3(a) for three different pattern wavelengths. First, note that the detector response, unlike a speedometer, does not increase linearly with increasing pattern velocity. Rather, it exhibits an optimum at a certain velocity. For velocities beyond that optimal velocity, the response falls off gradually toward zero. The speed at which the response is optimum is set by the time constant of the detector low-pass filter: the larger the time constant, the smaller the velocity at which the response is maximum. The time constant of the detector filter thus becomes a decisive model parameter that sets the operating range of the motion detection system in the velocity domain.

Figure 3 (a) Steady-state responses of the Reichardt detector as a function of pattern wavelength assuming a sampling base of 2°. (b) Dynamic response profile of the Reichardt detector in response to the on- (1 s) and off-set (4 s) of constant pattern motion. Shown are the summated output signals (black) of an array of eight such motion detectors (sampling base = 2°) covering one spatial wavelength ($\lambda = 16°$) of the pattern, together with the output signals of three neighboring individual detector signals (red, green, and blue, respectively). The pattern was moving at $32° s^{-1}$, resulting in a temporal frequency of 2 Hz.

In particular, it determines the slope of the detector response around velocity zero and, thus, the gain of the sensor. Furthermore, the response optimum can be seen to depend on the pattern wavelength: The larger the wavelength, the higher the pattern velocity at which the response becomes optimum. More precisely, the response optimum is directly proportional to the pattern wavelength; doubling the wavelength leads to a doubling of the optimum velocity. If we introduce the temporal frequency of the stimulus as being the ratio of the velocity and the pattern wavelength, the response curves for all different pattern velocities coincide at one frequency.

Furthermore, the response of a Reichardt detector also depends on the square of the pattern contrast. In motion-sensitive neurons of many animals, this contrast dependence has indeed been experimentally confirmed using low stimulus contrasts. For higher contrasts, the experimental data fail to follow a quadratic contrast dependence but, rather, tend to saturate. This can be explained most easily by saturation nonlinearities inside the detector. Another feature of correlation detectors, which is obvious in the previously discussed formulas, is that the steady-state response is proportional to the sine of the ratio of the sampling base and the pattern wavelength. The sampling base of the motion detector limits the spatial resolution of the system. As is the case for any discrete sampling system, wavelengths can only be resolved up to a certain limit. The smallest wavelength that can be resolved is given by twice the sampling interval (the 'Nyquist limit'). For smaller wavelengths, the response starts oscillating between positive and negative values. In this regime, when the

detector signals negative values for pattern motion along its preferred direction, its behavior is called 'spatial aliasing.' It can indeed be experimentally observed in the laboratory, but it usually does not affect the system performance since higher spatial frequencies are much reduced by the optics at the front end of the detector.

In addition to the steady-state properties, the dynamics of the local motion detector response are of great interest. **Figure 3(b)** shows the time course of the detector response to a moving sine grating, the velocity of which was stepped from zero to a constant value (corresponding to a temporal frequency of 2 Hz) at $t = 1$ s and back to zero at $t = 4$ s. Shown is the spatially summated output of all eight motion detectors used in this simulation together with the individual output signals of the first three motion detectors. There are several notable observations. First, the spatially summated response changes over time in the initial period of the stimulation. Before assuming its steady-state response given by eqn [4], the response is transiently ringing at the temporal frequency of the stimulus. The ringing is damped and settles over time to the steady-state value. The length of the transient period is in general determined by the time course of the intrinsic filters of the motion detection system. Another feature that can be seen in **Figure 3(b)** pertains to the individual detector signals. In contrast to the overall response that exhibits a ringing only initially, the individual detector output signals continue to oscillate at the temporal frequency of the pattern as long as the pattern is moving. The modulations of these signals are phase shifted due to the fact that they receive input from different spatial parts of the pattern. Only after spatially integrating the signals over different spatial phases do these oscillations become canceled, resulting in a smooth, constant steady-state response.

Due its absolute equivalency, all the characteristics discussed for the Reichardt detector also hold true for the energy model, with one exception: in the case of the energy model, the temporal modulations (**Figure 3(b)**) can already be eliminated at the level of a detector subunit if the signals are filtered in such a way that the filter responses to sine-wave gratings moving at a constant velocity differ in their phase by exactly one-quarter of a temporal cycle (i.e., they are in 'quadrature phase'). The same effect occurs in the Reichardt detector without prefiltering when the spatial wavelength is four times the sampling base. In general, gradient detectors should not exhibit any sort of pattern dependence or deviate from an ideal velocity sensor. This can be most easily seen for its lack of contrast dependence. Although a pattern with higher contrast leads to a larger spatial gradient, the temporal brightness change becomes larger accordingly. Thus, when dividing spatial and temporal brightness changes, the contrast factors out. For the same reason, a gradient detector does not show modulated responses to pattern motion with a constant velocity; instead, the time course of its response immediately reflects the time course of pattern velocity. However, these properties may differ if the gradient scheme is realized by technical or biological hardware. Due to the fact that both the spatial gradient and the temporal brightness change have to be approximated by certain filters and care has to be taken to prevent the spatial gradient from being zero (the denominator of the division in eqn [2]), the output signal even of gradient detectors may also become, at least to some extent, contrast sensitive and exhibit a velocity dependence which differs from that of an ideal velocity sensor.

Further Processing of Motion Detector Responses

Unless implemented in a very specific way, most detector models discussed here do not encode faithfully the velocity of the stimulus pattern. We have seen that this is reflected in two response characteristics: (1) the output signal of a detector may be modulated over time, even if the pattern moves with a constant velocity, and (2) the mean response amplitude may depend on the textural properties of the pattern. In the following, different ways of coping with these limitations are discussed.

One way to eliminate the temporal response modulations is to integrate spatially over an array of movement detectors looking at neighboring points in the visual field. Ideally, this array has to cover an integer multiple of spatial periods of a periodic stimulus pattern (**Figure 3(b)**). Since all local detectors 'look' at different spatial phases of the pattern, their output signals are also phase shifted. Spatially integrating these output signals leads to a smooth time course of the overall response which is, within certain limits, proportional to the time course of pattern velocity. However, these properties may differ if the gradient scheme is realized this useful consequence of spatial integration is paid for by a reduced spatial resolution of the motion detection system. It is obvious that the minimum range of spatial integration which is necessary for the response modulations to disappear depends on the spatial frequency content of the stimulus pattern which has access to the motion detection system. This implies that if the retinal image is spatially band-pass filtered peripheral to the site of movement detection, the minimum range of spatial integration depends on the low-frequency

cutoff of the spatial filters. Of course, the temporal modulations in the response of individual movement detectors are also eliminated when the signals are integrated over time instead of space. This suggests a trade-off between spatial and temporal resolution of a movement detection system. However, spatial or temporal integration only eliminates the temporal modulations of the detector signal. The mean response amplitude still depends on the structure of the stimulus pattern.

The time course of the spatially integrated movement detector response is proportional to pattern velocity only within a certain dynamic range. If the pattern velocity changes too rapidly, for instance, at the onset of motion, characteristic response transients may occur. This has been studied in detail for the Reichardt model. However, the response transients are neither a special feature of this model nor due to adaptational changes of some parameters of the motion detection system. Rather, they reflect the consequence of response transients of the temporal filters which are a constituent part of any motion detection system.

Figure 4 Motion in two dimensions. (a) A pattern consisting of a radially symmetric Gaussian luminance distribution is moving horizontally at a constant speed (arrow). (b) Response field of Reichardt detectors. (c) Response field of gradient detectors. Note that in both cases, the response vectors deviate locally from the actual pattern motion. Only after spatial integration is the correct direction of pattern motion recovered.

Motion in Two Dimensions

So far, the computation of motion information has been considered only for one spatial dimension. We now extend our analysis to motion in two spatial dimensions, thereby considering two major questions: How is the 2-D motion information represented at the output of arrays of motion detectors such as those discussed previously and to what extent is it possible to recover from these output signals the correct 2-D retinal velocity field as given by the geometrical projection of the three-dimensional motion vectors onto the retina?

Let us first consider the steady-state response of a pair of orthogonally oriented Reichardt detectors. In the limit of a small sampling base, the response can be approximated by the following expression:

$$\begin{pmatrix} r_x \\ r_y \end{pmatrix} = -\varepsilon \cdot \begin{bmatrix} F_x^2 - F \cdot F_{xx} & F_x F_y - F \cdot F_{xy} \\ F_y F_x - F \cdot F_{yx} & F_y^2 - F \cdot F_{yy} \end{bmatrix} \cdot \begin{pmatrix} V_x \\ V_y \end{pmatrix} \quad [5]$$

Here, the detector is assumed to have a delay line with delay ε instead of a temporal filter. Interestingly, the response of the x-detector (r_x) depends not only depends on the velocity component along the x-direction but also on the velocity component along the y-direction. The same holds true for the y-detector. Furthermore, both responses depend on a combination of the first and second spatial derivatives of the pattern, denoted by F_x, F_y, F_{xx}, etc. The pattern dependence of the response vectors of Reichardt detectors is illustrated by the computer simulation in Figure 4(a). Although the pattern moves with a constant velocity along the x-axis of the detector array only, the response vectors shown at a particular instant in time point to different directions depending on the local structure of the stimulus pattern. Thus, the local instantaneous response vectors may not coincide with the direction of pattern motion.

For a pair of orthogonally oriented, mathematically ideal gradient detectors, the responses are given, as in the one-dimensional case (see eqn [2]), by the relation between the temporal change of the pattern brightness at a given location and the corresponding spatial change along either the x- or the y-axis:

$$r_x(t) = -F_t/F_x \quad [6]$$

$$r_y(t) = -F_t/F_y \quad [7]$$

For motion in two dimensions, the so-called optical flow constraint equation, introduced by Horn and Schunck in 1981, holds:

$$-F_t = F_x \cdot v_x + F_y \cdot v_y \quad [8]$$

Combining eqs [6]–[8] then leads to the following equations for the responses of a pair of gradient detectors:

$$\begin{pmatrix} r_x \\ r_y \end{pmatrix} = \begin{bmatrix} 1 & F_y/F_x \\ F_x/F_x & 1 \end{bmatrix} \cdot \begin{pmatrix} v_x \\ v_y \end{pmatrix} \quad [9]$$

Each of the resulting response vector components thus depends on the brightness change of the retinal image along both the x- and the y-axis. Hence, in general, it does not coincide with the corresponding retinal velocity vector. The response vector field of such pairs of gradient detectors in response to the same stimulus as previously tested on pairs of Reichardt detectors is shown in **Figure 4(b)**.

Is it possible to compute the correct retinal velocity field from the response profiles of an array of Reichardt or gradient-type movement detectors? In principle, there are two ways to cope with it. One way is to take into account global features of the response field such as smoothness, which is equivalent to averaging over smaller patches of the response field. Another way is to recover the correct image velocity locally. In the case of Reichardt detectors, this is generally possible once the first and second spatial derivatives of the local pattern are available. In the case of the gradient detector, eq [8] has to be differentiated along the x- and y-directions separately, leading to two linearly independent equations:

$$-\begin{pmatrix} F_{tx} \\ F_{ty} \end{pmatrix} = \begin{bmatrix} F_{xx} & F_{yx} \\ F_{xy} & F_{yy} \end{bmatrix} \cdot \begin{pmatrix} v_x \\ v_y \end{pmatrix} \qquad [10]$$

Again, measuring the higher spatial and spatiotemporal derivatives, the equations can be solved for v_x and v_y, as long as the matrix containing the spatial derivatives of the image is nonsingular, which then leads to the correct image velocity field.

However, in case of a pattern consisting of parallel stripes crossing the receptive field of a motion detector, there is simply not enough information to recover the correct local velocity vector. This is often referred to in the literature as the 'aperture problem.' The motion vector can be decomposed formally into two components, one being orthogonal and the other parallel to the stripes. The orthogonal component is accompanied by a brightness change in this direction, whereas the parallel component is not. Hence, the latter component cannot be detected by any mechanism. Thus, the pattern brightness has to vary along two orthogonal directions. Only then can the 2-D velocity be recovered.

In addition to the Reichardt and the gradient detector, there exists an alternative method to calculate the optic flow which is quite commonly used in computer vision. This region-based matching approach defines the local velocity v as the shift $d = (d_x, d_y)$ that yields the best fit between image regions at different times. Finding the best match amounts to maximizing a similarity, such as the normalized cross-correlation, or minimizing a distance measure such as the sum-of-squared difference (SSD) over image patches consisting of $2n+1$ times $2n+1$ pixel at each image location x,y:

$$\mathrm{SSD}(x,y,d_x,d_y) = \sum_{j=-n}^{n}\sum_{i=-n}^{n}[F(x+i,y+j,t) - F(x+i+d_x,y+j+d_y,t+1)]^2 \qquad [11]$$

When comparing the matching algorithm outlined previously with the Reichardt detector, one can see the following important differences between the two algorithms: whereas the matching approach finds the maximum of the cross-correlation, relates the location of the maximum to the respective x and y shifts, and interprets these as the x- and y-components of the velocity vector, the Reichardt detector operates with fixed x and y shifts (the detectors' sampling bases along the x and y direction), calculates the cross-correlation for these shifts, and interprets the magnitude of the cross-correlation for both shifts as the x- and y-components of the local velocity vector. Therefore, in general, the outcomes of both operations are different.

Conclusions

Interestingly, only a small number of models of motion detection have been proposed in the literature. These different models can be grouped, according to the computational principle they are built on, into two classes – the so-called correlation and gradient detectors. Despite the apparent overall difference in the structure of the various model versions, some of them show a similar performance, for instance, with respect to their velocity tuning and their dependence on pattern structure. Thus, the dichotomy between at least some of the models starts to fade, and this is all the more true when the 'sloppy workmanship' of the neuronal hardware is taken into account. In addition, a closer examination of the internal structure of the models is necessary because predictions may differ significantly depending on the processing level which is considered. Hence, it is often not as easy as one might expect at first glance to determine what mechanism underlies motion detection in a particular biological system. Therefore, modeling is an indispensable tool for designing more specific experiments which may eventually allow us to distinguish between different mechanisms.

Visual Signaling in Animals

K J McGraw, Arizona State University, Tempe, AZ, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The human visual sense is the most accessible and the most often studied of our five senses. It is perhaps no surprise, then, that, as scientists, humans have been especially attracted to the diversity of forms and functions of visual traits in other animals. Visual features include overt behaviors that animals exhibit, as well as their body sizes, shapes, colors, patterns, and structures. It has been argued by biologists as far back as Darwin that animals use prominent, often exaggerated movements by or features on the body in a form of 'visual communication.' Much more than 'body language,' which might be the first thing that comes to mind when asked about examples of behavioral communication, many varieties and intricacies of behaviors and morphologies, including facial expressions, colors, courtship displays, and protruding tissues like horns or feathers, constitute the repertoire of animals aiming to communicate information without vocalizing, odorizing, tasting, or touching.

Animals use signals in a variety of behavioral contexts, including breeding, predator avoidance, social grouping, and foraging. Moreover, animals exchange information about numerous attributes of individuals, including sex, individual identity, location, mate quality, breeding strategy, and genetic make-up. A major thrust in research on animal communication today is to understand the mechanisms via which animals control their signals. In addition to nutritional and immunological factors, the neural and endocrine bases of signal production have received much attention. A great deal of this work has been done in relation to vocal communication, but the emphasis on the neuroendocrinology of visual signals nearly rivals that on acoustic signals.

The aim of this article is to highlight some of the uses of behavioral and morphological visuals in animals and to pay special attention to those examples that have clear neural or endocrinological bases or that have apparent value for future investigations at these levels. As the ability to characterize and quantify animal signals and neuroendocrine pathways continues to improve, there is no doubt that numerous neuroendocrinological underpinnings of animal signals will be uncovered.

Behavioral Visual Signals

Courtship Displays

Perhaps the most exaggerated and thoroughly studied of the behavioral visual signals in animals, especially from the proximate perspective, are the courtship displays. These are predominantly performed by males and include precopulatory food offerings, dances, or other movements in the presence of a prospective or secured mate. Those behaviors exhibited most frequently by females include receptivity postures just prior to mating, except in mutually mate-selecting or sex role-reversed animals, in which case, females actively pursue and display for males.

Clearly the species for which we have the most detailed neurological information about a male courtship display is *Drosophila melanogaster*. Prior to mating, male fruit flies orient toward females and vibrate an extended wing, in addition to performing other behaviors (e.g., tapping, licking). Specific genes, *dissatisfaction* and *fruitless*, are linked to the sex-determination pathway and govern neurally based courtship behavior. Mutations to *dissatisfaction* alter male recognition of females as mates, such that males actively court other males. This is believed to have a neural basis, but controlling brain regions have not yet been identified. The *fruitless* gene, in contrast, has been tied more closely to abnormal courtship, and male-specific protein products of this gene have been identified in the superior protocerebrum of the brain, which has been implicated in courtship initiation. The central nervous system circuitry encoded by *fruitless* also includes olfactory neurons that appear to be required for the behavioral response of males to female sex pheromones. The interactive nature of male–female courtship interactions has been elucidated recently for other animal signals, especially in bowerbirds, but for no other visual signal has such a detailed, complex neural and genetic basis been uncovered.

Proximate studies of courtship displays in vertebrates have traditionally centered on gonadal sex steroid mediation, and a diversity of hormonal control mechanisms exist. Courtship dances and displays are testosterone-mediated in a number of bird species. However, strutting in male Japanese quail (*Coturnix japonica*) is sensitive to estrogens, and this differs from the way hormones control their courtship vocalization (crowing), which is more androgen-sensitive (e.g., testosterone and 5α-dihydrotestosterone). Perhaps the two best-studied of the vertebrate courtship displays from a neuroscientific perspective are the

throat-fan (dewlap) extension of male anoles (*Anolis carolinensis*) and the bowing and nest soliciting of male ring doves (*Streptopelia risoria*). Male anoles evert a brightly colored flap of gular skin using (ceratohyoideus) muscles that bow out a piece of cartilage (retrobasal process) in the throat. This process is androgen-dependent, and the throat muscles are innervated by seasonally and sexually dimorphic motor neurons located in two regions of the brain stem. In male ring doves, bowing is testosterone-dependent, but nest-soliciting wing flapping (by both sexes) is estradiol-dependent, and both hormonally governed behaviors appear to be controlled in the anterior hypothalamus preoptic area (HPOA), as determined by carefully designed studies using hormone implants and enzyme blockers.

The flight displays of male dark-eyed juncos (*Junco hyemalis*) are an example of a courtship behavior that is testosterone-dependent and preferred by female mates. There are also a few excellent cases in which vertebrate courtship behaviors have been traced down to the neuromuscular and neuroendocrine paths. For example, loud, rapid courtship wingsnaps are produced by male, but not female, golden-collared manakins (*Manacus vitellinus*) resulting from a sexual dimorphism in wing musculature and sex steroid accumulation in regions of the spinal cord that innervate such musculature. Identifying such specific neuroendocrine paths for the musculature that controls other elaborate courtship behaviors, as has been done on the avian song system, should yield exciting avenues for future work.

Finally, despite these numerous examples, gonadal steroids are not always required for adult animals (e.g., certain cichlids, toads, sparrows, and primates) to maintain their courtship signals. In many cases, adrenal or brain-derived steroids are thought to be the sources of hormones that sustain the behavior. There can also be early-life effects of hormone that organize courtship later in life. Alternate hormones (e.g., peptide, protein) should also be considered as chemical signals for courtship behavior maintenance, much like the role of vasotocin in male rough-skinned newts (*Taricha granulosa*).

Parental Behavior and Aggression

Parental effort and aggression are two additional behaviors that often function as conspecific signals, in many cases increasing the attractiveness of potential male partners. There is an extensive literature on the endocrine basis for such behaviors in a wide variety of animals. Historically, prolactin has been viewed as 'the' parental hormone, but this is by no means universal. Prolactin stimulates milk letdown and subsequent delivery to young in mammal mothers and facilitates offspring rearing in male and female birds. However, prolactin has no influence on lamb recognition and acceptance by mother sheep and generally is thought to play more of a role in the maintenance of parental behavior rather than its onset. Steroids and peptides, in contrast, strongly induce parental instincts toward offspring. In sheep, it is oxytocin release during birth that stimulates maternal interest in young. Estrogen, aromatized in the brain from testosterone, is a key sex steroid that drives paternal behavior in male California mice (*Peromyscus californicus*); testosterone, along with progesterone, traditionally inhibits parental tendencies and can even facilitate paternal aggression toward offspring (e.g., in rodents; see more on aggression in the next paragraph). The neural centers that mediate paternal behavior have been described in a few instances, particularly for prolactin action and crop milk production and regurgitation in ring doves and for oxytocin action in the paraventricular nucleus of the hypothalamus that promotes lamb acceptance in sheep. Brain sites for parental behavior are typically the same as those for sexual behavior in general (e.g., preoptic area, bed nucleus of the stria terminalis).

Testosterone, often interfering with parental behavior, is widely viewed as the 'aggression' hormone. Threatening, competitive, and fighting behaviors fluctuate in response to changing levels of testosterone, or derivatives such as 11-keto-testosterone (in fish), in male animals from all major vertebrate groups. A good example of a sexually valued, hormone-dependent aggressive signal involves the gray partridge (*Perdix perdix*), whose vigilance behavior, a form of aggression aimed at deterring predators, is testosterone-dependent in males and is sexually attractive to females. Brain-derived (from testosterone) estrogens can also influence male aggression (e.g., in mice). Though the proximate underpinnings of female aggression have been comparatively neglected, gonad-derived sex steroids control aggression in some females as well (e.g., mountain spiny lizards, *Sceloporus jarrovii*).

Nonsteroid hormonal mechanisms can underlie aggressive behavior, and to date these provide some of the best neural links to animal aggression. The role of neuropeptides has received increased attention in recent years, as vasopressin in mice, vasotocin in songbirds, and adrenal catecholamines in lizards all play pivotal roles in modulating competitiveness, but with different relative outcomes, sometimes even in closely related species. For example, septal infusions of vasotocin inhibited aggression in territorially breeding male violet-eared waxbills (*Uraeginthus granatina*) and field sparrows (*Spizella pusilla*) but promoted aggression in a colonial songbird, the zebra finch (*Taeniopygia guttata*). Work on

the green anole has also yielded insights into the turnover of serotonin, dopamine, adrenalin, and noradrenaline in brain stem nuclei as a function of aggressive signaling. Finally, yawning in humans and other animals is often viewed as a threatening social signal and can come under diverse neural and endocrine controls. Dopamine, acetylcholine, serotonin, nitric oxide, and oxytocin are among the neurochemicals that facilitate yawning, while opioid peptides can inhibit this behavior. Functional magnetic resonance imaging has recently been used in humans to show that brain regions involved with self-(bilateral precuneus and posterior cingulate) and facial-information processing (bilateral thalamus and parahippocampal gyrus) are active during yawning, suggesting an important neural basis for the communication value of yawning. Beyond these examples, however, the neuroendocrine basis for an aggressive or parental behavior that serves directly as a signal has rarely been determined.

In many instances, aggressive behavior itself is signaled by a different trait, a morphological 'badge of status' (e.g., color patch; body, horn, or antler size), that can come under neuroendocrine control. Examples are discussed in the next section.

Morphological Visual Signals

Colors and Patterns

Animals use colors and patterns to signal in mating or competitive contexts within their species as well as in cryptic, aposematic, or species isolation contexts among species. In the latter case, with the exception of rapid background matching in ectotherms, signals are highly pattern-(as opposed to intensity-) dependent, generally invariant among individuals, and come under genetic control, which for some may involve hormonal pathways (e.g., the role of α-melanocyte-stimulating hormone (α-MSH) and the melanocortin-1 receptor (MC1R) for melanic color patterns). The majority of the emphasis here will be on intraspecifically variable mating or competitive color signals.

Physiological color changes in fishes, amphibians, and reptiles have served as model examples for studying the neuroendocrinology of visual color signaling in animals. This is because light-absorbing pigments (e.g., melanin, carotenoid, pterin, purine) are harbored in living cells (chromatophores) that can actively aggregate or disperse molecules, in response to physiological triggers (and ultimately environmental cues), on a minute-to-minute basis. Here, hormones like α-MSH and melanin-concentrating hormone have profound regulatory functions for melanosome accumulation (hence, skin darkening) in numerous ectotherms, although other hormones (e.g., epinephrine, serotonin, thyroxine, pro-opiomelanocortin, and somatolactin) have been implicated. An excellent example of such work on a color known to function as a signal is work on skin darkening in Arctic charr (*Salvelinus alpinus*) and the green anole. In charr, stressful social conditions induce serotonin and norepinephrine in the central nervous system to modulate pituitary release of adrenocorticotropic hormone and α-MSH, which together drive skin darkening. Detailed neural and cellular work, in the context of rapid cryptic (background-matching) color acquisition, has also been performed in the African clawed frog (*Xenopus laevis*), where melanotrope cells from the pars intermedia of the pituitary release pro-opiomelanocortin-derived α-MSH to redistribute melanosomes and change color, and superchiasmatic neurons, which produce the neurotransmitters γ-aminobutyric acid, dopamine, and neuropeptide Y, transport these factors to axons contacting the melanotrope cells and ultimately inhibit α-MSH secretion. A paracrine factor (macrophage migration inhibitory factor) and autocrine factors (e.g., brain-derived neurotrophic factor) can also influence amphibian melanophore action.

Most colors of endotherms differ from those of ectotherms in that they are contained in dead tissue like feathers or hair and thus cannot be as dynamically linked to neuroendocrine processes. A classic case of such a signal is the bright red plumage of house finches (*Carpodacus mexicanus*), which is dependent on adequate nutrition (intake of proper carotenoid pigments from plant foods) and health. Still, hormonal regulation of bird coloration has received considerable attention (more than mammal color regulation), mostly from the perspective of sexual plumage dichromatism. The carotenoid-based red beak of male zebra finches and the melanin-based badge of the male house sparrow (*Passer domesticus*) are classic examples of bird colors that are exaggerated (made richer or larger in size) by androgens. It is important to point out that the sexual variation (dichromatism) observed in these cases cannot be overcome by hormones (e.g., inducing a male-like condition in females by administering testosterone); instead, the sex difference has a genetic basis. In the majority of work in this area, however, no proper procedures have been followed to rule out estrogenic (via aromatization from testosterone) control of color, and no neural link to such coloration has been established. Melanic colors in songbirds, especially Old World ploceids (e.g., bishops and widowbirds), are also sensitive to luteinizing hormone (LH).

Coat colors of mammals typically vary among species in melanin pattern and are genetically

determined. Many of these melanic features can be sensitive to hormones like α-MSH and are governed by the MC1R locus, and evidence from this is extensive in domesticated mammals (e.g., cattle, rodents, dogs). Some species also exhibit fleshy red and blue colors on the face or rump that dynamically respond to social (competitive) conditions and androgen levels (e.g., in mandrills, *Mandrillus sphinx*). Fast-acting neuroendocrine paths are also implicated in the social signal known as facial blushing in humans (e.g., sympathetic arousal of beta-adrenergic receptors, resulting in vasodilation).

Enlarged Integumentary Features

Body structures that are exaggerated beyond the basic head-to-toe morphology of an animal (structures such as horns or antlers; manes; feather crests; or fleshy tissues such as wattles, combs, or sexual swellings) often play valuable roles as attractive or competitive signals. For each of these categories of traits, an endocrine basis for their formation has been established. High testosterone levels promote seasonal mane growth and antler pedicle initiation in red deer (*Cervus elaphus*) stags, and low levels induce antler casting when breeding has ceased, but high levels do not necessarily promote antler growth. It has recently been shown at the cellular level that androgen receptors seasonally upregulate in hair follicles and allow for testosterone-dependent formation of the enlarged mane in this species. The seasonal cycle for female reindeer (*Rangifer tarandus*) antlers, which are smaller than males' antlers, is similarly sensitive to sex steroids, although the relative roles of testosterone and estrogen have not been clarified.

Classic work on the ornamental feather plumes in males (e.g., neck fringes, hackles) from certain strains of domestic chickens (*Gallus gallus*) shows that the male plumage is the default (genetically programmed) pattern and that only in the presence of estrogen does the female plumage develop. This can even be extended to strains (e.g., Sebright) whose males display female feathering, and this plumage is maintained by the aromatization of estrogen from testosterone in skin. Such estrogen dependence (and androgen independence) of ornamental plumage dichromatism is very common in large, ancestral birds (e.g., ostrich, gamebirds, waterfowl).

In contrast, the size of exaggerated fleshy integumentary structures, beyond their color appearance, can come under androgenic control. The size of combs on the heads of male roosters, red grouse (*Lagopus lagopus*), and black grouse (*Tetrao tetrix*) is testosterone-dependent. Sexual swellings on the hind end of some female Old World primates (e.g., olive baboons, *Papio cynocephalus anubis*) advertize the timing of their fertility as well as their lifetime reproductive potential and thus are closely tied to ovarian hormone cycles.

Body Size and Symmetry

Generalized features of the body, including its overall size and the bilateral symmetry of certain attributes, have also received considerable attention as signals with which individuals can send and receive important information about a rival or prospective mate. In many species, for example, large males are dominant, and as indicated earlier, dominance is controlled by sex steroids. However, while hormones such as testosterone can increase muscle mass and other growth parameters in wild animals, as well as in humans, it appears that no study of a free-ranging animal has yet shown that testosterone or any other hormone modulates both body size and its role as a competitive signal.

Fluctuating asymmetries (FAs) in bilateral traits have been proposed to contain useful signaling information regarding the developmental (e.g., nutritional, health, genetic) history of individuals. Hormones may also play key roles in the development of features that later in life do not exhibit perfect symmetry and thus may be used as a signal. There was an outburst of studies on the signal content of FA in animals throughout the1990s, and while interest has waned, some scientists studying humans have shown recent interest in the endocrine basis for FA signals. Sexually attractive odors are linked to the facial symmetry (and hence sexual attractiveness) of men, and these can be pheromonal, but regarding visual signals, soft-tissue symmetry itself is argued to have a hormonal basis, even on a dynamic scale. In a sample of ten men, researchers found that fingers, wrists, and ears were more asymmetric when circulating levels of LH and thyroxine were high and when levels of follicle-stimulating hormone were low. It has been argued that highly asymmetrical men tend to be more aggressive and that an endocrine mechanism underlies FA-linked behavior (e.g., LH through its effects on testosterone). However, experimental work is needed to better understand whether and how hormones and neural pathways may influence FA.

Extended Phenotypes: Where Morphology and Behavior Meet

Some organisms develop signals, not on their own bodies, but on or as structures in the environment ('extended phenotypes'). Nests and their construction, for example, can serve as signals of effort on which males or females base mating decisions (i.e., in sand gobies, *Pomatoschistus minutus*). Bowerbirds from Australia are also a classic example of a species that

builds a signal in the environment. Male bowerbirds build dummy nest structures not used to hold eggs but as a display trait and an arena in which to display themselves. Among bowerbird species, bowers can range from simple piles of sticks to elaborate, tall towers of sticks glued together and decorated with a black-painted moss rug and colorful objects like flower petals, snail shells, and butterfly wings (i.e., in *Amblyornis inornatus*). Species that have little plumage or body ornament tend to have more exaggerated bowers. Also, species with more complex bowers have a larger cerebellum, which is perhaps associated with greater motor skills and learning. In the satin bowerbird (*Ptilonorhynchus violaceus*), males with higher testosterone levels have more exaggerated displays, are more likely to build and hold a bower, and have high mating success.

Signal Perception

While the majority of work on animal visual signals has centered on the production and characteristics of the signal itself (e.g., signal 'potential'), in reality this information is not technically what the signal receiver perceives and responds to as attractive or unattractive, dominant or submissive. Signal reception and perception require appropriate eye detection and tuning as well as neural information processing that decodes behavioral or morphological signal variation. A color, for example, is perceived by photoreceptors that are maximally sensitive to particular light wavelengths, and this light can be altered by both the ambient environment in which the animal is found and the light-filtering properties of the ocular media. Though vision researchers have now described the optical characteristics of some animal eyes and identified the true abilities and limits of signal reception, this is a field in its infancy and one that should prove fruitful for those keen on understanding variability in, control of, and interactions between signal perception and production. It is said that we cannot truly appreciate the 'color sensation' (or really any other visual sensation) of other animals until we map neuro-optical circuitry on top of visual acuity, and this should become more of a goal, collaborative or otherwise, of researchers studying signaling systems where truly 'beauty is in the eyes – and brain – of the beholder'.

Visual System Development: Invertebrates

P R Hiesinger, University of Texas Southwestern Medical Center, Dallas, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Visual system development in most invertebrate groups commences with photoreceptor differentiation in an ectodermal epithelium. Photoreceptors generally differentiate independently of the nerve centers they innervate, and peripherally derived visual interneurons are exceptional. This is in contrast to vertebrates, in which the 'retina' arises from an embryological outgrowth of the forebrain, which generates multiple classes of interneurons as well as photoreceptors. Most of what we know about the genetic and molecular bases of visual system development in invertebrates is derived from studies on the compound eyes of the fruit fly *Drosophila melanogaster*. While this focus on a single model system rewards us with the depth of our understanding of developmental mechanisms, it has given rise to a substantial gap in our often rudimentary knowledge of other deserving groups: cephalopods, pectinid scallops, spiders, cubomedusans, and salps, to name but a few, all with advanced eyes. The same is true for the development of neuronal connections within the visual centers in the brain (Figure 1). Here, too, *Drosophila* is the invertebrate model of choice to elucidate underlying molecular mechanisms. Our understanding of many aspects of invertebrate visual system development must, however, encompass knowledge not only of the compound eyes of arthropods, but also of eyes as diverse as, for example, the highly developed single-lens eyes of cephalopods, or ancestral eyecup eyes in forms such as planaria.

Evolution of Invertebrate Eyes

Different eye types are distinguished by substantial differences in morphogenesis as well as their embryonic origin. Two lines of photoreceptor evolution, rhabdomeric and ciliary, had been thought the exclusive domains of, respectively, protostomes and deuterostomes. However, various invertebrate groups have both types of photoreceptors, and in some cases (e.g., *Pecten*) both types are found in one eye. Various examples of developing rhabdomeric photoreceptors (which bear visual pigment upon microvilli) illustrate the transient appearance of ciliary structures. Such differences in form, development, and photoreceptor organelles among the different eye types have been taken to imply an independent origin for the eyes of the three main animal groups that have advanced visual systems: arthropods, mollusks, and vertebrates. Based on classical anatomical and developmental criteria, this view has been challenged by the advent of molecular genetics and the discovery of ancestral conserved genes such as *Pax6*. *Pax6* is essential for eye development in numerous species so far tested. Conversely, its overexpression induces ectopic eyes, as shown in flies and frogs. The *Pax6* gene – like its fly homologs *eyeless* and *twin of eyeless* – encodes a homeodomain transcription factor that regulates a cascade of downstream genes. In *Drosophila*, this cascade involves around 2500 genes that are required to make an eye. The *eyeless* gene and several other genes that are essential to specify eye development, as well as sufficient to induce ectopic eye development in other tissues, are therefore sometimes referred to as 'master control genes.' These are found throughout the animal kingdom, even in ancestral forms such as the freshwater sponge *Ephydatia*. In *Drosophila*, at least six such genes have been characterized to date: *eyeless* (*ey*), *twin of eyeless* (*toy*), *sine oculis* (*so*), *eyes absent* (*eya*), *dachshund* (*dac*), and *optix*; removal of any one results in reduction or deletion of the eye, while ectopic expression (except for *so*) can lead to ectopic eye formation (Figure 2). Genes of the *six* family are transcription factors with a six domain and a six-type homeodomain that share homology with *Drosophila so*. Tentacular eyes of the jellyfish *Cladonema radiatum* express orthologs of *six1/2* and *six3/6* in the eyecup, and during eye regeneration upregulate their expression, suggesting conservation of upstream regulatory mechanisms in eye development since prebilaterian ancestors. Additional molecular evidence supporting the relatedness of all animal eyes includes the primary signal for patterning, *hedgehog*; the *atonal*-related basic helix–loop–helix transcription factors that specify the first retinal neurons; and the highly conserved visual pigment protein, opsin. Most *opsin* genes contain putative *Pax6*-binding sites, for which reason *opsin* is proposed to form part of a conserved ancestral *Pax6–opsin* regulation module. Although the evolutionary relations between eye types are still unresolved, it seems likely that a common ancestral unit existed which may have been a simple photoreceptive cell using *Pax6* to regulate *opsin* expression. From there, gene regulatory regions may have diverged and different molecular pathways recruited in different groups. This scheme thus implies the independent evolution of different eye

types that nevertheless share a remote common ancestor. The widespread role of *Pax6* is consistent with its action in the last common ancestors of insects and vertebrates in simple pigment-cup ocelli, as represented by cerebral eyes in today's errant polychaetes, such as *Platyneiris*. In early developing *Platyneiris*, *six1/2* expression covers the complete visual system and *atonal* (*ath*) expression appears in its first photoreceptor cells. The same is true in insects, but not vertebrates. This sequence has suggested that *Pax6*-, *six1/2*-, and *ath*-positive larval eyes, as found in living trochophore larvae, were already present in the last common ancestor of all bilaterians, vertebrate and invertebrate.

Invertebrate Eye Types and Their Development

Most invertebrate eyes arise from an ectodermal epithelium in one of two main ways: (1) by the formation of a fold and invagination to create either a pit, open to the outside, or a vesicle that subsequently becomes internalized, and (2) by delamination, the thickening of a region as cells divide, grow, and differentiate, followed by the formation of the cell layers that eventually constitute the adult retina. These can either remain as part of the epithelium, or detach and move into the body cavity. The original topography of the epithelium is conserved in the retinal layer of photoreceptors following invagination and delamination *in situ*, whereas it must be reconstituted secondarily following the inward migration of surface epithelial cells. Unlike vertebrate groups, different groups of invertebrates use different modes of eye development and have varying numbers of eyes. Both developmental origins (invagination and delamination) are described in some invertebrate groups and even, in some cases, in the different eyes of a single species.

Evolutionary Divergence among Invertebrate Eyes

The flagellate protozoans, *Erythropsis* and *Warnowia*, have elaborate ocellar organelles with a dioptric hyalosome and pigmentary melanosome. These two components dissociate and duplicate during cell division, the daughter organelles recombining thereafter. In Cnidaria, the ocellus of the medusa of *Cladonema* arises from an ectodermal primordium from which photoreceptor, corneal, and pigment cells differentiate,

Figure 1 Continued

the lens arising in the latter. In turbellarians with direct development, eyespots appear in the ectoderm and then sink into the mesoderm, enlarge, and divide to provide multiple pairs. In annelids, eyes are usually simple eyecup ocelli, frequently with one or few photoreceptors arising, as in the prostomial eyecups in leeches, from epidermal thickenings. Only errant polychaetes have elaborate eyes, which are variably said to arise either from the epidermis, without invagination, or by delamination from an anlage, apparently of ectodermal origin, lying between ectoderm and pharynx and containing a special lens-secreting cell. Differentiation occurs in a wave – first in the inner, retinal layer. By contrast, the pair of ocelli in Onycophora invaginate from epidermal placodes, which pinch off to form a vesicle lined by everted microvillar photoreceptors. Echinoderms have multiple, simple ocelli on optic cushions that form when relatively few cells invaginate from the epidermis. Among prevertebrate chordates, interesting eyes are found in salps, which have a single, dorsal eye pushed out in vertebrate fashion from a crescent-shaped optic ridge of the cerebral ganglion, to form an ocular disk. In the chain form, the asexual part of the life cycle, the ocular disk folds up, flips over, and produces a layer of inverted photoreceptors abutting a layer of everted ones and then an everted secondary eye.

Mollusks and Arthropods

Clear accounts of eye ontogeny are generally restricted to groups with elaborate eyes, especially

Figure 1 Summary of development in the visual system in *Drosophila melanogaster*, viewed in steps of progressively finer cellular resolution. (a) The eye develops from an eye disk connected by an optic stalk (double arrowheads) to the developing optic lobe in the supraesophageal hemisphere, or ganglion, of the larval brain. (b) The optic stalk (os) penetrates the supraesophageal ganglion (seg) at the center of the crescent-shaped outer optic anlage (ooa). With later development, the arms of the anlage open in the direction marked 'X,' converting the cortices to which it gives rise from circular to rectangular forms. The outer anlage and the concentric inner optic anlage (ioa) are shown in relation to the point of entry of the optic stalk to the posterolateral surface of the right hemisphere. Neuroblasts and other progenitor cells in the anlagen proliferate in the directions of the arrowheads, contributing time-sorted strata of cells to the lamina (lamina-forming neuroblasts; lafn), medulla (mfn), and third optic neuropil (lobula; lofn). One stratum (shown cross-hatched in each cortex) was produced at the same time and has been displaced by newer strata in its respective cortex (lan, lamina neuropil; mn, medulla neuropil). The relationships between these cell populations is clearest in cross section (in diagram c). (c) Relationship between the generation of cell cortices in diagram b and the axonal pathways growing between them, in a horizontal plane of diagram b, that illustrates the close relationship between the waves of imaginal photoreceptor innervation and the path of the larval Bolwig's nerve (Bn). This runs from the inner face of the peripodial membrane (pm) to the lamina plexus (Lap) and medulla (Me) via the optic stalk (os). It and/or the axons of three optic lobe pioneers (olp), postulated interneurons, innervate a larval optic neuropil (lon), which is connected to the central brain by a pathway (X) that anticipates the posterior optic tract. New ommatidial clusters (o) accumulate behind the morphogenetic furrow (mf), contributing new axon bundles that fasciculate on previously extended axons in the optic stalk with the anterior expansion of the retinal field (arrow 1). Underlying cell populations expand in corresponding directions: arrow 2, lamina cortex (LaC); arrow 3, medulla (Me) and medulla cortex (MeC); arrow 4, lobula (Lo) and lobula plate cortex (LoPC). Cells add to the lamina cortex from one side of the outer optic anlage (ooa), the lateral proliferation zone (A), and to the medulla cortex from the other side, the medial proliferation zone (B). The first progeny from B are precocious medulla tangentials (MeT), growth cones from which weave across the medulla and intersect new columnar elements growing at the leading edge. Other tangential pathways correspond to the later paths of the anterior optic tract (Y) and of lobula tangential cells (Z). The inner optic anlage (ioa) proliferates in two directions: in direction C, to generate cells into the cortex of the lobula plate, and in direction D, to generate cell types T2, T3, or C, as judged only with reference to the positions of somata in the adult optic lobe. Axons of cellular progeny, and their growth cones, generate a plexus for each cortex, which will eventually form the adult neuropil. Crossing of fiber bundles between lamina and medulla results from the selective fasciculation of fiber pathways in a sequence of innervation like a conveyer belt and from the direction of approach between bundle and plexus. (Bundles penetrate the lamina cortex to innervate its plexus but grow along the inner margin of the medulla cortex to innervate the medulla.) Large glial cells lie along the paths of fibers in the external chiasma (ext.ch) and internal chiasma (int.ch); sg, subesophageal ganglion. (d) Proliferation from the lateral proliferation zone of the outer anlage (see diagram c). Cells are progressively displaced from neuroblasts in the outer anlage in a succession of stages in their cell cycle (G_2/M, G_1, S, G_2/M) around the lip of the anlage. Postmitotic cells lie in the lamina cortex (LaC), where they are innervated by photoreceptor axon bundles (arrowheads) from the optic stalk (os), which trigger the transition from G_1 to S in cells of the adjoining anlage (filled arrow) as well as the onset of differentiation and axonogenesis in cells already postmitotic (open arrow). (e) Ommatidial clusters mature in the eye disk, behind the morphogenetic furrow (mf), seen in elevation (clear profiles) and corresponding cross-sections in which nuclei are shaded. Arrows indicate directions of nuclear migration, matched in pairs of photoreceptors R1–R8 (labeled 1–8). Cross-sections from a (youngest) to f (oldest) are of preclusters (a, b), of immature (c) and symmetrical (d) eight-cell clusters, and of two-cone cell (e) and four-cone cell (f) stages. Cone cells are labeled 'C.' (f) R1–R8 in ommatidial cluster (corresponding to cross-section c in diagram e) comprise two central cells (R8, R7) and three pairs (R2/R5, R3/R4, R1/R6). Induction in R1–R6 involves a signal from R2/R5 that depends on expression of *rough* (*ro*) to induce development in R3/R4; *rough* product also appears in R3 and R4. The four cells defining the second line of symmetry (R3, R4, R1, and R6) all require the expression of *sevenup* (*svp*) to acquire their normal fates. Figure 2 Selected signaling pathways during eye specification, founder cell spacing via lateral inhibition, and assembly of the pigment cell lattice via apoptosis in *Drosophila*. (a) Several nuclear factors are reported as so-called master control genes of eye development. Of these, all but two (*eyg* and *optix*) are part of a complex signaling network that has been proposed to be induced by Notch signaling and inhibited by epidermal growth factor receptor (EGFR) signaling. (b) Atonal expression determines the R8 founder cell and prepatterns the eye. Positive signals for R8 formation include Hedgehog and EGFR signaling, whereas lateral inhibition acts through the Notch pathway to establish correct founder cell spacing. (c) After ommatidial assembly, excess interommatidial cells are removed by apoptosis. Notch and EGFR signaling again exhibit antagonistic roles, providing death and survival signals, respectively.

mollusks and arthropods. Large, single-lens cephalic eyes of gastropod and cephalopod mollusks, which project directly to the brain, generally arise from an invaginating ectodermal placode, either *de novo* or during regeneration (*Strombus*, *Cardium*, *Helix*, etc.). Details vary depending on whether development is direct or via a veliger larva, and on the complexity of nonneural ocular components. Mantle eyes in bivalves have diverse origins and include both single-lens eyes and the compound eyes of arcid clams. In *Pecten* they arise by delamination of an epithelial placode that is secondarily reconstituted after migrating from the epidermis. All show spectacular regenerative capabilities. Arthropods generally have ocelli that arise by invagination, delamination, or both in some insect groups. Spiders have single-lens frontal eyes that arise by invagination and lateral eyes that form by delamination. In contrast, compound eyes form by similar means in all groups (by delamination *in situ* from an embryonic epidermal placode) to form a patterned array of modular ommatidia. In holometabolous insects, the retinal epithelium is secondarily internalized within specialized imaginal disks borne inside a postembryonic larva (Figure 1(a)). Reminiscent of these additions, the ocelli of diplopod myriapods arise from individual anlagen and accumulate in rows with each molt.

In ametabolous insects such as silverfish and bristletails, as well as in hemimetabolous insects (dragonflies, grasshoppers, cockroaches, etc.), eye development is a continuous process that starts during embryogenesis. In contrast, in holometabolous insects (such as *Drosophila*) visual system development consists of separate phases: an early phase during embryogenesis and a second phase during metamorphosis, separated by a 'developmental silence' during early larval stages. Compound eyes arise during the passage of a wave of development. In hemimetabolous insects and many Crustacea, the eye generated in the embryo is augmented by ommatidial increments added in adulthood; the wave is interrupted at each molt, its front contributing a succession of vertical strips of ommatidia at the eye's anterior margin. Regional specializations of the eye, such as foveae in dragonflies or mantids, therefore shift in the visual field with each molt, or are successively reconstructed. Intermolt growth in eye size generally results mostly from increased cell numbers rather than hypertrophy of existing cells, but species differ. The anterior eye margin in hemimetabolous insects is said to be a budding zone, harboring ommatidial precursor cells. In holometabolous insects, retinal development lays down ommatidial rudiments during a double postero-anterior wave of mitoses (e.g., *Drosophila* and *Ephestia*) over the largely two-dimensional epithelium of undifferentiated cells in the imaginal disk. These possibly overlap within the single wave of mitoses seen in the dragonfly.

Compound Eye Development in *Drosophila*

Compound eye development in *Drosophila* is well characterized and has become a model system to study a wide range of events in neural development, including cellular and molecular mechanisms of both tissue patterning and growth control, and the determination of cell fate. The adult eye comprises about 750 ommatidia, each in turn containing eight photoreceptor neurons, R1–R8. The rigid geometrical organization of these arises through iterated cell-fate decisions mediated by cell–cell communication within the undifferentiated imaginal disk. These occur during and after a wave of development, morphologically visible as a morphogenetic furrow initiated at the posterior margin of the disk, that progresses anteriorly (Figures 1(e) and 3(a)).

The first photoreceptor to differentiate from a field of uncommitted cells is the photoreceptor cell R8. Selection of R8 cells occurs initially to establish the correct spacing and positioning of future ommatidia (Figure 3(a)). The differentiation of R8 is also crucial because the cells of one ommatidium do not derive from a single clone, but are instead recruited by R8 and subsequent downstream events. Such recruitment occurs in pairs from the existing field of undifferentiated cells, with the first pair, R2/R5, followed by R3/R4 and R1/R6 (Figure 1(f)). Last, R7 is recruited. The initial steps of R8 selection and spacing are therefore crucially instructive for the patterned development of the eye and involve a well-characterized signaling network (Figure 2(b)). R8 differentiates under the control of the transcription factor encoded by *atonal,* which is initially expressed in all cells during the passage of the morphogenetic furrow. Behind the furrow *atonal* expression becomes restricted to the exact number of required R8 founder cells. In *atonal* mutants, ommatidial assembly fails entirely. Thus, the developing eye is prepatterned by selecting cells that express *atonal* behind the morphogenetic furrow (Figure 3(a)). Initially, all cells have the potential to become R8 and to repress others, but through lateral inhibition of their neighbors' fates only a few finally do so. Many genes encoding products required to signal this lateral inhibition are known from mutants with altered numbers of R8 cells, most prominently those involved in signaling via the Notch and epidermal growth factor (EGF) receptors (Figure 2(b)).

Figure 3 Maturation of *Drosophila* ommatidia. (a) As the morphogenetic furrow (MF) passes over the eye imaginal disk epithelium (arrow), the ommatidial array emerges with the differentiation of ommatidial founder R8 cells, which express *atonal* (filled circles) and prepattern the eye. (b) Pattern formation in the *Drosophila* eye. At late larval stages and the beginning of pupation (P + 0%), the eye disk exhibits the four-cone-cell stage (stippled) in its posterior region. In the 20-h pupal eye disk (P + 20%), cone cells are surrounded by two primary pigment cells (light stippling); bristle cells (black) appear between ommatidia. At P + 40%, approximately one-third of all interommatidial cells have been removed by apoptosis. Unfilled profiles between ommatidia are prospective secondary pigment cells and (at vertices) tertiary pigment cells. The P + 60% pupal eye exemplifies adult organization. Secondary (dark stippling) and tertiary pigment cells (at vertices) surround ommatidia. Scale bar = 10 μm; anterior to right. Modified from Wolff T and Ready DF (1993) Pattern formation in the *Drosophila* retina. In: Bate M and Martinez Arias A (eds.) *The Development of Drosophila melanogaster*, pp. 1277–1325. Plainview, NY: Cold Spring Harbor Laboratory Press, with permission of the authors and Cold Spring Harbor Press.

Molecules that have been proposed to act as inhibitors include Delta and Scabrous, both of which interact with Notch. Hedgehog and ligands of the EGF receptor (EGFR) are positive signals for founder cell specification (Figure 2(b)).

The subsequent recruitment of R2/R5 and R3/R4 creates preclusters containing five cells, evenly spaced behind the morphogenetic furrow (Figure 3(b)). Now postmitotic, the cells of these preclusters commence differentiation, whereas all other undifferentiated cells reenter the cell cycle in the second mitotic wave. Also born during that wave are the remaining 14 cells required to constitute an ommatidium. The differentiation of these cells as well as of all photoreceptors other than R8 is controlled by different signaling pathways, again by the EGFR pathway as well as the mitogen-activated protein (MAP) kinase and other receptor-mediated signaling pathways. Secretion of the EGFR ligand Spitz is required for all non-R8 photoreceptor differentiation. The first such pathway to be identified, the signaling cascade leading to the final recruitment and differentiation of R7, is particularly well characterized. A membrane-associated protein encoded solely in R8 by the *boss* locus interacts with the Sevenless receptor tyrosine kinase on the presumptive R7. Internalization of Boss protein in R7 and induction of the downstream Ras/Raf MAP kinase pathway lead to R7 differentiation.

Finally, all ommatidia are positioned within a hexagonal array with shared interommatidial cells in between. The assembly of the secondary and tertiary pigment cell lattice depends on the spatially restricted apoptosis of excess cells, which also involves a complex signaling network implicating the Notch and EGFR pathways (Figure 2(c)). In this late phase of eye development, Notch promotes apoptosis of excess interommatidial cells, while EGFR signaling, initiated by cone or primary pigment cells, opposes Notch (Figure 2(c)). As a result, approximately one-third of the interommatidial cells are eliminated before eye development concludes.

The Eye's Connection with Its Visual Centers and Their Development

Wiring the invertebrate eye to its brain is as diverse a process as are the eye types themselves. A common feature of all is the retinotopy of mapping the optical world upon the visual brain. This is documented at single-cell level in the insect compound eye, but is also a clear feature in, for example, the single-lens eye of cephalopods. Development among invertebrate visual centers is once again best described in the arthropod optic lobe. Visual interneurons are the progeny of neuroblasts that reside in two groups, the outer and inner proliferation centers, or optic anlagen (Figures 1(b) and 1(c)). In insects, the outer anlage generates the first neuropil, the lamina, and the distal part of the second, the medulla, while the inner anlage gives rise to the remaining medulla and deeper optic neuropils (Figure 1(c)). In both anlagen, the cells are born by a sequence of divisions that matches the sequence of ommatidial assembly in the compound eye, but begins first in the medulla. The match between eye and lamina in *Drosophila* is attained by a competition between targeting signals at the N-terminus and C-terminus of the secretory Hedgehog protein: after cleavage, the N-terminal domain is targeted to the retina, while the C-terminal domain overrides this path and transports Hedgehog along the photoreceptor axons, where it induces the development of target neurons in matching numbers.

In Crustacea, the number and arrangement of the optic neuropils are more diverse than in insects, and details of crustacean development are less widely known. In decapod Crustacea, the shape, location, and mitotic patterns of proliferation zone 2 (PZ2) closely resemble the outer optic anlage of insects. In the water-flea *Daphnia*, the counterpart of an outer optic anlage is the sole so-called optic lobe primordium (Figure 4(b)). In *Drosophila*, photoreceptor innervation triggers the final cell cycle of lamina precursor cells, procuring targets for the next wave of innervation and matching the proliferative activities of eye and optic lobe (Figure 1(d)). (Lamina glial cells, by contrast, arise independently from R1–R6 input and from a lineage that is distinct from that of lamina cells.) Photoreceptor cell axons innervate new ganglion cells, so produced, in successive rows corresponding to the wavefront of retinal differentiation. Most lamina cells are thereby enlisted, five per axon bundle, and cell death, presumably among supernumerary cells, concludes the wave of development in the outer neuropils. In *Daphnia*, newly innervated cells are invariably just postmitotic. As ingrowing photoreceptor axons recruit them in final groups of five (Figure 4(b)), each soma displays a stereotypic response in which it envelops the incoming axons, forming gap junctions with them transiently. The same occurs in *Drosophila*, but is less clearly analyzed. In *Daphnia*, all cells contacted exhibit this envelopment. They do so in the exact sequence of contact, but cells from which retinal innervation has been withheld do not, while envelopment is delayed in cells to which innervation arrives late. Envelopment manifests a presumed inductive signal to each lamina cell, after which the latter differentiates, elaborating a neurite that will follow the retinal axon bundle in a secondary wave.

Figure 4 Development of the visual system in representative Crustacea. (a) Schematic diagram of the compound eye (top) and optic lamina (bottom) in *Daphnia*, showing locations of ommatidia (lettered rectangles) and of lamina cartridges (circles with corresponding letters) to which photoreceptor axons of each ommatidium project. Both are viewed in a transverse projection, dorsal side up, with the left eye to the left. The projection is direct, without an intervening chiasma. (b) Schematic representation of the development of the eye–lamina projection in *Daphnia* at an early stage in its development (left) and several hours later (right). Only the right halves of the eye and lamina are depicted, in a view perpendicular to that shown in diagram a. The ommatidia are shown in four rows (A–D), with each row at a different stage of development; cartridges a and b are depicted during assembly. At both stages illustrated the most lateral ommatidium, A, is also the most developed, while D, the most medial, is the least so. (Left) Axons from A have grown along the midline glial bridge that connects eye and lamina anlage and have reached the target region, where they begin to recruit lamina neurons to form cartridge a. (Right) Axons from B have followed the same path as those of A and complete the recruitment of five lamina neurons to form cartridge b, displacing cartridge a laterally. Axons from C and D will subsequently repeat this process until the projection is completed. (c, d) Assembly sequence of neuropil layers and axon projections between them in the optic lobes of a nonmalacostracan (c) and malacostracan (d) crustacean. In both examples, a common neuroblast population, the outer proliferation zone PZ2 (PZ) generates progeny in two antiparallel directions. These assemble the cell cortices of lamina (L) and medulla externa (ME) in chronotopic sequence, like a conveyor belt. After their birth, cells are continuously displaced from PZ2 to await innervation from overlying ommatidia (OM). The lamina and distal medulla in Crustacea both have major structural and developmental similarities to their possible evolutionary homologs in insects; malacostracan Crustacea grow chiasmal interconnecting pathways identical to those found in insects (diagram d). In nonmalacostracans, axons of cell bodies in the lamina cortex penetrate the lamina and enter the medulla externa from its neuropil face, thus traversing directly between corresponding neuropil faces. In Malacostraca, as in insects, on the other hand, a chiasma arises because the corresponding axons enter the medulla from the opposite direction, through its cortex, and in doing so invert their sequence. Tangential neurons (TN) from the medulla terminalis (MT) grow across the neuropil of the medulla externa and interna (MI), advancing to contact the newly grown retinal innervation and the higher order columnar pathways upon which it projects. (a, b) From Macagno E (1984) Formation of ordered connections in the visual system of *Daphnia magna*. *BioScience* 34: 308–312. (c, d) From Elofsson R and Dahl E (1970) The optic neuropiles and chiasmata of Crustacea. *Zeitschrift fur Zellforschung* 107: 343–360, used with permission of the authors and Springer-Verlag.

Axonal Outgrowth and Pathfinding

Photoreceptor axons grow centrally, innervating the lamina and distal medulla in a sequence that mirrors the ordered sequence of retinal differentiation. Outgrowth within the ommatidial axon bundle is asynchronous. The axon from one photoreceptor in *Daphnia* (R1) has a well-defined growth cone and is the first to grow and contact target cells. Axons of other cells following this lead axon (**Figure 4(b)**) have reduced growth cones or none. After R1 is ablated, the axon of another photoreceptor assumes the role of lead fiber, indicating that all photoreceptors are equivalent. In *Drosophila*, axon outgrowth occurs initially in groups of five (presumably R2–5 and 8), later supplemented by the remaining three. In many insect groups, photoreceptor axons grow postembryonically along the pathway provided by larval or nymphal visual systems. Best known is Bolwig's organ, a group of 12 internal photoreceptors at the tip of a fly larva, with optic lobe pioneers (their presumed interneurons in *Drosophila*), a larval nerve, and optic neuropil, all of which preempt the axon pathways of the earliest adult neurons, which assemble around them (**Figure 1(c)**). Bolwig's nerve is dispensable for adult wild-type photoreceptor axons to project normally, and is thus not an essential pioneer of axonal navigation to the lamina. Bolwig's organ later transforms into the four photoreceptors of an extraretinal posterior 'eyelet,' which entrains circadian rhythmicity in the larva. The terminals of Bolwig's nerve metamorphose into those of the eyelet nerve. Their branching parallels the arborization

of neurons immunoreactive to pigment-dispersing hormone, which serve as outputs from the circadian clock. In other insects, there are larval ocelli (in mosquitoes) and stemmatal nerves (in Lepidoptera and Coleoptera). Larval photoreceptor axons and adult axons in insects lacking larval visual centers grow in the embryo, thus initially spanning only short distances to reach their targets, but elongating dramatically with subsequent growth. Those in *Daphnia* grow initially over a glial substrate; later axon bundles follow the preexisting neural pathway to the center, reinforcing the fiber tract in which they grow while simultaneously providing the substrate for yet further growth (**Figure 4(b)**). The sequence in which new axon bundles accrue to existing fiber tracts, and their relative positions within the tract, confer the antero-posterior polarity of the resulting topographical map. Chiasmata form when this polarity inverts, as in the external chiasma of malacostracan Crustacea (**Figure 4(d)**) and insects, as revealed by subsequent rotation of the medulla in *Drosophila* (**Figure 1(c)**). Many arachnid groups also have chiasmata, but non-malacostracan Crustacea, such as *Daphnia*, lack them (**Figure 4(c)**). Eye rotation experiments in locusts indicate that ingrowing receptor axons fail to discriminate the particular column of neuropil in which they terminate. On the other hand, there is evidence that retinotopy is reinforced in *Drosophila* by guidance mechanisms that label both photoreceptor axons and their targets. For example, (1) in the mutants *sine oculis* and *Ellipse*, axons project to the correct retinotopic location even when not surrounded by axons from neighboring ommatidia, while (2) wild-type axons project normally, even when they neighbor mutant *glass* axons with aberrant projections. At a coarser level in *Drosophila*, mutant chiasmal phenotypes can result from the perturbed axon pathways of the larval optic lobe pioneer neurons (**Figure 1(c)**) caused by the displacement of their cell bodies in the larva.

Several *Drosophila* mutants have been isolated that affect pathfinding, target recognition, or medulla rotation. Photoreceptor axons R1–R6 enter the lamina as rapidly growing ommatidial bundles, where their growth cones stop between layers of glial cells; thus, the primary targets that terminate growth cone guidance are not the synaptic partners, but glia. Mutations in the *brakeless* gene cause the axons of R1–R6 to penetrate their normal lamina targets and project instead to the medulla, where normally only R7 and R8 terminate. A transcription factor encoded by the *runt* gene, which is normally repressed in R1–R6, is derepressed in *brakeless* mutants, and overexpression of *runt* causes the same mistargeting phenotype. Apart from these nuclear factors, genes encoding cell surface receptors, as well as downstream signal transduction proteins, have been characterized in *Drosophila*. Genes encoding cell surface receptors include *rst* (a transmembrane receptor of the immunoglobulin superfamily), *DPTP69D* and *DLar* (both receptor tyrosine phosphatases), *DN-Cadherin* (a classical cadherin), *Flamingo* (a protocadherin), *capricious* (a transmembrane receptor with LRR-repeats), and others. Mutants of all these genes exhibit targeting phenotypes of differing severities. Few studies have so far addressed the spatiotemporally controlled localization of guidance receptors during development. Mutants in the vesicle trafficking gene *sec15* suggest that trafficking of guidance receptors during axon targeting requires highly regulated intracellular trafficking. The best characterized signal transduction pathways required for photoreceptor growth cone guidance include *dreadlocks* (a SH2/SH3 adaptor protein), *pak* (p21-activated protein kinase), *trio* (a Rho family guanine exchange factor that activates Rac), *misshapen* (an Ste20-like serine/threonine kinase), and *bifocal* (a putative cytoskeletal regulator).

Synaptic Partner Selection and Synaptogenesis

Once in the lamina, the growth cone filopodia of R1–R6 in the fly continuously interact with neighboring growth cones in a distinct developmental step that follows initial target recognition until each gradually draws away from its parent ommatidial bundle. The growth cones then pass through a succession of shifting geometric arrays, apparently driven by filopodial interactions that are initially directed exclusively between R1–R6, but eventually directed to the growth cones of their monopolar cell targets, L1 and L2, around which R1–R6 assemble to form nascent cartridges. Among the previously mentioned genes, mutants in several (e.g., *DPTP69D*, *DLar*, *DN-Cadherin*, *Flamingo*) cause severe defects during this lateral sorting of photoreceptor terminals into the correct cartridges, whereas the protocadherin *flamingo* is required for the initial orientation of the R1–R6 bundle. In the medulla, the axon terminals of R7 and R8 initially occupy temporary strata relative to terminals of other cells, but then grow down deeper to their permanent stratum, R7 below R8. Synaptogenesis has been analyzed in detail only in the lamina, where it commences only in the second half of pupal development, after the R1–R6 terminals have grown centripetally, when neurites of lamina cells contact photoreceptor presynaptic sites. Starting with a neurite contact from L1 or L2, each synaptic site selectively accumulates other postsynaptic elements to constitute a final tetrad synapse (a synapse with four postsynaptic targets). Up to 50% of all contacts formed are lost. Although synaptic transmission

functions early, while synaptic junctions mature, pupal photoreceptors generate only small, slow responses to light and are not normally exposed to bright light anyway. In contrast to vertebrate visual systems, neither spontaneous nor evoked neuronal activity is required to form a normal visual map in the fly's brain.

The Morphogenetic Interdependence of Eye and Visual Centers

Development in the visual centers generally exhibits some dependence on innervation from the eye, but this is quantitatively variable; eye development is usually autonomous. In *Drosophila*, clones of mutant tissue with perturbed organization generated in either the eye or optic lobe reveal that abnormal pattern is communicated from the retina to the lamina, but not in the opposite direction. This refines conclusions from the coarser effects of deafferentation in many species. More central neuropils are volumetrically less affected by deafferentation than are peripheral ones. In congenitally eyeless mutant *Drosophila*, second-order neurons in the lamina never differentiate, but some medulla neurons grow axons, albeit their morphogenesis is abnormal, whereas many lobula neurons look quite normal and establish a regular array of neuropil columns. Tangential cells of all neuropils show complete autonomy from afferent innervation. Qualitatively similar results follow lesions in the embryonic *Daphnia* eye. Differentiation in the fly's lamina and medulla is largely unaffected by the absence of target cells on the lobula, indicating the relative absence of retrograde influences of central visual neuropils upon distal ones. On the other hand, ommatidia eventually degenerate after disconnection from the lamina, indicating that the optic lobe has a retrograde influence on the long-term maintenance of the retina.

Plasticity

Insect visual systems exhibit various forms of plasticity, many at a behavioral level. The developmental emergence of pattern discrimination and visual preference behavior in flies, for example, depends on prior visual experience, the flies preferring a pattern to which they were selectively exposed during a critical period as young adults. Various neurochemical correlates exist. Functional binocular vision, as revealed by prey-catching behavior in mantids, matures after emergence, and its development also exhibits a critical period. Praying mantises that are monocularly occluded as emerging nymphs nevertheless have normal monocular visual fixation and binocular distance estimation when they attain adulthood, indicating that binocular visual experience is not essential. Even so, monocular rearing initially impairs distance estimation, which then only gradually recovers; such recovery is progressively lost in older nymphs or adults. Bees reared in ultraviolet light are less sensitive to light of longer wavelengths; terminals of photoreceptors that peak in the green, in which the bees were deprived, also have fewer synapses. Other examples of structural plasticity are reported. In flies, lamina feedback synapses are more numerous in young dark-reared adults and, during subjective night, in flies held under constant darkness; these synapses also exhibit reactive synaptogenesis after losing their targets, R1–R6. Photoreceptor input synapses are not fixed synaptic sites: fly tetrads can both form and disappear rapidly (within minutes) in the adult, especially in response to functional reversals (e.g., light exposure after dark rearing; warm recovery after cold exposure). Central optic lobe neurons sprout after congenital deprivation of their visual inputs, procured either by lesion or mutation. The volume of the optic neuropils increases in *Drosophila* reared under 'enriched' conditions, relative to solitary rearing, and with various other rearing conditions. At the cellular level, L1 and L2 change the caliber of their lamina axons during a cycle of day/night changes.

Visual System: Adaptive Regression and Progression in Subterranean Mammals

E Nevo, Institute of Evolution, University of Haifa, Haifa, Israel

Introduction

The extensive convergent evolution of subterranean mammals across the planet represents a global, natural experiment of life without light under darkness stress (Figure 1). It began during the global climatic transition from the middle Eocene to the early Oligocene, 45–35 million years ago. It involved seasonal climatic stresses proceeding progressively throughout the Cenozoic. The open-country biota set the stage for a rapid evolutionary play of recurrent adaptive radiations of unrelated mammals on all continents to the subterranean ecotope. The biota comprised marsupial and placental mammals (insectivores and herbivores) that involve several hundreds of small mammalian species belonging, at present, to 50 genera, 11 families, and three mammalian orders.

The stressful underground ecotope (solid soil, darkness, low productivity, hypoxy, hypercapny, and high infectivity) provided subterranean mammals with shelter from extreme climatic (temperature and humidity) fluctuations and predators. All subterranean mammals share convergent molecular and organismal adaptations to their shared unique ecotope. The subterranean ecotope is simple, relatively stable, specialized, low in productivity, and discontinuous. Its major determinants are specialization, competition, and isolation. These characteristics led to convergent and divergent, regressive and progressive evolutionary patterns and processes, locally optimizing adaptations at all organizational levels for mammalian life underground.

Adaptive convergence comprises structural and functional reductions and expansions (hypertrophies) through molecular and organismal evolutionary tinkering. The reductions and expansions involve burrowing, energetics, and respiratory adaptations affecting molecular, morphological, physiological, and behavioral changes compared with small aboveground mammals. Likewise, life in underground darkness led to the differential loss of sight but simultaneously to the remarkable evolution of photoperiodic perception, affecting circadian rhythmicity through complex mosaic eye and brain evolution. Life underground in isolated territorial domains also triggered the evolution of aggression and seismic communication affecting the reorganization of the brain. Life underground also selected for a suite of progressive adaptive traits to the subterranean ecotope compensating for the regressive loss of sight. These traits involve vibratory or seismic, magnetic, auditory, chemical, nasal, and vomeronasal communication systems.

Evolutionary organismal and molecular tinkering involving regression, progression, and convergence of eye evolution advanced in subterranean mammals, climaxing in *Spalax*. The family Spalacidae of southwest Asia originated approximately 40 million years ago based on molecular data, although the earliest fossils from Greece and Turkey are younger. Spalacids are extremely adapted to life underground, which climaxed in mosaic eye and brain evolution.

Sensory and Brain Adaptations in Subterranean Mammals

Sense Organs

The senses of subterranean mammals display impressive, variable, structural, and functional convergent adaptations required for life underground. The sensory environment of subterranean mammals is deprived of the numerous aboveground complex stimuli. Diverse sensory communication modes are common to aboveground organisms: vision, photoperiodic perception, audition, smell, taste, touch, pressure, vibration, and electric and magnetic senses. Clearly, in extreme confinement to the underground dark environment, vision is variably excluded in many subterranean mammals and is replaced by other communication modalities. Here, the focus is on the visual apparatus, primarily on the extreme case of *Spalax*.

Visual Apparatus

Lightless subterranean ecotopes frequently lead to differential regression evolution or to the disappearance of the vertebrate and invertebrate eye. The complete disappearance of the eyes has not occurred in the evolution of any natural population of mammals. Maintenance of eye rudiments after millions of years of adaptation to a lightless environment might therefore suggest that such rudiments still have some developmental functions. Some laboratory mice strains can be completely eyeless, indicating that mutations in one or several genes can prevent eye development. Eyes of subterranean mammals display variable regressive stages in size, depending on whether the animal is strictly subterranean or occasionally emerges

Figure 1 Distribution of subterranean mammals across the planet. Palearctic region: *Talpa* (Talpidae, insectivores), *Spalax* (Spalacidae, rodents; southeastern Europe, Turkey, Near East, North Africa), and *Ellobius* (arvicolidae, rodents; Asia). Ethiopian: *Chrysochloris* and *amblysomus* (Chrysochloridae, insectivores; South Africa), *Tachyoryctes* (Rhizomyidae, rodents; South Africa). Oriental: *Scaptonyx* and *Urotrichus* (Talpidae, insectivores: East Asia) and *Rhizomys* (Rhizomyidae, rodents). Australian: *Notoryctes* (Notoryctidae, marsupial moles; Australia). Nearctic: *Scalopus* and *Scapanus* (Talpidae, insectivores) and *Geomys* (Geomyidae, rodents). Neotropical: *Spalacopus* (Octodontidae, rodents), *Ctenomys* (Ctenomyidae, rodents), and *Clyomys* (Echimyidae, rodents). Different symbols mark the different zoogeographical regions. Reproduced from chapter 7 – Rodents: Herbivorous subterranean mammals, fig. 2.1, p. 36 from *Mosaic Evolution of Subterranean Mammals: Regression, Progression and Global Convergence* by Nevo, Eviatar (1999), by permission of Oxford University Press. aboveground for foraging. Variation in eye size ranges from normal–medium (*Spalacopus*) to medium–small (ctenomyids and geomyids), small–minute (rhizomyids, subterranean cricetids, and bathyergids), minute (most talpids), vestigial, and completely covered by skin (*Notoryctes*, *Talpa caeca*, chrysochlorids, and spalacids) (Figure 1).

Minute microphthalmic eyes (<2 mm) are also found in the echolocating microchiropteran bats, species of insectivores and aquatic shrews, *Fukomys anselli*, and one cetacean – the blind river dolphin (*Platanista*). Reduction of the eyes is even more widespread in subterranean and cave-dwelling nonmammalian vertebrates, including cyclostomes, teleosts, amphibians, and reptiles. Birds are the only vertebrates in which small eyes are absent. Regression of the eye can thus be viewed as resulting from diverse parallel and convergent evolutionary causes, potentially leading to a mosaic of consequences affecting the peripheral and central visual system.

Variable degrees of reductions were described in eye size, ocular muscles, fixed eyelids, cornea thickening, amorphous lens, fibrous vitreous body, minimized optic nerve, regression in size of brain visual centers, and retinal changes in size and structure. Generally, the structure of the visual apparatus regresses differentially and structurally in all subterranean mammals, presumably correlated with confinement to life underground. The following section reviews the detailed study of the *Spalax* eye. This is clearly an extreme case of mosaic eye and brain evolution in subterranean mammals.

The Mosaic Evolution of the *Spalax* Eye: Morphology, Physiology, and Molecular Biology

The entirely subcutaneous minute eye of *Spalax* has been extensively studied. Concealed beneath the skin, the minute regressed eye is further embedded within a hypertrophied harderian gland. Thus, light can only penetrate to the retina with difficulty, and the thick covering of skin precludes proper image formation. The size of the eye is extremely reduced (700 μm diameter), although the neuroretina appears to be structured normally with thin inner and outer plexiform and nuclear cell layers. Ganglion cells are reported to be sparse, and the optic nerve contains less than 1000 unmyelinated fibers. Eye development

Figure 2 Light micrographs showing cross-sections of the developing eye of the mole rat, *Spalax ehrenbergi*. (a) Optic cup and lens vesicle initially develop normally (×100). (b) Eye at a later embryonic stage. Note the appearance of iris–ciliary body rudiment (arrows) and development of the lens nucleus (L). ON, optic nerve (×100). (c) Eye at a still later fetal stage. Note the massive growth of the iris–ciliary body complex colobomatous opening (arrow) (×100). (d) Early postnatal stage. The iris–ciliary body complex completely fills the chamber. The lens is vascularized and vacuolated (×100). (e) Adult eye. Eyelids are completely closed, and a pupil is absent. Note the atrophic appearance of the optic disc region (arrow) (×65). (f) Higher magnification of the adult retina. The different retinal layers are retained. PE, pigment epithelium; RE, receptor layer; ON, outer nuclear layer; IN, inner nuclear layer; GC, ganglion cell layer (×500). From Sanyal S, Jansen HG, De Grip WG, Nevo E, and De Jong WW (1990) The eye of the blind male rat. *Spalax ehrenbergi*: Rudiment with hidden function. *Investigative Ophthalmology and Visual Science* 31: 1398–1404.

is initiated normally but at an early stage displays a number of degenerative features (Figure 2). The optic fissure fails to close, the anterior chamber collapses, and the iris–ciliary body becomes hypertrophied and heavily pigmented. The lens remains vascularized and regressed. In contrast, neurogenesis develops normally, but the ganglion cell and photoreceptor layers remain relatively thin. Photoreceptors have been shown to form normal synapses in the outer plexiform layer. The visual system of *Spalax* presents a mosaic of both regressive and progressive features. The retina projects bilaterally to all visual structures, described as receiving retinal afferents in nonfossorial rodents. Structures involved in form analysis and visually guided behaviors are reduced in size by more than 90%, receive a sparse retinal innervation, and are cytoarchitecturally poorly differentiated. The main regressive feature is the drastic relative reduction of retinal input to the superior colliculus (Figures 3(a)–3(c)). The volumes of visual structures in *Spalax*, hamster, *Spalacopus*, rat, and microphthalmic rat appear in Figure 3(c).

In contrast to the foregoing, structures of the 'non-image-forming' visual pathway involved in photoperiodic perception are well developed in *Spalax*. The suprachiasmatic nucleus receives a bilateral projection from the retina and the absolute size, cytoarchitecture, density, and distribution of retinal afferents in *Spalax* are comparable with those of other rodents (Figures 3(a)–3(c)). A relatively hypertrophied retinal projection is observed in the bed nucleus of the stria terminalis. The percentage of relative retinal input to the size of primary visual structures is presented in Figure 3(a). The percentage of relative difference of retinal input to size of visual structure of *Spalax* contrasted with other aboveground, fossorial, and subterranean rodents is given in Figure 3(b).

These results indicate that the apparently global, morphological regression of the visual system conceals a selective progression of structures related to functions of photoperiodic perception and photoneuroendocrine regulation. The evolution of an atrophied eye and a reduced visual system is an adaptively advantageous response to the unique

Figure 3 (a) Relative degree of retinal input to primary visual structures in *Spalax*, hamster, rat, and *Spalacopus cyanus*. (b) Relative degree of change in the proportions of retinal input to different primary visual structures in *Spalax* compared to measures obtained in other rodents. Relative progressive development in *Spalax* is seen in structures involved in photoperiodic and neuroendocrine functions. The main regressive feature is the drastic relative reduction of retinal input to the superior colliculus. (c) Comparison of the absolute size (volume, $mm^3 \times 10^{-4}$) of several visual structures in *Spalax* and other rodents. The size of the suprachaismatic nucleus (SCN) is equivalent in all species. The ventral lateral geniculate nucleus (vLGN) and dorsal lateral geniculate nucleus (dLGN) are reduced by approximately 90% and 94%, respectively. The retino recipient layers of the superior colliculus (SC) are reduced by 98%. AOS, accessory optic system; BNSt, bed nucleus of the stria terminalis; PRT, pretectum. Data from Caballero B, Tomas-Zapico CI, Vega-Naredo I, et al. (2006) Antioxidant activity in *Spalax ehrenbergi*: A possible adaptation to underground stress. *Journal of Comparative Physiology A* 192 (7): 753–759; and Cooper HM, Herbin M, and Nero E (1993) Ocular regression conceals adaptive progression of the visual system in a blind subterranean mammal. *Nature* 361: 156–159.

subterranean environment. Factors favoring regression include mechanical aspects, metabolic constraints, and competition between sensory systems. The primary advantage of sensory atrophy is the metabolic economy gained by the reduction of visual structures that do not contribute significantly to the animal's fitness. Under total darkness, *Spalax* evolved a purely circadian eye, thus following underground circadian changes

aboveground. The following sections provide a description of the lens crystalline, starting with the drastically changed lens αA-crystallin followed by αB-crystallin of *Spalax* at the molecular level of existence and expression.

αA-Crystallin: Structure, Expression, and Evolution

αA-Crystallin apparently originated from the multigene small heat shock proteins (HSPs). The HSPs are induced upon stress and evolved in all eukaryotes by gene duplication and the subsequent sequence divergence that allows adaptation to novel functions, such as lens constituent. Because αA-crystallin is lens specific, we focused on its expression and structure at the DNA level.

Hendriks et al. determined the complete structure of the single-copy αA-crystallin gene of the blind mole rat superspecies, *Spalax ehrenbergi*, in order to elucidate the evolutionary effects of the loss of vision on a lens-specific protein and its gene. The αA-crystallin gene of *Spalax* consists of four exons and three introns, as found in the mouse and hamster. The gene appears to have all the necessary transcriptional and translational signal sequences to be expressed in the rudimentary lens of the mole rat and probably gives rise to two protein products by means of alternative splicing, as in sighted rodents. Comparisons of the αA-crystallin sequence of the blind mole rat with that of sighted rodents (involving representatives of 32 rodent families) reveal a considerable acceleration of the substitution rate at nonsynonymous positions in the mole rat lineage. These comparisons, however, demonstrate a selective constraint.

Adaptive Evolution of Small Heat Shock Protein/αB-Crystallin Promoter Activity of the Blind Mole Rat, *Spalax ehrenbergi*

Hough et al. compared the tissue specificity of the small heat shock protein (shsp)/αB-crystallin promoter of the mole rat superspecies, *S. ehrenbergi*, with that of the mouse. Earlier experiments showed that mouse shsp/αB-crystallin promoter/enhancer activity is high in the lens and moderate in the heart and skeletal muscle of transgenic mice. Using the firefly luciferase reporter gene in transgenic mouse experiments, Hough et al. showed that despite relatively few changes in sequence, the mole rat shsp/αB-crystallin promoter/enhancer had selectively lost lens activity after 13.5 days of embryogenesis (Figure 4). The ratios of mole rat/mouse promoter activity were 0.01 for lens, 1.7 for heart, and 13.6 for skeletal muscle in 8-week-old transgenic mice. These data indicate that the shsp/αB-crystallin promoter/enhancer has undergone adaptive changes corresponding to the subterranean evolution of the blind mole rat. Hough et al. speculated that selective pressures on the metabolic economy may have contributed to these tissue-specific modifications of promoter/enhancer function during adaptation to life underground. Whereas the gene differentially loses its lens function (regression), it dramatically retains and even augments muscle function (progression) in transgenic mice (Figure 4).

Intriguingly, it appears that minor sequence modifications, presumably associated with adaptation to life underground, can be associated with profound changes in promoter activity. These adaptive evolutionary changes may economize metabolic expenses by limiting expression of shsp/αB-crystallin in the degenerated lens but augmenting expression in the muscle, thereby increasing fitness.

Retinal Photopigments in *Spalax*

Coneopsin

The blind eye of *Spalax* was retained subcutaneously as a circadian eye to assess photoperiodicity in total darkness underground. *Spalax* retina harbors three circadian photopigments – coneopsin, rhodopsin, and melanopsin – mediating the circadian photoreception. The atrophied eyes of *Spalax* express a long wavelength-sensitive (LWS) cone opsin. This photopigment is spectrally tuned to enhance photon capture in the red light environment of the eye. The LWS opsin of *Spalax* acts as a functional photopigment, and it is not a 'residue' of the pre-subterranean visual system but is implicated in the entrainment of circadian rhythms to environmental light.

Rhodopsin

The visual rod pigment of *Spalax* shows >90% homology with mammalian rod pigments. This *Spalax* rod pigment is fully functional *in vitro* but also shows that all requirements for a functional pigment are present *in vivo*. During adaptation to a subterranean lifestyle, the visual system of *Spalax* has undergone mosaic reorganization, and the visual pigments have adapted to function in circadian photoreception.

Melanopsin

Hannibal et al. have shown that melanopsin, a recently identified opsin, is expressed in retinal ganglion cells that also co-store pituitary adenylate cyclase-activating peptide (PACAP), a neurotransmitter of the retinohypothalamic tract. The melanopsin component of retinal ganglion cells in the *Spalax* retina is well conserved, resulting in a relatively higher density of melanopsin-positive cells per area compared to the rat.

		Lens	Heart	Muscle
	Spalax	29 ± 26	782 ± 180	8891 ± 2778
	Mus	2256 ± 518	449 ± 176	652 ± 296
b	*Spalax/Mus*	0.01	1.7	13.6

Figure 4 Mole rat and mouse shsp/αB-crystallin promoter activity in 8-week-old transgenic mice. (a) Average of four lines of transgenic mice with the mole rat promoter (gray bars) and average of three lines of transgenic mice with the mouse promoter (black bars). The highest activity using the mole rat construct (muscle) and the highest activity using the mouse construct (lens) were given a value of 100. Setting the mole rat muscle activity to 100 lowered the heart activity relative to the mouse even though the average luciferase activity of the mole rat construct was actually higher than that of the mouse. (b) Average relative luciferase units per microgram of soluble protein, with standard deviations of the lens, heart, and skeletal muscle in the transgenic mice. The differences in activity between the mole rat and the mouse promoters were statistically significant in the lens ($p < 0.001$) and in the muscle ($p < 0.02$), whereas in the heart the differences were not statistically significant. From Hough RB, Avivi A, Joel A, et al. (2002) Adaptive evolution of small heat shock protein/αB-crystallin promoter activity of the blind subterranean mole rat. *Spalax ehrenbergi. Proceedings of the National Academy of Sciences of the United States of America* 99: 8145–8150.

Adaptive Loss of Ultraviolet-Sensitive/Violet-Sensitive Coneopsin

Most mammals are dichromats possessing, in addition to a single rod photopigment, two classes of cone photopigment LWS and ultraviolet-sensitive/violet-sensitive with differing spectral sensitivities, which mediate color vision. David-Gray et al. explored whether *Spalax* is a dichromat and has the potential to use color discrimination for photo-entrainment. Using immunocytochemistry and molecular approaches, they demonstrated that *Spalax* is a LWS monochromat.

The Evolution of Eyes and Photoreceptors

A monophyletic rather than a polyphyletic origin of the eye is supported by showing that *Pax6* (and its target sites) is the universally conserved master control gene for eye morphogenesis and eye evolution in all bilaterian metazoans from planarians to mammals (i.e., vertebrates and invertebrates). The prototypic eyes postulated by Darwin to consist of two cells only, a photoreceptor and a pigment cell, were accidentally controlled by *Pax6* and the subsequent evolution of the various eye types occurred by building on this original program. Intercalary evolution was proposed assuming that the eye morphogenetic pathway is progressively (or regressively) modified by intercalation of genes between the master control genes on the top of the hierarchy and the structural genes such as rhodopsin at the bottom.

The *eyeless* (ey) mutation in *Drosophila*, the *Small eye* mutation in mice, and the *Aniridia* gene in humans all correspond to the highly conserved *Pax6* gene, which might be a master control gene specifying eye development in both vertebrates and insects. A parallel situation in rodents applies to the *Sey* = *Pax6* gene, which is expressed first and controls a set of subordinate regulatory genes, including genes that influence cell–cell interactions and signal transduction. The *Sey* = *Pax6* gene in the mouse may be the master control gene in the mouse eye induction process and hence also in *Spalax* and other subterranean mammals. *Pax6* was also fully cloned in *Spalax*. As suggested by Gehring, the various *Pax* genes found in mice and flies (and also in *Spalax*) illustrate the principle of evolutionary tinkering, recombining bits and pieces of preexisting genes such as paired domains, homeodomains, octopeptides, and parts thereof. Evolution operates like a tinkerer rather than like an engineer.

The nematode *Caenorhabditis elegans* lost its eyes because it lives underground, but it retained its *Pax6*, like *Spalax*, with its reduced eye. Since photoperiodicity is retained in *Spalax*, the pleiotropic *Pax6* is essential for both the circadian eye and brain parts underlying photoperiodicity. Loss-of-function mutants in mice led to the reduction of the eyes and/or abolition of optic cups, and consequently the mutants lack eyes. Major evolutionary changes occur at the level of gene regulation, and coupled eye regression and progression might be generated by the same set of regulatory genes and/or by varying intercalary evolution of homeotic genes coupled with the genetics of loss- and gain-of-function mutations. The recombination of various coding and regulatory regions of different genes by 'evolutionary tinkering' might lead to recruitment and gene intercalation causing progression, whereas loss-of-function mutations might cause regression. Both gene groups may work epistatically and be under the *Pax6* master control gene involved in eye morphogenesis, resulting in mosaic eye evolution.

Brain Evolution of *Spalax*

No visual cortex has been identified in *Spalax*, either structurally or electrophysiologically. Instead, the occipital cortex of *Spalax* is occupied by the extension of the somatosensory cortex. Likewise, the somatosensory thalamus of *Spalax* almost reached the dorsolateral surface, without evidence of lateral geniculate body, the first station in the visual pathway. These findings indicate that the thalamocortical visual system in *Spalax* is minute, whereas the somatosensory system is expanded. Clearly, the brain area normally occupied by the visual cortex serves somatosensory functions. These findings, in addition to the prevalence of seismic communication in *Spalax* evolution, suggest that touch replaced vision as a major communication modality in the underground life of *Spalax* and probably in other subterranean mammals, although this calls for future investigation. Brain and eye mosaic evolutions might have evolved along similar patterns of evolutionary tinkering.

Conclusions

Blind subterranean mammals of the genus *Spalax* (Spalacidae and Rodentia) represent an extreme example involving combined natural visual degeneration and progression in mammals. Visual pathways are regressed and incomplete, and the absence of visual cortical potentials or behavioral response to light suggests that *Spalax* is completely blind.

Remarkably, however, the ocular regression in *Spalax* conceals adaptive progression of the visual system. The retina is functional in light perception, as indicated by structural and molecular evidence. Entrainment of circadian locomotory and thermoregulatory rhythms by ambient light demonstrates a capacity for photoperiodic perception. The severe thalamic and tectal structures' regression, involved in form and motion perception, is coupled with a selective hypertrophy of hypothalamic structures underlying photoperiodic perception. Ganglion cell retinal projections to the suprachaismatic nucleus (SCN) and the retinohypothalamic tract are increased 20-fold, and the SCN in which the circadian pacemaker resides is identical in *Spalax* and sighted rodents.

Photoentrainment is mediated by three photopigments: rhodopsin, coneopsin, and melanospsin. The differential regression and progression of visual structures and photopigments can be explained as an adaptive response to life underground. Natural selection appears to have operated via evolutionary tinkering, producing local optimization with available materials, constraints, and contingencies. Eye evolution in *Spalax* and other subterranean mammals evolved slowly by tinkering, which modified adaptively available molecular and organismal structures to generate emerging novelties. Only extensive future research could unravel the diverse modes of evolutionary tinkering in subterranean mammals.

Prospects

Molecular biology revolutionized evolutionary studies of the eye. Loss-of-function mutations in both insect and mammalian genes cause reduction or absence of eye structures, which suggest the function of the gene *Pax6* as a master control gene for eye morphogenesis across the metazoa. It remains to be determined whether *Pax6* is the master control for both reduction and expansion hypertrophy in the mosaic eye evolution of *Spalax* and other subterranean mammals. Future research will decipher the underlying genetic basis of mosaic eye evolution in *Spalax* on the basis of mutant phenotypes in homeotic gene clusters. These molecular genetic studies will highlight the molecular evolutionary tinkering within phylogenetic constraints underlying mosaic eye evolution, as it does in the evolutionary process in general.

Competing Local versus Global Views

The visual world appears to us in its entirety, coherent and understandable. Despite our belief that this view is unitary, it is actually comprised of multiple competing views at the local and global scales. This point cannot be better illustrated than by the paintings of Salvador Dali, the quintessential craftsman of depicting competing and conflicting cues within a single scene. In *The Hallucinogenic Toreador* (Figure 1), which is a 13 foot × 10 foot (4 m × 3 m) painting (exhibited at the Salvador Dali museum in St. Petersburg, FL), different scenes become apparent depending on the viewing distance. When standing close to the painting, in the bottom right corner a small boy is seen viewing a lake with a woman in a bikini on a pool chair and a dalmatian dog headed toward the lake. From a little farther back from the painting, just above the lake a bull can be seen stuck with multiple colorful spears. Several Venus statues can be seen across the center of the painting, one with a white dress, partly shadowed in green, and another with a red dress. At an even greater distance, one begins to appreciate the toreador himself, who's shirt and green tie are formed by the fabric and shadow of Venus's white skirt, respectively, his chin by her stomach, his nose by her breast, and his eye by the shadow of her neck. The outline of his cheek is formed by the hips of the Venus draped in red, his beret and cape dotted by the patterns of flies in the stadium and those above the bull. Thus, depending on the scale at which this painting is viewed, different scenes become apparent to the viewer. Moreover, an attempt to take in all views at once may lead to a sense of rivalry between local and global scales: at one scale the green swath is a tie, and at another it is the shadow of Venus's white dress.

A few simple visual illusions may help break this complex image into simpler components. Such illusions can be very useful tools for studying how competing cues are encoded in the brain. One example is shown in Figure 2(a). In this 'watercolor illusion,' blue and yellow dotted lines separate regions of a white background. Regions between the yellow lines appear yellowish and those between the blue lines appear bluish. In actuality (as measured by a spectrophotometer), the white regions are all the same in color. This is a demonstration of how local cues (white) can be overridden by distant, global cues (the blue and yellow lines), leaving the illusion of differently colored regions. Figure 2(b) is the classic 'cafe wall' illusion, in which parallel horizontal lines appear to be sloping. Superimposition of a horizontal bar demonstrates that these lines are indeed horizontal. Again, the local cues signaling horizontal are overridden by the global percept of sloping lines. In the realm of depth perception, in the random dot stereogram (RDS) illustrated in Figure 2(c), the borders of the square central region in the left figure are offset from that in the right figure. When fused by the two eyes, this induces a percept of a square surface behind (more distant than) four round holes in a nearer surface. This is perceived despite the fact that the pixels within the square are identical and have no disparity. Thus, the local disparity cues are overridden by the global border cues of the square. Similar illusions are used in the studies described in this article to distinguish the roles of primary (V1) versus secondary (V2) visual areas in the perception of contour, stereoscopic depth, and color and brightness (see Table 1). Moreover, the conflicting local versus global cues present in these illusions are used to elicit competition between V1 (which is local) and V2 (which is global).

The inherent conflict illustrated by these examples calls for a revision of the traditional view of hierarchical processing within the visual pathways. In the traditional view, early visual stages first identify elemental features by means of neurons with small, spatially and 'featurally' restricted receptive fields. These elemental inputs are then integrated into higher-order representations at higher cortical areas. Receptive fields of neurons in higher cortical areas are spatially larger and tend to be less sensitive to elemental 'featural' specificity and, via some unknown 'invariance circuitry,' become tuned to more-global features. This integration process is iterated at multiple cortical levels, culminating in a relatively complete spatial and featural representation that enables object recognition. This hierarchical view, in its strictest interpretation, raises the question of how the visual system maintains knowledge of details when higher cortical areas no longer track these details. It is apparent that the details encoded in earlier areas and the global views encoded in higher areas must be simultaneously accessible. Moreover, these different views can (and often do) give conflicting signals. Resolving this local versus global competition is likely to be context dependent and therefore dynamic. Thus, while the hierarchical view still carries validity, it alone is inadequate for creating the illusion of coherence across multiple spatial scales.

Figure 1 *The Hallucinogenic Toreador* by Salvador Dali (Salvador Dali Museum, St. Petersburg, FL).

This competition forms the basis for three theses presented in this article. Evidence supporting the first two theses is presented, and the third thesis is discussed largely as a future direction of study. The theses are as follows:

1. Each cortical area processes the visual world at a different spatial scale and, in that sense, 'sees' a different visual world.
2. Multiple views of the world which are encoded in parallel by multiple cortical areas can compete with each other. The dominance of one view over another may be resolved by a competitive balance between 'feedforward' and 'feedback' signals between different cortical areas.
3. This competition is dynamic and context dependent.

These theses are presented in this article through a set of studies which examine responses of primary (V1) and secondary (V2) visual areas in the macaque monkey. In this framework, V1's and V2's views of three featural spaces are examined: visual contours, visual color and brightness, and visual depth. These studies demonstrate the following:

1. V2 'sees' different things than V1 sees (see Table 1).
2. There is a balance of power between V1 and V2.
3. There is a dynamic network of V1 and V2 modules that participate in this power struggle.

Functional Organization in V2 Is Modular

V2 has been described as a distribution center from which modality-specific information feeds into the ventral and dorsal visual processing streams. In addition to its role in distribution, V2 plays a crucial preparatory role in midlevel vision, performing transformations that link local detail to higher-order percepts. A great deal of attention has been focused on the interareal interactions and integration between cortical areas. V2 holds a unique position in the

Figure 2 Global versus local competing cues in visual illusions. (a) The watercolor effect; see Pinna B, Brelstaff G, and Spillmann L (2001) Surface color from boundaries: A new 'watercolor' illusion. *Vision Research* 41(20): 2669–2676. (b) The cafe wall illusion. (c) Disparity capture illusion.

sense that it funnels information, both feedforward and feedback, between V1 and the larger cortical network.

To appreciate the role of V1 and V2 in contour, color–brightness, and disparity processing, it is first important to recognize the modularity of these areas. In contrast to V1, which is characterized by ocular dominance structure, a regular array of orientation domains, and a lattice of densely staining cytochrome oxidase blobs, V2 contains a pattern of large (millimeter-size) cytochrome oxidase stripes. Some evidence indicates these thin (cytochrome dark), pale (cytochrome light), and thick (cytochrome dark) stripes are involved in contour, color–brightness, and disparity processing, respectively. In macaques, these stripes are oriented roughly perpendicular to the V1–V2 border and are commonly seen in a repeating thin, pale, thick, pale sequence. There are also reports of interanimal variability and/or variability of stripe thickness (e.g., thin is not thin) or stripe sequence (e.g., thin, pale, thin, pale). A few studies have hinted that functional differences may accompany these differences in individual architecture.

Within these larger stripe structures are collections of 100–200 μm domains. The presence of substructure within stripes was perhaps first suggested by nonuniform staining in cytochrome oxidase-stained tissue and by patchy labeling of injected tracers in V1, V2, and V4. Studies with 2-deoxyglucose have revealed further patchy activation within V2 stripes. Optical imaging further confirmed the presence of subdomains (e.g., color-preferring and luminance-preferring domains within thin stripes). Although both anatomical and functional evidence support the presence of modules, the relationship of functional subdomains and anatomical patchiness is unknown. Functional evidence indicates that different modules play distinct functional roles and have specific connectivities. Indeed, this is visually apparent from localized injection of tracer into V2, which reveals arrays of clusters about 100–200 μm within V2 (Figure 3). These anatomical data suggest a degree of intra-V2 connectional specificity that parallels that of functional networks observed in V1.

In addition to summarizing more recent findings regarding V2, this article presents a common framework for understanding the different featural modalities in V2 and thereby the common functional transformations that V2 performs on its input, regardless of feature space.

Are There Functionally Distinct Domains in V2?

Following the discovery of cytochrome oxidase 'blobs' (also referred to as 'puffs' and 'patches') in macaque monkey visual cortex, researchers reported that blobs are characterized by a predominance of color-selective neurons which lacked strong orientation selectivity, whereas interblobs are characterized by a preponderance of orientation-selective cells lacking in color selectivity. Functional distinctions within V2 have also been reported whereby thin stripes are color selective and poor in orientation selectivity and pale and thick stripes are orientation selective and less selective for color. This proposed dichotomy led to a number of studies, some of which supported whereas others contradicted these findings. This controversy has continued without apparent resolution.

Figure 3 Intrinsic connections in V2 reveal 200 μm modules. (a, b) Boxed areas indicate regions of patchy label (indicated by arrowheads). Arrow: site of tracer injection. Scale bar = 100 μm. From Amir Y, Harel M, and Malach R (1993) Cortical hierarchy reflected in the organization of intrinsic connections in macaque monkey visual cortex. *Journal of Comparative Neurology* 334(1): 19–46.

The debate is fueled by two main issues. The first is whether color and orientation information are segregated in V1 (and V2). Some studies have found a clear association between color selectivity and a lack of orientation tuning. This finding is supported by studies which report that color-selective cells prefer low spatial frequencies and exhibit high contrast sensitivity. Results with 2-deoxyglucose are also consistent with these views, indicating blobs in V1 are preferentially activated by color stimuli and low spatial frequency stimuli.

With respect to spatial distribution, electrophysiological studies have also reached different conclusions. Some support the view that cytochrome oxidase blobs are centers of color preference and poor orientation preference. Others have found that centers of blobs exhibit higher contrast gain and lower spatial frequency response, which suggests that blobs do exhibit responses functionally distinct from that of interblobs. However, other studies differ. Some single-unit electrophysiological studies find blob and interblob domains exhibit no significant difference in color and orientation preference and report a range of associations between color selectivity and orientation selectivity within single cells of V1. Experimental factors may contribute to some of this controversy. Although electrode recording sites were carefully reconstructed in these studies, there is some intrinsic error associated with reconstruction of recording sites. Since cytochrome oxidase blobs are small (100–200 μm), a small degree of error could be significant. There are also differences in sampling methods and methods of receptive field characterization (e.g., hand plots with color filters, characterization with sinusoidal isoluminant gratings, mapping with reverse correlation of cone-isolating stimuli).

A related but distinct issue regards the association of color and orientation with blobs and interblobs, respectively. Studies which reveal population responses (2-deoxyglucose and optical imaging methods) tend to support the role of blobs in the processing of low spatial frequency and color information. As shown by 2-deoxyglucose methodology, blobs are preferentially activated by color-varying gratings of low and middle spatial frequencies and by spatially diffuse color stimuli. Optical imaging studies have shown good alignment between cytochrome oxidase blobs and centers of monocularity and between cytochrome oxidase blobs and regions of poor orientation selectivity. Less clear correspondence between blobs and color response has also been reported. Although one study reported a general correspondence between color domains and cytochrome oxidase blobs, it was not a simple one-to-one relationship: Some color-activated domains were irregular in shape and were observed to span two or more blobs.

A similar controversy exists on V2. Some researchers found little difference in the number of color-selective cells across the different cytochrome oxidase stripes in V2. Some single-unit studies have emphasized the multidimensional aspects of single cell function in V2. Others have reported some concentration of color-selective responses in thin stripes of V2, in contrast to some earlier studies.

In hopes of settling this debate, a recent intrinsic signal optical imaging study closely examined the alignment of large field views of color and orientation response in V1 and V2 of the macaque monkey. As shown in **Figure 4(a)**, the V1–V2 border is well delineated by ocular dominance imaging. Optical images revealed the characteristic orientation maps as well as a regular array of color domains in V1 (**Figure 4(b)**). In V2, orientation domains are larger than those in V1 and are localized to the thick and pale stripes (white bars in **Figure 4(b)** and **4(c)**). Regions of strong color activation in V1 (**Figure 4(c)**) are punctate and bloblike in appearance, are aligned along centers of ocular dominance columns, and tend to overlay regions of

Figure 4 Feature maps (ocularity, orientation, and color) within V1 and V2 of macaque monkey. (a) Ocular dominance (OD) map (left eye minus right eye). V1–V2 border (indicated by dotted line in (a)–(c)). (b) Orientation map (horizontal minus vertical; HV). V2 orientation domains are as much as several times larger than those of V1. (c) Color (Col) map (red–green luminance grating minus luminance grating) reveals V2 thin stripes and V1 blobs. Note that locations of color activations in V2 (dark bars) are complementary to locations of oriented domains in V2 (compare (b) and (c)). Scale bar = 1 mm. From Lu HD and Roe AW (2007) Functional organization of color domains in V1 and V2 of macaque monkey revealed by optical imaging. *Cerebral Cortex* (doi: 10.1093/cercor/bhm081).

Figure 5 Color domains align with cytochrome architecture. Alignment of cytochrome oxidase (cytox) stripes (a) and color domains (b) in V2, and cytochrome oxidase blobs (c) and color blobs (d) in V1. Tissue was aligned using blood vessels, V1–V2 border, tracer injections, and electrolytic lesions. Black ((a) and (b)) and white ((c) and (d)) arrows point to corresponding structures. Scale bar = 1 mm. From Lu HD and Roe AW (2007) Functional organization of color domains in V1 and V2 of macaque monkey revealed by optical imaging. *Cerebral Cortex* (doi: 10.1093/cercor/bhm081).

low orientation selectivity. In V2, color domains are complementary in location to the orientation-selective areas and overlay the thin cytochrome oxidase stripes. An alignment of cytochrome oxidase stained tissue, and functional images (using blood vessels, tracer injections, and electrolytic lesions as guides) have revealed good alignment of color domains with thin stripes in V2 (Figures 5(a) and 5(b)) and color blobs with cytochrome oxidase blobs in V1 (Figures 5(c) and 5(d)). These findings thus support, at the level of population response, significant functional segregation of color and orientation information in V1 and V2 and further strengthen their association in V1 with blobs and interblobs, respectively.

Although on the face of it, these studies appear at odds, they are, in fact, mutually consistent. Clearly, single cortical locations contain cells with a mixture of responses and cell types. Furthermore, each cell displays an array of responses in multiple feature domains. There is no question that individual neurons are multidimensional and that cells in V2 integrate information across multiple feature domains, a point that is made by a number of electrophysiological studies. This multidimensionality is precisely what leads to different views

of the same cortical area. Different electrophysiological samplings and somewhat different characterization methods can provide quite different impressions, indicating that methodology can strongly influence the apparent population response profile. (Indeed, being able to electrophysiologically target imaged color domains increases the yield of color cells tremendously.) Despite variability due to method, that functional imaging and functional anatomical studies consistently reveal blob and stripe structure suggests that there are overall differences in the local population response. The fact that functional responses reveal stripelike structures within V2 and that distinct responses are recorded in different stripes in V2 suggests the presence of at least some degree of segregation. On average, the cells in blobs and thin stripes prefer color stimuli over achromatic stimuli. Functional imaging provides, in a sense, a more unbiased view of the average population response. Perhaps some of the controversy is due to the perception that functional organization implies strict segregation. However, this is not the case, as each functional structure contains a mixture of neurons with varying selectivities. In sum, although single neurons are multidimensional (have some degree of responsiveness to both contour orientation and color), as a population, they are organized to some degree with respect to contour versus color.

Parallel Functional Channels in V2: A Useful Framework?

A framework that had its roots in the 1980s maintains that thin stripes are vehicles for processing surface feature information whereas thick and pale stripes are involved in contour and depth information processing. This framework has been supported by anatomical, electrophysiological, 2-deoxyglucose, optical imaging, and behavioral and lesion study data. This framework is not to be interpreted as a view of strict segregation. There is ample data to demonstrate that functional organization within V2 is not one of strict segregation. As noted above, single neurons in V2 are multidimensional and integrate different featural spaces. Each stripe type within V2 contains a myriad of cell types. Given the extensive connectivity between stripes in V2, cells from each stripe type have opportunity to influence and integrate information from other stripe types. Nevertheless, the proposal that different stripes subserve somewhat different functions is still a useful one. It is a framework which provides an understanding which can be experimentally tested and modified. To ignore this framework would be foolish. In the language of 'drivers and modulators,' there may be primary functions that can be modified by secondary, perhaps contextual, influences. A working framework provides much greater utility and testability than an approach in which every neuron is omnifunctional. Indeed, the ubiquity of functional organization in the brain – whether it be at the level of global networks, cortical areas, modules and columns, laminae, or synapses – indicates that such organization is a fundamental tenet of brain organization. Whether they be genetically determined, experientially determined, or a necessary prerequisite for specific computations, it is likely that functional organizations bear a strong (and possibly predictive) link to the brain circuits that produce function and behavior. The following paragraphs are thus presented in this framework.

Surface Properties

Surface features, such as color, brightness, texture, glossiness, and transparency, are those that help us identify the material quality of an object. There are ample demonstrations of the ways the perception of these surface features can be strongly influenced by lighting, local color and contour cues, global context, and experience. The human visual system can distinguish on the order of a million different colors. However, the inputs to the visual system are confined to three types of cones, those responsive to red, green, and blue wavelengths. How does the visual system create the illusion of color and transform a triadic cone-based representation into a perceptual continuum of salient hues? Add to this challenge the fact that the human visual system can adjust to 7 orders of magnitude of brightness (10 million to one, bright sunlight to faint starlight). The visual system must also factor in the influence of contextual cues such as color, brightness, and contrast of nearby borders and surfaces. In addition, the ability to see objects through transparent surfaces means we not only must segregate different planes of depth but also ignore features on the transparent plane.

Color Representation in V2

How do V1 and V2 separately and together contribute to these processes? The idea that V1 and V2 participate in encoding color information is well supported. At least one route for color information arises from the parvocellular layers of the lateral geniculate nucleus (LGN) and continues to layer 4Cb of V1, to cytochrome oxidase blobs of V1, and to the thin stripes in V2. Blue cone-driven input from S layers of the LGN project directly to the blobs, with blue–yellow inputs targeting layer 3B–4A and red–green inputs targeting lower layer 4C. There is also evidence to suggest a functional segregation of blue

'ON' and blue 'OFF' inputs within layer 4A of V1. In V2, although there is significant color response in each of the stripe types, a greater concentration of neurons responsive to color stimuli is found in the thin stripes than in either the pale or thick stripes.

Color versus luminance preference domains Optical imaging studies have revealed the presence of color-responsive domains within thin stripes. Some studies have used preferential response to isoluminant red–green gratings over achromatic luminance gratings to reveal color preference domains. Although there are both color and luminance contrast differences between these stimuli, experiments directly comparing high- versus low-contrast achromatic responses have revealed no structured maps in V2, indicating that the imaged substructure is not due to luminance contrast differences. Since spatial frequency, drift rate, and mean luminance were identical between these two stimuli, the differential response is attributed to the color content of the stimuli. Such stimuli elicit activations that appear more rounded and interdigitated in some thin stripes (Figures 6(a) and 6(c)) and more elongated across the width of the thin stripe in others (Figure 6(b)). It is not yet known whether there may be functional implications of these different architectures.

Figure 6 Color domains in thin stripes. (a) A single thin stripe (arrow) contains several rounded color domains. (b) A single thin stripe (arrow) contains color-preferring domains that span the width of the stripe. (c) Three thin stripes in V2, each containing a few color domains. Scale bar = 1 mm. (a) From Roe AW and Ts'o DY (1995) Visual topography in primate V2: Multiple representation across functional stripes. *Journal of Neuroscience* 15: 3689–3715. (b) From Roe AW and Ts'o DY (1999) Specificity of color connectivity between primate V1 and V2. *Journal of Physiology* 82: 2719–2730.

Color: Topography of hue in V2 thin stripes One of the first studies to establish a systematic representation of hues in V2 used isoluminant color–gray gratings of different hues and mapped responses in macaque V2 using intrinsic signal optical imaging. These images revealed hue-specific domains on the order of 100–200 μm, which were mapped in a systematic fashion in V2. These chromatic color maps were located within single thin stripes and not in thick or pale stripes of V2 (Figure 7(a)). This was the first demonstration of a hue-based map in which topographic location corresponded to hue wavelength. This study underscored three primary points: (1) although V1 contains color-selective cells tuned to red–green and blue–yellow axes, hue representation does not emerge until V2; (2) the topographic basis for this representation is based on 100–200 μm modules, the size of which is fundamental to other featural representations; and (3) the discovery of topographic maps within thin stripes poses perhaps the single strongest piece of evidence in favor of the color–thin stripe association.

Where is the blue response? Attempts at revealing blue response in V1 and V2 with imaging techniques proved unsuccessful. Similarly, comparing responses to isoluminant blue–yellow gratings versus achromatic gratings did not reveal any functional organization within either V1 or V2. However, more-recent studies have revealed clear and strong responses to blue stimuli. These studies examined responses to flashing blue versus flashing gray unstructured stimuli each at 30% luminance and drifting blue–gray square-wave gratings versus gray–gray square-wave grating at 30% luminance contrast. In V2, similar to red and green, blue stimuli preferentially activate the thin stripes whereas gray stimuli exhibited preferential thick-stripe activation. Within the thin stripes, color-specific stimuli typically revealed focal activations. Activations to red, green, and blue stimuli have been shown to shift in location within the thin stripes. Examination of responses to gratings of different duty cycles revealed that thin blue lines were a surprisingly effective stimulus. Thin blue lines elicited strong blob-like maps in V1 (Figure 7(b)). These data suggest that blue activations, like red and green hues, are mapped

Figure 7 Hue maps in V2. (a) Chromatic color maps located within a single thin stripe of V2 (imaged with isoluminant color/gray gratings of different hues). Outline color indicates peak response of that location. (b) Imaged responses Macaque V1 and V2 in response to thin blue oriented stimuli. In V1, blue activation reveals blobs. In V2, blue activation is mainly located in thin stripes. Scale bar = 500 μm. (a) From Xiao Y, Wang Y, and Felleman DJ (2003) A spatially organized representation of colour in macaque cortical area V2. *Nature* 421: 535–539. (b) From Roe AW, Lu HD, and Crewther D (2007) Blue Color Activation in V1 and V2 of Macaque Monkey. Melbourne: International Brain Research Organisation.

within 'color modules' in the thin stripes of V2. The surprisingly strong response to thin blue lines may suggest some interaction of color and spatial frequency that may contribute to contour response in V2. Data also suggest, counter to previous notions of dedicated red–green versus blue–yellow blobs in V1, that blue response may reside within every blob in V1.

A midlevel role in simultaneous contrast and color constancy? The color of a surface can be dramatically changed by its surround, such as commonly demonstrated with examples of simultaneous color contrast. A first step in achieving simultaneous color contrast response would be demonstrating a chromatically specific effect by the surround. Surround suppression of both achromatic and isoluminant gratings have been examined on the chromatic responses of V1 and V2 neurons. There is little evidence that colored surrounds alter the chromatic tuning of neurons in V1 or V2 (although background color shifts chromatic tuning of V1 neurons to a degree consistent with perceptual color contrast effects). However, V2 neurons, unlike V1 neurons whose surrounds exhibit little chromatic selectivity, have a chromatic signature in the surround similar to that in the receptive field center. Thus, although there is no evidence of the surround shifting chromatic tuning in V2, neurons in V2 are strongly affected by specific chromatic stimuli in the surround.

Another salient aspect of color perception is 'color constancy.' This term refers to the fact that the color of a surface remains constant under different lighting conditions (e.g., a red apple will appear red under different spectral lighting conditions, such as bright sunlight and ambient indoor lighting). This suggests that there must be neurons somewhere in the brain that encode 'redness' or 'greenness' of a surface regardless of light condition. Do such neurons exist in V2? A few recent studies have tried to dissect the difference between color responses in V2 and those in V1 or V4. Researchers have used isoluminant color patches to characterize the color preference of single cells in V2 thin stripes and Mondrian stimuli to examine the effects of color versus the illuminant. They found that V2 cells responded to the wavelength of the illuminant rather than the color of the stimulus. In contrast, the same stimulus paradigms revealed clear color constancy in a majority of V4 neurons: these neurons exhibited shifts in their color-tuning profiles in the direction of the shifted chromatic component of the illuminant (which was simulated by a shift in the background color presented on the computer monitor). In other words, V2 neurons did not exhibit behavior consistent with color constancy. However, about a third of V2 neurons studied were strongly influenced by the wavelength of the surround.

Thus, these studies suggest that V2 plays a midlevel role in the generation of color percepts such as simultaneous color contrast and color constancy. Although neurons in V1 and even in LGN are reported to be influenced by monochromatic surrounds, shifts of the entire color tuning curve have been reported only for V4 neurons. This is true for units recorded both in anesthetized and awake monkeys. Thus, computations leading to color constancy are likely to begin at stages before V4, but color constancy is not represented in its full extent until V4. V2 is likely an intermediate processing stage in these computations.

Brightness Representation in V2

With respect to V2's role, if the primary role of thin stripes is to encode surface properties, then in addition to color, thin stripes may be integral to representing surface brightness. The challenges of representing brightness in the visual system include representing light level (lightness and darkness), change in light level (either increase or decrease), and ability to adjust to a large range of light levels. Some of these challenges may be solved by the retina and LGN. However, other challenges are unlikely to be resolved by early precortical levels. Similar to context-dependent effects in color vision, the perceived brightness of a surface can be strongly influenced by surrounding cues. Brightness perception is influenced by multiple factors, including luminance, edge effects, distant color and brightness context (e.g., simultaneous contrast, Mondrians), and experience. Neurons in V1 of both the cat and the monkey exhibit response modulation to large field modulations in luminance and in background luminance modulation. Relatively few studies have examined the representation of brightness information in V1 and V2.

ON and OFF responses Many studies have demonstrated that visual cortical neurons exhibit contrast response functions which increase monotonically over a range of contrasts and saturate at higher contrasts. Most neurons in V1 respond to a large patch of luminance increment or decrement in a monotonic fashion. Roughly one-third of neurons are not affected by stimulation in the surround, consistent with the type I cells which lack inhibitory surrounds. The response is often characterized by an initial contrast-independent transient, followed by a sustained response which correlates with the luminance increment or decrement. Another third of neurons are enhanced by luminance in the surround and appear to signal level of illumination. And the remaining third are affected by luminance in the surround (type II) in a manner consistent with simultaneous contrast as first demonstrated in anesthetized cat visual cortex and later also observed in the alert monkey V1.

In addition to light increment (ON) and light decrement (OFF) responses, V1 and V2 contain cells that exhibit bandpass characteristics. That is, they respond to an intermediate range of luminance values (termed 'V-shaped' or 'gray-preferring neurons'). Some of these neurons also exhibit color sensitivity, suggesting a role for luminance response in color encoding.

ON and OFF domains in V2 Within V2 thin stripes, there are subdomains that exhibit luminance increment (ON) and luminance decrement (OFF) responses. These domains measure on the order of 0.5 mm and could be the same 'luminance-preferring' domains revealed in isoluminant color versus achromatic imaging experiments. Such domains had been hypothesized based on extended runs of tangentially recorded of ON or OFF single unit responses within V2 thin stripes. Such ON and OFF zones have not been observed in primate V1.

Contrast response in V2: Thin stripes have greater dynamic range One test of the hypothesis that thin stripes are brightness-processing structures has taken the form of examining contrast response in V2. The expectation was that if thin stripes were loci of brightness information processing, then they should have contrast response behavior consistent with such a representation. One would expect the contrast response of these stripes to exhibit sensitivity to a large range of contrasts, including sensitivity to low contrasts and nonsaturating response at high contrasts. More specifically, they should have high contrast gain, especially at low spatial frequencies consistent with encoding visual surface features, and they should exhibit large dynamic range for encoding visual brightness.

Previous studies had shown that in primates, magnocellular and parvocellular neurons in the LGN are characterized by distinct contrast response signatures. Magnocellular neurons exhibit nonlinear response characterized by greater sensitivity to small changes in contrast (have higher contrast sensitivity), especially at low luminance levels, and tend to saturate at high contrasts. Parvocellular neurons respond in a linear fashion to increasing contrast and are relatively insensitive at low contrasts (in fact, they are not responsive at contrasts lower than around 10%). Koniocellular neurons are a heterogeneous population of neurons and have a broad range of contrast response functions. In V1, interblobs tend to be dominated by parvocellular inputs, while blobs exhibit parvocellular (color selectivity), magnocellular (low spatial frequency, high contrast gain response), and koniocellular (blue response) characteristics. Although thick stripes are dominated by magnocellular inputs and therefore could exhibit higher contrast sensitivity than thin stripes do, in principle both magnocellular and parvocellular inputs reach all the stripe compartments in V2. The thin stripes receive both magnocellular and parvocellular input primarily by way of the blobs, and thick and pale stripes via the interblob columns. Thick stripes have the highest contrast sensitivity values, although semisaturation values have shown no significant difference between thin, pale, and thick stripes. Measures of V2 response have revealed surprisingly

few quantitative differences between thin, pale, and thick stripes, leading some to argue for homogeneity of stripe function in V2. With 2-deoxyglucose methodology, both thin and thick, but not pale, stripes have exhibited response to low contrast (8%) gratings, suggesting that magnocellular contribution could also be prevalent in the thin stripes.

A study using optical imaging methods has demonstrated that V2 thin stripes have greater contrast gain than thick and pale stripes and relatively nonsaturating response at high contrasts. As shown in Figure 8, contrast response functions of both blobs and interblobs in V1 were linear (Figure 8(a)), consistent with parvocellular-dominated response in superficial layers of V1. However, responses in V2 exhibited a nonlinear response, especially at low contrasts, reminiscent of magnocellular input (Figure 8(b)). At high contrasts, thin stripes exhibited significantly stronger and less-saturating responses than thick or pale stripes (Figures 8(c) and 8(d)). The response of V2 thin stripes is thus reminiscent of magnocellular response at low contrasts and parvocellular response at high contrasts. At low contrast levels, magnocellular inputs from V1 blobs may converge in V2 thin stripes, thereby conferring high-contrast response at low contrasts. At higher contrast levels, parvocellular-dominated inputs to thin stripes continue to signal changing contrast, while those in thick and pale stripes tend to saturate. Other contributions to nonlinear response in V2 thin stripes (such as koniocellular input and other thalamic inputs) may also be at play. In comparison with thick or pale stripes, these data suggest a larger dynamic range of V2 thin stripes, consistent with a preferential role in brightness perception.

Real and illusory brightness representation in V2 thin stripes Perhaps intermediate to local luminance response and lightness and color constancy which require rather large-scale integration are midlevel stages which are encoded in V2 (in cats). A potential example of midlevel integration was demonstrated in a recent study revealing the equivalence of V2 response to different types of brightness stimuli. Response to sinusoidally modulated stimuli counterphasing in

Figure 8 Contrast response in V2 stripes. (a, b) Contrast response functions in V1 are linear, both in blobs and interblobs, while those in V2 are nonlinear, in thin and thick/pale stripes. Different color lines represent response obtained at different spatial frequencies (same legend in (a) and (b), in cyc/deg). *x*-axis, visual contrast (0.2 = 20%); *y*-axis, d*R*/*R* – reflectance change. (c, d) Thin stripes have greater dynamic range. (c) Top: Cytochrome oxidase stain reveals thin (white arrows) and thick (black arrow) stripe in V2. Middle and bottom: Imaged response to low (lo, 40% contrast) and high (hi, 80% contrast) sinusoidal gratings. At high contrast, thin stripes still exhibit robust response, but thick stripe response is weak. Green outlines indicates activation areas, thresholded and outlined. (d) Thin and thick stripe responses are similar at lower contrasts, but thin stripe response dominates at high contrast. Thin (*y*-axis) and thick/pale (*x*-axis) stripe responses are similar at low contrasts (black, dark gray symbols), but thin stripe response dominates at high contrast light gray, white symbols, (d*R*/*R* – reflectance change). From Lu HD and Roe AW (2007) Optical imaging of contrast response in macaque monkey V1 & V2. *Cerebral Cortex* (doi: 10.1093/cercor/bhl177).

contrast was preferentially localized to the thin stripes of V2 (Figures 9(a) and 9(b)). In fact, similar thin stripe activations were obtained in response to 'illusory' brightness modulations as early as 1970 (Figure 9(c)), when a percept of brightness contrast between the left and right halves was achieved by an intervening 'Cornsweet' border (Cornsweet being one of the researchers involved). This border-induced contrast illusion evokes the percept of brightness differential where none is present. Neurons in V2 were shown to respond not only to sinusoidal modulation of the 'real' brightness stimulus but also to that of the Cornsweet border contrast. Optical imaging of V2 response indicated that such responsiveness was localized to the thin stripes of V2. Consistent with optical imaging evidence, of 89 neurons recorded in V1 blobs and interblobs and V2 thin, pale, and thick stripes, almost all those responsive to the Cornsweet were located in thin stripes. These results suggest that thin stripes are involved in not only the encoding of luminance response but, more generally, the response related to surface brightness perception.

Figure 9 Optical imaging of brightness response. (a) Single condition color map reveals thin stripes in V2 (black arrowheads above, thick/pale stripes indicated by white arrowheads). Pixels with strongest activation (top 10%) indicated by red outlines. Grayscale in (a) also applies to (b) and (c). (b) Single condition activation map in response to real luminance stimulation. Strongest activation is seen in thin stripes with weaker activation in thick/pale region. (c) Single condition activation map in response to Cornsweet stimulation reveals similar pattern. (d) Blank stimulus map. Scale bar = 1 mm. Each image sum of 50 trials. In all single condition maps, darker pixels indicate larger magnitude reflectance change. d*R*/*R* – reflectance change.

V1 Sees Local, V2 Sees Global

These data are consistent with the encoding of higher-order brightness processing in V2 and lower-order brightness processing in V1. That is, responses in V1 reflect local luminance values, whereas those in V2 reflect more global, edge-induced percepts. In the Cornsweet stimulus, V1 would report a lack of luminance modulation, whereas V2 would report a salient brightness modulation. To achieve such perceptual saliency, the V2's message must somehow overcome V1's. One obvious means is via feedback projections from V2 to V1 which lead to either relative suppression of V1 response or a modulation of V1 response that concurs with that in V2. This possibility remains to be examined.

Stereoscopic Depth

Binocular inputs are used by the human visual system to judge object depth in the three-dimensional world. This depth percept is created by the integration of two views of the world received by the two eyes. Stimuli nearer or farther from the fixation point will produce disparities from left and right eye with a negative or positive horizontal shift. In the pathway from retina to thalamus to cortex, ocular input remains segregated in the thalamus (the LGN) and is first combined in V1. In V1, disparity-selective cells have been characterized by their response to offset bars presented to the two eyes ('tuned excitatory,' 'tuned inhibitory,' 'near,' and 'far' cells), response to differential phase of sinusoidal gratings, and response to absolute disparity of RDSs. In V2, disparity-selective neurons have been described as 'obligatory binocular,' selective for disparity-defined contours, and tuned for relative rather than absolute disparity. Despite the number of studies on disparity responses in the visual cortex, there have been no published studies addressing any systematic representation of disparity response in either V1 or V2 of the monkey.

Given the known organizations of the other two featural maps in V2 (color in the thin and contour in the pale and thick stripes of V2), this gap in our knowledge regarding disparity representation in V2 is particularly conspicuous. Disparity-selective responses are believed to be preferentially localized to the cytochrome oxidase thick stripes of V2, but topographic representation within these stripes has not been examined. Thus, at issue are the questions of whether there is

a map for near-to-far depth information and whether disparity and orientation information, which are both represented in the thick stripes, are independently represented or not. The broader issue of parallelism and modularity across featural domains in V2 is also in question. Examination of these issues is further motivated by the presence of maps organized for disparity in the middle temporal area (MT), a primary target of V2 thick stripes.

Topography for Near–Far Disparity

Since it is known that many disparity-selective neurons in V2 include obligatory binocular cells, previous optical imaging studies had indicated localized thick stripes by locating domains preferring activation of two eyes over a single eye. These binocular-preferring domains were located primarily, although not exclusively, within thick stripes (Figure 10). Two recent studies have indicated the presence of topographic organization in V1 and V2. In one, two photon calcium imaging was used to study organization of cortical responses to phase offset gratings in the cat. This study revealed beautiful pinwheels of disparity response in cat V1. In another study, RDSs were used to probe disparity organization in primate V1 and V2. These stimuli were designed to produce the percept of surfaces at different depths relative to the background, ranging from -0.5° near to $+0.5^\circ$ far. Characterization of single units in V2 revealed that cells in V2 exhibited tuning for specific horizontal disparities (Figure 11(a), RDS). It is important that

Figure 10 Imaging V2 thick stripes. (a) Ocular dominance (od) map. (b) Color map reveals thin stripes (30% contrast blue/gray minus 30% contrast gray/gray grating). (c) Binocular (binoc) versus monocular preference map reveals thick stripes. Thick stripes (white dotted lines) and thin stripes (red dotted lines) are in complementary locations in V2.

Figure 11 Topography for disparity in V2 thick stripes. (a) Disparity tuning curves of a recorded unit from imaged disparity domain in V2 thick stripe. Random dot stereograms (RDSs) were shifted in disparity from -0.42° to $+0.42^\circ$. This cell is tuned to near 0.4°. Its response to antirandom dot stereograms (ARDSs) shows a flat curve, indicating that the cell's response correlates with the global depth percept and not simply with local disparity cues. (b) Optical images to RDS and ARDS stimuli. Left: RDS, differential image of all near (dark pixels) minus all far (light pixels) stimuli. Dotted box, region of activation in V2 thick stripe. Right: ARDS, differential image of all near minus all far stimuli. (c) Outlines of three disparity domains (0.34° near, 0.34° far, and zero). Location of activation shifts as disparity changes from near disparity (red) to zero disparity (green) to far disparity (blue). Scale bar = 1 mm (b, c). *R,* reflectance value. From Chen G, Lu HD, and Roe AW (2006) Functional architecture of macaque cortical area V2 for depth surfaces revealed by optical imaging. *Society for Neuroscience* 32: 114–116.

these cells showed little responsiveness to stereograms that do not induce depth percepts; these include anti-random dot stereograms (ARDSs, stereograms in which the contrast of corresponding pixels in the left and right eyes was reversed and uncorrelated stereograms) and stereograms in which the left and right eye dots have a random relationship to each other (Figure 11(a), ARDS). Similarly, optical imaging of such responses revealed strong responses to depth percept-inducing RDSs and little response to ARDSs (Figure 11(b)). Key to the success of these studies was a rapid spot imaging method that permitted quick confirmation of individual eye position and mapping of the imaged field of view. Consistent with previous studies demonstrating preferential disparity response within V2 thick stripes, these activations were located within thick stripes. Furthermore, analogous to a topographic hue representation within thin stripes, a near-to-far topography within the thick stripes was observed (Figure 11(c)). Imaged disparity responses correlated well with disparity preferences of electrophysiologically characterized single unit responses. Furthermore, disparity preferences of units recorded within single vertical penetrations were similar in disparity selectivities, suggesting the presence of a columnar organization for disparity within V2 thick stripes. No such topographies were observed in V1.

Orthogonality of Disparity and Orientation

It is well established that thick stripes in V2 contain maps for orientation. How, then, do disparity maps relate to orientation in V2? Indeed, how multiple maps coexist within the same two-dimensional cortical space is a fundamental issue that has been addressed by a number of studies. In V1, modeling studies suggest that competing intracortical influences result in observed functional organizations for ocular dominance and orientation. In V2, there is an interdigitation of color, contour, and disparity maps in single thin, pale, thick, pale stripe cycles. However, within single thick stripes, the relative organization of orientation and disparity in V2 has been elusive. Is there a full range of orientations represented at each disparity, and is there a full range of disparities represented at each orientation? Both psychophysical and electrophysiological evidence suggest that representation of horizontal disparity might be biased for vertical orientations. Some researchers have found that disparity-activated regions contained roughly equal representation for different orientations and that on average, each orientation domain overlay a range of disparity domains. This suggests strongly an orthogonality between orientation and disparity within V2 thick stripes.

Absolute versus Relative Disparity

Early studies described the tunings of V1 neurons in terms of absolute disparity. However, depth perception is clearly dominated by relative disparity. That is, if the background disparity moves forward, a relative disparity-tuned cell will shift its tuning forward; if the background moves backward, a relative disparity-tuned cell will shift its tuning backward. The response of an absolute disparity cell would remain unchanged with changing background disparities. Using RDSs and a disparity clamp that permitted stepping absolute disparities without changing any relative disparities within the stimulus, researchers have demonstrated that V1 neurons are tuned for absolute disparity. Of 253 neurons studied, roughly 20% were disparity-tuned. Of these, about 80% exhibited absolute disparity tuning; only two exhibited some (weak) shift consistent with relative disparity tuning. In contrast, others have demonstrated that in V2, many more neurons have responses shifted in the direction of the background shift. Clearly, the influence of surround disparity on center disparity response is greater in V2 than in V1. However, only a few V2 cells exhibit shifts indicative of true relative disparity (i.e., shifts equal to background shift). The distribution of these absolute and relative disparity responses in V2 is unknown. However, given the small number of true relative disparity responses in V2, such organization may not become evident until later processing stages (e.g., V4, MT). Although true relative disparity maps are not expected in V2, V2 activations are expected to be influenced by shifts in background.

As shown in Figure 12(a), a V2 disparity tuning curve shifts toward far if background shifts far (solid line) and shifts near if background shifts near (dotted line). Thus, at a fixed center patch disparity (vertical red line), the neuronal response should decrease for near shifts and increase for far shifts of the background (Figure 12(b)). Findings from one preliminary study have suggested this prediction is met (Figure 12(c)). Optical imaging of a thick stripe in V2 with a fixed center patch disparity (near +4) and different background disparities resulted in predicted decreasing activation values from far to near (imaged signal in three different disparity domains indicated by red, green, blue lines in Figure 12(c)). Thus, responses in V2 thick stripes exhibit some influence by shifts in background in a manner consistent with a degree of relative disparity tuning.

Summary

Together, these data suggest that topographic organization for near and far disparities may be established relatively early in the visual pathway, in V1 in the cat

Figure 12 Relative disparity in V2. (a) Disparity tuning curves of a relative disparity cell in V2. Tuning curves shift in direction of background shift. (b) For a fixed surface depth, shifting background from far to near should result in decrease of neuronal firing. (c) Reflectance amplitudes from three disparity domains (red, green, and blue) across shifts in background disparities from $-0.34°$ to $+0.34°$ far are consistent with predicted relative disparity response. Deg, degree; $-dR/R$, change in reflectance. (a) From Thomas OM, Cumming BG, and Parker AJ (2002) A specialization for relative disparity in V2. *Nature Neuroscience* 5(5): 472–478.

and in V2 in the macaque monkey. These data also suggest that the parameters of disparity and orientation in the thick stripes may be orthogonally represented. That is, within each orientation domain is a range of disparities, and within each disparity domain is a range of orientation representation. Further computational modeling may suggest how orientation and disparity maps are mutually arranged within V2. The overlap of orientation and disparity also suggests that orientation-selective domains within thick stripes are distinct from those in pale stripes. It is important that these data also raise the possibility that at least some aspects of the disparity organizations observed in MT derive from V2 and are not established *de novo* in MT.

V1 Sees Local, V2 Sees Global

The finding that V2 neurons are more strongly influenced by shifts in background disparity suggests that V2 encodes not simply the absolute disparity of a surface but, at least to some extent, the relative disparity. Thus, similar to the proposed view of V2 in color and brightness representation, these data are consistent with the encoding of what can be considered higher-order disparity processing in V2 and lower-order disparity processing in V1. Relative disparity signals may be important for figure–ground segregation, which suggests that V2 may be involved in coarse stereo vision.

Another example of V2's role in global perception is the presence of neurons in V2 which achieve disparity capture. The elements within the subjective figure are perceptually 'captured' and 'pulled' on the same depth plane as the figure. The phenomenon has been interpreted as the result of spreading of disparity signals from the subjective figure. In this sense, we consider disparity capture an illusory percept, one which is induced not by true disparity of elements on the surface but by disparity of distant features. In fact, some neurons in V2 have been reported to shift their disparity tuning curves in a manner consistent with disparity capture. If V2 encodes surface depth, then it is conceivable that such disparity capture responses may map to locations similar to those of the surface disparity responses. Again, to achieve such perceptual saliency, the V2's message (the entire surface is at the depth of the border) must somehow overcome V1's (the actual disparity of elements on the surface). This could occur via feedback projections from V2 to V1, resulting in relative suppression of V1. This possibility also remains to be examined.

Visual Contours

There are a myriad of contours in our visual world, some of which are defined by luminance contrast and many more which are defined by cues without luminance contrast. In addition to 'real' luminance-defined contours (sinusoidal grating or line grating), different texture patterns or abutting line stimuli can create strong percepts of borders or contours. These percepts can be perceived regardless of the orientation of the real line inducers (either with acute or obtuse inducers). Borders between motion fields can also produce very salient percepts of contours (motion contrast contours).

Cue Invariance

V2 neurons exhibit responses to so-called cognitive contours (also termed 'illusory contours'). Electrophysiological recordings of single units in V2 have demonstrated a population of cells that share tuning for orientations of both real and illusory contours (both abutting line and occluded contours). Optical imaging studies have demonstrated that orientation domains imaged in response to real contours (real lines or gratings) coalign with those imaged in response to illusory contours, suggesting the presence of higher-order orientation domains. Recent optical imaging studies in alert monkeys have also extended the invariance of response in V2 to include not only real (Figure 13(a)) and illusory contours (Figure 13(b)), but also motion contrast contours (Figure 13(c)). In V1, these studies reveal either a very weak (awake monkey) or an orientation-reversed (anesthetized monkey) response to illusory contours. This may be attributed to the difference in relative activation magnitudes in the alert versus the anesthetized states: V2 activation in the anesthetized monkey is typically weaker than that in V1 whereas it is at least as strong in the alert monkey.

V1 Sees Local, V2 Sees Global

The key observation is that real contours strongly activate both V1 and V2, whereas illusory contours (of several different types) elicit activation in V2 but not in V1. Thus while the 'essence' of the orientation signal is similar between real and illusory contours, the views in V1 and V2 of these two contour signals are quite different. The key point is that whereas V2 can readily distinguish the orientations of different types of contour stimuli, it is clear that V1 cannot distinguish the orientations of illusory contours. A corollary is that the encoding of contour type (real or illusory) cannot be accomplished by either V1 alone (signals either lack orientation contour or orthogonal orientation) or V2 alone (V2 cannot distinguish between real and illusory). Only with a paired V1 and V2 signal can the real versus illusory nature of a contour be decoded. Thus, both higher

Figure 13 Local and global V1–V2 networks inferred from cross-correlation studies. (a) Local networks are those that require spatially overlapping receptive fields. Such interactions are typically seen between orientation-matched cell pairs and between spatially overlapped nonoriented V1 and oriented V2 cells. (b) Global networks are those that do not require receptive field overlap. Strong interactions are typically seen between nonoriented V1 and nonoriented V2 cell pairs (surface–surface), oriented V1 and nonoriented V2 cell pairs (border–surface), and nonorientation-matched V1–V2 cell pairs.

and lower-order signals are necessary for proper contour identification.

Local versus Global Networks

How Is a Contour-Specific Paired V1–V2 Signal Achieved?

There is a broader view of V2 function which applies to the multiple feature spaces represented within V2. The view described earlier is a three-stage view of the relationship between V1 and V2. It is a framework based on both anatomical and functional connectivities between different types of V1 and V2 neurons. In brief, the first stage (V1) identifies elemental features such as local color, orientation, absolute disparity, and motion. The second stage (V1–V2 or intra-V2) involves surface-border capture, in which appropriate assignments of surfaces to borders and borders to surfaces are achieved. The third stage involves an competitive balance of feedforward and feedback interactions between V1 and V2. This is the stage via which global percepts might achieve dominance over local cues, perhaps via feedback from V2 to V1.

Based on cross-correlation studies of V1–V2 interactions, two types of V1–V2 networks may be described, one which subserves processing of local cues and another which is more global in extent. Based on approximately 250 recorded interactions between different cell types in V1 and V2 (e.g., oriented broadband, oriented color-selective, nonoriented broadband, nonoriented color-selective), two types of V1–V2 interactions have emerged. The local type of interaction requires spatial overlap of receptive fields. We have found that V1–V2 orientation-matched interactions, as well as some interactions between nonoriented color cells in V1 and oriented color cells in V2, are highly dependent on spatial overlap (Figure 14(a)). In contrast, interactions between nonoriented color cells and oriented cell pairs with nonmatching orientation selectivity do not require spatial overlap (Figure 14(b)). The interactions without spatial overlap may be mediated via extensive intra-V2 connections (stripe-to-stripe arrows in Figure 14(b)). Based on these recordings, it is hypothesized that the local interactions subserve local cue identification (e.g., local contour identification could arise via either Hubel–Wiesel-like integration of nonoriented input from V1 or feedforward of oriented signals already generated within V1). Global interactions subserve surface integration (integration and dissemination of surface feature information) as well as appropriate integration of surfaces and borders. This integration may involve surface capture (feedforward of surface-to-border signals via oriented V1 to nonoriented V2 interactions) or border capture. It is proposed that

Figure 14 Cue-invariant orientation domains in V2. (a) Different types of contour stimuli: sine wave gratings, line gratings, illusory contours with acute inducers, illusory contours with obtuse inducers, motion contrast illusory contours. (b) Orientation maps dervied from real lines (left) and from illusory contours (right). (a) From Lu HD and Roe AW (2007) *Response to Motion and Motion Boundary in Monkey V2*. Sarasota, FL: Vision Sciences Society. (b) From Ramsden BM, Hung CP, and Roe AW (2001) Real and illusory contour processing in Area V1 of the primate: A cortical balancing act. *Cerebral Cortex* 11: 648–665.

the larger global network within V2 is able to exert influence on the local network, resulting in context-dependent override. Although the mechanisms by which such override occurs are unknown, one possibility is that the strength and/or extensiveness of the global network in V2 results in activation of a suppressive feedback influence on V1.

A Competitive Balance

Based on these studies, a model of contour processing in early visual cortex has been proposed which comprises a competitive balance between feedforward V1–V2 and feedback V2–V1 influences (Figure 15). In this model, during real contour processing, the feedforward signals dominate and activate matching orientation domains in V1 and V2 (Figure 15(a), solid arrow). During illusory contour processing, feedback signals gain prominence and suppress domains which encode matching 'real' contour orientations

Figure 15 Depiction of feedforward versus feedback forces between V1 and V2. Color-coded orientation map in V1 and V2 (V1–V2 border and stripe borders are indicated). (a) Arrow depicts orientation-specific feedforward influence (local spatial network). (b) Dotted arrow depicts orientation-specific (local spatially localized network) feedback influence from V2 to V1. Solid arrows depict orientation-diverse and spatially extensive (global, spatially less restricted network) influence. Feedback activation is thought to differ between real and illusory contour stimulation. Real contour stimulus preferentially activates orientation-specific feedback (dotted arrow). Illusory contour stimulation preferentially activates orientation-diverse feedback (solid arrows). Scale bars = 1 mm (a, b).

(thereby leading to orientation reversal; Figure 15(b), dotted arrow). In this sense, there is a competitive process between real (feedforward, Figure 15(a)) and illusory (feedback, Figure 15(b)) signals. The perception of any contour would result from a competitive balance between these two orientation-selective forces.

This hypothesis has been tested using psychophysical methods. The reasoning is that if illusory contours activate suppressive feedback pathways, then adding a small amount of real input might push the balance in the feedforward direction. In other words, adding a real line on top of an illusory contour should change the balance. Increasing the contrast of this real line (from subthreshhold to suprathreshhold contrasts) should push the balance further in the feedforward direction and interfere with feedback-dependent illusory contour perception. Furthermore, since the original observation was one of orientation reversal in V1, the feedback interaction should act in an orientation-selective manner. In other words, it should matter whether the real line added is parallel or orthogonal to the illusory contour. Results support the predictions. Parallel lines had little effect at subthreshold contrasts but tended to interfere with discrimination at suprathreshold contrasts. This interference was orientation dependent, as orthogonal lines had no effect on discrimination at suprathreshold contrasts but interfered only at subthreshold contrasts. These psychophysical data thus support an orientation-specific and contrast-specific influence of real contours on illusory contour perception.

Summary

These studies provide further weight to the idea that V1 responds to local elements within the scene, while V2 encodes more global aspects. Relative to V1, V2 behaves in a more cue-invariant fashion. As summarized in Table 1, whereas V1 responds only to local luminance cues, thin stripes encode generalized brightness percepts. Whereas V1 encodes the orientation of only real contours, V2 exhibits cue-invariant encoding of contour orientation. Whereas V1 contains cells responsive to the disparity between pixels presented to the left and right eyes, whether they are the same or opposite in contrast, V2 contains a map of global coherent disparity response that a global coherent disparity that correlates with the perception near and far percepts.

This article (see Table 2) has summarized a body of evidence supporting the idea that each cortical area processes the visual world at a different spatial scale and, in that sense, 'sees' a different visual world. We suggest that these multiple views of the world compete with each other for dominance, perhaps via a competitive balance between feedforward and feedback signals between different cortical areas. This competition is necessarily context dependent and therefore dynamic. Additional studies in the awake, behaving preparation are likely to provide additional insight into the dynamic aspects of this proposed competition.

These studies have shown that the basis for some global percepts resides within 100–500 μm modules

Table 2 Local versus global competition

Why so many cortical areas?
Each area 'sees' different view
(V2 sees different things than V1 sees)
Which view dominates?

(Competition between V1 and V2 dominance)
Dynamic network of V1–V2 modules
Correlation with behavior

Figure 16 Modular basis of behavior. Higher-order percepts such as illusory contours, illusory brightness and color percepts, and stereo depth are encoded in 100–500 μm modules within specific V2 stripes. These modules include orientation domains (left, orange: horizontal; blue, vertical) in thick/pale stripes, 'brightless' modules (middle, red: modules responsive to real and illusory brightness modulation) in thin stripes, and stero depth modules (right, dotted box: all near (dark pixels) minus all far (light pixels)).

in V2 (Figure 16). Cortical modules clearly underlie not only encoding of elemental features such as contour orientation and color preference in V1, but also higher-order percepts such as illusory contour orientation, illusory brightness and color percepts, and stereo depth percepts. In relation to feedforward versus feedback competition, it is likely that in the awake, behaving brain, the relative dominance of V1 and V2 will be evident through the balance of V1 versus V2 modular networks.

Introduction

Of all the senses used by animals to gather critical information about their environments, vision is most important for providing rich, quick, and spatially detailed perceptual views of the surrounding world. In fact, it has been suggested that the first appearance of quality eyes in animals at the dawn of the Cambrian drove the rapid appearance of complex, formidable body plans as early invertebrates escalated their capabilities as long-distance predators – or as quick-evading prey. These eyes must have evolved from earlier sets of photoreceptors that had been devoted to sensing of light and darkness for photoperiodism, setting of circadian rhythms, simple orientation in a directional light field, or perhaps for the detection of shadows for the initiation of evasive responses. None of these functions demand much (or even anything) in the way of spatial resolution, but they provide a basic foundation for visual evolution. The formation of pigment cup eyes by adding receptor cells in a sheet to make a primitive retina and restricting how light reaches this retina by means of a surrounding pigment layer provided the likely ancestors of all eye types that animals use today.

Perhaps because some invertebrates still resemble the ancestral forms of all modern animal diversity, it is often thought that invertebrate neurobiology, and specifically invertebrate vision, is simple, primitive, and relatively ineffective. If anything, the opposite is true. Modern invertebrates have an equally lengthy evolutionary history as any other animal, and being generally small animals with compact nervous systems, their eyes must be extremely efficient at providing critical information. As will be demonstrated in this article, eyes found in one or another species of invertebrate outperform those of any vertebrate species in virtually any measure of visual excellence. In this article, we describe visual systems of invertebrates, starting with the pigments on which vision is based and then proceeding to receptor cell types, eye design, visual function and processing, and higher level aspects of vision.

Invertebrate Visual Pigments

General Properties of Visual Pigments

The basis of any visual system is the visual pigment, a molecule composed of a protein moiety (opsin) and a light-absorbing chromophore. Visual pigments are the photoreceptive molecules responsible for absorbing photons of light and transforming the energy into a cellular signal, initiating the visual cascade and resulting in a physiological response in the photoreceptor cell. The opsin component of the visual pigment is a G-protein-coupled receptor (GPCR) and thus a member of a large superfamily of receptors with similar protein structures. All GPCRs are composed of seven transmembrane α helices, with loops on both the extracellular and the cytoplasmic faces. The chromophore component, a derivative of vitamin A, is covalently attached to the opsin protein by a Schiff's base linkage to a conserved lysine residue in the seventh transmembrane helix. Within invertebrate visual systems, four different chromophores have been characterized, although the predominant chromophore is the A1 form, retinal.

Physiologically, visual pigments are characterized by the wavelength of maximal absorbance, which is determined by the interaction between the opsin protein and the chromophore. Therefore, the spectral absorbance of a visual pigment can be altered, or tuned, either by amino acid replacements, particularly at residues within the chromophore-binding pocket, or by the form of chromophore used. The diversity of invertebrate opsin amino acid sequences in combination with different chromophores has produced a vast range of visual pigment types and color vision systems, particularly within the arthropods, in which visual pigment spectral sensitivities range from deep in the ultraviolet (below 340 nm) to well into the red (600 nm or longer).

Opsin Evolution, with Special Reference to Invertebrates

The first invertebrate species from which the opsin gene was sequenced was *Drosophila melanogaster*, followed much later by sequences from the horseshoe crab *Limulus polyphemus* and then by a flood of data from various arthropods, mollusks, and other invertebrate taxa. Although numerous opsin genes related to visual pigments with a large diversity in spectral absorbance were found in *D. melanogaster*, limited sets of one or two opsins with similar spectral sensitivities are sometimes found in other arthropod species. In fact, many invertebrates have visual systems based on single opsin genes, as is the case for most cephalopod species investigated. Interestingly, although most cephalopod species are thought to lack color vision, in the Japanese firefly squid *Watasenia scintillans*, three different visual pigments have been identified with different spectral properties

based on pairing different chromophores with presumably a single opsin gene. However, most color vision systems in invertebrates are based on variations in the opsin protein.

During the course of metazoan evolution, opsin genes have diversified in relation to visual systems and color vision at least two times, once in arthropods and once in vertebrates (Figure 1). In both of these diversifications, gene duplications have led to multiple spectral classes of visual pigments, with arthropods having three main groups related to spectral tuning of the visual pigment – long wavelength, blue, and ultraviolet. This visual pigment spectral diversification based on opsin gene duplications has led to arthropods' having an enormous diversity of visual systems. The opsin diversity observed in *Drosophila*, and in most hexapod species, fits well with previous hypotheses that the ancestral Mandibulata, a taxonomic group uniting Crustacea, Hexapoda, and Myriapoda, was trichromatic, possessing ultraviolet-, blue-, and green-sensitive visual pigments.

Special Features of Invertebrate Visual Pigments

The independent evolutionary diversification of the visual pigments in different opsin lineages has shaped the general functioning of invertebrate visual systems, which is quite different in many aspects from the better understood vertebrate visual cascade of cellular signaling. In contrast to vertebrates, invertebrate opsins form visual pigments that have a light-activated conformation – metarhodopsin – that is thermally stable (Figure 2). The metarhodopsin state has an absorption maximum that is spectrally shifted relative to the rhodopsin and can be reconverted to rhodopsin with the irradiation of light of appropriate wavelengths. The presence of arrestin, a protein involved in deactivating

Figure 1 Invertebrate and vertebrate opsin evolutionary relationships reconstructed using maximum likelihood analyses of amino acid sequences from representative species from each spectral group. The spectral range of each clade is indicated as follows: LWS, long-wavelength sensitive; MWS, middle-wavelength sensitive; SWS, short-wavelength sensitive; UVS, ultraviolet sensitive. The vertebrate rod opsins are designated by Rh. Note that the rhabdomeric and ciliary opsin sequence types form two distinct clades. Diversification of opsin genes into multiple spectral classes can be observed in both the arthropod and the vertebrate visual pigment groups. A gray triangle at the end of a branch indicates that opsin sequences from this group have been isolated from a diversity of different species.

Figure 2 A typical bistable visual pigment system, in this case from the hermit crab *Petrochirus diogenes*. The absorbance of the visual pigment, or rhodopsin, has been normalized to 1.0. The spectral absorbance curves, obtained directly from individual photoreceptors, have been plotted as a thin, jagged line (rhodopsin) or as a dotted line (metarhodopsin). The thick, smooth line is the theoretical spectrum of a visual pigment and has been fit to the data for the rhodopsin. Note that the metarhodopsin absorbs generally at shorter wavelengths than the rhodopsin, and that its peak absorption is approximately 40% higher than that of the rhodopsin.

the light-activated form of rhodopsin, appears to play a role in extending the lifetime of metarhodopsin, allowing a second photon of light to convert metarhodopsin back to the original pigment state.

Unique features of invertebrate visual pigments are also found in chromophore–opsin interactions. In vertebrate visual pigments, a glutamic acid in the third transmembrane helix serves as a negative counterion to the positively charged chromophore. In contrast, most invertebrate pigments contain noncharged amino acids – either a tyrosine or a phenylalanine – at this same position. However, all visual pigments (whether vertebrate or invertebrate) have a conserved glutamic or aspartic acid in extracellular loop 2, which has been suggested to act as the invertebrate visual pigment counterion and may be the ancestral counterion for all visual pigments.

In general, invertebrate visual pigments are associated with rhabdomeric photoreceptor cells, whereas vertebrate visual pigments are associated with ciliary photoreceptor cells. Furthermore, invertebrate visual pigments typically activate the Gq class of G-proteins, leading to a depolarization of the receptor cell, whereas vertebrate visual pigments activate transducin, leading to a hyperpolarization of the cell. However, although it is true that most visual systems in invertebrates are based on rhabdomeric photoreceptor cells, both photoreceptor cell types and, therefore, opsin types are found throughout animal evolution, indicating that at some point an ancestral metazoan contained two different types of photoreceptor cells, each expressing a different copy of the opsin gene. Within most invertebrate lineages, the rhabdomeric photoreceptors and the associated opsins diversified into the visual pigments, whereas the ciliary photoreceptors and opsins were used in nonocular photoreception systems or took on as yet unidentified functions.

Invertebrate Photoreceptor Cells

Visual pigments, being GPCRs, are confined to the membranes of photoreceptor cells. Consequently, since visual cells generally must be effective photon catchers, their membranes are typically highly proliferated to insert as much visual pigment as possible into the arriving photon stream. As already noted, these receptor cells fall into two classes, each associated with one of the two types of opsins. Most invertebrates are now thought to use both opsin types and thus both receptor designs. However, all examples of highly developed visual systems among invertebrates are based on rhabdomeric photoreceptors. Therefore, this stands in stark contrast to the vertebrates, all of whom base their vision on ciliary photoreceptors. Most ciliary photoreceptors of invertebrates that have been studied seem to be used for sensing of light related to circadian function or other, similar nonvisual tasks.

Within the proliferated microvilli that are so characteristic of rhabdomeric receptor cells, absorption dipoles of the chromophores in visual pigments are generally aligned roughly parallel to the microvillar axis. Because most photoreceptive microvilli are shaped into straight tubes built around a stiff actin core (Figure 3), the visual pigments of a single microvillus are all oriented in more or less the same way. Furthermore, since each visual pigment molecule preferentially absorbs photons when the electric vector of polarization (the *e*-vector) of the photon is parallel to the chromophore's absorption dipole, the entire microvillus responds sensitively to the plane of polarization of incoming light. Photoreceptor cells of many invertebrate species are built specifically to enhance this inherent property. Microvilli are aligned parallel along the length of the cell, with their axes extended across the rays of light entering the eye. Consequently, the entire cell responds as a polarization analyzer, a property that permits orientation to natural polarized light fields. Moreover, if two or more classes of analyzers can be combined in a single retina, the visual system has the potential to see polarization patterns in the environment. A number of species of crustaceans, for example, have found a way to do this particularly elegantly. The microvilli of a ring of photoreceptor cells extend into a central fused photoreceptor, or rhabdom; and together the cells form two populations having perpendicular sets of microvilli (Figure 3). The microvilli of the two

Figure 3 Electron micrograph of microvilli from several individual photoreceptor cells in a single rhabdom of a mantis shrimp, *Neogonodactylus oerstedii.* The microvilli are in alternate layers, with those of successive layers facing parallel to the plane of the section (seen as long thin tubes) or perpendicular to it (seen as circular cross sections). This arrangement is ideal for a two-axis analysis of polarization since the absorption dipoles of visual pigments in microvilli are typically parallel to the microvillar axis. The arrowheads indicate actin fibers that serve as a skeletal framework for each microvillus. Photo CA King-Smith.

populations extend laterally into the rhabdom in a series of layers. Each layer's microvilli are orthogonal to those above and below, so the rhabdom as a whole encodes polarization information arriving from one point in visual space. The entire retinal array of receptors is therefore well suited to see polarization throughout the entire visual field. Other major invertebrate groups known to sense polarization include insects, mollusks, and echinoderms.

Invertebrate Eyes and Visual Optics

The simplest possible photoreceptive organ that can properly be called an eye must have three components: an array of at least a small number of photoreceptor cells, a surrounding shield of opaque pigment to block most light from reaching this retina, and a restrictive aperture or opening in the pigment shield that allows the retina to be illuminated from some part of the visual surround. Eyes like these exist in many small and simple invertebrate animals (e.g., jellyfish and flatworms), in which they are called pit eyes or eyecups. 'Cup' is a good literal description because the retina often extends along the bottom of an invaginated space that is surrounded by cells containing black pigment, and the opening of the cup admits light. These eyes obviously have terrible resolution, but they can distinguish the general direction of illumination (useful for orientation), they can provide a measure of light intensity and its sudden changes, they can in principle detect the movement of a shadow or edge, and (if the opening to the cup is fairly small) they can encode the general distribution of light and dark in the region being viewed. This is a lot of information for any nervous system to process, and it is likely to be all that a simple animal really needs to know.

The complex eyes present in almost all higher animals, invertebrate or vertebrate, certainly originated from cuplike eyes, although it is still a matter of debate whether these can all be traced back to a single ancestral organ. More likely, photoreceptors did arise from a primordial photoreceptive cell, but pit eyes independently appeared many times, and some of these served as the ancestors of superb eyes whose designs survive today. The most successful eye designs, based on the numbers and diversity of species bearing them, are compound eyes and lens (simple, or camera) eyes. Figure 4 illustrates diagrammatically how each can be derived readily from a pigment cup ancestor, and these two eye designs (and other rare and odd ones) are discussed in detail in the following sections.

Simple Eyes

Adding a surface covering (which often is present over pigment cups anyway) and a roughly spherical lens converts the pigment cup to a lens eye (Figure 4). Evolutionary modeling suggests that the process could occur in less than 1 million years, a result that supports the view that complex eyes might well have arisen many times from simpler ones. Lens eyes are often called 'camera eyes' because their operating principles are similar to photographic cameras, having a pigment-lined chamber, a retina in the back (where the film or CCD would be in a camera), and a lens in front; often, there is also a diaphragm or iris to control the amount of light reaching the retina (not shown in Figure 4). A similar eye type, although different in optical details, uses the corneal surface instead of an internal lens to form the retinal image. Since the ability to refract light at a surface relies on a sudden change in refractive index, eyes that rely on corneal refraction are effective only in air; water and typical living tissues are too similar in refractive index for good imaging. High-quality, simple eyes based on corneal or lens refraction are extremely widespread among invertebrates, being found in jellyfish, polychaetes, mollusks, and arthropods (as well as throughout the vertebrates).

Even tiny lens eyes can be optically excellent. Spherical lenses, the easiest to develop, have a number of inherent optical aberrations, but animals counter the most serious of these by controlling variations in the density of the lens material in layers within the lens. As a result, many biological lenses approach the theoretical limits of perfection, at least on the optic axis. By far the largest lens eye in existence occurs in

Figure 4 A schematic demonstrating how a pigment cup ancestral eye could be modified either to form a simple, or lens, eye by adding a cornea and a lens or to make a basic compound eye by multiplying in number, extending the pigment sheath upwards, and grouping into a geometrical array.

an invertebrate, the giant squid *Architeuthis*, in which they are approximately 25 cm in diameter – larger than a soccer ball. In principle, these eyes have the best resolution of any eye, although this might be compromised by pooling of receptors for sensitivity in the dim-light environment which these deep sea animals inhabit. Lenses of eyes of cubomedusans, jellyfish without even a central nervous system, are optically excellent, although the retina in these eyes is not placed at the lens's focal plane. The lens eyes of cubomedusans and giant squids cover the range of eye sizes for camera-type eyes, but there are some copepod crustaceans in which the lens is separate from the retina (thus not forming a chambered, camera-type eye) where the lenses are truly tiny – less than 150 μm in diameter.

Compound Eyes

In all likelihood, compound eyes also have arisen independently several times because they are present in such disparate invertebrates as tubeworms, clams, and arthropods. Basic compound eyes can be built simply by grouping pigment cups into an array of multiple tubes, each facing in a different direction (Figure 4). In essence, this is the modern form of the compound eyes occasionally found in annelids or mollusks, in which no other optics are present (however, some worm compound eyes do have simple lenses added). These eyes simply multiply the function of single pigment cups to add some basic spatial information about the distribution of light and shadow and its changes. Optically excellent compound eyes are found only in the arthropods, where they occur widely (in crustaceans, insects, xiphosurans, as well as in the extinct trilobites, eurypterans, and other arthropods). Surprisingly, the optical principles on which these eyes depend are fundamentally different, making it difficult to understand how the various types have arisen from what was presumably a single ancestral type. The most ancient eyes for which the optics are well understood are the compound eyes of trilobites (Figure 5), and in some species these incorporate quite sophisticated optics with unusual features to control aberrations.

Compound eyes have limited resolution since each corneal facet usually corresponds to a single imaging element, and no compound eye has more than a few thousand elements (or ommatidia). Nevertheless, they are obviously very successful, being the type used by the vast majority of animal species. They provide decent modular, panoramic vision, which is probably all that arthropods require. The compound eyes of modern arthropods fall into two optical types. The simpler design is called an apposition compound eye. Here, each corneal facet forms an image onto a single photoreceptor, or rhabdom, within the same ommatidium. These eyes are capable of quite good resolution but often have very limited sensitivity because light is usually collected over a tiny aperture (i.e., the diameter of one facet). Such eyes exist in bright-light, diurnal arthropods such as butterflies, bees, and shore crabs. Superposition compound eyes improve image brightness on the array of rhabdoms by pooling the light from a large number of corneal facets and focusing it on the retina. Here, the images from different facets all overlie images from other facets (hence the name superposition); image sharpness generally suffers, but sensitivity is high. Such eyes are appropriate for dim-light vision and are found in moths, mayflies, and many deep-sea crustaceans. In most cases, the superposition image forms either from refraction within optical elements near the cornea, making what is known as a refracting superposition eye, or by reflection from biological mirrors forming square mirror boxes below the cornea, making a reflecting superposition eye. However, other designs with quite exotic optics also exist.

Other Optical Designs

Because invertebrates are quite diverse in evolutionary ancestry, body plan, and habitat, it is logical that some species should have quite odd eyes. Of these, perhaps the most normal-looking are pinhole eyes, which are nothing but eyecups that have become nearly closed off at the entrance, providing a dim but reasonably sharp image. The best known examples are from the deep-sea *Nautilus*, in which the

Figure 5 A fossilized compound eye of a trilobite, *Phacops rana*. This very well-preserved right eye is suitable for reconstruction of the visual fields of the animal when it was alive, during the middle Devonian period (approximately 350 My before present). This type of eye is called a schizochroal compound eye, and it contains many fewer ommatidial units than the other type found in trilobites, the holochroal compound eye (which is more similar to modern compound eyes). In schizochroal eyes, each large lens probably collected light for a miniature retina, so the entire visual field was possibly reconstructed by patching together miniature subfields within it. Schizochroal eyes apparently represent an evolutionary experiment that ended with the trilobites.

pinhole eye is as large as the lens eyes of their octopus and squid relatives. Some invertebrate eyes look superficially like lens eyes, but the image is actually formed by a mirror behind the retina; the best examples occur in scallops, bivalves whose mantles are lined with dozens of tiny eyes whose mirrors reflect bright blue light. These eyes are not very different from eyecups, or from basic lens eyes, and since many lens eyes have a mirror (tapetum) behind the retina, it is not difficult to understand how an eye with an imaging mirror could evolve. Other unusual invertebrate eyes employ multiple lenses in series, much like a well-engineered camera lens, or have strangely modified compound eyes with a single large lens included in the array.

Visual System Properties

Behind the retina, most invertebrates have successive layers of nervous tissue to process incoming visual information. The details of how this processing is done rely on fundamentally different principles in different groups of invertebrates, and in most cases little is known of how the processing progresses. The best understood systems by far are those of flies, which have served as general models for visual processing in animals as well as models for artificial visual systems or for visual devices designed to control robots. Since most, but not all, invertebrates are small and have relatively small brains and optic ganglia, the hope has been that research to understand how they work should succeed. In fact, imaginative laboratory approaches have often been successful, but many laboratories headed by first-rank researchers have been employed for this success. Small invertebrates can still be fast-moving and behaviorally complex biological machines. In one or another species, invertebrate eyes are more competent than any vertebrate visual organ in sensitivity, resolution, color vision, and polarized light vision. The view that invertebrate eyes are simple is itself simple-minded.

Vision in Dim Light

Visual systems are pushed to their limits in dim-light environments, in which any limitations in optical or phototransductive systems can lead to completely inadequate performance. It is therefore safe to state that the visual systems that exist in animals living in caves, the deep sea, or nocturnal environments under forest canopy have evolved from bright-light ancestors. Extreme visual sensitivity generally implies large eyes, not available to small animals such as most invertebrates, although it has been claimed one huge invertebrate, the giant squid *Architeuthis*, has the most sensitive eyes (as well as the largest) alive today. Surprisingly, however, small deep-sea invertebrates, nocturnal hunting spiders, and night-flying forest insects all have rather small eyes with excellent dim-light vision. In fact, the eye with the highest sensitivity that has been documented in the literature is the apposition compound eye of a deep-sea isopod (a crustacean), *Cirolana borealis*. Recall that apposition compound eyes are typically the least sensitive design, so *Cirolana*'s extreme performance is a surprise. Deep-sea crustaceans in general have excellent light-gathering ability, feeding their rhabdomeric photoreceptors with sufficient photons to see light coming down from the surface at depths of 1000 m or more.

Some of the terrestrial environments with the most light-limited conditions are found under thick forest canopy at night, where on a cloudy night a human can see literally nothing at all. Some species of bees forage here at night, although they do prefer to fly at dawn or dusk rather than at midnight. These insects also have apposition compound eyes, which are optically modified for extreme dim-light performance using large corneal facets with relatively short focal lengths, producing a brighter image than a typical bee eye and falling on a markedly larger rhabdom. Optics alone are not enough, and sensitivity is further boosted by pooling signals across ommatidia (spatial summation) and by increasing photoreceptor integration time (temporal summation). These neural strategies require compromises in acuity and temporal resolution (both

important for flight), but modeling shows that highly adequate resolution both in time and in space can be achieved with careful tuning. As described next, compound eyes (in these cases, of superposition design) can also support polarization and color analysis at night in some insects.

Color Vision

Color vision refers to the ability to discriminate based only on spectral differences between stimuli that differ in no other property. This ability is thought to be widespread among invertebrates, but convincing behavioral demonstrations of its presence have only been documented for arthropods – flies, bees, butterflies, moths, crabs, and mantis shrimps. Color vision in invertebrates is often based on a large diversity of receptors, from probably two types in crabs to three in honeybees and hawkmoths, five in some swallowtail butterflies and possibly flies, and eight or more in mantis shrimps. Color processing is quite well understood in honeybees (in which it is almost as well studied as in primates or other mammals) and, to a lesser extent, in flies and butterflies, but high-level or central mechanisms of color vision have not been studied otherwise, at least not physiologically. Considering the receptor diversity that can contribute to systems of color vision, mechanisms of central analysis are very likely to be rather variable among taxa.

For invertebrates that see in color, identifying objects (e.g., potential mates, food sources, or host plants for egg deposition) can be simplified because color is generally a more reliable property of a surface than brightness. As is implied by the list of arthropod species with color vision, flower identity is often particularly important. Similarly, animals with color vision very often have communication systems that rely on color signals; butterflies and mantis shrimps are particularly colorful animals, and the colors are incorporated into signals that may have very specific significance. In general, however, color signals (either intraspecifically or interspecifically, as with flowers) are not useful until color vision evolves for other purposes, perhaps to expand the range of spectra sampled, to cancel out problems caused by intensity variations, or to improve discrimination of objects in general.

Polarized-Light Vision

Visual systems in some vertebrates are able to sense the polarization of the sky or underwater environment, and a large number of insects use skylight polarization patterns for orientation during foraging or migration. Invertebrates have a natural advantage for seeing polarized light because of their microvillar photoreceptors (Figure 3). Besides this general navigation ability, a few invertebrate species have been demonstrated to visualize patterns of polarized light, an ability sometimes called polarization vision. This kind of polarization analysis is in many respects like color vision because it allows the discrimination of objects and object properties that would otherwise be confused. Reflections of polarization patterns are unlike color patterns in important ways, however. Polarization can vary strongly with direction of illumination, orientation of the reflecting surface, and position of the viewer and therefore is not a reliable property of an object. Despite this, the ability to discriminate patterns of polarization in visual scenes can be very useful to an animal. Polarization does indicate the orientation of a surface, and many insects use this to look for the horizontal surfaces of natural waters and perhaps for those of leaves or other shiny objects. Underwater, using polarization vision can help animals see farther and can make otherwise well-camouflaged organisms discriminable; this probably explains why many species of cephalopod mollusks (octopus, squid, and cuttlefish) use only polarization vision, having no sense of color.

Research shows that, most surprisingly, many invertebrates use polarization patterns on their own bodies as signals, analogously to color signals. Unlike passive reflection of polarized light, these signals often maintain a nearly constant polarization appearance as lighting or body orientation shifts, making them very reliable as intraspecific signals. The optical mechanisms used to make these polarization-constant signals are diverse and poorly understood. Most invertebrates that use polarized-light signals live in the sea, but some tropical butterflies also signal using polarized light.

Conclusions

Visual systems of invertebrates are surprisingly diverse, with many optical designs having been derived from simple eyecup ancestors. Many invertebrates that are small and have limited nervous processing power have highly competent visual abilities, with outstanding dim-light performance, color vision, and ability to see patterns of polarized light. Invertebrate visual systems are important in research not only for their significance to general biological processes but also as models for biomimetic imaging devices.

Visual System: Multiple Visual Areas in Monkeys

D J Felleman, University of Texas Medical School, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Historical Overview of Visual Cortical Organization

The earliest views of the organization of visual cortex in monkeys relied on architectonic and lesion–behavior methods to identify the location, extent, and number of cortical areas involved in visual processing. The architectonic method subdivides cortex according to the laminar densities and sizes of neurons as determined through Nissl stains as well as the distribution of myelin. Using this approach, in conjunction with behavioral studies following surgical lesions or trauma, visual cortex in the occipital lobe was divided into three zones; primary visual cortex, area 17; a parastriate belt, area 18, often referred to as visuopsychic cortex; and a peristriate belt, area 19. Subsequent electrophysiological mapping, single unit functional studies, and additional architectonic studies have further subdivided areas 18 and 19 into a large number of occipital visual areas.

Behavioral lesion studies extended the traditional view of visual cortex to include portions of the temporal and parietal lobes. Lesions of the temporal lobe were found to produce a type of visual agnosia characterized by loss of ability to recognize objects or their significance. Anterior, as compared with posterior, temporal lobe lesions also tended to produce impairments in visual learning. Architectonic studies of ventral temporal cortex identified large regions of the inferotemporal gyrus (ITG) as Brodmann's areas 20 and 21 or as von Bonin and Bailey's area TE. In a parallel study of the baboon, a posterior portion of TE at the anterior border of the occipital cortex was identified as area TEO. Behavioral lesion studies of parietal cortex also demonstrated visual disturbances following lesions of the inferior parietal lobule in the region now known as area 7a and/or LIP. These lesions produced deficits in visual orientation and reaching. Similar lesions in humans produced a form of visual neglect that led investigators to believe that the parietal lobe played an important role in spatial mapping or perhaps attention.

Overall, behavioral studies, later supported by electrophysiological investigations, led to the idea that visual cortex consists of two distinct processing streams with differential contributions to vision. The ventral, 'what,' stream, leading into the temporal lobe, was thought to subserve visual object recognition and memory, while the dorsal, 'where,' stream was thought to subserve visual spatial abilities. While early investigators attributed these two cortical streams to the two major retino-geniculo-cortical pathways that are subserved by the parvocellular and magnocellular layers of the lateral geniculate nucleus, more recent analyses have demonstrated that these two pathways, in addition to the konicellular pathway, contribute to the activity of the ventral, temporal stream. Although area MT, a prominent member of the dorsal stream, is dominated by direct magnocellular inputs, this dorsal, 'where,' stream also receives parallel contributions from these three geniculate streams. Furthermore, multiple subdivisions of the pulvinar nucleus contribute projections throughout visual cortex, thus providing still another parallel subcortical stream of input to visual cortex.

Modern Methods to Study Visual Cortical Organization

The traditional views of visual cortical organization derived from architectonic and lesion–behavior studies have been supplemented over the past decades by a number of technical advances including microelectrode topographic mapping, single unit electrophysiological investigations of neuronal function, neuroanatomical pathway tracing, modern architectonics–chemoarchitectonics, refined behavioral analyses following cortical lesions, reversible inactivation or microstimulation, and functional magnetic resonance imaging (fMRI). These methods have allowed for the identification of visual cortical areas based on up to five major criteria; architectonics, topographic organization, cortical connectivity, receptive field (functional) properties, and behavior contribution–defects following inactivation. As summarized in Table 1, most cortical subdivisions have not been evaluated using all these criteria. Thus, cortical subdivisions differ in the degree to which they are recognized as functionally specific areas (designated A in Table 1) that are identified by convergent information from two or more of these five criteria or recognized as cortical zones (indicated by Z in Table 1) identified by only one or two criteria. Moreover, different cortical subdivisions have been identified using different criteria across laboratories, resulting in a lack of total consensus on the number and organization of visual cortical areas or zones. Nevertheless, there is widespread consensus that macaque visual

cortex consists of a large number of areas (and zones) that occupy more than 50% of the cortical surface in the occipital, temporal, parietal, and frontal lobes.

Significant progress in the identification of visual cortical areas has been achieved through standardized methods for visualization of anatomical and physiological data on three- and two-dimensional reconstructions of the cortical surface. For example, computer-assisted mapping of cytoarchitecture, myeloarchitecture, and immunoreactivity for SMI-32 and CAT-301 has led to a high-resolution atlas CARET (the Computerized Anatomical Reconstruction and Editing Toolkit) that allows for the analysis and communication of anatomical and physiological data in macaque monkeys as well as in humans. Recent progress in understanding the organization of visual cortex in macaques has come from functional imaging studies (mostly fMRI) that derive the topographic organization of retinotopic areas and the function of areas from indirect estimates of cortical activity based on changes in blood oxygenation and/or blood flow. Issues of cortical organization span many different levels of analysis, ranging from columnar organization and modular organization to areas and processing streams. Each of these levels of organization is best studied using a subset of available tools. For the analysis of cortical areas described here, architectonics, microelectrode mapping and functional studies, and functional imaging methods provide the best indicators of visual cortical area extent and function (see Figure 1).

Occipital Lobe

Area V1

Macaque occipital lobe contains at least ten distinct cortical subdivisions based on two or more key criteria. Primary visual cortex, V1, has a distinct laminar appearance and is perhaps the best-studied cortical subdivision in this species. V1 is characterized by a unique elaboration of layer 4 into a constellation of sublaminae that are well correlated with the pattern of thalamic inputs and intracortical projections. The supragranular layers of V1 are also characterized by a distinctive pattern of cytochrome oxidase blobs that receive direct thalamic input and are correlated with high incidence of color selectivity and low incidence of orientation selectivity. In contrast, cells in the supragranular layers corresponding to the interblob regions are orientation-selective and are spatially organized into distinct orientation pinwheels originating from nonoriented pinwheel centers.

V1 inputs from the lateral geniculate main and intercalated layers establish three parallel streams that convey different types of information. Intracortical circuitry re-orders these three parallel streams, and outputs to higher cortical areas no doubt reflect this intracortical integration. Cortical outputs of V1 arise from layer 4B (dominated by magnocellular lateral geniculate nucleus inputs), from the cytochrome oxidase blobs, and from the interblob regions of supragranular V1. Therefore, the main functions of V1 appear to include (1) formation of binocular representation of the visual field; (2) intermixing of subcortical streams to form new cortical streams; (3) elaboration of spatially organized maps of contour orientation, ocular dominance, and perhaps spatial frequency; and (4) parcellation of information to three to five different extrastriate visual areas.

Area V2

Area V2 is a belt of cortex that nearly completely surrounds V1, with which it shares a common border representing the vertical meridian. V2 contains a full visual field representation, but it is split along the representation of the horizontal meridian such that the lower field is represented in dorsal cortex and the upper field in ventral cortex. Like V1, V2 has a distinctive modular architecture that can be recognized in tissue stained for cytochrome oxidase. V2 is organized into repeating triplets of cytochrome oxidase stripes: thick, pale, and thin stripes that have distinctive cortical connections and physiological properties. V2 thick stripes receive major input from cells in layer 4B of V1, and its neurons tend to be disparity-selective and exhibit length suppression. V2 pale stripes and thick stripes contain orderly representations of contour orientation that can readily be visualized with intrinsic optical imaging. In contrast, V2 thin stripes receive the majority of their input from V1 blob neurons, and their neurons are selective for the surface properties of color and brightness of objects. Furthermore, optical imaging has revealed systematic maps of hue and luminance change within V2 thin stripes. V2 has a dense set of projections to higher cortical areas that arise from specific stripe

(b) Locations of visual areas of macaque monkeys displayed on an unfolded representation of cortical layer 4 generated using the Computerized Anatomical Reconstruction and Editing Toolkit software system. The delineation of areas is based on the architectonic studies of Lewis and Van Essen as well as on a large number of studies of cortical connections. Adapted from Lewis JW and Van Essen DC (2000) Mapping of architectonic subdivisions in the macaque monkey, with emphasis on parieto-occipital cortex. *Journal of Comparative Neurology* 428: 79–111.

compartments and thus distributes subsets of information to specific cortical areas. Thus, for example, V2 thick stripes project primarily to areas V3 and MT, with weaker projections to V3A. In contrast, V2 thin and interstripes project primarily to area V4 and TEO (PITv). For the most part, V4 projections to other cortical areas have not been characterized by their stripe compartment of origin.

Areas V3 and VP

Anterior to V2 is another belt of cortex that contains a representation of the visual field that is split along the horizontal meridian. This belt of cortex contains a number of anatomical and physiological asymmetries that have led some investigators to consider the dorsal and ventral halves to represent distinct visual areas. According to this view, dorsal cortex contains a representation of the lower visual field in area V3, which is characterized by a dense myeloarchitecture, distinct V1 inputs arising from layer 4B, and a high degree of direction selectivity and low incidence of color selectivity. In contrast, area VP, in ventral cortex, contains a representation of the upper visual field, is less highly myelinated, is reported not to receive substantial V1 inputs, and has a high incidence of color selectivity and a low incidence of direction selectivity. Some researchers considered the anatomical and functional differences between the dorsal and ventral halves of this cortical belt to be sufficient to warrant their distinction as separate cortical areas. An alternative approach, adopted by other investigators, is to recognize these dorsal–ventral asymmetries by recognizing distinct asymmetries within a single visual area and distinguishing these subdivisions as areas V3d and V3v. Functional imaging indicates that V3, but not VP, contains a high concentration of disparity-selective neurons.

Area V3A

Area V3A is located anterior to V3 on the anterior aspect of the annectant gyrus and posterior bank of the prelunate gyrus. V3A is distinguished from its surrounding cortical areas in that it contains a complete representation of the whole visual field; its lower field vertical meridian representation adjoins V3 (V3d), and its superior vertical meridian adjoins the vertical meridian of area V4. Originally, V3A was described as a larger cortical domain that extended into the posterior portion of the intraparietal sulcus at its junction with the parieto-occipital sulcus. However, more-recent investigations have suggested that the 'second' central field representation within this larger V3A belongs to a distinct visual area currently identified as the posterior intraparietal area (PIP) or the lateral occipitoparietal area (LOP). V3A receives feedforward input from areas V2, V3, and VP and provides feedforward input to areas V4, MT, and several subdivisions of the temporal and parietal lobes. Like V3, area V3A appears critical for binocular disparity analysis.

Area V4

Area V4 is a large cortical area at the anterior margin of the occipital lobe that provides a major input to the temporal lobe and thus is considered a major gateway for the ventral, object processing, visual stream. V4 was first identified as a topographically organized visual area of dorsal occipital cortex that occupied a large callosal-free zone of the prelunate gyrus. This dorsal portion of V4 represents the lower visual field, and its ventral extension, just anterior to area VP, contains a representation of the upper visual field. V4 contains a representation of the visual field that is split along the horizontal meridian, and its posterior borders with V3A, dorsally, and VP, ventrally, represent the vertical meridian. While the extent of V4 in both dorsal and ventral cortex has remained controversial, its position within a dense callosal ring suggests that another visual area or areas are located anterior to V4, within the callosal-free zone. Since area V4 contains a split representation of the horizontal meridian, with its posterior border forming a representation of the vertical meridian, its anterior border should fall within this callosal-free zone. According to this view, an additional area, area V4A (or perhaps a pair of areas, V4Ad and V4Av), adjoins V4 along the representation of the horizontal meridian, and its anterior border corresponds to the representation of the vertical meridian coincident with the anterior callosal band. Subsequent microelectrode mapping and anatomical pathway tracer studies have indicated that a thin strip of cortex adjoins ventral V4 and contains a representation of the upper visual field that is distinct from that contained within ventral V4. Since there are only very limited anatomical or physiological studies of receptive field properties within this V4A strip, this cortical region is tentatively identified as separate dorsal and ventral subdivisions, areas V4Ad and V4Av. In ventral cortex, area V4Av borders posterior inferotemporal cortex along the representation of the superior vertical meridian. The organization in dorsal cortex appears more complex in that V4Ad appears to border area V4t along a noncorresponding lower field vertical meridian–horizontal meridian border. More centrally, V4Ad appears to border dorsal posterior inferotemporal

visual area PITd along the representation of the inferior vertical meridian. Taken together, areas V4, V4Ad, and V4Av provide a major route for visual information to reach the temporal lobe. Whereas early studies suggested that V4 was specialized for color processing ('the color area'), subsequent studies demonstrated a role of V4 in color, shape, disparity, and attentional processing.

Areas MT, V4t (MTc), MST Complex, and FST

One of the major targets of area V1 (layer 4B) is area MT, located in the posterior bank of the superior temporal sulcus (STS). MT is distinguished from other visual areas by its architecture, connections, and nearly complete dedication to motion processing. MT is a relatively small visual area with a complete visual field representation that contains a systematic mapping of the direction of object motion. Furthermore, a modular organization within MT segregates neurons by the degree to which their responses are antagonized by motion in their nonclassical surrounds. Evidence from owl monkey MT suggests that this modular organization is reflected in the pattern of outputs to higher areas such that cells with weak surround antagonism project to area MST, but those with pronounced surround antagonism project to area FST in the temporal lobe. Overall, area MT has major feedforward projections to adjacent area MSTd and to areas VIP and LIPd in the intraparietal sulcus. These parietal projections of MT are thought to subserve the extrapersonal space analysis thought to be an important part of the dorsal, 'where,' cortical processing stream.

Little is known concerning the cortical connections or physiology of area V4t (MTc) in macaques. V4t is generally though to contain only a representation of the lower visual field, and it adjoins MT along the representation of the lower vertical meridian. In owl monkeys and galagos, a topographically corresponding region, area MTc, has been described that nearly encircles MT and thus contains representations of both the lower and upper visual fields. Since the upper field portion of MTc is located dorsal and anterior to MT, it is reasonable to suggest that the upper field representation of area V4t is located medial and dorsal to MT in macaques. This would suggest that a portion of area FST is contained within V4t, and thus the organization of this cortical territory needs closer examination in macaques. V4t has dense connections with area MT and may provide a linkage between the 'dorsal' and 'ventral' processing streams since area MT has weak and/or inconsistent connections with area V4.

Area MT has major feedforward outputs that are directed to both parietal and temporal lobe visual areas that appear to utilize visual motion information for spatial and object processing, respectively. Area MT projects dorsally to the MST complex, which consists of three architectonically distinct subdivisions: area MSTda (the densely myelinated zone) area MSTdp, and area MSTm. Neurons in the MST complex are selective for more-complex forms of visual motion including optic flow and object structure from motion. These cortical subdivisions project to parietal areas 7a, LIPd, and VIP, as well as to posterior portions of multimodal cortex of the roof of the STS (STPp, including portions of TPOc, TPOi, and perhaps TPOr). The second major output of MT is directed anteriorly toward area FST on the floor of the STS. Area FST is architectonically distinct and contains motion-selective neurons that encode the shape of objects based on global motion and texture cues. Thus, area MT plays an important role in distributing visual motion information to parietal and temporal lobe areas involved in spatial and object processing.

Temporal Lobe

Historical Overview

The organization of visual cortex within the macaque temporal lobe has remained a topic of continued investigation for almost a century. Whereas classical architectonic studies suggested that the inferior temporal cortex consisted of one to three distinct subdivisions, subsequent architectonic and connectional studies have continued to distinguish additional subdivisions as well as to subdivide previously defined regions. Early architectonic studies of the temporal lobe concentrated on cortex of the ITG, which was subdivided dorsoventrally into Brodmann areas 20 and 21, with the whole of this region identified as area TE by von Bonin. The posterior portion of TE, adjacent to occipital cortex, was later distinguished as area TEO, based primarily on architectonic studies in chimpanzee or Brodmann's area 37 in human. Behavioral and electrophysiological studies have reinforced this distinction by demonstrating simpler receptive field properties in TEO and more learning- or memory-related functions in anterior portions of TE.

Modern architectonic studies have identified both dorsoventral and anteroposterior differences within TE that distinguish areas TE1, TE2, and TE3. Furthermore, the architectonic analysis into the lateral bank of the STS identified three striplike cortical bands, TEa, TEm, and IPa, that run from near the lip of the ITG to the fundus of the STS. This region was first considered visual on the basis of connections with visual areas of the ITG. Finally, additional architectonic subdivisions of the temporal lobe on the

parahippocampal gyrus, areas TF, TL, and TH and the anteriorly situated perirhinal cortex (areas 35 and 36), were also considered visual on the basis of connections with visual cortical areas.

Posterior ITG

Current ideas concerning the organization of visual areas in the temporal lobe are based primarily on anatomical studies of neural connections, single unit recordings, and functional imaging studies in anesthetized and awake animals. The posterior portion of inferotemporal cortex, previously described as area TEO, is now thought to consist of at least two dorsoventrally distinct subdivisions, areas PITd and PITv. Furthermore, TEO traditionally was thought to adjoin occipital cortex along the anterior border of V4 at the representation of the horizontal meridian. However, based on receptive field mapping, callosal connections, and intracortical connections, two small visual areas, V4Av and V4Ad, are thought to separate V4 from temporal lobe cortical subdivisions. The distinction of PITd from PITv is based on both receptive field topography and cortical connections. PITd is located within the lateral bank of the STS anterior to area MT and medial to area PITv, which is located only on the ITG. Thus, traditionally defined TEO appears to consist of four different cortical areas, although they have yet to be distinguished using architectonic criteria. Microelectrode and functional imaging studies have demonstrated that areas PITv and PITd (TEO) contain neurons that are selective for the spatial configuration of two-dimensional objects and PITv may also be particularly involved in color processing. Finally, a broad swath of cortex of the parahippocampal gyrus, medial to ITG areas PITv and CITv (see below), have been identified architectonically and considered visual on the basis of cortical connections. Although some controversy remains concerning the precise number, architectonic fields TL, TF, and TH have been recognized here. Furthermore, more posterior cortex of the parahippocampal gyrus, medial to area V4 (and perhaps VP) have been identified as occipital or posterior extensions of these more anterior parahippocampal areas and thus have been named TLp, TFp, and THp.

Central and Anterior ITG

Although it is widely agreed that there are multiple cortical subdivisions in central and anterior IT (area TE), there is little agreement on their number, location, or organization. Just considering the ITG, the existence of separate anterior and posterior subdivisions has been commonly accepted, beginning with the distinctions of TE1, TE2, and TE3. A slightly modified version of this scheme identified two subdivisions; posterior TE (TEp) and anterior TE (TEa), with their border falling roughly at the posterior end of the anterior middle temporal sulcus (AMTS). More recently, largely on the basis of cortical and subcortical connections, these two subdivisions of the ITG have been further subdivided into four dorsoventral partitions: TEpv, TEpd, TEav, and TEad. This current partitioning scheme represents an emergent hybrid of schemes based on connections and architectonics and thus provides a useful unifying framework for future functional investigations. Microelectrode and functional imaging studies have demonstrated that neurons display more-complex selectivity for two- and perhaps three-dimensional shape, and many of the constituent neurons carry a signal encoding the memory of a recently presented stimulus. Anterior portions of TE may contain a modular organization such that neurons are clustered by local stimulus features and objects are represented by the distributed activity across a large number of object feature modules. Functional imaging studies also support the view that central and anterior ITG contain a functional clustering based on object categories.

Superior Temporal Sulcus

Cortex within the lateral bank, floor, and roof of the STS contains a number of visual subdivisions that have been recognized on the basis of architecture, connections, single unit properties, and functional imaging. On the basis of architecture, an anteroposteriorly elongated band of cortex within the lateral bank of the STS has been identified as area TEa/TEm. An architecturally distinct narrow band of cortex, area IPa, occupies the fundus of the STS along most of its extent. Cortex within the roof of the STS has been implicated in visual multimodal functions and has been identified as the superior temporal polysensory area (STP). Architectonic studies identified three divisions of TPO that extend from the posterior STS (TPOc) near area MT, through central TPO (TPOi), to anterior TPO (TPOr). This multimodal strip of cortex has connections with portions of the inferior parietal lobule (IPL) and area MST, as well as somatosensory cortex.

On the basis of cortical connections, area TEa/TEm of the lateral bank of the STS has been subdivided into a number of distinct subdivisions. While there remains some controversy concerning the naming of these various cortical divisions, it is clear that the posterior one-third of this strip, immediately anterior to area MT, corresponds to area PITd (see the discussion of ITG above). The middle portion of TEa/TEm has been identified as area CITd on the basis of its connections with areas V4 and PITv. The anterior

one-third of TEa/TEm has previously been described as the dorsal subdivision of TEa, but the connections of PITv and CITv suggest that the dorsal subdivisions of TEa reside on the ITG and that additional cortical subdivisions occupy the anterior lateral bank of the STS. This anterior stretch of TEa/TEm has been tentatively subdivided into anterior and posterior divisions (corresponding to anterior and posterior subdivisions of anterior inferotemporal cortex and labeled PLSTS and ALSTS in Table 1).

Microelectrode and functional imaging studies of visual processing within the STS also reveal a number of distinct subdivisions related to different aspects of high-level processing of object shape, including three-dimensional structure from motion and shape from texture cues. Differential activation to intact versus scrambled objects is observed throughout the STS beginning in area FST and continuing along the lateral STS to include areas CITd, PLSTS, and ALSTS. In addition, activity was observed within the middle and anterior portions of the upper bank of the STS (areas TPOi and TPOr) and within the AMTS of the anterior ITG. It is important to note that differential activation to three-dimensional motion and texture-defined objects has generally not been observed in posterior and middle portions of the ITG (areas PITv and CITv and perhaps others). This is somewhat surprising since these cortical subdivisions demonstrate pattern and shape-selective responses, but they may be more related to two-dimensional form. Finally, a motion-sensitive static-sensitive, and moving shape-sensitive region, area LST, has been identified along the floor of the STS, approximately 5 mm anterior to area FST. This region partially overlaps with architectonic area IPa and medial portions of TEa/TEm and appears to be located medial to other previously identified 'shape from motion' areas within the lateral bank of the STS (e.g., area CITd). Overall, these functional imaging results demonstrate that object shape, extracted from motion cues, is processed by a constellation of areas within the STS.

Parietal Lobe

The inferior and superior parietal lobules contain a constellation of visual subdivisions that can be distinguished on the basis of architectonic or connectional criteria, topographic organization, or other functional criteria. These subdivisions vary in their degree of sensory, motor, and multimodal function, with some areas appearing almost entirely visual sensory (e.g., PIP, CIPS (LOP), and PO), others containing a high percentage of visuomotor neurons (e.g., LIPd, LIPv, and 7a), and still others likely to be multimodal (e.g., visuosomatosensory or visuovestibular; VIPm/VIPl, MIP, and MDP). Traditional views of visual functions of the parietal lobe have focused on its role in space perception (the 'where' function of the dorsal visual system), and lesions of this region produce a visual neglect of the associated visual field. However, recent anatomical and physiological studies suggest that this dorsal visual system consists of two separate streams that have different roles in visual spatial perception, eye movements, and arm and hand guidance. One stream, originating in medial occipital cortex (area PO or V6), provides visual information to areas V6A and MDP, which have complex sensory-motor functions related to arm movements to visual targets. In humans, lesions in presumed homologous regions of the superior parietal lobule produce an optic ataxia characterized by errors in reaching, particularly toward objects in the visual periphery. The second dorsal stream reaches parietal cortex through projections from areas MT and MST (complex), which are directed primarily at subdivisions of the inferior parietal lobule, areas VIP and LIPd. These cortical areas appear to utilize motion information to build a representation of three-dimensional space. Unlike occipital areas, VIP appears to utilize vestibular and other sources of information to build a true head-centered, rather than occulocentric, representation of visual space. Area LIPd provides presaccadic activity that is utilized by the frontal eye fields to guide eye movements to visually selected targets.

Cortical areas VIP and AIP of the inferior parietal lobule are also involved in visual guidance of hand and arm movements, which is consistent with their connections with posterior visual areas and anterior somatosensory and motor cortex hand representations. In humans, lesions of presumed homologous areas of the inferior parietal lobule produce a disorder known as apraxia, which involves an inability to retrieve motor plans with respect to specific visual objects. This disorder exemplifies how the IPL utilizes visual spatial information in conjunction with object shape information to guide specific hand movements. Thus, parietal cortex may best be viewed as a constellation of areas that provide a spatial reference system to guide eye and arm–hand movements. However, visual areas of the IPL also appear to utilize shape information to guide specific hand and arm movements necessary for the appropriate manipulation of visually presented objects. Finally, functional imaging studies have identified shape from motion-selective responses in parietal areas LIPd and LOP.

Frontal Lobe

Frontal cortex is usually considered to participate in high-level cognitive function, including attention,

working memory, and social emotional evaluation of stimuli. Although most of prefrontal cortex is multimodal in function, its involvement in visual processing is perhaps the best understood. Prefrontal cortex has been traditionally divided into dorsal, dorsolateral, and orbital subdivisions on the basis of cytoarchitecture, connections, and physiology. In general, visual processing in prefrontal cortex can be characterized as consisting of three circuits, each associated primarily with either the dorsal parietal, the ventral inferotemporal, or the anterior inferotemporal medial temporal processing stream, although there is some overlap. The first prefrontal circuit consists primarily of two cortical subdivisions, within dorsal and dorsolateral prefrontal cortex, that have been implicated in visual function by virtue of both their physiology and their preferential connections with visual areas in parietal cortex. Microstimulation of dorsal portions of area 8 produces large-amplitude saccadic eye movements, while stimulation of more-lateral cortex at the border with area 45 produces small-amplitude saccades. Areas 8 and 45 receive direct projections from both parietal area LIPd and posterior and anterior inferotemporal cortex. The more anteriorly situated area 46 is more closely associated with visual executive function and is implicated in many aspects of visual working memory. Overall, this circuit appears to emphasize spatial information in working memory tasks. The second prefrontal circuit is also involved in visual working memory but, unlike dorsal prefrontal cortex, appears more object specific. Prefrontal area 12 is also implicated in visual function, both by its dense connections with anterior inferotemporal cortex and by its visual properties, which share many similarities with those observed in anterior inferotemporal cortex. These results suggest that anterior inferotemporal cortex and prefrontal area 12 participate in a cortical circuit underlying visual recognition memory. Finally, orbitofrontal areas 11 and 13 are implicated in visual function by their reciprocal connections with anterior inferotemporal cortex and receptive field properties. In contrast to the prefrontal circuit involving area 12, orbitofrontal areas 11 and 13 may contribute to the analysis of the social-affective and motivational aspects of visual stimuli.

Hierarchical Organization of Visual Cortex

Neuroanatomical studies have demonstrated that cortical areas are almost always reciprocally interconnected and that the laminar locations of labeled cell bodies of origins and layers of axonal terminations provide evidence for the direction of information flow through a hierarchy of visual areas. In general, feedforward pathways arise from cells located in the supragranular cortical layers, and their axons terminate in layer 4 and deep layer 3. Feedback pathways arise from infragranular layers and terminate outside layer 4, usually in layers 1 and 6. Lateral pathways, thought to link cortical areas at the same hierarchical level, arise from both supragranular and infragranular layers and usually terminate in a column spanning all cortical layers. By making pairwise comparisons between all interconnected visual areas and placing each target of a feedforward pathway one level higher than all areas that provide its input, researchers have been able to assign more than 30 cortical areas to one of seven (or more) levels of an anatomical cortical hierarchy. This hierarchy begins at V1 and reaches to the highest levels of processing in the temporal and frontal lobes. This hierarchical analysis has been extended via the ratio of supragranular- to infragranular-labeled cells to define quantitative criteria for assigning areas specific hierarchical distances from one another. The pairwise analysis of laminar origins and terminations generally yields clear feedforward–feedback or lateral–lateral relationships between interconnected visual areas in the occipital, temporal, and parietal lobes. However, there are several documented instances, primarily concerning prefrontal and orbitofrontal areas, in which these relationships break down. Whereas this might be expected concerning connections between highly differentiated, six-layer cortices with less differentiated dysgranular or agranular areas, there are also instances of apparent internal inconsistencies within pairs of parietofrontal cortical areas.

It is important to point out that this hierarchical analysis is based solely on laminar features of reciprocal cortical connections and indicates the direction of information flow, but not its timing. This is an important consideration since many cortical areas receive input, not only from the layer immediately below, but often from many layers below. For example, area MT is logically located at the fifth hierarchical level and clearly receives feedforward inputs from V1, V2, V3, and V3A at the first through fourth hierarchical levels, respectively. Therefore, MT is in a position to receive input from cells in layer 4B of V1 before it receives input from V2. Thus, in some way, MT can functionally be considered to be located at the second hierarchical level.

Introduction

A fundamental property of vision is that it operates in closed loop. Behavior changes the pattern of light on the retina and as a result, most image motion experienced by mobile animals is generated by self-motion. In many ways, the closed-loop nature of vision is not only a nuisance, but it also creates opportunities. The main problem with self-induced image motion is that it produces motion blur, in the same way as a photograph becomes blurred by camera shake. Because photoreceptors have a finite integration time, a moving image becomes 'smeared' across the retina, which reduces the ability to resolve fine spatial detail. On the other hand, the spatially and temporally correlated way in which light patterns move across the retina carries information on an animal's own movements, on the depth structure of the world, and on the movement of objects. However, accessing this information and extracting its different contents is not trivial. The similarities in the way in which animals, including humans, move their eyes reflect the universal need to reduce motion blur and to facilitate the analysis of self-induced optic flow. In addition, many animals move in such a way as to generate specific visual information that would otherwise not be available, as in the case of image motion-based distance cues. Behavior thus plays an important role in visual information processing and, as documented later, some basic aspects of behavioral organization are determined by the needs of vision.

Optic Flow

As an animal moves through the world, it creates a distinct pattern of image motion on its retina, called optic flow. The specific pattern of optic flow is determined by both the layout of the environment and the animal's own movements. During a purely linear (translational) movement, the flow pattern expands from one pole of the flow field (focus of expansion), which lies in the direction of heading and contracts toward the second pole in the opposite direction (the focus of contraction) (Figure 1(a)). The image motion in the rest of the visual field flows backward across the retina from the focus of expansion to the focus of contraction. The size of local flow vectors depends on their position relative to the direction of heading and on the distance of objects in the environment. The images of close objects move faster across the retina than those of more distant objects; the closer objects are to the poles of the flow field, the less image motion they produce (Figure 1(b)). A pure translational flow field thus contains information on the direction of heading and on the spatial layout of objects in the world. In contrast, a pure rotational movement generates image motion that revolves around the axis of rotation, in directions opposite to the direction of rotation (Figure 1(a)). The length of local motion vectors varies predictably across the visual field in relation to the axis of rotation, but it is independent of the distance of objects. The rotational flow field thus only contains information on the rotational self-motion component of an animal's movement. When an animal rotates and translates at the same time, both flow field components superimpose and the extraction of their respective information content becomes much more difficult because rotational optic flow tends to dominate the resulting flow field (Figures 1(c)–1(h)). To extract translational and rotational optic flow information separately from such superimposed flow fields is not a trivial task, even if the local flow vectors could be accurately determined, which is not the case. Local image motion needs to be computed from the spatially and temporally correlated changes in light intensity in neighboring receptors. The mechanisms of local motion computation which have been identified in biological systems do not necessarily represent the direction and the speed of image motion in a veridical (accurate) manner. Local motion detectors can measure only the component of motion perpendicular to a contour that extends beyond its field of view and thus suffer from the so-called aperture problem. In addition, their output depends on scene contrast and pattern properties, and their directional tuning can be very broad. As a result, the motion signal distributions generated by the output of local motion detector arrays under natural, low-contrast, and visually cluttered conditions can be noisy, sparse, and patchy, making it difficult to extract useful information from optic flow (Figures 1(e)–1(h)).

Controlling Optic Flow

Keeping Still

One way to cope with the negative impact of image motion on visual processing is to keep still. Animals using vision have powerful visual and nonvisual

Figure 1 (a) Schematic diagram of rotational optic flow around the roll axis and translational optic flow along the same axis. Local flow vectors are projected on the spherical visual field under the assumption that all objects are at equal distance from the observer. (b) The image motion field produced by a 50 cm translation (top), mapped onto the plane. Bright parts of the map indicate the location of objects that generate high image velocities in the visual field of the moving observer, and black parts indicate the location of objects that produce low image velocities (see color bar on right). The dotted red line indicates the position of the red transect in (d). (c) Same as for (b), but for a 50 cm translation combined with a 10° rotation to the left. The green dotted line indicates the position of the green transect in (d). (d) Horizontal transects through image velocity maps in (b) and (d). The blue curve shows the situation for a 50-cm translation combined with a 45° rotation to the left. Image velocities are calculated with the assumption that both rotation and translation are carried out in 1 s. (e) Panoramic image recorded in an outdoor scene with the aid of a reflective cone. (f–h) Local motion signal maps for different kinds of movements through the scene shown in e. (f) Translation along a 1 m-long path in the azimuth direction −90°. (g) 45° rotation to the left around the vertical axis. (h) Combined 1 m translation and 45° rotation. Motion signals were calculated using panoramic image sequences as input to an elementary, correlation-type motion detector network. Local motion signals are color-coded depending on their direction (see inset), with hue coding their strength. Motion signals were calculated with a time constant of 80 ms and a sampling base of 3°, and they were averaged over 32 frames. They are plotted in full-color saturation for all signals above 2% of the maximum response. (a) Modified from Karmeier K, Krapp HG, and Egelhaaf M (2003) Robustness of the tuning of fly visual interneurons to rotatory optic flow. *Journal of Neurophysiology* 90: 1626–1634, with permission. (http://www.tandf.co.uk/journals).

reflexes, which serve to compensate for global image motion to produce a stationary retinal image. However, only a few animals can truly stabilize the retinal image as they actively or passively move. When walking or landing, birds employ elaborate leg, body, and neck movements to keep the head position in space still for extended periods of time; these movements are interrupted by rapid linear head movements into the direction of travel ('head bobbing') (Figures 2(a)–2(c)). Birds sitting on moving perches, like wind-driven branches, also keep their head still by leg and neck movements. Head stabilization in birds thus

Figure 2 Head stabilization in birds. Walking whooping cranes (a) keep their heads perfectly still in space, depending on walking speed, between 30% and 80% of the time. This is indicated by arrows in (b), which shows the superimposed successive positions in space of the eye (yellow), the head (blue), the body (brown), and the two legs (green and red). The head is repeatedly advanced by a rapid linear movement into the direction of movement. (c) Little egrets show similar head stabilization during walking. (a, b) Reprinted from Cronin TW, Kinloch MR, and Olsen GH (2006) Head-bobbing behavior in foraging whooping cranes favors visual fixation. *Current Biology* 15: R243–R244, with permission. (c) Modified from Fujita M (2003) Head bobbing and the body movement of little egrets. *Journal of Comparative Physiology A* 189: 53–58, with kind permission from Springer-Verlag.

minimizes image motion caused by both rotational and translational self-motion in a similar way as head and body movements do in hovering animals, such as hummingbirds, hoverflies, hawkmoths, and stingless bees.

Clearly, there are limits to how long an animal can keep still. Animals need to view the world around them and thus have to move their heads or eyes. They do so by shifting their gaze in a saccadic manner. Between these fast gaze changes, gaze is kept constant so that self-induced optic flow is compressed into very short time windows. For most of the time, therefore, the retinal image is still, a condition which allows the animal to exploit the best resolution and sensitivity of its eyes to detect moving objects, for instance. Even birds, however, like most other animals, have to tolerate some image motion when they move fast, and the best they can do is to employ eye, head, and body movements to keep rotational and translational optic flow components separate.

Compensatory Eye, Head, and Body Movements

Mobile animals cannot fully stabilize the retinal image, as is often misleadingly stated. However, compensatory eye, head, or body movements can minimize rotational optic flow. These compensatory eye movements are driven only in part by visual feedback loops. Closed-loop visual control systems are relatively slow because the reaction kinetics of phototransduction and the limited conduction velocities of neurons introduce time lags that need to be balanced with the overall gain to avoid instabilities. Therefore, in addition to visual feedback, compensatory eye movements in most animals receive open-loop (feed-forward), multimodal input involving the vestibular system in vertebrates; leg proprioceptors and statocysts in crabs (**Figure 3(A)**); gyroscopes (halteres) in Strepsiptera; and leg proprioceptors, neck proprioceptors, and halteres in flies (**Figure 3 (B)**). As a result, insect head orientation in free flight is stabilized around all three rotational axes most of the time except for fast, saccadic changes in gaze direction.

The functional significance of these compensatory eye movements is not only to minimize the rotational components of optic flow but also to control the absolute orientation of the visual system in space. Most animals keep their eyes horizontally aligned (e.g., flies), whereas a few align them with the local visual horizon (e.g., ghost crabs) (**Figure 3(C)**). Such alignment is a prerequisite for many neural computations that rely on some useful geometric properties of the visual world. For instance, in a flat environment, humans, toads, and crabs infer depth from retinal elevation, which requires the local visual horizon as a reference. Many insects possess specialized areas of dorsal retina which allow them to use the pattern of polarized skylight as a compass. The need for pattern and scene recognition may be a general reason why it is important to keep the visual system aligned with a geocentric frame of reference.

Figure 3 Control of eye movements in crabs and flies. (A) The efficacy of different sensory inputs in driving the compensatory eye movements of different species of crabs. Eye movement control is dominated by visual input in crabs that live in mudflat habitats with a visually salient line of horizon. Eye orientation in rock crabs is mainly driven by input from the legs and in swimming crabs by input from the statocysts. Crabs were stimulated by 1-Hz sinusoidal roll movements with 20° amplitude; the area of the circles shown is proportional to the amplitude of compensatory eye stalk movements, relative to maximal stimulus amplitude. (B) The eight different sensory subsystems determining head roll orientation in *Calliphora* flies. The schematic diagrams show the sense organs used by the fly to keep the head aligned with the vertical and the experimental conditions which have allowed identifying the visual (a–d) and mechanosensory cues (e–h) involved. (C) Ghost crabs (*Ocypode ceratophthalmus*) which live in the flat world of tropical sandy ocean beaches orient their eye stalks perpendicular to the local visual horizon when operating on inclined sections of the beach. This aligns the horizontal equatorial acute zone of their eyes with the local visual horizon. Depending on the mobility of their head and eyes, animals minimize the rotational components of optic flow in different ways. For example, waterstriders are unusual in that they use leg movements to compensate for drift and unwanted rotations on the water surface. They compensate for drift with coordinated strokes of their middle legs, using a discontinuous position servo, and minimize rotations by

Figure 4 Separation of rotational and translational optic flow by waterstriders (*Gerris palludum*). Waterstriders compensate for drift on a moving water surface by periodic jumps against the direction of drift (left). The jumps are executed by a coordinated rapid rowing movement of the two middle legs (lower traces). (Right) When waterstriders are subjected to additional rotation on a water surface with slanted laminar flow, they compensate separately for rotation by smooth rowing movements of one leg only (bottom) and occasionally for drift by a coordinated saccadic rowing movement with both middle legs. Modified from Junger W and Dahmen H-J (1991) Response to self-motion in waterstriders: Visual discrimination between rotation and translation. *Journal of Comparative Physiology A* 169: 641–646, with kind permission of Springer-Verlag.

continuous unilateral rowing movements of one middle leg only (Figure 4).

Saccadic Locomotion

Compensatory eye, head, and body movements thus serve to minimize changes in gaze direction relative to an external (geocentric) coordinate system. This essentially eliminates rotational optic flow. In addition, many animals, especially insects, control the type of optic flow they experience even further. They move in a way that avoids smooth or frequent changes in the direction of heading, which would cause the poles of the translational flow field to wander across the retina. Hoverflies, for instance, move in a series of straight lines, the direction of which can be independent of their body axis (Figure 5(a)). Even insects that do not have a similar degree of hovering control, such as the blowfly *Calliphora* (Figure 5(b)), the housefly *Fannia canicularis* (Figure 5(c)), and the fruitfly *Drosophila melanogaster* (Figure 5(d)), move in such a saccadic manner during territorial and exploration flights, whereby compared to hoverflies, their longitudinal body axis tends to be much more aligned with flight direction. Compensatory eye movements together with saccadic locomotion along straight paths thus maximize the time animals experience a pure translational flow field with a constant orientation in the visual field. The pole of expansion and the direction of gaze are then changed together during the saccadic change of flight direction. There are some indications that this behavioral organization indeed supports the extraction of useful information from optic flow. The compound eyes of many flying insects have forward-pointing acute zones with high spatial resolution, which decreases systematically toward the back of the eyes. These gradients of spatial resolution are thought to have evolved to reduce motion blur associated with the optic flow field encountered during forward flight, when retinal image motion is minimal in the direction of heading and largest in the lateral visual field especially when vegetation is close by. Because image contrast is inversely related to the ratio between receptor acceptance angle and receptor integration time, larger receptor spacing and larger acceptance angles in the lateral field of view allow to resolve details at higher angular velocities.

Using Optic Flow

Animals use the translational component of optic flow for a variety of tasks, and they can do so because it has high information content with respect to the layout and the distance of objects in the world. In blowflies, for instance, the behavioral separation of translational from rotational optic flow has been shown to be essential for the visual system to extract distance information. Similarly, when an animal approaches an object, the retinal image of this object expands. Flies have been shown to use such looming cues to initiate deceleration and to extend their legs in preparation for landing.

Figure 5 Saccadic gaze changes and saccadic locomotion in flies. (a) Flight path of a cruising hoverfly (*Syritta pipiens*). The head of the fly is marked by a small dot and the orientation of the longitudinal body axis with a line attached to it. Positions are shown every 20 ms. Arrowheads mark saccadic gaze changes. Bottom diagram shows gaze direction over time. (b) Flight path of a blowfly (*Calliphora* sp.). Positions are shown every 8 ms and labeled every 40 ms. Bottom diagram shows changes in body axis orientation over time. (c) Flight path showing saccadic locomotion of a male housefly (*Fannia canicularis*) patrolling the airspace beneath an indoor landmark (star). Bottom diagram shows changes in flight direction over time. (d) Saccadic flight path of a fruitfly (*Drosophila melanogaster*) cruising inside a large patterned drum. Bottom diagram shows changes in flight direction over time for the same sequence. Landing is essentially controlled by spatiotemporal integration of looming optic flow patterns, which may also be used for time-to-impact judgments, obstacle avoidance, and predator avoidance. Diving birds, for instance, judge the time of their impact with the water surface by the rate of expansion of its surface texture; hovering stingless guard bees (*Tetragonisca angustula*) and hawkmoths interpret expanding and contracting image motion as indicating unintended displacements in space.

Many other elements of flight control in insects involve the use of translational flow field components. When landing on flat horizontal surfaces, bees keep ventral optic flow constant and thus regulate their flight speed to be roughly proportional to their height above ground, which guarantees smooth landing without requiring information about the exact height above a landing site. The same mechanism allows bees to adjust their flight speed depending on the space they fly through: when a tunnel they negotiate narrows, they slow down, and they speed up again when it widens. In flight tunnels, wind tunnels, and in tethered flight, flies, locusts, and bees control their flight speed by keeping the average image motion they perceive at relatively constant values. In the case of hovering, image motion is clamped to zero. Hovering insects, such as hoverflies, hummingbirds, hawkmoths, and stingless bees, hold their position in space by minimizing translational optic flow through compensatory translational movements. By balancing image motion on either side when flying through gaps or narrow tunnels, honeybees keep clear of obstacles and to the center of negotiable airspace. Honeybees and stingless bees are also able to measure the distance they have flown by integrating the image motion they generate during flight.

Honeybees and flies use relative motion cues to detect objects by foreground–background segregation and to infer their distance relative to the background. For a moving observer, a nearby object appears to move faster than the background, which allows both bees and blowflies to discriminate between objects at different heights above ground. Bees identify landing sites or target objects with the aid of motion cues and approach the edges of elevated objects in such a way as to maximize motion parallax. Ladybird beetles move along straight-line segments (saccadic locomotion) and use the motion parallax information gained during these translations to identify close landmark which they then approach and climb.

Shaping Optic Flow

A number of animals, including birds, lizards, insects, and humans, produce eye, head, and body movements that are not compensatory in nature but are tailored to generate specific patterns of image motion that carry motion parallax information. Only for insects and birds, however, is there clear evidence that the visual information generated by these 'peering' movements is actually used to gauge the distance of objects. The peering movements in insects, birds, and lizards are predominantly highly controlled linear movements of the head, during which gaze direction is held constant, resulting in a purely translational flow field on the retina. In contrast, some wasps and birds generate a pivoting parallax field in response to objects of interest by moving along arcs around the object while fixating it (Figures 6(a)–6(d)). The visual consequences of these pivoting movements in terms of image motion are similar to those when a moving human observer fixates and tracks an object in a viewing direction other than the direction of travel.

Arguably the most elaborate examples of behavioral shaping of optic flow are the learning flights made by bees and wasps in the context of landmark guidance when leaving their nests for the first time or when leaving a newly discovered food source. Insects are known to navigate with the aid of remembered views. They are guided by landmarks along routes and when pinpointing places of interest, such as nests and feeding sites: they remember the apparent size of landmarks, their brightness or color, and also their absolute distance from the goal. It is presumably this last aspect, namely the need to identify salient objects close to the goal, which requires homing insects to move in specific ways during the acquisition of a visual representation of the goal environment.

During a learning flight, ground-nesting wasps, for instance, turn to face the goal and then back away from it in a series of increasing arcs during which they gain distance from the goal at approximately the same rate as their height above ground increases. While the wasp pivots about the nest location, it keeps the image of the goal area in a frontolateral position in the visual field (Figure 6(e)). High-resolution and high-speed records of these flights show that wasps move their heads in a saccadic manner during learning. Sections of flight in which gaze is held constant are linked by rapid head movements that change gaze (Figure 6(f)). The insects thus do not generate a pivoting parallax field as had been deduced previously from an analysis of their body axis orientation alone but, rather, a sequence of translational parallax fields. Both these fields of behaviorally shaped optic flow would allow the insects to segregate objects from background and to judge the relative and possibly absolute distance of landmarks. What determines the use of one or the other parallax field in different contexts remains to be elucidated.

Optic Flow while Tracking Targets

There are situations in which animals cannot compensate for large-scale rotational image motion. For instance, when following a moving object with our eyes during smooth pursuit, the image of the rest of the visual scene moves in the opposite direction across our retina. Such global rotational image motion

Figure 6 Continued

would normally trigger compensatory eye movements. Because these stabilizing reflexes would counteract target tracking, they are suppressed during human smooth pursuit eye movements. The same problem arises during fast, saccadic changes in gaze, although the self-induced global image motion in this context is easier to cope with because these voluntary gaze changes are preprogrammed, rapid, and ballistic. Their effects, in terms of image motion direction and motion speed, are therefore predictable and can be taken into account by the brain. In vertebrates, there is evidence that this is achieved by saccade-triggering neurons sending corollary signals to inhibit motion-sensitive neurons during the execution of a rapid gaze change.

Like many other insects, blowflies chasing after dummy targets use a continuous tracking strategy analogous to human smooth pursuit eye movements (Figure 7(a)), which, as in humans, becomes saccadic when the target moves too quickly (Figure 7(b)). It is unknown how stabilizing reflexes and pursuit movements interact in target tracking insects: whether they simply add with different gain, whether an efference copy is needed to prevent compensatory reflexes from interfering with tracking, or whether interference is minimized by the different spatial frequency tuning of tracking and optomotor systems. Some animals do not seem to have a solution to this problem: the tracking strategy of the praying mantis, for instance, depends on the visual background. The mantis tracks insect prey with head movements which keep the insect's frontal acute zone pointing at the target. When the background is visually homogenous, the mantis is able to track a moving target with smooth pursuit head movements (Figure 7(c)). However, tracking becomes saccadic when the target is seen against a visually cluttered background such as vegetation (Figure 7(d)). Unlike the praying mantis, male hoverflies are able to track females by smooth pursuit even against a textured background; however, like humans and blowflies, they do switch to saccadic tracking when the target moves too fast for the smooth pursuit system to keep up. Similarly, tiger beetles are able track high-contrast objects using smooth pursuit, but they pursue live prey in a stop-and-go manner – a strategy which serves to improve the signal-to-noise ratio of the motion signal generated by moving prey. For the stationary beetle, compared to when it is running, the moving prey is easier to detect against a stationary background.

A special case in which background motion during target tracking contains useful information occurs in animals with mobile eyes such as humans, who can fixate stationary objects independently of their own direction of movement at any distance and direction as they walk or drive. If the object is not at infinity and does not lie in the direction of heading, the tracking movement exactly compensates for the local translational optic flow component associated with the object by rotating the eyes and/or the head at the same angular speed. The result is a pivoting parallax field, a combination of a translational and a rotational optic flow field that is characterized by opposite image motion directions associated with objects that are further away or closer than the fixation point. Such a pivoting parallax field thus produces an increased motion contrast between foreground and background objects and therefore has high information content with respect to the relative location of objects in the world.

Vision and the Organization of Behavior

Because of the intimate interdependence of vision and behavior, behavior plays an important role in visual information processing. It can simplify computations by separating rotational and translational optic flow components, and it can generate visual information, as in the case of motion parallax. However, behaviorally guided vision can take more complex forms, as in the case of predator avoidance strategies, in which distinct sequences of prey behaviors are driven by the need to gather different kinds of visual information on the

Figure 6 Active vision strategies of homing wasps. (a) Ground-nesting wasps (*Odynerus spinipes*) respond to novel objects in the vicinity of their nests with rapidly swaying zigzag flight maneuvers, with gaze centered on the object, as shown in the scatter diagram of consecutively intersecting gaze directions (b), which generates a pivoting parallax field on the retina of the insect (c, d). (e) The organization of learning flights in ground-nesting *Cerceris* wasps. The three-dimensional flight path of a learning flight is shown from different directions in the three panels on the left (see inset for definition of axes). The time course of distance from goal, height above ground, orientation, bearing, and retinal azimuth position of the nest entrance are shown in the two panels on the right (for definitions of variables, see inset). Because the wasp gains distance from the goal and height above ground at approximately the same rate, the nest entrance is always seen approximately 45° below the horizon (see inset histogram). Moving along arcs around the nest entrance, the wasp counterrotates in such a way as to keep the nest entrance at frontolateral retinal azimuth positions (green trace in bottom right panel). (f) High-speed, high-resolution digital video recordings reveal that head movements play an important role in learning flights: gaze changes are not smooth but, rather, saccadic as a wasp flies along an arc so that gaze is stabilized for most of the time. (a–d) Modified from Voss R and Zeil J (1998) Active vision in insects: An analysis of object-directed zig-zag flights in a ground-nesting wasp (*Odynerus spinipes*, Eumenidae). *Journal of Comparative Physiology A* 182: 377–387, with kind permission of Springer-Verlag.

Figure 7 Target-tracking behavior in insects. Male blowflies perform aerobatic pursuits belonging to the fastest visual behaviors that can be observed in nature. The tracking strategies of blowflies appear to be very similar to pursuit eye movements in primates: a combination of smooth pursuit with catch-up saccades. (a) Top view of a flight trajectory of a fly chasing a black sphere that moves on a circular track in a horizontal plane (gray line). The head position (dot) and the longitudinal body axis orientation (line) of the fly are shown every 20 ms. The time course of orientation and angular velocity of the fly are shown for the first 740 ms of the sequence in the panels below. The angular path velocity of the dummy target of approximately 716° s^{-1} is indicated by the dashed line. (b) Flight path of a fly chasing another fly in top view. Conventions are the same as in a. The time course of orientation and of angular velocity is plotted in the lower panels. Note saccadic changes of gaze direction, marked by arrows in the orientation over time diagram. (c) Praying mantis track moving targets with smooth head movements, provided the background is visually homogenous. (d) Praying mantis tracking head movements become saccadic if the target is seen against various structured backgrounds. (a, b) Modified from Boeddeker N and Egelhaaf M (2005) A single control system for smooth and saccade-like pursuit in blowflies. *Journal of Experimental Biology* 208: 1563–1572, with permission of The Company of Biologists. actual threat posed by an approaching predator. In these situations, behavior does not directly influence visual information, as in the cases discussed previously, but serves to prepare the conditions in which relevant information can be gathered in a risk-free way.

Many visually guided prey animals react to predators in a distinct sequence of behavioral acts: freeze, run for cover, monitor (vigilance), hide, and monitor again on reemergence from a refuge. This organization of predator avoidance can be interpreted in terms of risk, in terms of lost opportunity, and in terms of

visual information. The point to note in the present context is that animals freeze when first becoming aware of a predator, at a predator–prey distance where visual information is insufficient to identify a predator or determine its distance and direction of movement. Freezing thus basically serves to stabilize the retinal image, minimize blur, and increase the signal-to-noise ratio. At this stage, visual information is not well correlated with actual threat. More robust visual information can be gathered once the animal is in relative safety – for example, close to a refuge, where a predator has little chance of intercepting and catching it. At this stage then, prey animals can afford to allow a predator to come closer and to determine its direction of approach by detecting looming cues or its identity by analyzing shape, color, or motion parameters. These visual signatures of a predator have a high correlation with actual threat and thus allow the prey animal to make informed decisions regarding two crucial elements of its antipredator defense: when and for how long to hide.

Such examples of behavior supporting visual information processing have been analyzed in great detail in fiddler crabs, which are quite unique because their full behavioral repertoire and the visual cues they attend to can be continuously monitored in the field. The crabs live in intertidal mudflats and operate from burrows which provide protection from predators, access to water and food, and which need to be defended against other crabs. As the crabs move away from their refuge, they quickly lose sight of it because the burrow's opening disappears in surface undulations. The crabs therefore need to rely on their path integration system, which monitors the direction and distance in which they move so that they can keep track of their distance from the burrow and in which direction they need go to return to the burrow. The animals use this information to align their longitudinal body axis with the home direction, which is also the orientation that coincides with their fastest mode of locomotion (sideways). However, it also allows crabs to visually determine the distance between an intruding conspecific and their own burrow. The crabs do this by aligning the retinal position of the burrow with the zero position of a retinotopic distance map, which then maps retinal location to distance from that zero point. Such a mapping relies on compensatory eye movements to align the retina with the external world and can only work reliably in a flat world, such as the intertidal mud and sand flats which fiddler crabs inhabit, in which retinal elevation is a robust cue to depth. The resulting distance information is crucial for a crab to decide whether or not another crab has come too close to its home burrow.

There are likely many other examples in which behavior can be shown to be organized in such a way as to serve visual information processing. Visual search, vigilance behavior, and the attraction to observation posts can be interpreted in this way, as can the calibration of the skylight polarization compass by desert ants, which turn on the spot before leaving on their foraging trips.

Most animals depend heavily on vision for behavioral guidance. However, as this brief review has emphasized, behavior in turn is often organized to support visual information processing by minimizing the problems created and by maximizing the opportunities offered by the visual closed loop.

Visual–Vestibular Interactions

L R Harris, York University, Toronto, ON, Canada

Introduction

The visual and vestibular systems together form a consortium that informs an organism about its motion and orientation relative to gravity. The visual and vestibular contributions are complementary, with each system tending to make up for inadequacies and ambiguities in the other. Their combined information is used for three main purposes: eye movement control, posture control, and perception. Other systems, such as the somatosensory system indicating the sites of pressure resulting from the weight of the body against a support surface, and the auditory system, can also inform about the relationship of the body to the world. This article concentrates on the use of visual and vestibular information in humans.

Visually Transduced Information Concerning Self-Motion and Orientation

The visual system provides continuous and usually unambiguous information about motion and orientation of the body relative to the world. However, visual information is subject to delays, because of the time needed for retinal processing and for combining signals across time and space to derive motion information. Visual information can also sometimes be irrelevant or misleading for deducing motion and orientation, such as when looking at anything other than features of the environment, for example, when watching films or looking at pictures. It is also subject to interruption in low light, during eye blinks, or when the eyes are closed.

Visual information about the movement of a person comes from the systematic displacement of the visual directions of all visible features as a consequence of movement relative to them. This pattern of motion is called 'optic flow.' Optic flow generated by 'translation' (movement from one place to another) contains enough information to determine in which direction a person is 'heading.' The direction of heading during translation can be determined from the location of the 'focus of expansion' of the optic flow, as JJ Gibson told us. When a person moves toward a particular point, the visual direction of that point (and the point in the diametrically opposite direction) does not change relative to the mover. The images of all other points move by an amount that depends on each point's angular distance from the heading direction and its distance from the observer. Because of this systematic arrangement, the location of the focus of expansion can be deduced from even a small area of visible optic flow. The relative distance a person has traveled (e.g., movement halfway to some visible object) can be extracted from optic flow. But determining the absolute distance (e.g., movement of 1 m) requires additional information about the distance of visible objects, since the motion of an object's image on the retina depends not only on the velocity and direction of self-motion but also on these distances. There are therefore high computational demands in reconstructing the self-motion that created a given optic flow pattern. Furthermore, optic flow evokes compensatory movements of the eyes. This complicates the process of determining the underlying optic flow since the retinal motion is affected by both the movement of the eyes in the head and the overall motion of the person. Nonvisual information about compensatory eye movements can often be helpful, and in some cases is indispensable, for distinguishing these components.

Optic flow generated by 'rotation' (movement that does not involve an overall change in position) contains information about the axis of rotation and instantaneous rotational velocity. This also has to be interpreted in the context of evoked eye movements which can remove most of the rotational optic flow from the retinal image. Optic flow can be experienced in the absence of physical motion, for example, when a neighboring car or train moves. Such visual movement can generate a compelling sensation of self-motion called 'vection.' Vection can have both translational ('linear vection') and rotational ('circular vection') components and generally takes several seconds to build up. The onset of vection is speeded by the presence of actual motion even if it is a pulse or a vibration unrelated to the self-motion signaled by the optic flow.

Visual information relevant to orientation of a person relative to gravity includes: (1) the 'visual frame,' comprising the ground plane and the view of features known to be approximately vertical or horizontal relative to gravity, such as trees, walls, ceilings, and floors; (2) the orientation of the 'visual horizon'; (3) the assumption that light generally comes from above; (4) 'support relationships' between objects, determined by the laws of physics, such as objects resting on other objects or supported by the ground; and (5) 'visual polarity' cues of objects with recognizable tops and bottoms such as faces, lamps, and chairs that have a most-familiar orientation relative to gravity. Some of these properties, such as the direction from

Figure 1 A photograph of a typical scene showing examples of the various visual cues to the direction of gravity. On the right, the possible directions reported by the cues in the photograph are detailed. The four possible directions of gravity signaled by the frame, defined by the orientation of the walls, floor, ceiling, and window stripped of their other cues, are indicated by red arrows. The two indicated by the horizon are shown in black, and the unique direction signaled by the relationships of objects in the world (e.g., the fruit bowl on the stool), the expected orientation of objects (fruit bowl curved side down), and light coming from above is indicated by the yellow arrow.

which light comes or the orientation of the horizon, could have a recognition mechanism with an innate component; others must be learned by association, such as the orientation of writing on advertising signs. Figure 1 illustrates some of the visual cues that are available to specify orientation in a typical scene.

Figure 1 also illustrates that the various visual cues to orientation have greater or lesser degrees of ambiguity. The frame structure of a room, stripped of visual polarity and support relationship cues, indicates four possible directions of gravity; the horizon indicates two possible directions; whereas the direction of illumination, support relationships, and visual polarity cues signal only one unique possibility.

Vestibularly Transduced Information Concerning Self-Motion and Orientation

The 'vestibular system' comprises two sets of mechanical sensors, both of which are activated by physical force. Force, as Isaac Newton told us, is the product of mass and acceleration. Thus, the vestibular system can only detect motion that involves acceleration: movement at a constant speed cannot stimulate the vestibular system. The 'semicircular canals' detect angular acceleration of the head, and the 'otoliths' detect linear acceleration. Gravity, as Albert Einstein told us, is equivalent to an upward linear acceleration of $9.8\,\mathrm{m\,s^{-2}}$, and so the vestibular signal also contains information about the orientation of the head relative to gravity.

Since the vestibular system is sensitive only to acceleration, position and velocity information need to be derived from the accleration. However, such a derivation can only provide relative values of position and velocity for both rotation and translation. For example, the changes in linear velocity (i.e., acceleration) from 10 to $20\,\mathrm{m\,s^{-1}}$; 0 to $10\,\mathrm{m\,s^{-1}}$; –10 to $0\,\mathrm{m\,s^{-1}}$; and –20 to $-10\,\mathrm{m\,s^{-1}}$ are all the same although the final velocities are very different. Before the invention of modern modes of transport, the assumption that the starting velocity was close to 0 was more or less valid, but even so, the need to add assumed starting values makes the vestibular system fundamentally unsuited for tasks such as keeping track of position and orientation during translation and rotations in space. Many disorientation illusions related to aviation can be traced to this limitation.

It might be thought that the constant pull of gravity would provide a reference direction to which the perception of self-motion and orientation could be anchored. However, since gravity cannot be distinguished from linear acceleration, a given signal from the otoliths organs is ambiguous. This signal could be produced by any one of an infinite number of combinations of linear accelerations and tilts of the head as shown in Figure 2. Since the accelerations of everyday life are not generally confused with tilt, the gravity vector must somehow be subtracted from the signal. The direction of the gravity vector can be obtained from the visual cues described above.

However, solving the geometrical problem of the double vector requires knowledge not only of the direction of gravity, but also of its magnitude. If its magnitude is not available, then, when acceleration with a component orthogonal to gravity is experienced, it is hard to distinguish the resultant vector from gravity alone after an appropriate tilt of the head. This is the 'tilt-translation' ambiguity. The two eventualities

Figure 2 (A) The acceleration vector transduced by the vestibular system (thick black arrow) is the resultant of gravity (red arrows) and physical acceleration (thin black arrows). The lengths of the arrows represent the magnitudes of the accelerations. The components cannot be reconstructed unambiguously from the resultant. Several possible solutions out of an infinite, three-dimensional set are illustrated in (A). The person experiencing these accelerations is shown in a random orientation, since their orientation relative to gravity is determined by the solution of this geometry. (B, C) Show two possible solutions that are labeled by dotted lines labeled 'a' and 'd' for gravity, and 'b' and 'e' for the physical accelerations corresponding to the resultant 'c' as sensed by the vestibular system. The labeled vectors are the same (relative to the observer) in (A), (B), and (C).

illustrated in Figure 3 can be distinguished by knowledge of magnitude, by detecting the preceding tilt, or by additional knowledge about the direction of gravity. By providing both rotation and direction cues, vision provides the most reliable way of solving the tilt-translation ambiguity. The fact that gravity is equivalent to acceleration thus requires visual–vestibular interactions to indicate the direction of an imposed acceleration and to indicate the pose of the head relative to gravity.

Despite these limitations to working effectively on its own, the vestibular system does have the advantage of always being available for the detection of accelerations greater than a certain minimal amount and of gravity: there is nothing equivalent to closing the eyes for the vestibular system. Also, the vestibular system is extremely fast, providing a signal to the brain in just a few milliseconds.

Figure 3 Tilt-translation ambiguity. Because gravity (g) is equivalent to an acceleration, when accelerating physically forward (A) a person is subject to two simultaneous stimuli that combine to produce a vector ('resultant'). A subject tilted backward (B) experiences gravity in that same direction. The only differences between the cues sensed by the otolith organs are the absolute magnitudes (always greater than g for (A) and less than g for (B) and the history of what happened immediately leading up to these situations. However, they can be easily disambiguated by vision. The person illustrated here is wearing a virtual reality helmet in which visual environments can be simulated that attempt to encourage one or other interpretation.

Visual–Vestibular Interactions for Determining the Direction of Translation

Vestibular information concerning the direction of head translation is highly ambiguous (see Figure 2). When visual and vestibular cues to direction are put in conflict (e.g., with prisms or virtual reality displays), the perceived direction of motion is dominated by the visual cue, so much so that even if the actual physical motion (the vestibular cue) is opposite to the optic flow, the perceived direction is determined by vision. There are no significant visual–vestibular

interactions in the determination of the perceived direction of translation. This is supported by the observation that perceived motion direction (even when not generated by self-motion) is not affected by concurrent linear vestibular stimulation.

Visual–Vestibular Interactions for Determining the Magnitude and Velocity of Translation

Neither optic flow nor vestibular signals indicate either the absolute distance traveled or the velocity of self-motion, but the consortium is able to estimate distance traveled by combining information from the different sources. Vision can provide the starting position and velocity estimates that are lacking in the vestibular signal. The vestibular signals produced by active self-motion (e.g., walking) of a planned magnitude can, however, provide a rough scale. When transported passively in the dark (vestibular information only), or when motion is simulated by viewing optic flow while physically stationary (linear vection; vision only), the perceived distance of travel is generally further than the motion experienced, especially for distances further than a few meters with a low acceleration. Artificial combinations of visual and vestibular cues of different magnitude presented, for example, using virtual reality simulations, reveal an averaging of the two signals with a greater weighting of vestibular information when motion is in the operating range of the vestibular system (above about $0.1\,\mathrm{m\,s^{-2}}$).

Attempts to influence the perceived distance of linear vection by tilting a subject, thus applying a component of gravity in the plane of optic-flow-induced movement (see Figure 3), have been unconvincing.

Visual–Vestibular Interactions for Determining Tilt

When forced to rely on the vestibular system, for example, when suspended in water with eyes closed that effectively removes somatosensory pressure cues, subjects can orient themselves either vertically or horizontally relative to gravity to within about 5° with no systematic biases. This ability to detect tilt of the body relative to gravity is a measure of the 'postural vertical.' Systematic errors appear, however, when aligning a line of light with the perceived direction of gravity to indicate the 'subjective visual vertical' while tilted in an otherwise dark room. Small tilts of the body (e.g., 10° to the left) can cause the line to be set in the opposite direction (e.g., 2° right of true vertical), a rather small and variable effect known as 'the E-effect' (for *entgegengesetzt*, German for opposite). Larger tilts, beyond about 60°, usually cause the line to be tilted away from true vertical but in the same direction as the tilt (known as the 'Aubert or A-effect'). The 'perceptual upright,' the orientation at which visually polarized objects such as faces, animals, or letters appear correct and are most easily and speedily recognized, is also subject to an A-effect.

The perceptual vertical, subjective visual vertical, and perceptual upright are all influenced by visual cues concerning the direction of gravity, as well as by the vestibularly transduced physical direction. Subjects, especially children, can be induced to sway by moving the visual environment indicating the effect of vision on the postural vertical. How the subjective visual vertical and perceptual upright can be measured is illustrated in Figure 4 and the effect of visual background and of physical tilt on these two measures is illustrated in Figure 5. The A-effect exhibited by the perceptual upright is substantially larger than that induced in the subjective visual vertical. This is shown in the figure by the distance of the judgments from the 90° line (which corresponds to the veridical direction of gravity relative to the subject) when lying on one side. The effect of the visual background, indicated by the depth of modulation, is larger for the perceptual upright than the subjective visual vertical. Although compensatory rotation of the eyes in response to head tilt might play a small role in these effects, it cannot account for the differences between the two measures. Misalignments of the subjective visual vertical or the perceptual upright from the true direction of gravity indicate that the relevant perception of 'up' arises from a weighted sum of the different cues to 'up'. These cues include (1) the orientation of the body axis, which seems to be known since it can be accurately aligned with gravity in the absence of other cues; (2) visual cues to vertical (described in detail above and in Figure 1); and (3) the otoliths' gravity signal. The perceived orientation of the body is qualitatively different from the other cues as it cannot be sensed directly but is an internal representation. The representation of body orientation is often referred to as the 'idiotropic vector' or the 'M-vector' after Horst Mittelstaedt, who first developed this concept. The orientation of the subjective visual vertical and the perceptual upright can be approximated by linear weighted sums of these three vectors: vision, body axis, and gravity, as illustrated in the lower part of Figure 5. The orientation of the visual and idiotropic cues has relatively little effect on the subjective visual vertical, but the perceptual upright is influenced approximately equally by all three cues.

If a subject is tilted relative to gravity with an acceleration below the semicircular canals' detection threshold (no vestibular cues to the reorientation) and the visual cues to orientation are moved along

Figure 4 The subjective visual vertical (a) and the perceptual upright (b). These two measures can be used to assess the effect of visual and vestibular cues on perceived orientation. To assess the subjective visual vertical, subjects align a line with the perceived orientation of gravity. Performing this task requires introspection and estimation. The perceptual upright can be assessed by having subjects identify a character or shape the identity of which depends on its orientation. The direction between the orientations of maximum ambiguity (most easily detected psychophysically as the 50% correct identification point) indicates the perceptual upright: the orientation at which objects are most easily recognized

with the subject (visual cues indicate no tilt), then the direction of gravity is not perceived to move during the tilt. This is most easily arranged in a rotating room. For subjects who have been tilted onto their backs, objects hanging from the wall in front of them now appear to levitate as they hang under the influence of gravity, giving the illusion its name, the 'levitation illusion.' The levitation illusion demonstrates the importance of visual and semicircular canal cues for updating the internal representation of gravity. If those cues are absent, even in the presence of a 90° change in the direction of gravity, the perceived direction of gravity can remain unchanged.

When a textured background lacking visual cues to gravity is rotated around the line of sight of an upright observer, it produces a paradoxical perceptual effect in which subjects feel they are rotating constantly, but at the same time statically tilted. This is because of an anchoring effect of gravity (which indicates no tilt). When the same background motion is around an axis aligned with gravity, or when the strength of the visual cues is increased by using a scene rich in frame, horizon, lighting, polarity, and support relationship cues, continuous vection is often experienced.

Visual–Vestibular Interactions for Determining the Axis of Self-Rotation

Determining the axis of self-rotation from vestibular cues alone is also complicated by the vestibular systems' exclusive sensitivity to acceleration: constant velocity rotations are not sensed after the response to the initial acceleration has died away (after about 20–30 s). Subsequent rotations around other axes can then produce complex 'Coriolis effects,' in which, predictable from the laws of conservation of angular momentum, rotation about an axis orthogonal to the (undetected) constant velocity axis produces illusory rotation about an axis orthogonal to both of them. Curiously, tilting one's head (or moving the visual stimulus) during constant velocity circular vection can also evoke complementary complex effects, known as 'pseudocoriolis illusions.'

Visual–Vestibular Interactions for Determining the Amplitude of Rotation

The sensation of rotation from vision alone, circular vection, takes several seconds to build up, but it increases at the same rate that the vestibular response to an actual body rotation decreases. Thus, when rotating in the light a relatively accurate response made up of visual and vestibular components is maintained. This complementarity is reflected in the visual and vestibular responses of cells in the vestibular nucleus. Spinning people around is a classic way of disorienting them: children are intuitively aware that the vestibular system cannot signal position. However, for short-duration rotations, such as natural head movements, the vestibular system is capable of deriving the size and direction of the movement. Even this feat, however, may need help from higher cognitive centers since, when head movements are performed in the dark, only if an Earth-stationary target is imagined can appropriate eye movements be generated. If a small, subject-stationary target is provided as a subject accelerates angularly, the target appears paradoxically to be both moving in orbit around the subject's head, and at the same time not to be advancing from the straight ahead position. This is the 'oculogyral' illusion and might be connected to failures of the process involved in deducing the linear speed of an object under such unnatural conditions.

Figure 5 How the perceptual upright and the subjective visual vertical vary with visual and vestibular cues. The graphs plot the orientation of the subjective visual vertical (a) and the perceptual upright (b), relative to the subject, as a function of the visual background for two body orientations, upright and right side down. The subjective visual vertical is less influenced by vision and more influenced by gravity than the perceptual upright. Fitted through the data is the output of a simple, weighted, linear model illustrated in panels (c) and (d) where the lengths of the three vectors are weighted as shown. Data from Dyde RT, Jenkin MR, and Harris LR (2006) The subjective visual vertical and the perceptual upright. *Experimental Brain Research* 173: 612–622. M is datum from Mittelstaedt H (1986) The subjective vertical as a function of visual and extraretinal cues. *Acta Psychologica* 63: 63–85 where subjects lay in a room oriented earth vertically.

Suppression of Visual Responses by Vestibular Signals

Perception of visual motion in general is suppressed by concomitant angular or linear vestibular stimulation. This may be related to the use of optic flow resulting from the visual background motion to inform about self-motion. The suppression may be related to mutual inhibitory pathways between vestibular and visual cortical areas. Motion thresholds are increased during rotation but curiously seem to be elevated most during motion in the direction opposite to that of the associated optic flow. For example, when moving to the left, visual motion to the left is more suppressed.

Suppression of Vestibular Responses by Visual Signals

Although under natural circumstances visual and vestibular cues to motion are usually complementary and, within the constraints described above,

redundant, they can also frequently be opposed to each other. For example, reading a newspaper in a moving vehicle or while walking requires fixation on the paper, not on Earth-stationary features. Visually controlled eye movements, including those involved in stabilizing the image, now work on the subject-stationary image of the paper, whereas the vestibular system is simultaneously required to guide locomotion and to maintain balance. This feat of suppressing vestibular cues for some aspects of perception while simultaneously using it for others can only be successfully carried out at frequencies below about 0.5 Hz and probably only by primates with well-developed smooth pursuit capability. At higher frequencies of movement, eye movements of vestibular origin cannot be suppressed by vision and attempts to fixate on near objects will generate large compensatory eye movements appropriate for maintaining gaze on something that remains Earth stationary, even in the presence of subject-stationary objects.

The Detection of Conflict in Visual–Vestibular Interactions

In many documented instances, information that arises from different senses is combined linearly using a weighted average where the weights are assigned according to the reliability of the contributing sources. This is true for visual–vestibular combinations for both the distance traveled and the perception of orientation (as described above). A linear combination does involve an interaction since the response to both cues can be predicted from the responses to either of the two cues alone. However, conflict between visual and vestibular signals can be independently detected, leading to long-term adaptive changes, especially significant for calibrating vestibular responses as measured subsequently in the dark and, in the short term, to the too-well-known symptoms of motion sickness. Conflict detection is a nonlinear process with its own detection threshold. The nonlinear conflict detection process is a process parallel to the examples of visual–vestibular cooperation described above.

Conclusions

For the detection of self-motion, either rotational or translational, both the visual and the vestibular systems have their weaknesses, which are largely overcome when both signals are present. However, even when both systems are present, systematic errors in assessing velocity and displacement are still found. It may be necessary to include additional sensory and extrasensory information, such as anticipation, prediction, and 'efference copy' of active motor commands to reach natural performance levels.

In assessing orientation, neither visual nor vestibular systems are directly sensitive to gravity. Both must rely on observing the effects of gravity on objects: either on the stones within the inner ear's labyrinth (detected by the hair cells of the vestibular system) or on objects in the environment (detected by the visual system). There is a weighted average of the cues involved in which more weight is placed on the more reliable cues.

The visual–vestibular consortium provides a best estimate of self-motion and orientation cues that enable us to interact effectively with our environment.

Introduction

Studies of vocal behavior in birds have made central contributions to animal behavior and the neurosciences. A well-known body of research has built on the discovery that vocal production in birds, particularly songbirds, is underpinned by an elaborate, hierarchical array of song nuclei distributed throughout the brain. Elucidation of the 'song system' has proceeded apace, powered by a host of methodological advances including *in vivo* single-cell recording, *in vitro* recordings from brain slices, selective lesioning, and neuronal tracings. The specialized nature of the song system for vocal production is exemplified by two key observations: the neural morphology of the song system varies seasonally, in a manner that corresponds to variation in vocal output, and in species in which males sing but females do not, song system nuclei are comparatively reduced in females. Studies of the avian vocal system continue to provide key insights into neural mechanisms of motor control.

This entry focuses on three additional, complementary lines of research in the avian vocal system that hold particular relevance for the neurosciences:

- The vocalizations of some bird groups, including songbirds, hummingbirds, and parrots, develop through imitative learning, in a manner that parallels speech acquisition in humans. Vocal learning in songbirds is now known to be mediated by a specialized neural pathway, the anterior forebrain pathway, the development of which depends on birds' auditory experiences. A 'developmental stress' hypothesis suggests that learned song can provide a reliable indicator of a male's neural developmental history and that females may thus use vocal parameters to assess the quality of prospective mates. Experimental studies with hand-reared birds illustrate a previously unrecognized axis of plasticity in sensorimotor development, in which birds faced with physical limits on vocal model reproduction can calibrate their 'targets' of learning.
- Vocal production entails extensive use of peripheral mechanisms. The vocal acoustic source, the syrinx, is dynamically coordinated with activity of the respiratory and vocal tract motor systems. Rapid and precise modulations in breathing patterns are required for the production of intricate vocal timing patterns, and modulation of vocal tract configuration during phonation enables birds to adjust vocal tract resonances and thus the spectral properties of song. It is not yet clear how birds manage to coordinate these multiple motor systems in vocal production, in terms of both neural control and its development. Limits on vocal performance, associated in particular with peripheral systems of vocal production, have been shown to constrain the production and evolution of certain vocal parameters.
- The biological function of birdsong has been examined with vocal playback studies, which are providing new insights into birds' perceptual and recognition abilities. Field playback tests have been conducted primarily with territorial males, in which vocal stimuli are presented to simulate territorial intrusions. Laboratory playback tests have been used to test birds' perceptual capabilities and limitations, and the preferences of females for different vocal stimulus classes. In conjunction with analyses of vocal variation, these studies are helping to specify the role of song in species recognition. 'Interactive' playback studies are helping researchers assess how birds modulate vocal output to convey varying levels of aggressive intent.

Vocal Learning

Songbirds learn to sing using a diversity of learning strategies or 'programs.' As with human speech development, vocal imitation in birds includes sensory and sensorimotor phases. During the sensory phase, birds memorize song models to which they are exposed. The sensorimotor phase, defined by transitions of vocal output from babblelike 'subsong' to crystallized adult forms, is mediated by comparison of vocal output to memorized song models via auditory feedback. During this phase, birds develop general proficiency with the vocal apparatus, as well as proficiency in the reproduction of memorized song models.

Species vary considerably in the timing of closure of their sensitive phases of song acquisition, in innate tendencies to memorize species-specific song stimuli, and in the relative impacts of social interactions on song model development. Within-species studies have proven especially beneficial in addressing the evolutionary causes of diversification in learning programs. The most comprehensive such studies to date have focused on white-crowned sparrows. Some populations of this species engage in long-distance migrations, whereas others remain essentially sedentary

throughout the year. Migration tendencies in white-crowned sparrows have now been shown, in both laboratory and field studies, to correlate with at least three aspects of song learning programs. First, migratory birds tend to experience earlier closure of the sensory phase of song learning. Second, birds from migratory populations tend to memorize more song types than do their sedentary counterparts, as revealed in vocal output during the initial stages of sensorimotor learning. Third, migratory populations show more evidence of 'selective attrition' during the sensorimotor phase of song learning; that is, they retain only a subset of previously memorized models. Interpopulation differences in learning programs enable birds from across the spectrum of migratory tendencies to crystallize song types that are shared by neighboring territorial rivals; as such, this diversity in learning programs may facilitate aspects of song function (see the section titled 'Song function'). In addition to highlighting ecological correlates of song learning, these data raise interesting new questions about the hormonal and neural bases of diversity in song learning programs.

Another recent body of research on vocal learning in songbirds focuses on the potential impacts of phenotypic condition on song learning and development. This work is motivated in part by advances in sexual selection theory, which posits that mating signals such as bird songs should evolve to provide accurate, reliable indicators of male genetic and phenotypic quality. Female choice of mates in many animals is informed by male signaling behavior. Females presumably evolve to attend to signal features that honestly and reliably reflect male quality because of the enhanced reproductive fitness of females that choose higher-quality mates. To explain the putative link between male quality and signal evolution, evolutionary biologists often refer to the so-called 'handicap' principle, which posits that high costs in signal production or expression enforce the honest and reliable nature of signaling. In this context, a stated goal of many current studies of mating signal evolution is to elucidate their underlying metabolic, developmental, and fitness costs.

Bird vocalizations are a promising system for studies of signal costs, given the elaborate neural and motor mechanisms that underpin vocal expression and development. Available evidence suggests that vocal production in adult birds requires only minimal increases in metabolic output above and beyond basal metabolic rates. However, accumulating evidence suggests that during vocal development, birds do face significant costs associated with stresses incurred during birds' early months of life. Young birds may suffer developmental stress from numerous sources, including insufficient nutrition, parasite infection, and trials of thermal regulation. Recent experimental work indicates that developmental stress can indeed interfere with the acquisition and expression of certain song features. Canaries infected with malaria at a young age and zebra finches reared under conditions of stress were found as adults to produce smaller song repertoires and smaller syllable repertoires, respectively. Swamp sparrows reared with restricted access to food copied song model notes less accurately than did birds reared with *ad libitum* access to food.

Degradation of vocal imitation abilities caused by developmental stress would likely be caused by subpar neural growth and development. Consistent with this hypothesis, the volume of the higher vocal center (HVC), a telencephalic song nucleus, was found to be significantly diminished in canaries reared under developmental stress compared with HVC volume in control birds. Similar results have been reported for zebra finches and swamp sparrows, although for the latter species, another song nucleus, the robust nucleus of the archistriatum (RA), suffered the greatest impact under conditions of developmental stress. These results are broadly consistent with comparative studies showing positive correlations between song nuclei size and song or syllable repertoire size. Males that suffer from only limited developmental stress would theoretically be able to devote more metabolic resources to developing larger song nuclei, and thus to developing larger song repertoires.

The evolutionary relevance of developmental stress can be tested by assessing, using song playback, the functional impact of variation in song features affected by developmental stress. In one such test, wild-caught female song sparrows were presented with songs recorded from males that had been imitated either with high accuracy or with poor accuracy. The dependent variable in this study was the copulation solicitation display, a behavioral pattern that normally precedes copulation in the wild and is thus regarded as a valid indicator of female song preferences. Subjects in this study displayed more often to playback of songs that had been learned with high accuracy. In a similar experiment, female zebra finches were shown to significantly prefer the songs of males that had been reared in a nonstressed environment over songs from males reared with nutritional stress. Available data thus provide increasingly strong support for the developmental stress hypothesis.

Studies of song learning have also revealed that birds can adjust the targets of song learning during sensorimotor development. Birds normally reproduce, with impressive accuracy, song models they had memorized previously. However, under some

Figure 1 Sensorimotor calibration of song learning targets in swamp sparrows, Each column shows a song model (top row), a crystallized copy of the model (bottom row), and three ontogenetic intermediaries of those models produced during sensorimotor development. Song models featured trill rates manipulated to exceed natural trill rates. The bird in each example is observed to 'experiment' during ontogeny with potential motor solutions in reproducing manipulated song models. In the first column, the bird is seen to attempt but eventually fail to integrate the low-frequency notes of the model into the crystallized song (with the exception of the opening syllables). In the second column, the bird is seen to experiment with varying trill rates and reduced frequency bandwidths before settling on the 'broken' syntax that was eventually crystallized. *X*-axis scale, 0–2.5 s; *y*-axis scale, 0–8 kHz. Reproduced from Podos J, Peters S, and Nowicki S (2004) Calibration of song learning targets during vocal ontogeny in swamp sparrows. *Animal Behaviour* 68: 929–940, with permission.

circumstances, birds may face performance limitations in the reproduction of certain vocal parameters. For example, some song features may be situated near the limits of a species' production capacities, or some birds may develop generally poor proficiency in vocal learning and reproduction because of developmental stresses. Young swamp sparrows reared with artificially manipulated song models, in which trill rates were elevated above natural rates, showed flexibility during sensorimotor learning in the reproduction of these rapid models. Memorized model targets were calibrated, over the course of sensorimotor learning, to better match birds' motor performance capacities (Figure 1). These data support 'active' models of song learning and sensorimotor development and suggest that the song-learning template retains plasticity through sensorimotor development even for birds with closed-ended memorization programs.

Peripheral Mechanisms of Vocal Production

Research on the neural bases of vocal behavior has traditionally focused on the nature and architecture of connections that descend to the brain stem and ultimately to the syrinx, the sound source. More-recent studies have started to evaluate the contributions in vocal production of the respiratory system

and the vocal tract. Above and beyond interest in questions about vocal mechanics, this work is motivated by evidence that peripheral mechanisms can delimit the range of vocal behaviors that can be expressed and thus evolve.

The temporal features of vocalizations can be shaped by dynamics of respiratory ventilation. In recent studies, respiratory and syringeal motor output was monitored in vocalizing birds by means of surgically implanted microbead thermistors and pressure transducers. One finding of this work is that birds vocalize almost exclusively during respiratory exhalations; by contrast, birds generally do not phonate during respiratory inspirations. As birds breathe out, airflow across the syrinx induces syringeal tissues to vibrate and thus produce sound. Patterns of breathing help define the structure of vocal trills, in which one or more notes (syllables) are repeated in rapid succession. For trills with slow to moderate rates of syllable repetition, birds employ a 'minibreath' motor strategy, with each respiratory expiration followed by a respiratory inspiration. As such, birds are able to maintain a steady tidal volume of air and thus produce trills of extended duration. For the production of more-rapid trills, however, birds appear to switch to another motor program, 'pulsatile' respiration, in which the tidal volume of the singing bird is rapidly depleted through expirations only. In a recent study, mockingbirds were presented with recordings of canary trills, with syllable repetition rates of 20 Hz and of extended duration. Mockingbirds that attempted to mimic these trills proved unable to reproduce them accurately, presumably as a result of performance limitations in their respiratory dynamics. More specifically, mockingbirds reproduced the rapid trill models using pulsatile rather than minibreath respiration, and resulting trills featured 'broken' syntax in which multisyllable segments were separated by pauses. Broken syntax had been observed previously in young swamp sparrows trained with trilled song models in which trill rates had been artificially elevated (e.g., **Figure 1**, right column).

The vocal tract, which includes the trachea, glottis, tongue, and beak, also affects song expression. The vocal tract acts as a resonance filter of sound produced by the syrinx, as first demonstrated in a study of birds that sang in an experimental helium-enriched environment. Vocalizations produced in this environment included harmonic overtones that would not otherwise have been expressed. These results indicate that the tonal quality of song is shaped by resonance properties of the vocal tract. Recognition of an acoustic function for the vocal tract helps explain the evolution of unusually elongated trachea in a wide diversity of birds including cranes, swans, curassows, and geese.

In songbirds, song production often includes rapid reconfigurations of the vocal tract. High-speed video recordings of several species of sparrows and finches indicate that changes in beak gape co-occur with temporal changes in vocal fundamental frequency. This observation concords with a resonance model of vocal tract function: wider beak gapes effectively shorten the volume of the vocal tract, thus providing a more appropriate resonance filter for high-frequency sounds. Performance constraints in vocal tract modulation have been offered as an explanation for an observed trade-off between two vocal parameters, trill rate and frequency bandwidth, in the evolution of trills in emberizine finches and sparrows (**Figure 2**). Rapid trill rates require rapid vocal tract modulations, and wide frequency bandwidth production requires broad vocal tract modulations. Because of a trade-off in the rapidity versus the breadth of vocal tract modulations, trills beyond a certain rate can presumably be accompanied only by vocal tract modulations of narrow breadth. Similar trade-offs between trill rate and frequency bandwidth have now been described in other taxa, including blackbirds, wrens, and warblers.

Recognition of the beak's contribution to vocal production has suggested a previously unrecognized mechanism of vocal evolution. Birds are known for diverse adaptations of their beaks, as they have occupied diverse feeding niches. Evidence now suggests that the evolutionary diversification of beaks can invoke incidental consequences on the evolution of song structure. In particular, a 'vocal tract constraint' hypothesis predicts that birds with comparatively large beaks, adapted for crushing hard seeds, should suffer comparatively severe constraints on vocal performance because of biomechanical trade-offs between the force and speed of beak gape modulations. Support for this hypothesis comes from studies of several bird groups, including Darwin's finches of the Galápagos Islands, Ecuador. Analysis of song structure from birds with different beak morphologies, both across and within species, reveals differences in expressed 'vocal performance' that are consistent with the vocal tract constraint hypothesis (**Figure 3**). As birds adapt to new habitats, adaptations of the beak may thus drive secondary changes in song structure.

Because song is used in mate and species recognition, beak adaptations and subsequent evolutionary changes in song may facilitate reproductive isolation and speciation. This hypothesis is supported by field studies of a population of medium ground finches at *El Garrapatero* on Santa Cruz Island, Galápagos. This population features two discrete beak-size morphs, with small-beaked birds producing songs with consistently higher

Figure 2 (a) Songs of eight North American Emberizine sparrows, illustrating the diversity of songs that can be expressed even among closely related species. Each of these songs contains trilled sequences, which can be characterized in part by trill rate (the rate of syllable repetition) and frequency bandwidth (the range of fundamental frequencies expressed over the course of the trill). This horizontal scale bar is 0.5 s, and y-axis spans 2–8 KHz. (b) Plot of trill rate versus frequency bandwidth for 740 trilled sequences across 34 species from the family Emberizidae. Triangular distributions evident for the family (here) as well as for individual species and genera support a vocal tract constraint hypothesis. (a, b) Reproduced from Podos J (1997) A performance constraint on the evolution of trilled vocalizations in a songbird family (Passeriformes: Emberizidae). *Evolution* 51: 537–551, with permission from Blackwell publishers.

levels of vocal performance. Differences in the songs of small- and large-beaked birds can be detected by both ornithologist and finch, the latter as indicated in playback studies to territorial males. Female Darwin's finches generally choose mates based primarily on song structure, and preferences for morph-specific songs in the *El Garrapatero* population presumably explain observed patterns of assortative mating and incipient genetic divergence among morph types.

Song Function

Species Recognition

Birds sing mostly to communicate with individuals, such as potential mates or rivals, of their own species. For song to function in this way, individuals must have the ability to recognize the songs of their own species and to differentiate such songs from those produced by heterospecifics. Songs indeed have diverged markedly among species, to the extent that most species produce songs that can be considered 'species-specific.'

Interspecific divergence of songs is thought to be driven largely by selection against hybrid (cross-species) mate selection and offspring production. Males that produce species-distinctive songs, and females that are able to successfully identify conspecific songs, will be more likely to achieve conspecific matings and thus avoid costly hybrid matings. Thus the production and recognition of species-distinctive songs should propagate along distinctive trajectories in different songbird lineages. Support for this 'sound–environment' hypothesis has been garnered from studies showing that species living in proximity, especially those that are closely related, tend to evolve songs that occupy distinct positions in 'acoustic space,' defined by dimensions of song structure. A recent study of neotropical antbird songs provides strong support for the sound–environment hypothesis. This study evaluated song similarity within nine species trios, each representing a genus of the antbird family Thamnophilidae. Each trio was comprised of a focal species, a closely related species living in sympatry (at the same location as the focal species), and a closely related species living in allopatry (at a different location from the focal species). Across all nine trios, the songs of allopatric species pairs were found to be significantly more similar than songs of sympatric species pairs. This finding suggests a recent history of independent song divergence events within sympatric species, presumably caused by selection favoring the evolution of species-specific song production and song recognition abilities.

Compared with song features that vary among individuals, song features that do not vary within a species ('invariant' features) presumably serve as reliable species identification signals. This is especially true for invariant features that are clearly distinct (i.e., have little structural overlap) from songs of

Figure 3 Beak morphology and representative song spectrograms from eight species of Darwin's finches. Interspecific variation is evident in both morphology and song structure. Each of these songs includes trilled segments. Birds with larger beaks, for which rapid gape modulations are comparatively difficult to achieve, tend to produce trills with lower trill rates and more narrow frequency bandwidths than the trills of their smaller-beaked counterparts. Reproduced from Podos J (2001) Correlated evolution of morphology and vocal signal structure in Darwin's finches. *Nature* 409: 185–188, with permission.

sympatric species. A recent study of field sparrows tested, using a series of playback trials, the functional significance of multiple invariant song features. Playback stimuli were synthesized in which single invariant features were modified, one at a time, to values outside of the species-typical range. Territorial males were then presented with a choice of modified and control (unmanipulated) songs. Males were found to approach speakers broadcasting control songs more often than speakers broadcasting modified songs, as expected. Follow-up trials were then performed in which test stimuli expressed modifications in all possible combinations of invariant features. These trials enabled an assessment of feature 'weighting' in the perceptual salience of field sparrow song, with song frequencies ultimately shown to be the invariant song features of the greatest import.

Song matching

The functional consequences of variation in song structure have traditionally been assessed using 'loop' playback studies, in which song stimuli are presented according to previously determined sequences and rates, for example as recorded in advance on a cassette tape taken to the field. With the advent of portable

computers and specialized software packages, however, it is now possible to 'interact' with focal birds by selecting a specific playback song from a set of available digitized stimuli. Interactive playbacks are allowing researchers to test hypotheses that before they could investigate only through correlative analyses.

A growing number of experiments using interactive playback focus on the question of how birds signal aggressive intent. In bird species with large repertoires, neighboring individuals often share subsets of song types. In such species, males engaged in territorial skirmishes can respond to rivals with song types that are either shared or not. According to theory, the degree to which birds match the song types of rivals may reflect levels of aggressive intent. This theory has now been supported by an experiment with song sparrows that used interactive playbacks. Territorial male song sparrows were found to escalate their levels of response when they received playback of song types similar to the ones they had been singing, compared with their response to playback of non-matching song types. Matching can also occur for other vocal parameters. Black-capped chickadees were found to approach a playback speaker more closely and make more flights over the speaker when presented with songs in which the acoustic frequency of the stimulus closely matched frequencies of their songs, compared with their responses to playback of songs with different frequencies.

Song overlapping

Studies of chickadees and other species have examined another type of aggressive signaling, termed 'overlapping.' Overlapping occurs when a bird begins to sing before another individual has completed its song. In some species, such as European thrushes, the efficacy of communication is more compromised in the overlapped bird than in the overlapper, given that the degree of information encoded in songs tends to increase toward the end of songs. Nightingales have shown intense responses to playbacks of overlapping song. When presented with songs from two speakers, one speaker that broadcast overlapping songs and one that did not, male nightingales responded more rapidly, more vocally, and with closer approaches to the speaker that broadcast the overlapping song. In an experiment that varied both frequency matching and overlapping, male chickadees were most agitated when presented with playback stimuli that both overlapped and matched the frequency of their songs.

Eavesdropping

In most vocal interactions, individuals other than the intended receiver are able to overhear the signaling individuals. In a series of studies on great tits, researchers showed that both males and females can use information gathered by eavesdropping to assess rivals or prospective mates. In one such study, researchers broadcast a simulated interaction of two 'virtual' individuals, unknown to the focal bird, in stereo over two speakers outside his territory. In this interaction, one of the two virtual individuals either switched song types (to match the other simulated individual or not) or continued to sing a single song type. The songs of this individual were subsequently presented to the focal bird. For the former condition, in which the virtual bird had matched song types during its earlier simulated interaction, focal birds responded more strongly than they did when virtual territorial intruders had not matched during simulated interactions. Thus it was shown that by eavesdropping, male great tits extract information about the level of perceived threat from potential rivals.

Another clever experiment addressed the topics of eavesdropping and song overlapping simultaneously by providing male great tits the opportunity to gather information from both direct and indirect interactions. Songs of a simulated intruder stranger male (X) were broadcast to focal territorial males. With the use of interactive playback, these songs were varied either to overlap or to alternate with a subject's songs. A simulated interaction between this intruder male, X, and another virtual, stranger male, Y, was then played outside the subject male's territory, with a different speaker for each bird. Male X was manipulated to either 'win' or 'lose' the interaction in terms of patterns of overlap. Finally a territorial intrusion by male Y was then simulated and the focal male's responses measured. If the subject male had been manipulated to 'beat' male X, and male X to 'beat' male Y, the subject tended to respond with less effort, fewer songs, and diminished approach to male Y, presumably because of diminished perceived threat. By contrast, in scenarios in which the threat level of male Y was ambiguous (if, for example, the subject was manipulated to 'beat' male X, but X subsequently lost to male Y) or the level of threat was high (if X beat the focal male, but Y subsequently beat X), subjects responded with significantly more songs and closer approaches to the speaker, presumably because of a comparatively elevated perceived threat.

Females presumably could also use eavesdropping to evaluate social mates or potential extrapair partners. In an experiment with great tits, focal males were presented with overlapping ('escalated') playback songs, but neighboring males were presented with de-escalated (fewer songs, with shorter phrases) playback songs. Females mated to males that

had received escalated playback (apparent 'losers') subsequently visited territories of neighboring males more often than did females whose males had received the de-escalated treatment (apparent 'winners'). This finding holds functional relevance because females might visit neighboring male territories to seek copulations from perceived higher-quality neighbors. In another experiment, female black-capped chickadees were found to engage in extrapair copulations with greater frequency if their mates had received aggressive, overlapping playbacks at an earlier time. These studies together provide new evidence of advanced perceptual and cognitive abilities in birds and suggest avenues for future studies that integrate neurobiological, psychological, and ecological perspectives.

Voltage Gated Potassium Channels: Structure and Function of Kv1 to Kv9 Subfamilies

B Rudy, J Maffie, Y Amarillo, B Clark, E M Goldberg, H-Y Jeong, I Kruglikov, E Kwon, M Nadal, and E Zagha, New York University School of Medicine, New York, NY, USA

Voltage-gated potassium channels have K^+-selective pores that are opened by membrane depolarization. This opening allows the movement of K^+ ions across the plasma membrane and the generation of K^+ currents that tend to repolarize the membrane toward the equilibrium potential for K^+ (E_K). Voltage-gated potassium channels contribute widely to the electrical properties of neurons. They influence subthreshold properties, including the resting potential and membrane resistance. They influence the amplitude and frequency of subthreshold oscillations, the responsiveness of the cell to synaptic inputs, and the probability of spike generation. They help shape postsynaptic potentials, and they are the main determinants of the repolarization of the action potential governing spike shape and frequency. Their voltage-dependent activity ensures a non-ohmic current–voltage relationship, which thereby enables the channels to contribute to the nonlinear properties of neurons. Voltage-gated potassium channels have similar functions in other excitable cells, including all varieties of muscle. In non-excitable cells, they contribute to the resting potential and to the regulation of Ca^{2+} entry and secretion.

Voltage-gated K^+ channels differ dramatically in their kinetic and voltage-dependent properties as well as their cellular and subcellular distributions. This diversity is a main contributor to the varied electrical properties of neuronal populations throughout the nervous system. Thus, understanding the input–output relationship of neuronal elements demands the continued effort to study the properties and localization of these channels and analyze their physiological roles in native membranes.

Voltage-gated K^+ channels are tetramers of primary, or pore-forming, subunits (also known as α subunits). These tetramers form the infrastructure of the channels and in most cases are sufficient to form functional channels. However, many voltages-gated K^+ channels in their natural environment also include associated or auxiliary proteins (sometimes referred to as β subunits). These proteins have primary sequences not resembling those of the pore-forming subunits, can significantly modify the properties of the channels, and can be essential for the efficient expression of functional channels in the plasma membrane. In addition, other proteins such as regulatory enzymes and elements of the cytoskeleton have been shown to interact with many K^+ channel molecular complexes.

Based on sequence similarity, the pore-forming subunits of mammalian voltage-gated K^+ channels can be classified into three groups of proteins that correspond to distinct functional classes. The first group includes the proteins of the Kv1–Kv6, Kv8, and Kv9 subfamilies (collectively called here the 'Kv_F family' for fast-activating Kvs), components of voltage-gated K^+ channels that activate quickly upon membrane depolarization. In contrast, proteins of the Kv7 subfamily (often called the KCNQ family) and of the Kv10–Kv12 subfamilies (also known as the EAG family) are pore-forming subunits of voltage-gated K^+ channels with comparatively slow kinetics. The subunits of the Kv7 family form the M-type K^+ channels underlying the current known as I_M, a subthreshold operating current of considerable importance in the regulation of neuronal excitability. This article discusses the channels formed by the pore-forming subunits of the Kv_F and Kv7 families (Kv subfamilies 1–9; Figure 1). A separate article in this encyclopedia discusses the more distantly related EAG (Kv10–Kv12) family.

Structure of Kv Proteins

Kv subunits consist of six membrane spanning domains (S1–S6) flanked by intracellular NH_2 and COOH terminal sequences of variable lengths (Figure 1). The linker between the S5 and S6 transmembrane helices partially enters the membrane and is known as the P loop or P domain. This domain contains the 'K^+ channel signature sequence' (TVGYG), which is highly conserved not only among Kv proteins but also among all K^+ channel subunits, including those from prokaryotes, and contributes to the formation of the K^+ selective pore (Figures 1 and 2). At the N-terminus, preceding the S1 helix, there is a sequence known as the tetramerization or T1 domain. T1 domains of members of the same subfamily are very similar and determine subfamily specific association.

The fourth membrane spanning domain (S4) is characterized by the repetition of a motif consisting of two neutral residues (usually hydrophobic except toward the COOH end of S4) and one positively charged residue (usually arginine). The number of repetitions of this motif is characteristic of each Kv_F subfamily: seven in Kv1 subunits, five in Kv2s (as well as Kv5, Kv6, Kv8, and Kv9) and Kv4s, and six in Kv3s. The S4 domain in Kv7 (KCNQ) subunits has six positive charges, except in Kv7.1, which has four.

Figure 1 (a) Phylogenetic relations of Kv1–Kv9 K^+ channel subunits. The functional classes discussed in this chapter also form closely related subgroups based on sequence similarities. (b) Schematic representation of a Kv subunit. Kv subunits have six membrane spanning domains (S1–S6) flanked by cytoplasmic amino and carboxyl ends. The pore loop region (P), critical to the formation of the K^+ channel selectivity filter is found between the S5 and S6 helices. The T1 domain, involved in the formation of tetrameric structures among members of the same subfamily and in interactions with auxiliary proteins, is in the amino end region preceding the S1 domain. Some Kv proteins contain N-inactivation domains at the N-terminus. The membrane is shown in yellow. (a) From Yu FH and Catterall WA (2004) *The VGL-chanome: A protein superfamily specialized for electrical signaling and ionic homeostasis*. STKE Science's 253: re15.

The S4 domain is a critical part of the voltage sensor; the positively charged residues are likely the gating charges, which move in response to changes in membrane potential to open and close the channel's pore.

The structure of a mammalian Kv channel, a complex consisting of four Kv1.2 subunits and four auxiliary Kvβ2 proteins, has been resolved at 2.9 Å in the laboratory of Roderick MacKinnon (Figure 2a). In the channel structure, four T1 domains, one from each of the four Kv1.2 subunits, interact to form a tetrameric assembly at the intracellular membrane surface. This assembly is located directly under the cytoplasmic side of the channel's pore. As a result, the pore communicates with the cytoplasm through side portals or windows formed by the linkers connecting the T1 domains to the first membrane spanning helices. These portals allow K^+ ions to flow freely between the pore and the cytoplasm. These portals are also large enough to allow the entry of the N-terminal inactivating polypeptide responsible for N-type inactivation. Four Kvβ2 subunits interact with the T1 domains.

In the structure derived by MacKinnon and colleagues, the channel consists of two relatively independent domains: a voltage sensor domain consisting of the S1–S4 helices of the four Kv subunits and a pore domain consisting of the S5 and S6 membrane spanning helices with the P loop in between, as shown in Figure 2. The structure of the pore domain is similar in voltage-gated K^+ channels and in K^+ channels that are not voltage dependent, such as the potassium channels know as inward rectifiers. These channels consist of subunits that have only two helices (inner and outer, equivalent to the S6 and S5 helices, respectively) and a P loop. The pore domains of the four subunits create an 'inverted teepee,' or cone, with the S6 (or inner helix) facing the inside. The P loops of the four subunits are located in the wider third of the teepee, near the extracellular surface, forming the selectivity filter, which surrounds the narrowest part of the pore. The selectivity filter is determined by the amino acids of the K^+ channel signature sequence, oriented in such a way that they expose their main chain carbonyl oxygen atoms to the pore. During dehydration of the K^+ ion, these carbonyl oxygen atoms replace the oxygen atoms of the water hydrating the ion, allowing its entrance into the narrow pore delimited by the selectivity filter. The carbonyl oxygens are too far apart to properly surround and stabilize the smaller Na^+ ion, thus explaining K^+ selective permeation.

In the crystal structure, the voltage sensor domain is connected to the pore domain through helices made by the S4–S5 linker, which makes several amino acid contacts with the S6 or inner helix lining the pore

Figure 2 Comparison of the Kv1.2–Kvβ2 channel complex with a modeled Kv4.3–KChIP1-DPPX channel complex. (a) Side view of the $Kv_{1.2}$–Kvβ2 channel complex derived from the crystal structure obtained by MacKinnon and colleagues (Long SB, Campbell EB, and Mackinnon R (2005) Crystal structure of a mammalian voltage-dependent Shaker family K^+ channel. *Science* 309: 897–903 and Long SB, Campbell EB, and Mackinnon R (2005) Voltage sensor of Kv1.2: structural basis of electromechanical coupling. *Science* 309: 903–908). Image obtained from Wang H, Yan Y, Liu Q, et al. (2007) Structural basis for modulation of Kv4 K^+ channels by auxiliary KChIP subunits. *Nature Neuroscience* 10: 32–39. The four Kv1.2 subunits are labeled in cyan, yellow, red, and green. The four Kvβ2 subunits are labeled in wheat color. The upper third shows the transmembrane part of the channel. The inverted tepee, formed by the pore domains (S5-P-S6) of the four Kv1.2 proteins, is in the center, and the voltage sensor domains (S1–S4) are lateral. The middle portion of the figure contains the T1 domains interacting with the Kvβ2 proteins at the bottom. (b) Side view of the Kv4.3-KChIP1-DPPX channel complex. This figure was obtained by adding molecules of DPPX (based on the crystal structure of the DPPX extracellular domain: obtained by Strop et al. (2004). Strop P, Bankovich AJ, Hansen KC, Garcia KC, and Brunger AT (2004) Structure of a human A-type potassium channel interacting protein DPPX, a member of the dipeptidyl aminopeptidase family. *Journal of Molecular Biology* 343: 1055–1065) to the model of the Kv4.3-KChIP1 channel complex by Wang H, Yan Y, Liu Q, et al., Structural basis for modulation of Kv_4 K^+ channels by auxiliary KChIP subunits. *Nature Neuroscience* 10: 32–39. The four Kv4.3 subunits are labeled in cyan, yellow, red, and green. The four KChIP1 proteins interacting with the channel T1 domains, are labeled in blue. The transmembrane domains of DPPX are shown interacting with the membrane spanning helices of the voltage sensor domains. Only two DPPX molecules are shown to facilitate viewing, but we believe that the channel complex is likely to include four DPPX proteins. Each DPPX subunit includes an α/β hydrolase domain (close to the membrane and a β propeller domain shown on top and to the side. The extracellular domains of two DPPX proteins interact forming a dimer.

(Figure 2). The cytoplasmic end of the S6 helix is flexible around a 'hinge' provided by the conserved sequence Pro-X-Pro. The movement of the voltage sensor in response to changes in membrane potential displaces the S4–S5 linker affecting its interactions with the S6 helix, allowing the cytoplasmic end of S6 to move and thus constrict or dilate the inner opening of the pore.

The Fast-Activating Kv Subfamilies

All members of the Kv1–Kv4 subfamilies form functional homomultimeric channel complexes when expressed in heterologous expression systems, whereas the members of the Kv5, Kv6, Kv8, and Kv9 subfamilies are 'silent' pore-forming subunits that do not form functional homomultimeric channels by themselves and must co-assemble with subunits of the Kv2 subfamily to express functional channels.

Subunits of the Kv1, Kv3, and Kv4 subfamilies can form heteromeric channels with other members of the same subfamily in heterologous expression systems. Heteromeric channels have properties that are intermediary to those of homomeric channels, although some properties of one subunit may dominate in the heteromultimeric channel. It is not clear whether the two members of the Kv2 subfamily can associate with each other to form heteromeric channels, but both can form heteromeric channels with the silent Kv5, Kv6, Kv8, and Kv9 proteins.

Most Kv proteins are expressed in the nervous system, and there is considerable overlap of expression of multiple Kv subunits of the same subfamily in many neurons, suggesting that native channels in many cells might be heteromultimers (Table 1). Heteromultimerization largely increases the number of channels with distinct functional properties that can be generated by Kv subunits (the number of different

Table 1 Kv subunits[a]

Channel subunit	*Associated proteins*	*Expression pattern*	*Channel function*	*Associated pathology*
Kv1 subfamily Kv1.1 Gene symbol: KCNA1[b]	Kvβs (see **Table 2**) PDZ domain-containing proteins such as PSD95 and SAP97 SNAP25, CASPR2	Tissue: strong in brain and sensory neurons; weak in atria, aorta, skeletal muscle, retina, smooth muscle. CNS: RNA – widely expressed in rodent CNS. Protein – predominantly in axons, axon initial segment (AIS), and presynaptic terminals. Juxtaparanode of myelinated fibers. Staining of neuronal somata and proximal dendrites in some neurons.	Kv1.1 expresses TEA, DTX, and 4-AP sensitive fast-activating low-voltage-activating delayed rectifier channels in heterologous expression systems. In neurons: Kv1.1 subunits contribute to the formation of dendrotoxin (DTX-I)-sensitive K^+ channels mediating the DTX-sensitive current I_D. I_D in neuronal somata and AIS regulates neuronal subthreshold excitability and spike initiation as in neurons in the MNTB, where it ensures that the timing and pattern of AP firing is preserved across the relay synapse. In presynaptic terminals, it regulates the excitability of the terminal and prevents aberrant excitation.	Mouse: knockout – frequent epileptic seizures, short life span. Point mutation V408A – model of episodic ataxia type-1 (EA1). Spontaneous 11-bp deletion – megencephaly. Human: Kv1 mutations – EA1 with myokymia, sometimes associated with epilepsy; autoantibodies to several Kv1s found in autoimmune disorders such as Morvan's syndrome and limbic encephalitis.
Kv1.2 Gene symbol: KCNA2	$K_V\beta$s. PDZ domain-containing proteins Small GTP-binding protein RhoA. Protein tyrosine kinases phosphorylate and thereby suppress Kv1.2 channels. RhoA is a necessary component in this process and mediates M1 receptor inhibition of Kv1.2 by tyrosine phosphorylation. CASPR2	Tissue: brain, vascular smooth muscle, sensory neurons. CNS: very widely expressed. Kv1 heteromers often contain Kv1.2. Protein predominantly in axons and terminals. Pattern highly overlapping with other Kv1s but not identical. For example, in hippocampus, cerebellum, and spinal cord. Present in axon initial segment; juxtaparanode in myelinated axons Also in proximal dendrites and soma in some neurons.	In heterologous expression systems, Kv1.2 expresses 4-AP and DTX-sensitive low-voltage-activating delayed rectifier channels with slower activation kinetics than other Kv1s. Kv1.2 subunits contribute to forming DTX-sensitive channels in neuronal somata, axons, and terminals (see Kv1.1). Likely to contribute to I_D with slower kinetics. Regulation of subthreshold excitability in striatal medium spiny neurons.	Human: autoantibodies to several Kv1s found in autoimmune disorders such as Morvan's syndrome and limbic encephalitis.

Kv1.3 Gene symbol: KCNA3	$K_V\beta$s PDZ domain-containing proteins PSD95, SAP97, and hDLg KCNE4 (MirP3) – an inhibitory subunit to Kv1.1 and Kv1.3 β_1 integrins	Tissue: brain, lymphocytes (type n channel), macrophages, microglia, kidney, testis and spermatozoa, osteoclasts. CNS: prominent in olfactory bulb, cerebellum, parallel fibers, deep nuclei, Purkinje cell somata; weak in hippocampus and stratum lucidum. Protein: mitral and granule cells of the olfactory bulb.	In heterologous expression systems, Kv1.3 expresses fast-activating 4-AP-sensitive channels with prominent 'slow' P/C-type inactivation and prominent cumulative inactivation. Blocked by several toxins with some specificity. Regulates neuronal excitability, possibly in heteromers with other Kv1s. Mediates the type n K^+ channel in lymphocytes, required for lymphocyte activation. Kv1.3 channels contribute to the neuronal killing ability of microglia.	Kv1.3−/− mice have a 1000- to 10 000-fold lower threshold for odor detection and increased ability to discriminate between odorants. Mice weigh significantly less than control littermates, suggesting regulation of energy homeostasis as well as peripheral insulin sensitivity. Multiple sclerosis: blockers of Kv1.3 are being considered for MS treatment.
Kv1.4 Gene symbol: KCNA4	$K_V\beta$s PDZ domain-containing proteins PSD95, SAP97, and hDLg α-actinin-2 KChaP σ receptor	Tissue: brain, heart atria, low levels aorta, skeletal muscle PNS: altered expression after axotomy; sole Kv1 in small-diameter neuron nociceptors CNS: mRNA prominent throughout brain, much weaker in cerebellum and brain stem. Strong in hippocampus, striatum, thalamus, and CX. Widespread Kv1.4 immunoreactivityin brain, probably in axons.	In heterologous expression systems, Kv1.4 expresses fast-activating and -inactivating 4-AP-sensitive channels. Neurons: contributes inactivation to DTX-sensitive K^+ channels. Regulates spike repolarization and spike broadening during repetitive activity in mossy fiber terminals. Heart: mediates slow component of I_{to} in atria.	Kv1.4−/− mice show increased spontaneous seizures. Patients with myasthenia gravis produce autoantibodies to Kv1.4.
Kv1.5 Gene symbol: KCNA5	Kvβs Src tyrosine kinase PDZ-containing proteins Kchap Fyn α-actinin-2 Caveolin SAP97	Tissue: heart > skeletal muscle > brain > lung > kidney. Pancreatic β cells, microglia, Schwann cells. Brain: Purkinje cells, DCN. Hippocampus: somatodendritic.	In heterologous expression systems, Kv1.5 expresses fast-activating 4-AP-sensitive delayed rectifier channels. 4-AP-sensitive component of I_{Kslow} in mouse ventricle and I_{Kur} (ultrarapid-activating K^+ current) in human atrium. Potential use in management of atrial fibrillation via blockade of I_{Kur}.

Table 1 Continued

Channel subunit	*Associated proteins*	*Expression pattern*	*Channel function*	*Associated pathology*
Kv1.6 Gene symbol: KCNA6	Kvβs CASPR2	Tissue: brain, smooth muscle, PNS, oligodendrocytes, astrocytes, AV node. CNS: widely distributed in cerebral cortex and hippocampus in axons. Purkinje cells (somatodendritic, not axonal) and in various olfactory and amygdaloid structures.	In heterologous expression systems, Kv1.6 expresses fast-activating subthreshold-activating DTX- and 4-AP-sensitive delayed rectifier channels. Kv1.6 subunits contribute to forming DTX-sensitive channels in neuronal somata, axons, and terminals (see Kv1.1).	Kcna6^{tm1Lex} lexicon genetics Homozygous mutation results in increased thermal nociceptive threshold (MGI). Autoantibodies to several Kv1s found in autoimmune disorders such as Morvan's syndrome, neuromyotonia, and limbic encephalitis.
Kv1.7 Gene symbol: KCNA7		mRNA: expressed in pulmonary arteries, heart, skeletal muscle, pancreatic islet cells, but not in brain.	In heterologous expression systems, Kv1.7 expresses fast-activating 4-AP-sensitive channels. Two channel isoforms with different functional characteristics; the long form, Kv1.7L, inactivates faster than the short isoform, Kv1.7S, predominantly due to an N-type related mechanism, which is impaired in the short form. Kv1.7L, but not mKv1.7S, is regulated by the cell's redox state.	
Kv1.8 Gene symbol: KCNA10	KCNA4B: increases current magnitude and sensitivity to cAMP	RNA expressed in kidney, renal blood vessels, heart, brain (weakly), and aorta	Voltage- and cyclic nucleotide-gated K^+ channel. In heterologous expression systems, Kv1.8 expresses slowly activating high-voltage-activating delayed rectifier channels. KCNA10 may facilitate renal proximal tubular sodium absorption by stabilizing cell membrane potential. Its presence in endothelial and vascular smooth muscle cells suggests that it also regulates vascular tone.	

Kv2 subfamily			
Kv2.1 Gene symbol: KCNB1	Kv5–Kv6, Kv8–Kv9 subunits KChaP (binds to N-terminus of Kv2.1) Fyn SH2 domain SNAP25	Tissue expression: brain, atria, ventricle, skeletal muscle, olfactory epithelium, retina, kidney, SCG (also Kv2.2); spinal motor neurons; lung, pancreatic β cells, pulmonary artery. Brain: widely expressed, but no detailed distribution of Kv2.1 or Kv2.2 mRNA or protein reported. Protein localized in clusters in somatic and proximal dendritic membrane. Little neuropil staining.	In heterologous expression systems, Kv2.1 expresses slowly activating high-voltage-activating delayed rectifier channels that are blocked by high millimolar concentrations of TEA. Kv2 channels mediate I_K, the TEA-sensitive, 4-AP-'insensitive' delayed rectifier K^+ current recorded in many neurons. Potential therapeutic targets for diabetes due to their prominent expression in pancreatic β cells.
Kv2.2 Gene symbol: KCNB2	Kv5–Kv6, Kv8–Kv9 subunits mKvβ4 associates with Kv2.2 and enhances expression level KChaP	Tissue: brain, tongue epithelium; SCG, sympathetic neurons; GI/mesenteric artery smooth muscle. Brain: neuropil (axons), maybe in some somas.	In heterologous expression systems, Kv2.2 expresses slowly activating high-voltage-activating delayed rectifier channels that are blocked by high millimolar concentrations of TEA. Kv2 channels mediate I_K, the TEA-sensitive, 4-AP-insensitive delayed rectifier K^+ current recorded in many neurons.
Kv5.1 Gene symbol: KCNF1	Kv2.1 and Kv2.2 subunits	Rat and human brain, heart, skeletal muscle, liver, cardiac myocytes. Brain: limited mRNA expression in rat brain – deep cortical layers, amygdala, and medial habenular nucleus.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: decreases current levels, slows down activation, produces negative shifts in inactivation, and slows down deactivation.
Kv6.1 Gene symbol: KCNG1	Kv2.1 and Kv2.2 subunits	Human: brain, placenta, skeletal muscle. SA cardiac nodal cells.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: produces negative shifts in activation and inactivation and slows down deactivation.
Kv6.2 Gene symbol: KCNG2	Kv2.1 and Kv2.2 subunits	Primarily rat and human heart.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: modifies kinetics and voltage dependence and confers submicromolar sensitivity to antiarrhythmic drug propafenone.

Continued

Table 1 Continued

Channel subunit	*Associated proteins*	*Expression pattern*	*Channel function*	*Associated pathology*
Kv6.3 Gene symbol: KCNG3	Kv2.1 and Kv2.2 subunits	Human, rat: brain, testis, thymus, adrenal glad, small intestine, kidney, lung, pancreas, ovary, colon. Brain: widely expressed in rat. RNA most prominent in cortex, hippocampus, striatum, amygdala.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: slows down inactivation and deactivation.	
Kv6.4 Gene symbol: KCNG4	Kv2.1 and Kv2.2 subunits	Human: brain, liver, small intestine, colon.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: produces negative shifts in activation and inactivation, slows down deactivation, and speeds up activation.	
Kv8.1 Gene symbol: KCNV1	Kv2.1 and Kv2.2 subunits	Hamster brain: mRNA very widespread.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: produces negative shift in inactivation, slows down activation and inactivation.	
Kv8.2 Gene symbol: KCNV2	Kv2.1 and Kv2.2 subunits	Human: lung, liver, kidney, pancreas, spleen, thymus, prostate, testis, ovary, colon.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: produces small negative shifts in activation and inactivation and slight acceleration of activation.	
Kv9.1 Gene symbol: KCNS1	Kv2.1 and Kv2.2 subunits	Human: brain, prostate, testis by PCR. Mouse: mainly in brain. mRNA in mouse brain: Kv9.1 and Kv9.2 subunits show very similar expression – olfactory bulb, cortex, hippocampus, habenula, basolateral amygdala, cerebellum	Silent subunit, interacts with Kv2 subunits and modifies channel properties: reduces currents, produces negative shifts of activation and inactivation. Slows down activation of Kv2.1. Slows down deactivation of Kv2.1 but speeds up deactivation of Kv2.2.	
Kv9.2 Gene symbol: KCNS2	Kv2.1 and Kv2.2 subunits	Mouse: mainly in brain Pulmonary artery Distribution in mouse brain, (see Kv9.1).	Silent subunit, interacts with Kv2 subunits and modifies channel properties: reduces currents, produces negative shifts of inactivation. Slows down deactivation of Kv2.1.	

Kv9.3 Gene symbol: KCNS3	Kv2.1 and Kv2.2 subunits	Widespread expression in human by PCR.	Silent subunit, interacts with Kv2 subunits and modifies channel properties: produces negative shifts of activation and inactivation, slows down deactivation, and speeds up recovery from inactivation.	
Kv3 subfamily				
Kv3.1 Gene symbol: KCNC1		Broadly expressed in somas, axons, and terminals in brain and spinal cord structures but in specific cell populations, including many (but not only) GABAergic neurons and brain stem sensory neurons. Dog atrium Molecular basis of canine atrial $I_{Kur,d}$. T lymphocytes.	In heterologous expression systems, Kv3.1 expresses high-voltage-activating, fast-activating and -deactivating delayed rectifier channels that are very sensitive to TEA and 4-AP. Important for spike repolarization and high-frequency firing of brain stem auditory neurons and fast-spiking GABAergic interneurons. Regulate spike repolarization and duration in presynaptic terminals. Spike repolarization in nodes of Ranvier in central myelinated axons. Type I channel in T lymphocytes.	Kv3.1−/− mice exhibit impaired motor skills, hyperactivity, and sleep loss. Kv3.1/Kv3.3 double knockout mice show ataxia, tremor, myoclonus, and hypersensitivity to ethanol.
Kv3.2 Gene symbol: KCNC2		Tissue expression: mRNA mainly in brain. Prominently in thalamus. GABAergic interneurons of the neocortex, hippocampus, and caudate; globus pallidus, SNR, sensory nuclei in brain stem. Protein in terminal fields of thalamocortical axons. Somata and axons of cortical interneurons and other mRNA-expressing neurons. Pancreatic β cells; Schwann cells and (also Kv3.1b); smooth muscle.	In heterologous expression systems, Kv3.2 expresses high-voltage-activating, fast-activating and -deactivating delayed rectifier channels that are very sensitive to TEA and 4-AP. In heteromeric complexes with Kv3.1 important for spike repolarization and high-frequency firing of fast-spiking GABAergic interneurons and in spike repolarization and duration in GABAergic presynaptic terminals. Activity modulated by protein kinase A in heterologous cells and in neurons.	Kv3.2−/− mice show alterations in cortical EEG and increased seizure susceptibility consistent with an impairment of cortical inhibitory mechanisms.

Continued

Table 1 Continued

Channel subunit	*Associated proteins*	*Expression pattern*	*Channel function*	*Associated pathology*
Kv3.3 Gene symbol: KCNC3		Expressed predominantly in the CNS. Broadly expressed in somas, axons, and terminals in brain and spinal cord structures but in specific cell types. In many (but not all) GABAergic neurons throughout forebrain and midbrain, and in mossy fiber axons of dentate granule cells in hippocampus. Very strongly expressed in cerebellum, particularly in Purkinje cell somas, axons, and dendrites. Expression in brain stem sensory and reticular neurons and motor neurons.	In heterologous expression systems, Kv3.3 expresses high-voltage-activating, fast-activating and -deactivating channels that are very sensitive to TEA and 4-AP and inactivate fast in *Xenopus* oocytes but slowly and variably in mammalian transfected cells. Regulation of Na^+ and Ca^{2+} spike repolarization and spontaneous firing frequency of Purkinje cells. May contribute to Kv3.1-containing channels in auditory brain stem (see Kv3.1). Channels probably containing Kv3.3 and Kv3.4 regulate transmitter release at motor end plates, and channels containing Kv3.1 and Kv3.3 transmitter release from cerebellar parallel fiber terminals.	Kv3.3−/− mice exhibit cerebellar dysfunction, altered Purkinje cell discharges, and lack harmaline-induced tremor. Kv3.1/Kv3.3 double knockout mice display severe ataxia, tremor, myoclonus, and hypersensitivity to ethanol. Human: mutations in Kv3.3 cause spinocerebellar ataxia SCA13.
Kv3.4 Gene symbol: KCNC4	MiRP2 forms potassium channels in skeletal muscle with $K_V3.4$.	Prominent in skeletal muscle. Brain: weakly in hippocampal granule cells, Purkinje cells, and pontine nuclei.	In heterologous expression systems, Kv3.4 expresses high-voltage-activating, fast-activating and fast-inactivating channels that are very sensitive to TEA and 4-AP. In association with MirP2, forms low-voltage-activating potassium channels that regulate skeletal muscle resting potential. Channels probably containing Kv3.3 and Kv3.4 regulate transmitter release at motor end plates.	Human: an R83H missense mutation in MiRP2 that diminished the effects of MiRP2 on Kv3.4 is associated with periodic paralysis.
Kv4 subfamily				
Kv4.1 Gene symbol: KCND1	Not investigated	Rat brain: mRNA very weakly expressed in rat. Expressed in human brain, uterus.	In heterologous expression systems, Kv4.1 expresses transient K^+ currents blocked by millimolar concentrations of 4-AP with slower inactivation kinetics than Kv4.2 and Kv4.3.	

			Kv4 channels underlie the fast transient outward current I_{to} in cardiac myocytes and most of the subthreshold-operating somatodendritic A-type K current in mammalian neurons (I_{SA}). However, Kv4.2 and Kv4.3 appear to be the main Kv4 subunits in brain and heart.	
Kv4.2 Gene symbol: KCND2	KChIPs, DPPX (DPP6), and DPP10	mRNA: brain – expressed in selective brain areas, sometimes overlapping with Kv4.3 (e.g., thalamus), but often in areas not expressing Kv4.3 (predominant form in the caudate putamen, pontine nucleus, and several nuclei in the medulla); granule cells in the OB; CA1 pyramidal cells in the hippocampus; reciprocal expression with Kv4.3 in the cerebellar granule cell layer.	In heterologous expression systems, Kv4.2 expresses low-voltage-activating, fast-inactivating K^+ currents that recover quickly from inactivation and are blocked by millimolar concentrations of 4-AP resembling neuronal I_{SA}. Native-like properties are enhanced by association with associated proteins KChIPs and DPPs.	Mouse: the loss of Kv4.2 protein in hippocampal CA1 pyramidal neurons of Kv4.2 produces a near-complete elimination of I_{SA} from apical dendrites, resulting in an increase in the amplitude of backpropagating action potentials and an increase of concomitant Ca^{2+} influx, facilitating the induction of long-term potentiation.
		Protein: predominantly dendritic expression in hippocampal pyramidal cells and cerebellar granule cells. Heart: rodent ventricular muscle.	Kv4 channels underlie the fast transient outward current I_{to} in cardiac myocytes and most of the subthreshold-operating somatodendritic A-type K current (I_{SA}) in mammalian neurons. I_{SA} regulates firing frequency in neurons and dendritic excitability.	In dorsal horn neurons, genetic elimination of Kv4.2 increases excitability, resulting in enhanced sensitivity to tactile and thermal stimuli. Furthermore, ERK-dependent forms of pain hypersensitivity are absent in Kv4.2−/− mice.
Kv4.3 Gene symbol: KCND3	KChIPs, DPPX (DPP6), and DPP10	Kv4.3 mRNA predominant Kv4 in cortical GABAergic interneurons, cerebellar Purkinje cells and dopaminergic neurons in substantia nigra pars compacta, restrosplenial cortex, superior colliculus, raphe, and amygdala; in cerebellar granule cells, predominant in posterior lobules. Protein: strong expression in dendrites. Heart: Kv4.3 main Kv4 gene in canine and human ventricle.	In heterologous expression systems, Kv4.3 expresses low-voltage-activating, fast-inactivating K^+ currents that recover quickly from inactivation and are blocked by millimolar concentrations of 4-AP resembling neuronal I_{SA}. Native-like properties are enhanced by association with associated proteins KChIPs and DPPs. Kv4.3 kinetics is somewhat slower than that of Kv4.2.	

Continued

Table 1 Continued

Channel subunit	*Associated proteins*	*Expression pattern*	*Channel function*	*Associated pathology*
			Kv4 channels underlie the fast transient outward current I_{to} in cardiac myocytes and most of the subthreshold-operating somatodendritic A-type K^+ current (I_{SA}) in mammalian neurons. I_{SA} regulates firing frequency in neurons and dendritic excitability. The pacemaker frequency of individual dopaminergic neurons, and hence the amount of dopamine release, correlates with I_{SA} levels, which in turn correlate with the concentration of Kv4.3 mRNA	
Kv7 (KCNQ) family				
Kv7.1 (also known as KvLQT1) Gene symbol: KCNQ1	KCNE1(MINK) KCNE2(MiRP1) KCNE3(MiRP2)	Heart, kidney, colon, pancreas, lung, pituitary, cochlea (marginal cells of stria vascularis), placenta. Exocrine pancreas.	Slow sustained current. Does not associate with other Kv7 subunits. Co-assembles with minK/KCNE1 to form the cardiac I_{Ks} channel involved in repolarization of cardiac action potentials and in epithelial cells of the inner ear, where they mediate K^+ secretion into the endolymph. Associates with KCNE3 to form leakage channels involved in intestinal chloride secretion.	Human: KCNQ1 loss-of-function mutations cause long QT syndrome (including Romano–Ward syndrome and Jervell and Lange-Nielsen syndrome (JLNS)). JLNS includes deafness; gain-of-function mutations in KCNQ1 cause atrial fibrillation and short QT syndrome. Associated with Beckwith–Wiedemann syndrome. Knockout mouse: model of JLNS.
Kv7.2 Gene symbol: KCNQ2	Calmodulin Kv7.3, Tubulin, PKA KCNE2	Expressed mainly in neural tissue: CNS, pituitary, SCG, thoracolumbar ganglia. Widely expressed in many neuronal populations also expressing Kv7.3. Highest levels of both Kv7.2 and Kv7.3 expression are found in the cerebral cortex, striatum, hippocampus, thalamus, reticular nucleus of thalamus, anterior olfactory nucleus, and red nucleus. Protein expression in neuronal somata, Nodes of Ranvier and axon initial segment.	Slow delayed rectifier in heterologous cells. Associates with Kv7.3 to form M-type channels. Highly TEA sensitive in homomultimeric channels. Sensitivity to TEA drops to millimolar concentrations when associated with other Kv7 subunits. Blocked by M-channel blockers XE991 and linopirdine. Activated by the M channel opener Retigabine.	Human: benign familial neonatal convulsions (BFNC) Mouse: KCNQ2-/- mice die soon after birth due to pulmonary atelectasis. KCNQ2+/- mice have increased seizure susceptibility.

Kv7.3 Gene symbol: KCNQ3	Kv7.2, Kv7.4, KCNQ5, calmodulin, tubulin, PKA KCNE2	See Kv7.2.	Slow delayed rectifier in heterologous cells. Associates with Kv7.2, Kv7.4, and Kv7.5 to form M-type channels. Blocked by M-channel blockers XE991 and linopirdine. Activated by the M channel opener retigabine.	Human: BFNC.
Kv7.4 Gene symbol: KCNQ4	Kv7.3	Brain stem auditory neurons (cochlear nuclei, nuclei of the lateral lemniscus, and inferior colliculus). Cochlea (outer hair cells (OHC)), inner hair cells (IHC), vestibular hair cells). Protein in basal membrane of OHC, in type I hair cells in vestibular organs, and in the calyx-like terminals on these cells.	Slow delayed rectifier in heterologous cells. Associates with Kv7.3 to form M-type channels. Blocked by M-channel blockers XE991 and linopirdine. Activated by the M-channel opener retigabine. In OHCs, currents are large and constitute the dominant currents at rest and during depolarization. Principal exit pathway for K^+ ions entering the cells through the transduction channels. In IHCs, the current is relatively small and it influences mainly resting membrane properties.	Human: mutations in KCNQ4 cause autosomal dominant nonsyndromic deafness type 2 (DFNA2). Mouse: degeneration of OHCs and progressive hearing loss. DFNA2 might be caused by a slow degeneration of OHCs resulting from chronic depolarization.
Kv7.5 Gene symbol: KCNQ5	Kv7.3 Calmodulin	CNS, SCG, sympathetic ganglia, overlapping with Kv7.2 and Kv7.3 in several brain regions (cortex, hippocampus, and striatum). Also expressed in skeletal muscle. Protein: pyramidal cells and interneurons in neocortex and hippocampus.	Slow delayed rectifier in heterologous cells. Associates with Kv7.3 to form M-type channels. Blocked by M-channel blockers XE991 and linopirdine.

[b]Per convention, human gene names use uppercase and mouse names lowercase (e.g., KCNA1 and Kcna1, respectively).

subunit combinations can be calculated from the equation $[p + (n\text{-}1)]!/[p!(n\text{-}1)]$, where p is the aggregation number (4), and n is the total number of different subunits that can heteromultimerize), predicting an enormous diversity of channels, which is even larger if one considers other factors that can also lead to functional diversification, such as interactions with diverse auxiliary proteins or posttranslational modifications.

Given the subfamily specific heteromultimerization, each Kv subfamily describes an independent functional unit. This emphasizes the need to discuss each subfamily as a group, as we do in this article. As described previously, the members of the Kv5, Kv6, Kv8, and Kv9 subfamilies must co-assemble with subunits of the Kv2 subfamily to form functional channels. Therefore, they are integral parts of Kv2 channels and are treated together with the members of the Kv2 subfamily. Members of the Kv1–Kv4 subfamilies are homologs of the *Shaker, Shab, Shaw*, and *Shal* genes in *Drosophila*, respectively. Therefore, the mammalian counterparts are sometimes referred to using the nomenclature in flies (e.g., Kv1 or Shaker genes or channels).

N- and C/P-Type Inactivation of Kv Channels

Voltage-gated K^+ channels (as well as most other voltage-gated channels except the HCN pacemarker channels) activate and open upon membrane depolarization. However, most Kv channels do not remain open, even if the depolarization remains constant, but undergo a process known as inactivation. The rates at which the channels inactivate vary by orders of magnitude depending on the channel type: Fast-inactivating channels mediating transient (or A-type) K^+ currents inactivate with time constants in the range of 10–100 ms. There are probably several mechanisms by which Kv channels inactivate, two of which have been well characterized: N- and P/C-type inactivation. N-type inactivation is usually fast and is produced by the cytoplasmic N-terminal sequence of some Kv subunits, which acts as a peptide that enters and occludes the channel's pore, blocking ion permeation. The following Kv pore-forming subunits – Kv1.4, Kv3.3, and Kv3.4 – as well as the Kv1 auxiliary proteins Kvβ1 and Kvβ3 contain such N-terminal inactivation domains, producing N-type inactivation of channels containing one or more of these subunits.

P/C-type inactivation is produced by a time-dependent conformational change that constricts the external mouth of the pore (a 'pore collapse'), although the molecular details are not completely understood. Many Kv channels undergo P/C inactivation, but the rates can differ by two or three orders of magnitude, from tens of milliseconds to seconds. The rate of P/C inactivation depends on the amino acid sequence of both the P domain and the S6 domain, and it can be affected by extracellular ions that interact with the channels pore.

Next, we discuss the physiological contributions and other salient features of each of the four groups of Kv_F proteins in mammalian species.

Kv1 (Shaker) Subfamily

This is the largest Kv subfamily, with eight genes identified to date (Table 1). However, we focus on the first six members of the subfamily (Kv1.1–Kv1.6). Kv1.7, the only Kv1 gene known to produce more than one protein isoform, is prominently expressed in cardiac and skeletal muscle, as well as in pancreatic islet cells, but not in the nervous system. Kv1.8 (better known as KCNA10), the most recently identified Kv1 gene, is intriguing because it is structurally and functionally related to both voltage-gated and cyclic nucleotide-gated channels. Although RNAse protection analysis has suggested that KCNA10 transcripts are present in brain, nothing is known about its function in neural cells.

Kv1.1–Kv1.6 subunits are components of voltage-gated K^+ channels, which overall tend to activate faster and at lower membrane potentials than Kv channels of the Kv2 and Kv3 subfamilies. (Several Kv1 channels also tend to activate at more negative membrane potentials than Kv4 channels; however, the voltage-dependence of Kv4 channels is shifted toward more negative voltages by interaction with their auxiliary proteins DPPX and DPP10.) They can conduct current at voltages below threshold for spike generation and therefore contribute to the subthreshold properties of neurons. They are also highly sensitive to 4-aminopyridine (4-AP), with IC_{50}s of <1 mM for all Kv1.1–Kv1.6 homomeric channels. Most Kv1 proteins are widely and prominently expressed in neurons throughout the nervous system, except for Kv1.5, Kv1.7, and Kv1.8 (Table 1). It is likely that most, if not all, neurons in the central nervous system (CNS) and peripheral nervous system (PNS) express several Kv1 proteins. This suggests that native Kv1 channels in many cells might be heteromeric complexes of several Kv1 proteins.

Neuronal Kv1.1–Kv1.6 channels are complexes of Kv1 and Kvβ subunits

Pongs and colleagues discovered a group of proteins now known as Kvβ subunits that associate with Kv1 pore-forming subunits. Kvβ proteins identified to date are products of three genes, Kvβ1–Kvβ3, each

of which produces several isoforms by alternative splicing at the N-terminal region (Table 2). They have a mass of approximately 40 kDa and lack putative transmembrane domains, potential glycosylation sites, or leader sequences, suggesting that they are cytosolic proteins. This has been confirmed by structural analysis. Kvβ proteins bind 1:1 to the T1 domain located in the N-terminal region of the channel pore-forming subunits, creating channel complexes of eight polypeptides (Figures 1(b) and 2(a)). In fact, it is likely that most, if not all, Kv1 channels in neural cells are complexes that resemble the structure shown in Figure 2a, containing four Kv1 pore-forming subunits and four Kvβ associated proteins.

All Kvβ subunits share a conserved core domain, which has sequence and structural similarity to aldo-keto reductases. In addition, the Kvβ1 and Kvβ3 subunits contain an extra, isoform-specific, N-terminal sequence that resembles the inactivation domain found in Kv1.4, which produces N-type inactivation.

A key function of the Kvβ subunits is to act as chaperones during channel biosynthesis, facilitating proper trafficking and expression at the cell surface. In addition, by virtue of their N-type inactivation domain, Kvβ1 and Kvβ3 proteins can accelerate the inactivation of Kv1.4-containing channels or induce fast inactivation in otherwise non-inactivating or slowly inactivating Kv1 channels (except in Kv1.3, for which inactivation is not affected by Kvβ1 and Kvβ3, and Kv1.6, for which inactivation is not affected by Kvβ1). Kv1.6 proteins contain an N-type inactivation prevention domain that prevents inactivation of channels containing one or more Kv1.6 subunits. On the other hand, Kvβ2 proteins, which lack N-terminal inactivation domains, accelerate inactivation only when Kv1.4 subunits form part of the Kv1 channel complex, probably via interactions with the intrinsic Kv1.4 inactivation domain. Thus, the Kvβ subunits diversify the inactivating properties of Kv1 channels. In some cases, the Kvβ subunits may also shift the voltage dependence of activation in the hyperpolarizing direction.

The amino acid sequence and structural similarity with aldo-keto reductases has remained an intriguing feature. One study has provided data suggesting that Kvβ proteins may actually function as redox

Table 2 Kvβ accessory subunits[a]

Subunit	*Spliced isoforms (with accession numbers)*	*Expression pattern*[b]	*Function*
Kvβ1 Gene symbol: KCNAB1	Kvβ1.1:NM_172159 Kvβ1.2:NM_003471 Kvβ1.3:NM_172160	Widely distributed in brain tissue with cell-specific distribution. Co-expressed with Kv1.1 and Kv1.4 in cortical interneurons, in the hippocampal perforant path and mossy fiber pathways, and in the globus pallidus and substantia nigra. Kv1.1 and Kv1.4 and, to a lesser extent, Kv1.2 and Kv1.6 are detected in channel complexes containing Kvβ1. Most of these also contain Kvβ2. More prominent in young animals (before P21).	Structural component of Kv1 channels. Facilitate trafficking and expression at cell surface. Accelerate inactivation of Kv1 channels. Cell metabolic state sensor.
Kvβ2 Gene symbol: KCNAB2	Kvβ2.1:NM_003636 Kvβ2.2:NM_172130	Widely distributed in brain tissue; more abundant in adult brain than Kvβ1. Co-expressed with Kv1 subunits in the juxtaparanode in myelinated fibers. The bulk of K^+ channel complexes in brain containing Kv1.1, Kv1.2, Kv1.4, and Kv1.6 contain Kvβ2.	Structural component of Kv1 channels. Facilitate trafficking and expression at cell surface. Only accelerate inactivation of Kv1.4 channels. Cell metabolic state sensor.
Kvβ3 Gene symbol: KCNAB3	Kvβ3.1: (human, rat) NM_004732 Kvβ3.2 (first named Kvβ4): (mouse) U65593	More restricted pattern of expression than Kvβ1 and Kvβ2. No high-resolution localization studies. Most prominent in cerebellum. Also expressed in neocortex.	Structural component of Kv1 channels. Facilitate trafficking and expression at cell surface. Accelerate inactivation of Kv1 channels. Cell metabolic state sensor.

(1999) Functional and molecular aspects of voltage-gated K^+ channel beta subunits. *Annals of the New York Academy of Sciences* 868: 344–355.

[b]Data derived largely from Rhodes KJ, Strassle BW, Monaghan MM, Bekela-Arcuri Z Matos MF, and Trimmer JS Association and colocalization of the Kvβ1 and Kvβ2 β-subunits with Kv1 α-subunits in mammalian brain K^+ channel complexes. *Journal of Neuroscience* 17: 8246–8258.

enzymes. It was observed that Kvβ2 can use 4-cyanobenzaldehyde as a substrate and reduce it to an alcohol. The catalytic reaction was found to be very slow, suggesting that this might not be the primary function of Kvβ proteins. Instead, it has been suggested that the Kvβs endow Kv1 channels with a sensor module to detect the metabolic state of the cell. This hypothesis is based on the observation that application of the substrate to the cytoplasmic side of the cell influenced the rate of inactivation of Kv1.4–Kvβ2 complexes.

All Kvβ subunits are predominantly expressed in brain tissue. Kvβ1 and Kvβ2 are widely distributed but display cell-specific distributions. Kvβ2 proteins are much more abundant, and a much larger portion of the total brain pool of Kv1-containing channel complexes is associated with Kvβ2 rather than with Kvβ1. Complexes containing Kvβ1 often also contain Kvβ2. Kvβ3 shows a more restricted pattern of expression (Table 2).

Kv1.8 (KCNA10) interacts specifically with the auxiliary subunit KCNA4B, which is unrelated to the Kvβ subunits. When co-expressed with KCNA10, KCNA4B increases KCNA10 current and also increases its sensitivity to activation by cAMP.

In addition to association with Kvβ subunits, most Kv1 proteins are able to interact with scaffolding, membrane-associated putative guanylate kinases (or MAGUKs), which are PDZ domain-containing proteins such as PSD-95 and SAP97. The association is important for the clustering of the channels in microdomains at the neuronal surface, and it is mediated by the interaction of the PDZ domains with the C-terminus of Kv1 proteins, which has the sequence ETDV or ETEV (except for Kv1.8). Mutation of this C-terminal sequence abolishes binding to the MAGUKs and prevents channel clustering.

Functional properties of Kv1 channels

Kv1 channels can be delayed rectifiers or fast-transient A-type channels, depending on their subunit composition. Delayed rectifier channels are slowly inactivating voltage-gated potassium-selective ion channels so called because potassium flux occurs in a voltage- and time-dependent manner with a delay after a depolarizing voltage step, which is longer than the time required to activate fast inward sodium currents (hence, delayed) and normally flows in one direction (outward; hence, producing rectification of the current–voltage relation). The term A-type K^+ channels or 'A channels' is applied to voltage-gated K^+ channels that inactivate fast during depolarization (usually with time constants of <100 ms in mammals). Among the Kv1 subunits prominently expressed in brain (Kv1.1–Kv1.6), Kv1.4 subunits are the only ones that contain an N-terminal inactivation domain capable of producing fast N-type inactivation. Kv1.4 subunits contribute fast inactivation to heteromultimeric channels. The rate of inactivation of a heteromeric channel depends on the number of inactivating subunits in the channel complex. In addition, as described previously, several Kvβ subunits have N-terminal inactivation domains which confer fast N-type inactivation to Kv1 channels, including those with slow or no inactivation. Therefore, the inactivation rate of native channels will depend on subunit composition, in terms of all the subtypes of pore-forming subunits in the channel complex as well as the type of Kvβ present. Furthermore, inactivation mechanisms can be the subject of posttranslational modifications, and these modulations can change inactivation properties of native channels.

K^+ channels containing Kv1.4 proteins, with or without Kvβ subunits, recover from inactivation very slowly, resulting in cumulative inactivation during repetitive activity. It has been suggested that this mediates activity-dependent spike broadening in hippocampal mossy fiber boutons (MFBs), the large presynaptic terminals of the axons of the granule cells of the dentate gyrus. The action potential in these terminals is very brief during low-frequency stimulation but is prolonged up to threefold during high-frequency stimulation. Prolongation of the presynaptic spike results in an increase in the number of Ca^{2+} ions entering the terminal per action potential, and this in turn leads to potentiation of evoked excitatory postsynaptic currents at MFB–CA3 pyramidal cell synapses.

Many Kv1 channels inactivate slowly via P/C-type inactivation. This inactivation is prominent in Kv1.3 channels. Due to the slow rates of recovery from inactivation, P/C inactivation of Kv1.3 channels produces pronounced cumulative inactivation during repetitive stimulation.

Kv1 channels mediate dendrotoxin-sensitive K^+ currents

Three Kv1 subunits – Kv1.1, Kv1.2, and Kv1.6 – express homomultimeric channels which are blocked by the mamba snake toxins dendrotoxin I (DTX-I) and α-dendrotoxin (α-DTX). In heteromeric channels, a single Kv1.1, Kv1.2, or Kv1.6 protein is sufficient to confer DTX sensitivity. Hence, Kv1 channels are the mediators of the D-type current or I_D. This current, originally described in CA1 pyramidal neurons, is of great interest due to its effects on the subthreshold properties of neurons. Given the heteromeric association of Kv1 proteins, the widespread expression of Kv1.1, Kv1.2, and Kv1.6 proteins in the nervous system (Table 1), and the total number of Kv1 pore-forming subunits and Kvβs, the possible combinations of subunits producing channels

containing one of the Kv1 subunits conferring DTX sensitivity is extremely large, resulting in a large diversity of I_D with variations in a number of properties including inactivation rates. For example, a channel containing Kv1.1, Kv1.4, and Kvβ1, a combination that has been detected in hippocampus, will produce a fast-inactivating DTX-sensitive current. Inactivation would be much slower if the channel contained Kvβ2 instead of Kvβ1. Similarly, Kv1.2 homomultimers activate more slowly than other Kv1.1–Kv1.6 channels (Table 1); thus, the presence of Kv1.2 subunits will lead to I_D with slower activation kinetics.

Mutations in the gene encoding Kv1.1 cause episodic ataxia type 1 and epilepsy

Consistent with their role in regulating neuronal subthreshold excitability, mutations in the human KCNA1 gene encoding Kv1.1 proteins produce a disease with perturbed excitability – episodic ataxia type 1 (EA1) with myokymia, an autosomal dominant disease affecting central and peripheral nerve function, sometimes associated with epilepsy. Similarly, Kv1.1 knockout mice have severe, often lethal, epilepsy. Although the cellular basis for the heightened seizure susceptibility of the mice is not understood, this phenotype also emphasizes the importance of Kv1 channels in regulating neuronal excitability.

Kv1 channels in axons

Another feature of Kv_1 channels of considerable interest is their localization in axons (Figure 3), where they are concentrated in specific microdomains. The T1 domain (Figures 1 and 2) has been found to be essential for the axonal targeting of Kv1 proteins. This domain is also the major site of association between Kv1 pore-forming and Kvβ subunits, and it has been shown that one of these, Kvβ2, is important for the targeting of Kv1 channels to the axon. This function depends on its ability to associate with the microtubule plus-end tracking protein EB1.

Kv1.1 and Kv1.2 channels are concentrated in a distal part of the axon initial segment, where they co-localize with ankyrin G and may contribute to regulating action potential initiation (see Figure 6). Kv1 channels are also prominent in presynaptic terminals, where they might be specifically localized to the preterminal axon. They reduce the excitability of the nerve terminal, thus preventing aberrant firing at the terminal (produced by reflection of the action potential from the terminal to the axon) and, hence, aberrant transmitter release. However, in two cases in which it has been investigated, the calyx of Held terminal in the auditory brain stem and the terminals of cortical GABAergic interneurons, the Kv1 current does not seem to contribute to the repolarization of the action potential.

In myelinated axons, Kv1.1, Kv1.2, and Kv1.6 are present in the juxtaparanodal region (Figure 6). Although their role here is not clear, it has been suggested that they may function to dampen re-entrant excitation. This juxtaparanodal localization is affected by demyelination. Myelin loss results in the exposure and dispersion of these juxtaparanodal K^+ channels – effects that in turn contribute to the neurological symptoms associated with demyelination.

Kv2 (Shab) Subfamily

There are two known members of this subfamily, Kv2.1 and Kv2.2. Both are widely expressed in brain tissue and are believed to be present in many, if not all, principal cells and interneurons throughout the brain. In contrast to the other Kv_F families, in which heteromultimer formation is prevalent, immunohistochemistry shows that the two Kv2 subunits produce distinct subcellular staining patterns even in cells that express both proteins, suggesting that Kv2 subunits may not form heteromultimeric channels *in vivo*. Furthermore, immunoprecipitation experiments failed to show association of the two subunits in rat superior cervical ganglion (SCG) cells, which express both Kv2.1 and Kv2.2, or in HEK-293 cells transfected with cDNAs encoding both subunits. However, Blaine and Ribera's studies using a dominant negative Kv2.2 subunit suggest that the two Kv2 proteins are capable of associating with each other.

Kv2 subunits do heteromultimerize with subunits of the Kv5, Kv6, Kv8, and Kv9 subfamilies, which, as mentioned previously, are silent pore-forming subunits that do not form conducting channels by themselves. These associations change the voltage dependence and kinetics of the channels (Table 1). For example, co-expression of Kv9.1 with Kv2.1 in *Xenopus* oocytes slows the rate of activation, causes a hyperpolarizing shift in the voltage dependence of activation and inactivation, and changes sensitivity to tetraethylammonium (TEA).

Kv2 channels mediate the delayed rectifier current I_K

Kv2 channels have a low sensitivity to 4-AP (Table 1). They are blocked by extracellular, 10–20 mM TEA and are thought to mediate the 'TEA-sensitive, 4-AP-insensitive' delayed rectifier K^+ current recorded in many types of neurons known as I_K.

In heterologous expression systems, Kv2 channels can display different voltage-dependence and kinetic properties, including the degree of inactivation, depending on which silent pore-forming subunits

Figure 3 Contrasting expression patterns of Kv1 and Kv2.1 subunits in the hippocampal formation. In contrast to Kv2.1, Kv1 protein expression is predominantly observed outside the layers containing neuronal somata. Lesioning studies indicate that the observed staining is predominantly associated with local and projecting axons and nerve terminals. The patterns of expression of each Kv1 protein are specific, but there is significant overlap between different subunits. Reproduced from Rhodes KJ, Strassle BW, Monaghan MM, et al. (1997) Association and colocalization of the Kvbeta1 and Kvbeta2 beta-subunits with Kv1 alpha-subunits in mammalian brain K^+ channel complexes. *Journal of Neuroscience* 17: 8246–8258.

form part of the channel complex (Table 1). However, the molecular composition of Kv2 native channel complexes and its relationship to I_K diversity in neurons and other cell types remain to be determined. There is also little knowledge about the functional roles of these currents in nerve cells. In one study, it was suggested that because these channels activate and deactivate slowly compared to other Kv_F

channels, they do not contribute to the repolarization of single action potentials in cortical pyramidal cells but instead regulate excitability and Ca^{2+} influx during repetitive firing. However, Malin and Nerbonne found that elimination of Kv2 channels in tonic firing sympathetic neurons increased spike duration. The channels have also been implicated in mediating apoptosis in neurons and are potential therapeutic targets for diabetes due to their prominent expression and activity in pancreatic β cells.

Modulation of Kv2.1 channels

Kv2.1 channels are found in high-density clusters in the somata and proximal dendrites, whereas Kv2.2 subunits typically present diffuse localization in somata and neuropil. Kv2.1 clusters are organized in specific subcellular patterns, such as opposite astrocytic processes or inhibitory synapses in cortex and hippocampus and opposed to cholinergic synapses on spinal motor neurons. The mechanisms of clustering of Kv2.1 channels have been the subject of intense investigation.

Kv2.1 channels are extensively phosphorylated when expressed in HEK 293 cells and in neurons. The phosphorylation state of Kv2.1 subunits influences channel properties, including localization and voltage dependence. Furthermore, phosphorylation, localization, and channel properties are dynamically regulated by neuronal activity. Following kainate-induced seizures in mice, Kv2.1 channels in pyramidal neuron membranes were found to be dephosphorylated relative to control animals and no longer clustered. In cultured hippocampal pyramidal neurons, glutamate exposure also caused dephosphorylation of Kv2.1 subunits, continuous localization (as opposed to clustered), and a hyperpolarizing shift in the voltage dependence of I_K. Similar modulations of Kv2.1 expression and activity were found following hypoxia and chemical ischemia *in vivo* and *in vitro* and cholinergic stimulation *in vitro*. Hyperpolarizing shifts of voltage dependence, as observed concomitant with dephosphorylation, would cause an increase in I_K, which in turn is expected to decrease membrane excitability. Considering their strong and widespread expression, dephosphorylation of Kv2.1 subunits may be an effective and widespread homeostatic mechanism by which neurons are able to alter excitability in response to their chemical environment.

Kv3 (Shaw) Subfamily

There are four known Kv3 genes in mammals – Kv3.1–Kv3.4. In contrast to the other Kv subfamilies, the four Kv3 genes undergo extensive alternative splicing, resulting in the generation of more than ten Kv3 isoforms with different intracellular C-terminal sequences. In heterologous expression systems, Kv3 proteins express fast-activating voltage-gated channels with unique properties. Compared to the currents expressed by other Kv_F subunits, Kv3 currents become apparent at more depolarized potentials (more positive than −20 to −10 mV; Table 1) and deactivate very quickly upon repolarization. The rightward shifted voltage dependence and fast deactivation rates of Kv3 channels are likely related properties, probably reflecting instability of the channel's open state at voltages near the resting potential.

In heterologous expression systems, Kv3.1 and Kv3.2 subunits mediate slowly inactivating delayed rectifier-type currents, whereas Kv3.4 proteins produce fast-inactivating A-type currents. In *Xenopus* oocytes, Kv3.3 currents are inactivating with time constants on the order of tens of milliseconds, but in mammalian cell lines the inactivation of Kv3.3 currents is slow and variable. The reason for this discrepancy is unclear; it has been suggested that it might be the result of differential usage of a starting methionine preceding or following an N-inactivation domain. Differences in the posttranslational modulation of Kv3.3 proteins in these two heterologous expression systems could also explain the differences in inactivating properties. Indeed, the degree of inactivation of Kv3.3 and Kv3.4 currents in *Xenopus* oocytes is affected by oxidation and protein kinase C (PKC)-mediated phosphorylation.

Little is known about the function of the alternatively spliced C-termini. In the cases in which it has been explored, the currents expressed in heterologous expression systems by the isoforms of each Kv3 gene are very similar. Preliminary studies suggest that the C-termini may confer isoform-specific regulation by second messenger signaling systems and targeting to distinct neuronal compartments.

Functional roles of Kv3 channels

Three of the four known Kv3 genes (Kv3.1–Kv3.3) are prominently expressed in specific neuronal populations throughout the CNS (Figure 4). Kv3.4 transcripts are weakly expressed in a few neuronal types in the brain, usually in neurons also expressing other Kv3 genes (hippocampal granule cells, cerebellar Purkinje cells, and neurons in the pontine nucleus), whereas they are much more abundant in skeletal muscle and sympathetic neurons. Nevertheless, Kv3.4 proteins might be important components of Kv3 channels in some neurons, even when expressed at low levels, since a single Kv3.4 subunit is capable of enabling fast-inactivating properties to a Kv3

Figure 4 Specific but overlapping expression of Kv3 mRNAs in rodent brain. Diagrams illustrating the patterns of expression of Kv3 mRNAs obtained using *in situ* hybridization by Weiser et al. Darkness indicates level of expression. Reproduced from Rudy B, Chow A, Lau D, et al. (1999) Contributions of Kv3 channels to neuronal excitability. *Annals of the New York Academy of Sciences* 868: 304–343.

tetrameric channel. In skeletal muscle, Kv3.4 subunits assemble with MinK-related peptide 2 (MiRP2) to form subthreshold, voltage-gated potassium channels that regulate the resting potential of the muscle cell. An R83H missense mutation in MiRP2 that diminished the effects of MiRP2 on Kv3.4 has been associated with a form of periodic paralysis.

There are no specific blockers of Kv3 channels that can be used to study Kv3 currents in native cells and to investigate their functional roles. BDS toxins ('blood depressing substance') from the sea anemone *Anemonia sulcata* were initially reported to specifically block Kv3.4 channels but were later shown to block other Kv3 channels with similar affinity. These toxins are gating modifiers that shift the voltage dependence of the channels in the depolarizing direction. They tend to produce only partial channel block at physiological membrane potentials and modify channel properties. Typically, Kv3 currents have been isolated using the classical K^+ channel blockers TEA and 4-AP. These are nonspecific K^+ channel blockers; however, Kv3 channels are very sensitive to these drugs and hence can be useful to isolate native Kv3 currents. In particular, low ($\leq$1 mM) TEA blocks Kv3 channels nearly completely, as well as Kv1.1 homomultimeric channels, BK Ca^{2+}-activated K^+ channels, and Kv7.2 (KCNQ2) channels. Specific toxins that block these non-Kv3 TEA-sensitive channels (dendrotoxin, charybdotoxin or iberotoxin, and linopirdine, respectively) can be used to inhibit these other channels and isolate Kv3 currents or Kv3-mediated effects. However, caution should be exercised in pursuing this method since 1 mM TEA could block a significant amount of the current mediated by channels with a higher IC_{50} for TEA (e.g., Kv2s) if they are very abundant in a particular preparation.

The positively shifted voltage dependence of activation and fast activation/deactivation kinetics of Kv3 channels bestow these channels with the ability to efficiently and specifically accelerate the repolarization of the action potential. Kv3 currents are activated during the repolarizing phase of the action potential and are quickly deactivated following the spike. Hence, when present in sufficient amounts, Kv3 channels facilitate action potential repolarization and dictate action potential duration without significantly compromising action potential threshold, rise time, or magnitude and, more important, without contributing repolarizing current that would increase the duration of the refractory period (in contrast to voltage-gated K^+ channels activating more negatively and deactivating more slowly).

Kv3 channels are particularly prominent in neurons that have the ability to fire sustained trains of

action potentials at high frequency or to follow high-frequency stimulation (Table 1), and they have been shown to facilitate high-frequency firing in cortical fast-spiking GABAergic interneurons, cerebellar Purkinje cells, and neurons in the subthalamic nucleus, globus pallidus, and auditory brain stem. This role is likely the result of their function in spike repolarization. By increasing the rate of spike repolarization and keeping action potentials brief, Kv3 currents reduce the amount of Na^+ channel inactivation that occurs during the action potential and minimize the activation of K^+ channels with slow kinetics. Moreover, the large, fast afterhyperpolarization produced by the Kv3 current can speed up recovery from Na^+ channel inactivation and Kv3 channel deactivation. By accelerating the recovery of Na^+ channel inactivation and by deactivating quickly, Kv3 currents efficiently restore resting conditions and prepare the membrane for a second spike soon after the first spike, thus minimizing the duration of the refractory period and allowing high-frequency firing. It has been suggested that by regulating the ability to follow high-frequency stimuli in auditory neurons in the brain stem, these channels contribute to preserving the fidelity and timing of firing codes and thus the computation of sound features, such as frequency, intensity, and localization in space.

Kv3 gene products are also found in neurons that are not known to fire at high frequencies, such as magnocellular neurosecretory neurons and starburst cells in the retina, suggesting that Kv3 channels may have other physiological roles. Some of these functions of Kv3 channels may still be related to their ability to specifically maximize fast action potential repolarization and the consequences of this function: brief action potentials with quick restoration of membrane properties following activity and limiting calcium entry. In starburst neurons, which normally do not spike, it has been proposed that Kv3 channels provide a voltage-dependent shunt that limits the amplitude of neuronal depolarization and might be critical to the ability of these cells to mediate inhibition of ganglion cells, which depends on the direction of movement of visual stimuli.

Kv3 channels and neurotransmitter release

In addition to their localization in neuronal somata, Kv3 channels are also prominently expressed in axons and presynaptic terminals of several neuronal populations, suggesting roles in regulating neurotransmitter release (Figure 6). This function has been investigated in the basket terminals of fast-spiking interneurons in the cerebral cortex, in the calyx of Held (the large presynaptic terminals from the ventral cochlear nucleus bushy cells innervating the neurons in the MNTB), in motor nerve terminals, and in cerebellar parallel fiber terminals. In these synapses, Kv3 channels are key determinants of the repolarization of the local action potential, keeping action potentials brief, limiting Ca^{2+} influx and, hence, neurotransmitter release probability. As a result of these effects, Kv3 channels in presynaptic terminals contribute to the short-term dynamics of synaptic contacts and to maintaining the speed and fidelity of synaptic transmission.

Mutations in Kv3.3 channels cause spinocerebellar ataxia

Mutations in the human Kv3.3 gene (KCNC3) have been identified as the cause of a spinocerebellar ataxia (SCA13), a disease that can also include cognitive defects, suggesting cerebellar and extracerebellar dysfunction. Two missense mutations have been described; both mutations are likely to perturb the role of Kv3.3 channels in the repolarization of action potentials in Purkinje cells (and other neurons) and change their output characteristics.

Knockout mice have been generated for the three Kv3 genes that are prominently expressed in CNS neurons (Kv3.1–Kv3.3). Kv3.1 and Kv3.3 knockout mice show alterations in motor behavior, including increased locomotor activity and sleep loss in Kv3.1 knockout mice; impaired gait and reduced motor performance associated with abnormal Purkinje cell discharges and abnormal olivocerebellar system properties in Kv3.3 knockout mice; and, in the case of the Kv3.1 and Kv3.3 double mutant, severe ataxia, tremor, and myoclonus. Kv3.2 knockout mice have altered EEG rhythms, increased cortical excitability, and enhanced seizure susceptibility, perhaps resulting from alterations in GABAergic control of cortical structures.

The Kv4 (Shal) Subfamily

There are three Kv4 genes in mammals: Kv4.1–Kv4.3. The Kv4.1 and Kv4.2 genes produce a single product each, but the Kv4.3 gene encodes for two splice variants via alternative splicing: Kv4.3S and Kv4.3L (short and long; Table 1). Two of these genes, Kv4.2 and Kv4.3, are prominently expressed in the rodent CNS. Kv4.1 is expressed very weakly and only in a few neuronal populations, such as the auxiliary olfactory bulb, granule cells of the olfactory bulb, hippocampus, dentate gyrus, and cerebellar cortex, and possibly in Purkinje cells. In contrast to the Kv1 and Kv3 subfamilies, for which there is extensive overlap expression of multiple subfamily members in the same neurons, in the case of Kv4.2 and Kv4.3 transcripts, there is a differential, and sometimes reciprocal, pattern of expression, yet there is overlap expression in several neuronal populations (Figure 5).

Figure 5 Pattern of expression of Kv4.2 and Kv4.3 mRNAs in rat brain. Kv4.2 and Kv4.3 gene expression overlaps in certain areas, but in others expression of one of the two predominates (e.g., Kv4.2 in the striatum, hippocampal CA1 area, and cerebellar granule cells in anterior lobules, and Kv4.3 in SNC, superior colliculus, Purkinje cells, and cerebellar granule cells in posterior lobules). Reproduced from Serodio P and Rudy B (1998) Differential expression of Kv4 K^+ channel subunits mediating subthreshold transient K^+ (A-type) currents in rat brain. *Journal of Neurophysiology* 79: 1081–1091.

Kv4 proteins produce fast-inactivating channels in heterologous expression systems and are believed to underlie fast-inactivating or A-type K^+ currents (I_A), including the fast transient outward current I_{to} in cardiac ventricular myocytes, which mediates the initial repolarization of the action potential and is considered a target for arrhythmia treatment, as well as most of the subthreshold operating somatodendritic A-type K^+ current in mammalian neurons (I_{SA}). In neurons, the rapid, transient activation of these channels in the subthreshold range of membrane potentials causes delayed excitation, influences spike repolarization, and determines the duration of the interspike interval. The currents are essential in regulating excitability in many neuronal types. By regulating the duration of interspike interval, they pace the frequency of repetitive firing. Furthermore, Kv4.2 and Kv4.3 proteins are expressed prominently in dendrites. Consistent with this pattern, Johnston and colleagues observed that there is a gradient of I_{SA} channels in CA1 hippocampal pyramidal neurons with maximum density in distal dendrites. These dendritic channels regulate action potential backpropagation into the dendritic tree, the integration of synaptic inputs, and the establishment of long-term potentiation (LTP). Utilizing Kv4.2 knockout mice, it has been confirmed that these functions are mediated by a Kv4.2-dependent I_{SA}.

Kv_4 channels use novel inactivation mechanisms

Kv_4 channels are characterized by having fast inactivation and fast recovery from inactivation. In

Figure 6 Neuronal K_v proteins are localized to specific membrane microdomains. (a) Kv1.1 (red) in the juxtaparanodal region of myelinated axons. Green, Na^+ channels at the node Ranvier; blue, NCP1 at the paranode. (b) Kv1.2 in the axon initial segment of cortical pyramidal neurons (arrows). The cell body is indicated by an asterisk. (d) Reproduced from Dodson PD and Forsythe ID (2004) Presynaptic K^+ channels: Electrifying regulators of synaptic terminal excitability. *Trends in Neurosciences* 27: 210–217.

contrast to most voltage-gated K^+ channels, in which open-state inactivation predominates, Kv_4 channels seem to inactivate preferentially from closed states. This implies that modest membrane depolarizations that may not open the channels can render them unable to open in response to a subsequent stronger membrane depolarization. This can result in cumulative inactivation upon repetitive stimulation. Moreover, the equilibrium between the open state and a pre-open activated state does not favor residence in the open states even during depolarization. Therefore preferential closed-state inactivation produces most of the inactivation that occurs during a depolarizing pulse and the transient character of the Kv4 current. The molecular mechanisms of inactivation of Kv4 channels are poorly understood and do not seem to simply conform to the classical N- or P/C-type inactivation described previously.

The fast recovery from inactivation characteristic of Kv4 channels is also an essential feature of these channels given their role in repetitively firing cardiac and neuronal cells (Table 1). The mechanisms underlying this fast recovery are not understood.

Auxiliary subunits

Several proteins that associate with Kv4 proteins have been identified, including KChIPs (for Kv channel-interacting proteins), which are members of the neuronal calcium sensor family of cytosolic Ca^{2+}-binding

EF-hand proteins, and a family of single-pass integral membrane glycoproteins related to dipeptidyl aminopeptidases, known as DPPX (or DPP6) and DPP10.

KChIPs bind to the N-terminal region and the T1 domain of Kv4 proteins; facilitate the trafficking, subunit assembly, and surface expression of channel complexes; and modify the electrophysiological properties of Kv4 channels, which inactivate more slowly and recover from inactivation with faster kinetics in the presence of KChIPs. There are four known KChIP genes (KChIP1–4). All KChIPs exert similar effects on Kv4 channels except for the alternative spliced version KChIP4a: Kv4 channels containing KChIP4a lack fast inactivation. The effects of KChIPs on inactivation are likely mediated by the sequestration of the N-terminus of the Kv4 proteins in a groove on the surface of the KChIP molecule.

DPPX and DPP10 (DPPs) belong to a family of dipeptidyl-aminopeptidase enzymes that have amino acid replacements in the catalytic active site and lack enzymatic activity. Instead, they seem to have evolved to function as channel-associated proteins. The DPPX and DPP10 genes produce several N-terminal spliced isoforms. Products of each gene share the same putative transmembrane domain – a long C-terminal extracellular domain with an hydrolase fold and a β-propeller (**Figure 2b**) – but are divergent in the short intracellular N-terminal sequence. They increase the rate of inactivation of Kv4 currents, considerably decrease the time required for the currents to reach a maximum (time to peak), and increase the rate of recovery from inactivation. In addition, they produce large negative shifts in the conductance–voltage relation and in the voltage dependence of steady-state inactivation. Furthermore, like KChIPs, DPPs increase the trafficking of Kv4 proteins to the cell surface, contributing to the major increase in current magnitude observed in the presence of these auxiliary subunits. In addition, DPPX increases the single channel conductance of Kv4 channels by 50%, a factor that may also contribute to the observed increases in total current magnitude.

Antibodies to Kv4 proteins coprecipitate KChIP and DPPX proteins, suggesting that the native channel might be a ternary complex of all three types of subunits. Consistent with this view, the currents expressed in heterologous cells by Kv4 proteins in the presence of KChIPs and DPPs closely resemble the properties of native channels. As in neuronal I_{SA} channels, heterologously expressed channels containing Kv4 proteins and the auxiliary subunits inactivate and recover from inactivation quickly, and they cover the range of voltage dependencies seen *in vivo*. The diversity of Kv4 and auxiliary subunits contributes to I_{SA} diversity in native cells.

DPPX and DPP10 are related to DPPIV or CD26, a cell adhesion protein with dipeptidyl-aminopeptidase activity that has important roles in T cell activation, metabolism of peptide hormones, and cell adhesion. This raises the intriguing possibility that DPP proteins may confer targeting or cell adhesion properties to Kv4 channels through their homologous extracellular domains, which is reminiscent of the cell adhesion properties conferred on Na^+ channels by the extracellular immunoglobulin-like domain of their β subunits.

Modulation of Kv4 channel function by phosphorylation

Kv4.2 channels in hippocampal neurons are modulated by extracellular signal-regulated kinase (ERK)–mitogen-activated protein kinase (MAPK) and by protein kinase A (PKA) and PKC. Activation of these signaling systems reduces channel activity by producing an approximately15 mV depolarizing shift in the voltage dependence of activation of the I_{SA}. It is possible that the effects of PKA and PKC activation are mediated by a common downstream mechanism, the activation of ERK, since blockers of MEK, the kinase responsible for the activation of ERK, block I_{SA} modulation by reagents that increase PKA and PKC activity. These modulations have considerable physiological significance. In hippocampal neurons, a Rap1-mediated coupling of cAMP and p42/44MAPK participates in the regulation of the excitability of pyramidal cells, the early and late phases of LTP, and the storage of spatial memory. These effects are mediated at least in part by modulation of Kv4.2 activity.

Furthermore, it has been observed that in spinal cord dorsal horn neurons, I_{SA} is also modulated by ERKs, mediating central sensitization during inflammatory pain. In Kv4.2 knockout mice, I_{SA} in dorsal horn neurons is absent, and their excitability is enhanced. This was accompanied by elevated sensitivity to tactile and thermal stimuli. Moreover, the ERK-mediated modulation of excitability and the ERK-dependent forms of pain hypersensitivity were absent in Kv4.2−/− mice.

Kv4 channel function, as well as the trafficking and expression of functional channels at the plasma membrane, may also be modulated by other signaling pathways. In *Xenopus* oocytes, phorbol esters produce a potent inhibition of channel activity without shifts in voltage dependence. This is mediated by PKC activation, but the downstream targets of PKC activity remain to be characterized. On the other hand, CaMKII phosphorylation of Kv4.2 has been shown to be important for the expression of functional

channels at the cell membrane, both in heterologous cells and in hippocampal neurons.

Kv7 (KCNQ) Channels

There are five genes in this group: KCNQ1–KCNQ5. The proteins encoded by these genes constitute the Kv7 subfamily of pore-forming potassium channel subunits. Many publications also use the KCNQ nomenclature for the protein products; however, to be consistent with this and other articles in this encyclopedia, we use the Kv7 nomenclature when referring to the protein products of the KCNQ genes. Kv7 (Kv7.1–Kv7.5) channel proteins are homologous to the Kv_F proteins discussed previously (Figure 1) and have important roles in the nervous system as well as in other tissues. Of the 80 potassium channel genes in humans, approximately 10 are known to underlie human diseases. Four of the five known members of the KCNQ subfamily, however, are associated with well-characterized channelopathies causing cardiac arrhythmia, epilepsy, and hearing loss, highlighting the physiological significance of this group of channels.

Structural Features of Kv7 Pore-Forming Subunits

The Kv7 subfamily of voltage-gated K^+ channel genes encodes a group of K^+ channel pore-forming subunits with structural similarity to the Kv_F subunits (Figure 1), containing six membrane spanning domains (S1–S6), a positively charged S4 domain that acts as a voltage sensor, and a single pore-forming (P) loop with the K^+ channel signature sequence that forms the selectivity filter of the channel's pore. In contrast to the Kv_F subfamilies, the number of positively charged residues in the S4 domain varies among Kv7 proteins. Kv7.1 has four, whereas Kv7.2–Kv7.5 have six. Furthermore, the degree of overall sequence similarity between different Kv7 proteins is less than that observed within Kv1–Kv4 pore-forming subunits (as illustrated by the length of the Kv7 branches in the dendrogram in Figure 1).

It is expected that the Kv7 channel complex is a tetramer of Kv7 proteins with a structure resembling those shown for Kv1.2 and Kv4s in Figure 2.

In comparison to most of the Kv proteins discussed previously, Kv7 subunits have very long intracellular C-terminal tails, particularly Kv7.2 and Kv7.5. The C-terminal tail contains a highly conserved domain known as the 'A domain.' This domain and a less conserved sequence that follows it form a subunit interaction domain (SID) involved in subunit-specific assembly among Kv7 proteins. This feature distinguishes these proteins from the Kv_F subunits, in which subunit assembly depends largely on the T1 domain present in the N-terminus. The SID determines which Kv7 subunits can assemble to form tetrameric channels, and it contains two motifs of approximately 30 amino acid residues each exhibiting a high probability for coiled-coil formation known as TCC1 and TCC2 (for tetramerizing coiled-coil 1 and 2) with a variable linker region in between.

Data suggest that the TCC1 domains are required to form functional homomeric as well as heteromeric channels, at least for Kv7.2 and Kv7.3, and that the TCC2 domains facilitate transport of heteromeric channels to the plasma membrane.

Subunit Assembly of Kv7 Proteins

The five Kv7 proteins can form functional homomeric channels. Heteromultimer formation does occur among Kv7 subunits, but it seems to be restricted to certain combinations. For example, Kv7.1, which is expressed in the heart but not in the nervous system, does not associate with other Kv7 proteins. On the other hand, Kv7.3 can associate and form functional heteromeric channels with Kv7.2, Kv7.4, or Kv7.5, all of which are expressed in neural tissue. This specificity depends on the C-terminal SID described previously. This domain is sufficient to transfer assembly properties between Kv7.3 and Kv7.1 since Kv7.1 chimeras containing Kv7.3 SID fragments acquire the broad assembly properties of Kv7.3.

In native cells, Kv7.1 subunit tetramers are found in association with KCNE accessory proteins such as KCNE1 (MinK) and KCNE3. Kv7.2 and Kv7.3 proteins can also co-assemble with KCNE proteins.

Expression and Function of Kv7 Channels: The 'M' Current

Expression of Kv7 channels in heterologous systems yields an outwardly rectifying voltage-dependent K^+ current with slow kinetics of activation (in the range of hundreds of milliseconds to seconds) and deactivation and little or no inactivation. There is appreciable activation of the currents at voltages more positive than −60 mV; hence, Kv7-mediated currents are 'subthreshold operating' in that the greatest influence of these currents is predicted to be in the range between resting membrane potential and the voltage threshold for action potential generation.

Comparison of the biophysical and pharmacological properties (including moderate TEA sensitivity, inhibition by muscarine, sensitivity to Ba^{2+} blockade, and blockade by both XE991 and linopirdine) of Kv7.2 and Kv7.3 heteromeric channels in heterologous expression systems with the so-called 'M' current in sympathetic neurons led to the conclusion

that Kv7.2 and Kv7.3 heteromeric channels mediate this current.

The M current (I_M) was discovered by Paul Adams and David Brown in sympathetic neurons, and it was later found to be present in many neurons, including sensory peripheral neurons as well as neurons in the CNS. I_M is believed to be one of the most important currents modulating the subthreshold excitability of mammalian neurons. I_M exhibits voltage dependence and becomes significant above −60 mV. Hence, the M current is operative in the subthreshold range of membrane potentials, a feature rendering it central in the control of neuronal excitability. Because it does not inactivate, or it inactivates extremely slowly and incompletely, it contributes K^+ current during long depolarizations and leads to substantial steady-state conductance at depolarized potentials. Therefore, I_M opposes depolarizing signals and drives the membrane potential towards E_K, functions as a 'brake' on repetitive action potential discharges, and suppresses responsiveness to synaptic inputs.

I_M was discovered as the current in sympathetic neurons that is inhibited by activation of muscarinic receptors, mediating muscarinic excitation of these neurons which releases the cell from the control of excitability exerted by I_M. This current was termed M because of this muscarinic modulation. Subsequent studies have shown that I_M is modulated in a similar manner by other neurotransmitters (e.g., serotonin, glutamate, and histamine) as well as several neuropeptides (bradykinin, angiotensin, substance P, and opioid) acting through G-protein-coupled receptors. These modulations, providing additional powerful means of physiologically modulating neuronal excitability, have been observed in both peripheral and CNS neurons.

Given their abundant, widespread, and largely overlapping expression in the nervous system (Table 1), Kv7.2 and Kv7.3 (probably often as components of heteromeric channels containing both subunits) are likely mediators of I_M in many central and peripheral neurons. However, all Kv7 channels expressed heterologously are able to form functional homomultimeric channels that express currents with electrophysiological and pharmacological characteristics of M-type currents. They all express currents with similar time and voltage dependence, they are all inhibited by the I_M blocker linopirdine, and they are similarly inhibited by neurotransmitters.

Among the Kv7 proteins, Kv7.1 is the only member not detected in the nervous system (Table 1). Kv7.1 is present in the heart (found in atrial and ventricular myocytes), where, in combination with the accessory subunit KCNE1, it forms the channels mediating a current known as I_{Ks}, which is important in the repolarization of cardiac action potentials. It is also present in a variety of transport epithelia, including the stria vascularis of the inner ear, intestinal crypt cells, and the proximal tubule epithelium of the kidney. This pattern of expression rules out this subunit as a contributor to M-type channels in neurons. Kv7.4 is found in the nervous system, but it has a more restricted pattern of expression than other neural Kv7 subunits, with its expression being limited to the inner ear and central auditory nuclei in the brain stem (Table 1). This limited distribution indicates that this subunit likely contributes to I_M only in this part of the brain. On the other hand, Kv7.5 is widely expressed in brain, often overlapping with Kv7.2 and Kv7.3, and may therefore, either in its homomultimeric form or as heteromultimers, generate I_M in many neurons, potentially adding to the heterogeneity of this current.

Classically, the M currents have been considered to lack inactivation, and the only Kv7 subunit for which inactivation is widely recognized is Kv7.1. Nonetheless, it has been found that homomeric channels containing Kv7.4 and Kv7.5 subunits (but not Kv7.2) expressed heterologously can undergo inactivation. This inactivation is voltage dependent and develops slowly with time constants of several seconds. However, it has an impact on the magnitude of the steady current at voltages in the resting membrane potential range (the current is reduced more than 30% at these voltages), indicating that this mechanism of regulation could be of physiological significance. Importantly, it was also shown that BMS-204352, a selective Kv7 channel opener, exerts its effect, at least partially, by abolishing the inactivation of these channels.

Some members of the voltage-gated K^+ channel family EAG express currents that activate slowly and do not inactivate, as is the case of typical M currents. Therefore, the currents mediated by these EAG channels have been referred to as M-like. EAG channels are prominently expressed in specific neuronal populations, especially in the forebrain, and may contribute M-like K^+ currents in neurons.

Results from immunolocalization of Kv7.2 and Kv7.3 proteins suggest that the currents mediated by Kv7 channels may have additional functions besides mediating the I_M recorded in neuronal cell bodies. These include localization at the axon initial segment in a variety of neurons and at the node of Ranvier in myelinated axons. Furthermore, Kv7.2 is expressed in the mossy fibers of the hippocampus, and there is pharmacological evidence for the presence of Kv7

currents in the Schaffer collaterals, where they appear to regulate transmitter release.

Diseases Associated with Kv7 Channels

We briefly describe the diseases associated with mutations in the genes encoding Kv7 proteins.

KCNQ1 and LQTS/JLNS Long QT syndromes (LQTS) are inherited cardiac disorders caused by mutations in the genes that encode sodium or potassium transmembrane ion channel proteins, characterized by arrhythmias which are often fatal. More than 200 mutations, in at least six genes, have been found in these patients. Mutations in the KCNQ1 gene are responsible for the most common form of the disease (LQT1), accounting for more than 50% of the cases. An autosomal dominant form of LQT1, known as Romano–Ward syndrome, is the result of dominant negative mutations; on the other hand, the Jervell and Lange-Nielsen syndrome (JLNS) is the recessive form of the disease and is associated with deafness, resulting from failure of K^+ transport into the endolymph in the cochlea. These phenotypes have been reproduced in knockout mice.

KCNQ2 and KCNQ3 in neonatal epilepsy Given the extensive overlap in expression patterns of Kv7.2 and Kv7.3 in brain tissue and the evidence that in most neurons the I_M channels are heteromeric channels containing both subunits, it is perhaps not surprising that mutations in each gene produce the same phenotype – an autosomal dominant idiopathic epilepsy known as benign familial neonatal convulsions (BFNC).

BFNC is a rare disease characterized by unprovoked partial or generalized clonic convulsions, sometimes with ocular symptoms and apnea. BFNC typically begins soon after birth, and remission usually occurs after 3–10 weeks, although approximately 15% of patients have seizures later in life. BFNC was initially linked to two different loci, 20q13.3 and 8q24, which are now known to contain the KCNQ2 and KCNQ3 potassium channel genes, respectively. A large number of mutations have been identified, particularly in KCNQ2, and include missense, frame-shift, and splice-site mutations as well as a deletion. The functional effects of the mutations have been explored in heterologous expression systems, and many of these were not found to have dominant negative effects, indicating that the dominant inheritance of BFNC is due to haploinsufficiency. Interestingly, the reduction of current observed with some of the mutations was rather modest, approximately 25%, indicating that the levels of the current are critically maintained within certain levels in early infancy. Why seizure activity disappears in most patients after a few weeks is not clear. Perhaps the maturation of inhibitory GABAergic systems later in life allows for better control of the increased excitability resulting from KCNQ mutations.

Deletion of Kcnq2 in mice is lethal. Homozygous animals die a few hours after birth due to breathing problems. Heterozygous animals develop normally and lack spontaneous epileptic activity, but they have an increased susceptibility to pentylenetetrazole-induced seizures. On the other hand, transgenic mice that conditionally express dominant negative Kv7.2 subunits in brain have spontaneous seizures, behavioral hyperactivity, increased neuronal excitability consistent with a reduced M current, and morphological changes in the hippocampus. Temporal control of expression of the transgene showed that Kv7 channel activity is critical to the development of normal hippocampal morphology during the first postnatal weeks.

KCNQ4 and inherited deafness KCNQ4 maps to the DFNA2 locus in human chromosome 1p34, one of more than 30 loci for dominant inherited deafness, and DFNA2 patients have been found to have mutations in the KCNQ4 gene. The mechanism leading to deafness in DFNA2 is different than that causing the hearing defect found in JLNS (produced by KCNQ1 mutations), consistent with the different patterns of expression of the two genes in the ear (Table 1). In DFNA2, hearing loss develops slowly, progressing over decades, probably as a result of degeneration of the outer hair cells (OHCs). Although KCNQ4 is also expressed in sensory hair cells of the vestibular organ, people with DFNA2 have no vestibular symptoms.

KCNQ4 is expressed in both inner and outer hair cells of the inner ear, where the currents may serve different functions. In OHCs, Kv7 currents are large and constitute the dominant currents at rest and during depolarization, also representing the principal exit pathway for K^+ ions entering the cells through the transduction channels. In inner hair cells, the current is relatively small and it influences mainly resting membrane properties. Loss-of-function mutations of the KCNQ4 gene, causing hearing loss in humans, also result in OHC degeneration. Similarly, KCNQ4 knockout mice or mice carrying KCNQ4 mutations also develop progressive OHC degeneration, which parallels a progressive hearing loss. OHC degeneration is believed to result from Ca^{2+}-dependent excitotoxicity produced by use-dependent chronic depolarization of the cell as a consequence of reduced K^+ current. Interestingly, some investigators have

suggested an association between increased frequency of age- and job-related deafness and specific KCNQ4 polymorphisms.

Modulation of Kv7 Channels

The mechanism of inhibition of I_M by neurotransmitters has been the subject of intense investigation since the current and its modulation were discovered in 1980. Yet, the mechanism of modulation remained elusive for more than 20 years. Classical second messengers known at the time of the discovery of the M current did not seem to be involved. By the early 1990s, it was clear that M-type channel inhibition by neurotransmitters uses G-protein activation, as is the case for other G-protein-coupled receptor (GPCR)-mediated modulations, and specifically the $G\alpha_q$ subunit (with occasional contribution from G_{11}). Activation of these G-proteins is known to stimulate the activity of the membrane-associated phospholipase Cβ. This enzyme hydrolyses the membrane phospholipid phosphatidylinositol-4,5-bisphosphate (PIP_2), leading to the production of inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). These products are key messengers involved in the signaling mediated by G_q and G_{11}, as well as several other G proteins. IP_3 leads to elevation of intracellular Ca^{2+} via release from intracellular stores, and DAG activates PKC. However, experiments investigating the roles of these signaling molecules on the modulation of M currents produced conflicting results at best.

A breakthrough occurred in 2002 when Byung-Chang Suh and Bertil Hille performed experiments that suggested that perhaps it is the depletion of PIP_2 from the membrane and not the products of its hydrolysis that causes the inhibition of the M-type channels. Suh and Hille studied the recovery of the M channels from muscarinic inhibition and showed that this process requires hydrolysable ATP and is slowed if PIP_2 resynthesis is inhibited with wortmannin, a blocker of PI4K kinase, which is an enzyme required for the generation of PIP_2. Soon after, Diomedes Logothetis and colleagues showed that Kv7.2 and Kv7.2–Kv7.3 channels in inside-out oocyte membrane patches undergo a rundown that could be recovered by the addition of PIP_2. The rundown could be restored using an antibody directed against PIP_2 or polylysine to sequester PIP_2, providing direct evidence that Kv7 channels require PIP_2 for activity, as had been shown to be the case for several other ion channels.

A large body of research now exists supporting the view that the primary mechanism by which GPCRs inhibit I_M is via depletion of membrane-associated PIP_2. Hille and colleagues have used translocatable enzymes to rapidly alter the PIP_2 levels. When PIP_2 is depleted, the Kv7 current declines to zero without changes in Ca^{2+}, DAG, or IP_3, and it increases when PIP_2 levels rise. This result shows that PIP_2 depletion alone without changes in other second messengers is able to fully suppress the current. PIP_2 comprises only approximately 1% of the cell membrane, and it is found mostly in the inner cell leaflet. Muscarinic and bradykinin receptor activation have been shown to produce large decreases in PIP_2 in neuroblastoma cells and in mammalian cell expression systems – approximately 35% for bradykinin and more than 75% for muscarine within 30–60 s. Experiments have shown that different Kv7 subunits have very different affinities for PIP_2: Kv7.3 > Kv7.2 > Kv7.4, with EC_{50} ranging from three to several hundred micromolar. This heterogeneity could confer diversity to Kv7-mediated neurotransmitter effects in different sites in the nervous system.

Although regulation of PIP_2 levels is likely the main mechanism of M current inhibition, other molecules and signaling events are likely to contribute as well in specific cases. For instance, Ca^{2+} ions inhibit, at concentrations of approximately 100–200 nM, M channels containing Kv7.2, Kv7.4, and Kv7.5 (but not Kv7.1 or Kv7.3) through an interaction with calmodulin. It appears that the inhibition of I_M currents by bradykinin in sympathetic neurons is due mainly to Ca^{2+}-dependent block resulting from an IP_3-mediated increase in intracellular Ca^{2+}. In these cells, bradykinin does not produce sufficient depletion of PIP_2 to inactivate the channels via this mechanism because the increase in Ca^{2+} concentration promotes PIP_2 synthesis. The reason why the mechanism of I_M modulation by muscarine in sympathetic neurons differs from the mechanism of modulation by bradykinin is that muscarinic receptors are too distant from the IP_3 receptors to induce a large release of Ca^{2+}. This is in contrast to the closer localization of bradykinin receptors to the intracellular Ca^{2+} stores.

Other signaling pathways may also contribute to I_M inhibition, including PKC, cyclic ADP-ribose, and tyrosine kinases. The action of at least some of these signals on Kv7 channels may converge on the requirement of PIP_2 for channel activity. For example, since one of the Ca^{2+}-calmodulin binding sites on the channel overlaps a putative PIP_2 binding site, Brown and colleagues have suggested that Ca^{2+} binding may produce channel closure by displacing PIP_2.

At normal resting concentrations of PIP_2, M channels are not fully open, allowing for the possibility of enhancing the resting I_M pharmacologically. Enhancing I_M should reduce excitability and counteract convulsions. This is the effect of the drug retigabine. Retigabine originated from the National Institutes of Health Antiepileptic Drug Development Program. The main action of this compound is to shift the

current–voltage curve of Kv7 currents to the left (although it also increases the maximum opening probability) via an interaction of retigabine with residues in the S5 and S6 domains of Kv7 proteins, with a tryptophan residue in the S5 domain as the key determinant. This tryptophan is absent from the cardiac Kv7.1 channel, which is therefore resistant to retigabine action. Retigabine has potent anticonvulsant activity. It also enhances I_M in nociceptive sensory neurons and exerts antinociceptive effects, particularly against neuropathic pain. No published accounts of retigabine efficacy in the clinical treatment of chronic pain exist. However, numerous open-label and double-blind controlled trials have shown that the close structural analog and Kv7 channel opener flupirtine is effective in alleviating pain associated with a diverse range of etiologies.

Kv7 channel modulation with retigabine has also been shown to reduce the distonia in a mouse model of paroxysmal dyskinesia. Substantial effects of retigabine have also been seen on dopaminergic neuron firing rate in slice preparations.

Native Voltage-Gated Calcium Channels

Calcium ions are divalent cations that affect the electrical properties of cells and also act as second messengers regulating a variety of intracellular pathways. This unique dual role is initiated by the rapid influx of Ca^{2+} through voltage-activated calcium channels in the plasma membrane which triggers the release of neurotransmitters at nerve terminals, the initiation of muscle contraction, the regulation of intracellular signaling cascades and calcium-dependent gene expression, hormone secretion, and the control of electrical excitability and firing patterns (Figure 1). The alteration of normal calcium channel function and intracellular calcium regulation are implicated in a number of human pathophysiological conditions, including epilepsy, chronic pain, muscle dysfunction, mood disorders, autism, and certain types of cardiovascular disease, cancer, and blindness.

Electrophysiological recordings from neurons, muscle, endocrine, and other cell types reveal multiple distinct types of calcium channels which differ in their biophysical, pharmacological, and modulatory properties. Generally, two major classes of calcium currents can be distinguished based on the membrane potentials at which they first open as well as other biophysical properties (Figure 2). The low-voltage-activated calcium channels (also known as T-type) transiently open in response to small changes from resting potentials, whereas high-voltage-activated calcium channels usually require stronger depolarizations for activation. The high-voltage-activated channels are a diverse class consisting of L-, N-, P/Q-, and R-types that can be distinguished by their unique pharmacological, kinetic, and voltage-dependent gating characteristics. Most electrically excitable cells express multiple subtypes of both low- and high-voltage-activated calcium channels, the specific combination of which helps to define unique cellular phenotypes.

The high-voltage-gated calcium channels are integral membrane multisubunit protein complexes, with the best biochemically characterized of these being the skeletal muscle T-tubule-associated L-type channel. This L-type calcium channel consists of five distinct polypeptides designated α_1, α_2, β, δ, and γ (Figure 2). The α_1, β, and γ subunits are each derived from distinct genes, whereas the α_2 and δ subunits are derived from a single gene product that is proteolytically cleaved to form separate α_2 and δ subunits that are then linked by disulfide bonding. Examination of the reconstituted T-tubule L-type complex using electron microscopy shows an asymmetric distribution of ancillary subunits surrounding the α_1 subunit central core. The entire complex appears to be roughly cylindrical, with dimensions of approximately 9 nm wide by 20 nm high. The high-voltage-activated neuronal P/Q-type and N-type channels are also complexes consisting of an α_1 subunit in association with one of four different β subunits (β_1–β_4) and one of four $\alpha_2\delta$ subunits ($\alpha_2\delta_1$–$\alpha_2\delta_4$). It is unclear whether there is an associated γ subunit as part of native P/Q-type or N-type complexes. A general model has been proposed in which four or five proteins form the multisubunit high-voltage-activated calcium channel complex, although subunit composition may differ depending on channel type (Figure 3). In the complex, the α_1 subunit forms the channel proper, comprising the voltage-sensing and -gating mechanisms, the Ca^{2+}-selective pore, and interaction sites for drug binding and second messenger-dependent regulation. The ancillary proteins interact with the α_1 subunit to modulate channel activity and trafficking to the plasma membrane. The functional characteristics of the low-voltage-activated T-type calcium channels can be reconstituted by an α_1 subunit alone.

α_1 (Ca_v) Subunits

The large α_1 subunit proteins (~200–250 kDa) bear a high degree of similarity to the voltage-gated sodium channel α_1 subunits and are also evolutionarily related to voltage-gated potassium channels and other members of the ion channel superfamily. The mammalian genome contains 10 pore-forming calcium channel α_1 (Ca_v) subunit genes grouped into three interrelated subtypes (Figure 4). It is generally accepted that the distinct Ca_v subunits account for the known types of native voltage-activated calcium channels. Two branches of the Ca_v subunit phylogenetic tree account for the high-voltage-activated channels. In one branch, the $Ca_v1.1$–$Ca_v1.4$ subunits all encode distinct L-type calcium channels, whereas a second branch $Ca_v2.1$ encodes the P/Q-type, $Ca_v2.2$ the N-type, and $Ca_v2.3$ the R-type channel. The third Ca_v branch ($Ca_v3.1$–$Ca_v3.3$) encodes variants of low-voltage-activated T-type calcium channels. All of the Ca_v subunit genes are subject to extensive alternative splicing, resulting in multiple functionally distinct isoforms of each of the 10 calcium channel subtypes.

Figure 1 Voltage-gated calcium channels mediate numerous physiological functions. In response to depolarizing changes in membrane potential, voltage-gated calcium channels rapidly open (within ~1 ms), raising intracellular calcium to affect membrane electrical properties such as bursting and firing patterns as well as to regulate calcium-sensitive processes including muscle contraction, neurotransmitter release, cellular differentiation, and gene transcription.

The Ca_v subunit structure is similar to voltage-activated sodium channels, consisting of four homologous domains (I–IV) that form the main integral membrane components of the channel (Figure 5). The 10 Ca_v subunits share the most similarity in the membrane-spanning portions of domains I–IV and the least similarity in the cytoplasmic linkers separating the domains and the cytoplasmic and amino carboxyl tails. The highly divergent regions in the Ca_v subunits are the target sites of subtype-specific second messenger-dependent modulation and other protein–protein interactions.

The permeation profile of the high-voltage-activated calcium channels for cations is $Ca^{2+} > Ba^{2+} > Li^{+} > Na^{+} > K^{+} > Cs^{2+}$. Although Ca^{2+} and Na^{+} ions are of roughly similar diameter, the permeation pathway of voltage-gated calcium channels is approximately 1000-fold more selective for Ca^{2+} than for Na^{+} ions. The carboxylate side chains of four conserved p-loop glutamate residues within the lumen of the pore form the selectivity filter with a single high-affinity Ca^{2+} binding site. The four glutamate side chains are not functionally equivalent and may flex to enable a single Ca^{2+} ion to bind with high-affinity or two Ca^{2+} ions with lower affinity. This process would simultaneously contribute to both selectivity of Ca^{2+} over Na^{+} and electrostatically to a high rate of ionic flux. T-type calcium channels exhibit distinct permeation characteristics, including a smaller pore diameter; the ability to open with a half-size conductance level; and roughly similar permeation for Ca^{2+}, Ba^{2+}, and Sr^{2+}. The permeation differences between high-voltage-activated and T-type channels are in part due to distinct amino acids flanking the p-loops as well as to the domain III and IV p-loops of T-type channels possessing aspartates rather than glutamate residues in their selectivity filters.

Both high- and low-voltage-activated calcium channels intrinsically exhibit fast voltage-dependent inactivation, a process that limits the amount of Ca^{2+} entering cells during depolarization. Site-directed mutagenesis and chimeric channel approaches have identified various specific amino acids and transmembrane segments of the Ca_v subunit as well as interactions with β subunits as being critical components of inactivation. Overall, the rapid voltage-dependent inactivation of high-voltage-activated calcium channels is likely similar to that of both sodium and potassium channels and involves regions of the intracellular mouth of the pore (S6 segments) being occluded by a movable intracellular segment in 'ball-and-chain'- or 'hinged lid'-type mechanisms. T-type

Figure 2 High-voltage-activated (HVA) and low-voltage-activated (T-type) calcium channels exhibit distinct biophysical properties. T-type calcium channels can generally be distinguished by their more negative voltage dependencies of activation and inactivation, faster kinetics of inactivation, and slower kinetics of deactivation (closing).

calcium channel inactivation and activation are strongly coupled, and the inactivation properties of T-type channels can be distinguished as both very fast and calcium independent. Although many structure–function-type studies have been reported, until a calcium channel crystal structure becomes known, naturally occurring alternatively spliced variants provide both insightful structure–function information and clues toward how Mother Nature has altered specific channel regions to affect downstream physiological processes. For example, lengthening the $Ca_v3.1$ T-type channel domain II–III and III–IV linkers through alternative splicing variously affects activation and inactivation kinetics, recovery from inactivation, closing rates, and the voltage dependence of both activation and inactivation. As another example, an alternative splicing event that alters 14 amino acids in the proximal carboxyl region of the $Ca_v2.2$ subunit affects N-type current densities, electrophysiological properties, and sensitivity to G-protein modulation. Furthermore, one $Ca_v2.2$ splice variant is preferentially expressed in dorsal root ganglion nociceptors and is required for both the mediation of basal thermal nociception and the development of thermal and mechanical hyperalgesia associated with inflammatory and neuropathic pain. Similarly, there appear to be pathophysiological consequences associated with cardiovascular disease and alternative splicing that affect the biophysical properties of $Ca_v1.2$ L-type channels.

β Subunits

The β subunits are cytoplasmic proteins that directly associate with the high-voltage-activated Ca_v subunits to modulate channel trafficking and biophysical properties. Structurally, the β subunit proteins contain an internal Src homology 3 (SH3) domain linked to an enzymatically inactive guanylate kinase (GK) domain and are members of the membrane-associated GK (MAGUK) family of scaffold proteins albeit with some distinct features. Analogous to other MAGUKs such as PSD-95, the calcium channel β subunit SH3 and GK domains exhibit a stable intramolecular interaction.

Figure 3 Subunit composition of high-voltage-activated L-type calcium channel complex. Schematic diagram of the high-voltage-activated L-type calcium channel complex originally purified from skeletal muscle T-tubule membranes. The complex consists of five subunits: α_1, α_2, δ, β, and γ. The α_1 subunit forms the channel proper, comprising the voltage-sensing and-gating mechanisms, the calcium-selective pore, and the target of most pharmacological agents. Functional T-type calcium channels consist of an α_1 subunit alone, and there is no biochemical evidence indicating that other proteins are associated with native T-type channels in a multisubunit complex.

Figure 4 Similarity tree of the metazoan calcium channel α_1 (Ca_v) subunit family. The amino acid sequences of representatives of the 10 metazoan calcium channel α_1 subunits were aligned using Clustalx and the overall similarities are represented in the form of a similarity tree using HyperTree.

Ca_v–β subunit binding occurs in 1:1 stoichiometry with low nanomolar affinity to affect current amplitude, kinetics, and the voltage dependences of activation and inactivation. The basis for affecting the level of calcium channel whole cell currents seems to be through promoting translocation of the Ca_v subunit protein from the endoplasmic reticulum to the plasma membrane. On the α_1 subunit, the Ca_v–β subunit binding interaction occurs in a short cytoplasmic consensus motif in the domain I–II linker found in all high-voltage-activated Ca_v subunits (termed the α_1-interaction domain (AID)).

There are four different β subunit genes in mammals (β_1–β_4), each of which is subject to alternative splicing and each of which differentially affects the kinetic and voltage-dependent properties of high-voltage-activated Ca_v channels. The various β subunit isoforms vary significantly in primary sequence in their N- and C-termini and in the linker separating the SH3 and GK domains. The only available high-resolution structural information concerning voltage-gated calcium channel complexes is the X-ray crystallographic definition of the interaction between the Ca_v domain I–II AID region and portions of the β subunit. The consensus motif of the Ca_v AID binds as an amphipathic helix to a deep groove of the β subunit GK domain termed the AID-binding pocket.

$\alpha_2\delta$ Subunits

The disulfide-linked α_2 and δ subunit proteins are heavily glycosylated, with the $\alpha_2\delta$ subunit predominantly extracellular and anchored in the membrane by a transmembrane segment formed by the

Figure 5 Schematic of the predicted structure and transmembrane topology of calcium channel complex proteins. Ca$_v$ α_1 subunits contain four homologous domains, each possessing six α-helical membrane-spanning segments (S1–S6) and a pore-forming p-loop. The S4 segment in each domain contains positively charged lysine or arginine residues at every third or fourth position forming a crucial part of the voltage-sensing mechanism of the channel. All high-voltage-activated channel Ca$_v$ subunits possess a conserved EF hand motif in the C-terminus and also a conserved region in the domain I–II linker that binds in 1:1 stoichiometry to the cytoplasmic β subunit. The α_2 and δ subunits are derived from a single gene product which is proteolytically cleaved to form the approximately 140 kDa α_2 and approximately 30 kDa δ subunits, which are then disulfide bonded to each other in the native state. The γ subunits are composed of four membrane-spanning regions with their C- and N-termini located intracellularly and with predicted extracellular N-glycosylation.

δ subunit. Co-expression of $\alpha_2\delta$ subunits with Ca$_v$ subunits affects current density, channel kinetics, and current–voltage relations, although generally the $\alpha_2\delta$ functional effects are more subtle that those for the β subunits. In mammals, there are four known $\alpha_2\delta$ genes, $\alpha_2\delta_1$–$\alpha_2\delta_4$. All four $\alpha_2\delta$ subunit genes are subject to alternative splicing, with tissue and cellular specificity demonstrated for many of the variants.

In humans, the small organic molecules gabapentin and pregabalin are clinically effective anticonvulsants that are also effective in neuropathic pain conditions such as diabetic neuropathy, postherpetic neuralgia, trigeminal neuralgia, and pain associated with cancer and multiple sclerosis. Although synthetic analogs of the neurotransmitter γ-aminobutyric acid (GABA), gabapentin and pregabalin do not exert their effects via interacting with GABA receptors or transporters but, rather, bind with high-affinity to the high-voltage-activated calcium channel $\alpha_2\delta_1$ and $\alpha_2\delta_2$ subunits. Peripheral nerve injury in animals upregulates $\alpha_2\delta$ expression in the dorsal root ganglia and spinal dorsal horn, suggesting that the $\alpha_2\delta$ subunit contributes to central pain sensitization. Interestingly, whereas $\alpha_2\delta_1$ and $\alpha_2\delta_2$ subunits associate with high-voltage-activated calcium channel α_1 subunits, including the L-type channels found in skeletal, smooth, and cardiac muscles, gabapentin and pregabalin exhibit relatively few motor or cardiovascular adverse effects at therapeutic doses.

γ Subunits

There are at least eight γ subunit genes in the mammalian genome (γ_1–γ_8), all of which are considered to be members of the Claudin family of tight junction-associated adhesion molecules. Structurally, the C-termini of γ_2–γ_4, and γ_8 have a PDZ-binding motif, whereas the analogous regions of γ_7 and γ_5 lack this consensus motif but, rather, possess an SS/TSPC site likely designated toward specific protein interactions.

The γ_1 subunit is part of the skeletal muscle L-type calcium channel complex and is also found in heart, lung, spleen, kidney, liver, and testis. Mice lacking the γ_1 subunit display altered skeletal muscle L-type calcium currents, including a hyperpolarized shift in steady-state inactivation properties. Three other γ subunits, γ_2–γ_4, are of closest similarity to γ_1 and make up a subfamily of neuronal γ subunits.

Co-expression of some γ subunits in combination with Ca$_v$, β, and $\alpha_2\delta$ subunits shows diverse and γ subtype-specific effects on peak current levels, kinetics, current–voltage relations, and steady-state inactivation properties. However, in other instances, γ subunit co-expression does not appear to affect Ca$_v$ properties, leaving open the question as to which γ subunit isoforms are *bona fide* components of high-voltage-activated calcium channel complexes. In one intriguing instance, co-expression of γ_7 with Ca$_v$2.2 results in the complete abolition of N-type currents,

an effect apparently mediated by blocking expression rather than interfering with trafficking or channel biophysical properties. Additionally, a subset of γ subunits (γ_2–γ_4, and γ_8) represent TARP family members (transmembrane AMPA receptor regulator proteins) that regulate AMPA receptor trafficking as well as contribute to synaptic plasticity.

Low-Voltage-Activated (T-Type) Calcium Channels: $Ca_v3.1$–$Ca_v3.3$

The low-voltage activated (T-type) calcium channels first activate at negative potentials (approximately −75 to −60 mV) and are distinctive in their fast and strongly voltage-dependent kinetics of activation and inactivation, rapid recovery from inactivation, slow closing, and small single channel conductances (Figure 2). Their hyperpolarized and overlapping activation and inactivation ranges allow some calcium entry at resting membrane potentials (window current). This combination of unique biophysical characteristics allows T-type calcium channels to generally act as pacemakers, helping to trigger bursts of sodium-dependent action potentials after membrane hyperpolarization. They also contribute to oscillatory and rebound burst-firing behaviors relevant to normal physiological functions, such as thalamocortical-mediated deep sleep. Since T-type channels often generate a resting inward current, they also likely contribute to the gating of calcium-dependent ion channels and regulation of calcium-dependent enzymes and gene expression.

Although commonly referred to as a single class of channels, they are in fact physiologically and pharmacologically distinct T-type calcium channels encoded by three different Ca_v subunit genes (Figure 4). All three Ca_v subunits ($Ca_v3.1$–$Ca_v3.3$) support strongly voltage-gated calcium currents with the properties expected of T-type channels, although they each exhibit distinct kinetic, permeation, pharmacological, and other voltage-dependent properties, most likely reflective of their unique primary sequences. Multiple Ca_v3 alternative splice variants have been identified and probably also account for some of the observed heterogeneity in native T-type currents. The Ca_v3 N- and C-termini and the intracellular linkers joining the transmembrane domains share little sequence identity with high-voltage-activated Ca_v subunits. Furthermore, Ca_v3 subunit channels do not possess several specific functional motifs found in high-voltage-activated calcium channels, including the AID β subunit binding site in the domain I–II linker and EF-hand/calmodulin motifs in the C-terminus, the latter being consistent with the lack of Ca^{2+}-dependent inactivation for T-type channels.

T-type calcium channels are widely distributed to many central and peripheral neurons. At the subcellular level, the $Ca_v3.1$, $Ca_v3.2$, and $Ca_v3.3$ isoforms differentially distribute to somatic and dendritic compartments, implying that they uniquely contribute to neurophysiological processes. Outside the nervous system, T-type channels are found in many excitable and nonexcitable cells, and evidence indicates roles for T-type channels in pathophysiological states such as tumor proliferation, renal injury, and cardiovascular disease (Tables 1–3).

T-type channels as a class generally lack selective, high-affinity ligands. Small organic compounds such as octanol, amiloride, and mibefradil have been utilized as T-type channel antagonists, although they also variously inhibit high-voltage-activated calcium channels and other conductances. Several classes of the clinically utilized antipsychotics and antiepileptics block T-type calcium channels, although in most instances these agents are not specific (Figure 6).

$Ca_v3.1$ Subunit: CACNA1G Gene

$Ca_v3.1$ channel biophysical properties are very similar to those of the $Ca_v3.2$ T-type, although $Ca_v3.1$ channels do appear to exhibit a faster recovery from inactivation when membrane potential returns to negative values following depolarization. $Ca_v3.1$ subunits are expressed abundantly throughout the brain and the sinoatrial node of the heart, and lower levels are expressed in placenta, lung, and kidney.

Mice in which the $Ca_v3.1$ gene is genetically deleted appear anatomically and physiologically normal, although there are several alterations to nervous and cardiovascular system functions. Nervous system-associated defects include an absence of $GABA_B$ receptor agonist-induced spike-wave discharges, a lack of thalamic 1–4 Hz delta waves, a reduction of sleep spindles associated with normal sleep, and an enhanced visceral pain response. Overall, it appears that $Ca_v3.1$ channels play a crucial role in thalamocortical burst-firing processes relevant to a number of higher central nervous system functions, including thalamic sensory gating and the control of consciousness. In the heart, $Ca_v3.1$ gene deletion is associated with both slowing of the heart rate (bradycardia) and atrioventricular dysfunction, indicating that this T-type calcium channel normally contributes to setting the basal heart rate and to atrioventricular conduction.

$Ca_v3.2$ Subunit: CACNA1H Gene

$Ca_v3.2$ T-type channels are widely expressed in the central and peripheral neurons, cardiac tissue, kidney, and liver. In dorsal root ganglion neurons, $Ca_v3.2$

Table 1 Voltage-gated calcium channels

Native channel type	*α_1 Subunit*	*Pharmacological sensitivity*	*Major distribution*	*Major cellular functions*
P/Q	$Ca_v2.1$	ω-Aga-IVA (P-type), ω-CgTx-MVIIC (Q-type)	Neurons, heart, pituitary Subcellular: cell bodies, dendrites, presynaptic terminals	Neurotransmitter release, dendritic signaling
N	$Ca_v2.2$	ω-CgTx-GVIA, ω-CgTx-MVIIA	Neurons, neuroendocrine cells Subcellular: subset of cell bodies, dendrites, presynaptic terminals	Neurotransmitter release, dendritic signaling, neurite outgrowth
L	$Ca_v1.1$	Dihydropyridines, benzothiazapines, phenylalkylamines	$Ca_v1.1$: skeletal muscle T-tubules	$Ca_v1.1$: excitation–contraction coupling
	$Ca_v1.2$		$Ca_v1.2$: neurons, smooth (blood vessel, uterine, lung, stomach, intestine) and cardiac muscle; endocrine cells	$Ca_v1.2$: excitation–contraction coupling, Ca^{2+}-dependent gene transcription
	$Ca_v1.3$		$Ca_v1.3$: neurons, endocrine cells, heart atria, cochlea	$Ca_v1.3$: hormone secretion, Ca^{2+}-dependent gene transcription, atrial and neuronal pacemaking activity
	$Ca_v1.4$		$Ca_v1.4$: retina (photoreceptors, horizontal, bipolar, and amacrine cells), immune system, low levels in spinal cord and skeletal muscle Subcellular: $Ca_v1.2$ and $Ca_v1.3$ on cell bodies and proximal dendrites of neurons; $Ca_v1.4$ at photoreceptor synapses	$Ca_v1.4$: neurotransmitter release in visual system
R	$Ca_v2.3$	SNX-482	Neurons, heart Subcellular: cell bodies, some distal dendrites and presynaptic terminals	Selective neurotransmitter release, repetitive firing
T	$Ca_v3.1$	Poorly defined–nonspecific block by mibefradil, amiloride, pimozide, flunarizine, Ni^{2+}, Zn^{2+}, Cd^{2+}	Neurons, smooth muscle, endocrine cells, placenta, testis, lung, kidney cardiac sinoatrial cells, neuroendocrine cells, spermatogenic cells, developing skeletal muscle, fibroblasts, osteoblasts, astrocytes	Pacemaking activity, repetitive spiking and bursting, dendritic neurotransmitter release, cellular differentiation
	$Ca_v3.2$		Subcellular: soma, proximal and distal dendrites	
	$Ca_v3.3$			

channels contribute to both acute and neuropathic pain behaviors, whereas in mechanoreceptors they are required for the transduction of slow-moving mechanical stimuli. In sperm, the activation of $Ca_v3.2$ channels is required for triggering the acrosome reaction and allowing sperm to become competent for fusion with oocytes. Pharmacologically, $Ca_v3.2$ channels can be distinguished from both $Ca_v3.1$ and $Ca_v3.3$ by the higher sensitivity to nickel blockade (IC_{50} of $\sim$10 μM vs. $\sim$200 μM).

Genetic deletion of $Ca_v3.2$ in mice results in smaller but viable animals that possess constricted coronary arteries and develop cardiac fibrosis. In agreement with the high levels of $Ca_v3.2$ channels in small dorsal root ganglion cells, knockout mice also exhibit attenuated responses to mechanical, thermal, and chemical pain stimuli.

Point mutations in the CACNA1H gene in humans are associated in a subset of patients with childhood absence epilepsy (CAE) and idiopathic generalized epilepsy (IGE). The majority of the mutations are localized in the $Ca_v3.2$ channel intracellular linker between domains I and II, and biophysical analyses reveal both gain-of-function and loss-of-function effects. The gain-of-function effects are predicted to result in increased calcium influx at lower membrane potentials, which would result in neuronal hyperexcitability and increased spike-wave discharge. The polygenic, non-Mendelian inheritance of CAE and IGE suggests that interaction with other gene products must also be considered with regard to disease pathogenesis.

Missense mutations in the CACNA1H gene resulting in a predicted overall decrease in calcium entry through $Ca_v3.2$ channels have also been associated with a small subset of individuals with autism spectrum disorder (ASD). Considering the tight regulation of intracellular calcium levels necessary for normal

Table 2 Spontaneous mutations in mammalian calcium channel subunit genes

Gene and human chromosomal location	*Channel subunit*	*Disease state/phenotype*
CACNA1S 1q31–32	$Ca_v1.1$	Human (dominant mutations): hypokalemic periodic paralysis-periodic muscle weakness; malignant hypothermia susceptibility type 1-elevated skeletal muscle contraction, glycogenolysis, increased heat and lactic acid acidosis, tachycardia, and cardiac arrhythmia and arrest Mouse: recessive mutations, muscular dysgenesis (*mdg*)
CACNA1C 12p13.3	$Ca_v1.2$	Human: Timothy syndrome–severe functional and developmental abnormalities in several organ systems, including heart, skin, eyes, teeth, immune system, and the brain; autism
CACNA1F Xp11.23	$Ca_v1.4$	Human (recessive and dominant mutations): incomplete X-linked congenital stationary night blindness–variable degrees of night blindness, low visual acuity, nystagmus, and hyperopia or myopia; X-linked cone–rod dystrophy–low visual acuity, reduced color vision, central scotomas in visual field, photophobia, and myopia
CACNA1A 19p13.1	$Ca_v2.1$	Human (dominant mutations): episodic ataxia type 2–spontaneous episodes of ataxia, nystagmus, and often migraine-like symptoms; familial hemiplegic migraine type 1–migraine with aura, motor aura typically manifests as hemiplegia in upper and lower extremities, often associated with ataxia or nystagmus; spinal cerebellar ataxia type 6–gate ataxia, reduced coordination, nystagmus, dysarthia and proprioceptive sensory loss, severe cerebellar Purkinje cell loss Mouse (recessive mutations): tottering (*tg*), leaner (tg^{la})–ataxia, dystonia, spike-wave epilepsy; dominant mutation; wobbly ataxia
CACNA1H 16p13.3	$Ca_v3.2$	Human: idiopathic generalized epilepsy/childhood absence epilepsy–absence seizures including short seizures followed by sudden impairment of consciousness; autism spectrum disorder Rat (recessive mutation): absence epilepsy
CACNA2D	α_2–δ_2	Mouse: recessive mutation; ducky–spike-wave epilepsy
CACNB4 2q22-23	β_4	Human: generalized epilepsy–recurrent generalized seizures, episodic ataxia Mouse: lethargic (*lh*)–spike-wave epilepsy
CACNG2	γ_2	Mouse (recessive mutations): stargazer (*stg*); waggler (stg^{wag}), altered skeletal muscle L-type current, spike-wave epilepsy

Table 3 Targeted gene deletions in mouse calcium channel subunit genes

Gene	*Channel subunit*	*Disease state/phenotype*
CACNA1S	$Ca_v1.1$	Nonviable, suffocate at birth due to inability to contract diaphragm
CACNA1C	$Ca_v1.2$	Die approximately embryonic day 12.5
CACNA1D	$Ca_v1.3$	Viable, deaf, atrial arrhythmias, bradycardia
CACNA1F	$Ca_v1.4$	Viable, impaired vision
CACNA1A	$Ca_v2.1$	Usually die approximately 3 weeks postnatal, absence seizures, ataxia, dystonia, spasms, abnormal cerebellar synapses and cerebellar cell death, altered acute and inflammatory pain responses
CACNA1B	$Ca_v2.2$	Viable, reduced neuropathic and inflammatory pain responses, altered responses to ethanol and anesthetics, hyperactive, increased basal vigilance state, reduced baroreflex, decreased anxiety, impaired long-term memory
CACNA1E	$Ca_v2.3$	Viable, altered visceral pain response, impaired spatial memory and locomotion, altered responses to cocaine, anesthetics and cerebral ischemic damage, decreased insulin response and glucose tolerance
CACNA1G	$Ca_v3.1$	Viable, absence of $GABA_B$ receptor agonist-induced spike-wave discharges, decreased heart rate, slower atrioventricular conduction
CACNA1H	$Ca_v3.2$	Viable, impaired relaxation of vasculature, altered acute and chronic pain responses
CACNB1	β_1	Perinatal lethality, no excitation–contraction coupling
CACNB2	β_2	Embryonic lethal
CACNB3	β_3	Viable, altered blood pressure in response to high-salt diet, reduced acute and inflammatory pain responses
CACNB4	β_4	Ataxia, focal motor seizures, absence epilepsy
CACNG1	γ_1	Viable, no visible phenotype
CACNG4	γ_4	Viable, no visible phenotype

Figure 6 Clinical agents utilized to treat human cardiovascular and neurological disorders. The L-type calcium channel antagonists (dihydropyridines, phenylalkylamines, and benzothiazepines) block all Ca_v1 subunits *in vitro*, but they predominantly act *in vivo* on the cardiovascular system and exhibit selectivity between cardiac and vascular functions. Gabapentin and pregabalin bind to specific arginine residues in the $\alpha_2\delta_1$ and $\alpha_2\delta_2$ subunits, but determination of the exact mechanism of action of gabapentin has proven elusive, with reports both supporting and refuting direct actions on high-voltage-activated calcium channel properties. Ziconotide is a 25-amino acid synthetic version of ω-contotoxin MVIIA that reversibly blocks N-type channels and is highly effective in multiple types of human chronic and neuropathic pain conditions. Side effects of ziconotide administration include orthostatic hypotension, confusion, nystagmus, sedation, auditory and visual hallucinations, and agitation. Clinical antipsychotics such as pimozide and flunarizine block T-type channels, but they also target dopamine receptors. Ethosuximide, an absence epilepsy therapeutic, blocks T-type channels at millimolar concentrations.

cell signaling and gene expression, it is possible that the biophysical effects of the CACNA1H mutations translate into neuronal development abnormalities. Similar to that for CAE and IGE, the strong polygenic inheritance pattern of ASD, together with the fact that many patients do not have associated mutations in CACNA1H, indicates a likely minor role for the $Ca_v3.2$ channel in overall ASD susceptibility.

$Ca_v3.3$ Subunit: CACNA1I Gene

Compared to the $Ca_v3.1$ and $Ca_v3.2$ T-type channels, recombinant $Ca_v3.3$ channels uniquely exhibit voltage-dependent facilitation, a larger time constant of activation (slower opening), as well as a slower rate of inactivation and a faster deactivation (closing). Together, these properties predict that $Ca_v3.3$ channels generate sustained inward calcium current under conditions of prolonged depolarizations as well as a large window calcium current under resting conditions. Also compared to $Ca_v3.1$ and $Ca_v3.2$ channels, $Ca_v3.3$ T-type channels are differentially modulated by second messenger signaling pathways, including those acting through muscarinic acetylcholine and metabotropic glutamate receptors.

High-Voltage-Activated Calcium Channels

L-Type Calcium Channels: $Ca_v1.1$–$Ca_v1.4$

High-voltage-activated L-type calcium channels are expressed in almost all excitable cells as well as many types of non-excitable cells (Table 1). In cardiac, skeletal and smooth muscles they are the primary route for calcium entry and are responsible for triggering muscle contraction. In neurons, L-type channels are primarily located on cell bodies and proximal dendritic regions where they are vital players in linking electrical excitability to the control of calcium-dependent gene transcription. Some L-type channels are also involved in exocytotic release from both endocrine cells and specialized neurons such as photoreceptors.

L-type calcium channels generally require large depolarizations to become activated, typically opening at potentials positive to -30 mV, although they can activate at significantly more negative potentials in chromaffin cells, sensory neurons, photoreceptors, and cardiac cells. In addition to voltage-dependent mechanisms, L-type currents inactivate rapidly through a Ca^{2+}-dependent negative feedback process that serves to finely control Ca^{2+}-dependent signaling and protect against toxic Ca^{2+} overload.

L-type calcium channels are readily distinguished by their sensitivities to several classes of small organic molecules widely used in the clinical treatment of hypertension, angina, Raynaud's disease, and cerebral vasospasm. The 1,4-dihydropyridines (DHPs), phenylalkylamines, and benzothiazepines interact at allosterically distinct binding sites on the L-type Ca_v subunit to block channel activity. The *in vivo* specificity of physiological actions of these agents likely reflects a number of factors, including pharmacokinetic aspects, the existence of distinct L-type molecular isoforms

($Ca_v1.1$–$Ca_v1.4$), and the state dependence of drug interaction. The state dependence of channel blockade is of particular relevance since both drug access to its binding site and the affinity of drug binding are highly dependent on the conformational state of the channel. Several DHP agonists have also been developed, the most highly utilized being (-)-Bay K 8644, which increases both L-type channel open time and single channel conductance.

$Ca_v1.1$ Subunit: CACNA1S Gene

$Ca_v1.1$ L-type calcium channels are crucial in striated muscle for coupling membrane depolarization to the release of calcium from cytoplasmic stores which then triggers excitation–contraction (EC) coupling. Depolarizing changes in skeletal muscle membrane potential cause a conformational change in $Ca_v1.1$ which induces an allosteric interaction with the sarcoplasmic reticulum (SR) ryanodine receptor (RyR1), ultimately triggering calcium release from the SR and subsequent muscle contraction. Unique in this process is the fact that calcium entry through the $Ca_v1.1$ channel is not required for muscle contraction; rather, the $Ca_v1.1$ channel complex acts simply as a voltage sensor to initiate the contraction process.

Related to its role as a voltage sensor for the RyR1, the $Ca_v1.1$ L-type channel is implicated in two muscle disorders in humans: hypokalemic periodic paralysis (HypoPP) and malignant hyperthermia susceptibility (MHS; Table 2). Missense mutations in the CACNA1S gene encoding $Ca_v1.1$ result in reduced current density and reduced rates of activation, loss-of-function effects predicted to result in less calcium influx into muscle cells during depolarization. Although reduced calcium influx through $Ca_v1.1$ channels could indirectly affect membrane potential, given the dual functions of $Ca_v1.1$ it is also possible that the pathophysiology of HypoPP is independent of Ca^{2+} flux but is associated with an uncoupling of EC between $Ca_v1.1$ and RyR1 and indirectly results in reduced Ca^{2+} release from internal stores.

MHS is an autosomal dominant disorder characterized by a predisposition in otherwise healthy individuals for muscle hypermetabolism in response to exposure to volatile anesthetics or depolarizing muscle relaxants. The majority of patients would die without early administration of the SR calcium release inhibitor dantrolene. Most mutations associated with MHS are in the RyR1 gene, although several have also been identified in CACNA1S.

$Ca_v1.2$ Subunit: CACNA1C Gene

In both cardiac and smooth muscles, $Ca_v1.2$ L-type channels are involved in an EC coupling mechanism requiring Ca^{2+} influx through $Ca_v1.2$ channels to activate RyR2 receptors to release calcium from internal SR Ca^{2+} stores in order to initiate muscle contraction. In the cardiovascular system, $Ca_v1.2$ channels are critically linked to vasodilation and cardiac depression and are the target of the clinically used L-type channel blockers. Cardiovascular $Ca_v1.2$ L-type channels are also a target for modulation by noradrenaline and angiotensin II, both of which are critical regulators of vascular control. Within the brain, $Ca_v1.2$ is the major L-type channel, with $Ca_v1.2$ channels being diffusely distributed at low levels on cell bodies and proximal dendrites. Multiple alternatively spliced $Ca_v1.2$ variants have been identified that exhibit distinct biophysical properties, including rates of activation and current–voltage relations. Many $Ca_v1.2$ splice variations are localized to the cytoplasmic linker between domains II and III and the carboxyl region, likely reflecting cell-specific protein interactions and physiological functions. Interestingly, some splice variants exhibit cell-, tissue-, and pathophysiological state-specific expression patterns. Reflective of its physiological importance in cardiac and nervous system development, genetic deletion of $Ca_v1.2$ in mice is lethal and animals die on approximately embryonic day 12.5.

Mutations in the domain I S6 transmembrane segment of the human $Ca_v1.2$ gene are associated with a serious multisystem disorder called Timothy syndrome (TS). More than half of TS patients die between 2 and 3 years of age. Functional analysis of TS $Ca_v1.2$ mutations shows a near complete loss of voltage-dependent inactivation and altered CaMKII-dependent channel gating, both of which are predicted to prolong Ca^{2+} influx. Computer simulation of these effects suggests significant cardiac action potential prolongation and prolonged QT intervals, a phenomenon known to result in abnormal secondary depolarizations, arrhythmia, and sudden death.

$Ca_v1.3$ Subunit: CACNA1D Gene

$Ca_v1.3$ L-type channels have sometimes been termed 'neuroendocrine' L-type channels because of their presence in neuroendocrine cells, such as pancreatic β and adrenal chromaffin cells. However, they are also found in the brain, cardiac atrial myocytes, retina, ovaries, and cochlear hair cells of the ear. Within the central nervous system, $Ca_v1.3$ channels are found in most regions, although they are generally less abundant than $Ca_v1.2$ L-type channels. In contrast to the $Ca_v1.1$ and $Ca_v1.2$ L-types, $Ca_v1.3$ currents possess more negative current–voltage relations and have a lower sensitivity to block by dihydropyridines. In adult substantia nigra neurons, the

more hyperpolarized activation of Cav1.3 channels contributes to the autonomous Ca^{2+}-dependent pacemaker activity of these cells. Interestingly, the inhibition of substantia nigra pacemaking activity by the pharmacological blockade of $Ca_v1.3$ channels is protective in mouse models of Parkinson's disease.

Cav1.3 gene-deficient mice are largely anatomically and behaviorally normal, with notable exceptions. (1) The inner hair cochlea cells completely lack L-type currents, which results in deafness, and (2) sinoatrial node dysfunction results in atrial arrhythmias and bradycardia, effects reflective of the negative activation of $Ca_v1.3$ channels toward contributing to cardiac pacemaking activity and diastolic depolarization.

$Ca_v1.4$ Subunit: CACNA1F Gene

$Ca_v1.4$ currents are unique in their small unitary conductance, slow inactivation kinetics, and lack of Ca^{2+}-dependent inactivation. Similar to that for the $Ca_v1.3$ L-type, $Ca_v1.4$ channels activate at relatively negative potentials and are predicted to support a substantial resting window current.

In contrast to the rapid and transient nature of neurotransmitter release at most neuronal synapses, synaptic release from photoreceptors occurs through graded changes in membrane potential and is dependent on $Ca_v1.4$ L-type calcium channel activity. In the dark, photoreceptors tonically release glutamate, whereas light stimulus causes membrane hyperpolarization and the termination of glutamate release. The lack of calcium- and time-dependent inactivation together with the occurrence of a large window current make $Ca_v1.4$ channels ideally suited to support tonic glutamate release from photoreceptors. In support of this notion, mutations in the CACNA1F gene are implicated in the vision-related channelopathies, incomplete X-linked congenital stationary night blindness (IXLCSNB) and X-linked cone–rod dystrophy (CORDX).

More than 60 missense and truncation mutations scattered across most $Ca_v1.4$ structural regions have been identified in the CACNA1F gene of patients with IXLCSNB. Biophysical investigation of some mutations indicates no obvious measurable affect on $Ca_v1.4$ channel properties, whereas others cause either a loss of function or a gain of function. Overall, the analysis of IXLCSNB mutations to date does not give a clear or consistent indication regarding how the distinct point mutations might result in abnormal neurotransmission in photoreceptors.

CORDX is a progressive disorder including clinical features of reduced visual acuity and poor color vision. In one CORDX family, a mutation has been identified in the splice acceptor site of intron 28 in the CACNA1F gene and is predicted to cause either a premature stop codon or variable size deletions. The functional consequences of this mutation are unknown.

P/Q-Type Channel – $Ca_v2.1$ Subunit: CACNA1A Gene

P/Q-type calcium channels are one of the most abundantly expressed calcium channel subtypes in the mammalian central and peripheral nervous systems. $Ca_v2.1$ channels are highly localized at presynaptic terminals throughout the brain, spinal cord, and neuromuscular system, where they mediate calcium influx essential for a large portion of excitatory neurotransmitter release. At postsynaptic sites, $Ca_v2.1$ P/Q-type channels contribute to the precise modulation of intracellular calcium levels important for dendritic firing and also second messenger signaling relevant to calcium-dependent gene transcription. Originally defined as separate channel types, P-type and Q-type channels differ in their relative sensitivities to the spider peptide toxin ω-agatoxin IVA and the cone snail toxin ω-conotoxin MVIIC, and they also display distinct time- and voltage-dependent properties. In fact, the single $Ca_v2.1$ subunit gene encodes both P- and Q-type channels with their distinctive properties reflecting small protein alterations generated by alternative splicing. There may also be some contribution to the phenotypic differences between P-type and Q-type currents by the inclusion of different β subunit isoforms to form distinct channel complexes.

Deletion of the $Ca_v2.1$ subunit gene in mice results in animals with largely normal embryonic and early postnatal development but with the onset of severe neurological complications starting on approximately postnatal day 10 and resulting in the death of most, but not all, animals by approximately postnatal day 21 (Table 3). In surviving animals, cerebellar defects such as Purkinje cell swelling and abnormal granule cell migration are present.

Mutations in the human CACNA1A gene are associated with severe neurological channelopathies, including familial hemiplegic migraine (FHM1), episodic ataxia type 2 (EA2), and spinocerebellar ataxia type 6 (SCA6). FHM1 is a rare autosomal dominant subtype of migraine with an aura phase linked to cortical spreading depression (CSD). Mutations in CACNA1A resulting in FHM1 are primarily localized to $Ca_v2.1$ channel S4 voltage sensors and flanking regions. Phenotypic dissection of these mutations in isolation has proven difficult and may be due to the fact that distinct $Ca_v2.1$ alternatively spliced variants are differentially affected by FHM1 mutations. More revealing data from mice carrying introduced FHM1 mutations predict a P/Q-type channel gain-of-function phenotype

resulting in a lower threshold for CSD depression and an increased velocity of propagation across the cortex. It is unknown how headache pain is manifest, although one possibility is that CSD activates trigeminovascular afferents and evokes meningeal and brain stem activity consistent with migraine pain. It is also possible that $Ca_v2.1$ P/Q-type channels directly contribute to modulation of the trigeminal pain pathway.

EA2 is an autosomal dominant disorder in which patients experience spontaneous episodes of ataxia lasting from hours to days. Approximately half of patients also experience migraine-like symptoms. EA2 is genetically variable with more than 40 individual missense, truncation, and alternative splice site mutations distributed throughout the channel. Some truncation and missense mutations cause a reduction in current density, possibly due to fewer channels being properly folded and reaching the plasma membrane. Alternatively, some missense mutations show a net reduction of available channels due to a depolarizing shift in the voltage dependence of activation, an increased rate of inactivation, and a reduced rate of recovery from inactivation. Overall, all EA2 mutations exhibit a net reduction in $Ca_v2.1$-mediated calcium currents, likely resulting in reduced neurotransmitter release at critical synapses.

Patients with SCA6 have a polyglutamine (CAG) expansion in exon 47 of the CACNA1A gene, making SCA6 a member of the group of neurodegenerative disorders containing CAG repeats and which includes Huntington's disease (Table 2). Unaffected people have a low copy number of CAG repeats (4–16), whereas patients with SCA6 have expansions of more than 21 CAG repeats. The length of the expansion appears to be directly correlated with age of onset, with the greater CAG expansion being associated with early age of disease onset. Biophysical analyses of polyglutamine expansions in the $Ca_v2.1$ calcium channel show a range of effects on voltage- and time-dependent properties with a strong dependence on both auxiliary subunit and $Ca_v2.1$ subunit splice variant composition.

N-Type Channel – $Ca_v2.2$ Subunit: CACNA1B Gene

Unique among the high-voltage-activated calcium channels, the expression of N-type channels is largely restricted to neurons and neuroendocrine-derived cells (Table 1). Biophysically, N-type channels exhibit conductances intermediate between that of T-type and that of L-type channels and display time-dependent inactivation slower than the rapid inactivation of T-type channels but faster than that of L-type channels. In some cells, such as sympathetic neurons, N-type currents do not always inactivate rapidly and the decay rate can be slow and incomplete. Pharmacologically, N-type channels can be distinguished by their high sensitivity to irreversible block by ω-conotoxin GVIA, a 27-amino acid peptide from the marine hunting snail *Conus geographus*.

N-type channels are distributed throughout the peripheral and central nervous systems and appear especially concentrated in regions of high synaptic density where they are responsible for triggering neurotransmitter release at a subset of terminals. In addition to their presynaptic functions, N-type channels are also localized postsynaptically on dendrites, where they likely contribute to the integration and amplification of neural inputs. They also appear to play a role in nervous system development and neurite outgrowth.

Although no natural mutations in the CACNA1B gene have been described, $Ca_v2.2$ gene knockout and pharmacological interventions indicate that the N-type calcium channel plays a critical role in the primary afferent nociceptive pathway. N-type calcium channels are highly concentrated in the cell bodies and synaptic terminals of a subset of primary afferents that terminate in the dorsal horn of the spinal cord (mainly C-fibers and A-δ fibers). Deletion of the $Ca_v2.2$ channel gene in mice results in animals largely resistant to the induction of neuropathic and inflammatory pain but otherwise exhibiting normal sensory and motor functions (Table 3). Pharmacologically, the marine snail *C. magus* peptide toxin, ω-conotoxin-MVIIA (also known as ziconotide), reversibly blocks N-type currents and has been widely used to define the contributions of N-type channels in both animal model and human pain conditions. The intrathecal administration of ziconotide in animals shows strong analgesic effects on inflammatory pain, postsurgical pain, thermal hyperalgesia, and mechanical allodynia. In humans, the intrathecal administration of ziconotide to patients unresponsive to intrathecal opiates significantly reduces pain scores in chronic conditions such as cancer and HIV-related pain. Ziconotide has also been shown to be effective for the management of intractable spasticity following spinal cord injury.

Other behavioral phenotypes associated with deletion of the $Ca_v2.2$ gene in mice include a decrease in both the voluntary consumption and the hypnotic effects of ethanol and the accentuation of ethanol-based place preference, decreased anxiety, reduced baroreceptor response, and impaired long-term memory (Table 3).

R-Type Channel – $Ca_v2.3$ Subunit: CACNA1E Gene

A component of high-voltage-activated calcium current remains in some neurons even after the application of pharmacological agents to block L-, N-, and P/Q-type channels. Categorized as R-type for residual

or resistant, this current can be blocked by the African tarantula venom peptide SNX-482. Although it is possible that a portion of the native R-type calcium current as defined pharmacologically may result from incomplete blockade by the applied antagonists and/or to the existence of pharmacologically distinct splice variants of the P/Q- and N-type channels, the $Ca_v2.3$ subunit can account for many native R-type properties.

In some instances, the voltage-dependent parameters of $Ca_v2.3$ channels (current–voltage relationship and voltage dependence of inactivation) are more hyperpolarized than those of the other high-voltage-activated channels, and $Ca_v2.3$ channels also appear unique in being equally permeable to Ca^{2+} and Ba^{2+} and being highly sensitive to Ni^{2+} blockade, properties which are usually ascribed to T-type calcium channels.

The exact physiological functions of R-type channels are the least defined of the high-voltage-activated subtypes. Although N- and P/Q-type channels dominate neurotransmitter release, at some synapses R-type channels also contribute to release. Mice with deletion of the $Ca_v2.3$ subunit gene appear anatomically normal but exhibit a number of physiological defects, including increased anxiety, decreased spatial memory and locomotor activity, altered sperm motility, and decreased insulin secretion and glucose tolerance. Pain responses are also affected, with a decrease in acute formalin-induced inflammatory pain but an increased long-term response to formalin-induced visceral pain.

Regulation of Calcium Channel Activity – Interacting Proteins

The activities of all calcium channel subtypes are highly regulated by intracellular second messengers, which has significant consequences concerning downstream physiological functions (Figures 7 and 8). For example, the modulation of presynaptic P/Q-type and N-type channels by G-protein-coupled receptors (GPCRs) is a common strategy for regulating synaptic strength and efficacy. Many GPCRs, including those for dopamine, opioids, neuropeptide Y, glutamate,

Figure 7 Second messenger-dependent modulation of calcium channels. The functional activities of all high-voltage-activated and low-voltage-activated T-type calcium channels are subject to modulation (upregulation and downregulation) by the activation of intracellular second messenger pathways acting via most known G-protein-coupled receptors (GPCR). DG, diacyl glycerol; ER, endoplasmic reticulum; IP3, inositol triphosphate; NT, neurotransmitter; PTX, pertussis toxin; PKA, protein kinase A; PKC, protein kinase C; PKG, protein kinase G; TK, tyrosine kinase. Redrawn from Chemin J, Traboulsie A, and Lory P (2006) Molecular pathways underlying the modulation of T-type calcium channels by neurotransmitters and hormones. *Cell Calium* 40: 121–134.

Figure 8 Voltage-activated calcium channels interact with multiple types of intracellular signaling molecules. Structure–function and biochemical analyses indicate that multiple types of intracellular proteins bind to and modulate calcium channel activity, trafficking, and interactions with intracellular signaling proteins. These include a high-affinity G-protein βγ subunit binding, distinct regions involving functional interactions with the synaptic release machinery (SNAP-25, syntaxin-1, and synaptotagmin), binding to anchoring proteins (AKAP-79 and AKAP-15), interactions with the skeletal and cardiac muscle excitation–contraction coupling machinery, as well as binding with regulatory molecules such as calmodulin, CaM kinase II, Ca^{2+}-binding protein-1, CASK, and mint-1.

GABA, substance P, canabinoids, adenosine, and somatostatin, all act to attenuate calcium presynaptic channel activity and to thereby decrease neurotransmitter vesicle fusion and release.

In another prominent example of calcium channel modulation, calmodulin acts in a Ca^{2+}-dependent feedback mechanism to either inhibit (Ca^{2+}-dependent inhibition (CDI)) or facilitate (Ca^{2+}-dependent facilitation (CDF)) high-voltage-activated calcium activity. CDF and CDI are mechanistically linked, predominantly involving several regions of the Ca_v subunit carboxyl tail, including an EF-hand motif and several downstream regions that form calmodulin (CaM), Ca^{2+}-binding protein, and CaM kinase II tethering/binding sites.

T-type channel activity can also be upregulated or downregulated by many types of neurotransmitter and hormone receptor-coupled pathways. T-type current inhibitory pathways include those mediated via acetylcholine, endocannabinoids, angiotensin II, atrial natriuretic factor, bradykinin, dopamine, enkephalin, estradiol, GABA, serotonin, somatostatin, substance P, and norepinephrine. T-type current upregulation includes pathways acting via acetylcholine, aldosterone, angiotensin II, ATP, L-cysteine, erythropoietin, estrogen, GABA, serotonin, norepinephrine, vasoactive intestinal peptide, insulin-like growth factor, and substance P. Altering T-type channel activity is predicted to critically affect neuronal and cardiac physiological processes such as firing patterns, rhythmic oscillations, and pacemaker activities.

Presynaptic P/Q-type and N-type channels provide the initial calcium trigger to initiate neurotransmitter release and contribute to anchoring synaptic vesicles at release sites. Direct interaction occurs between the synaptic protein interaction site in the domain II–III linker of P/Q-type and N-type channels and the SNARE proteins syntaxin-1A and SNAP-25. The $Ca_v2.1$ channel subunit also binds to the synaptic calcium sensor protein, synaptotagmin. Disruption of the Ca_v subunit–SNARE protein interaction in neurons inhibits neurotransmitter release.

There are examples in which parts of individual calcium channel complexes perform roles other than mediating calcium influx or voltage-sensing activities. In one instance, a β_4 subunit splice variant independently and directly interacts with a nuclear protein implicated in gene silencing and transcription. In another instance, the β_3 subunit appears to affect glucose-mediated excitability in pancreatic cells by negatively affecting inositol 1,4,5-triphosphate-induced calcium release. Furthermore, an approximately 75 kDa proteolytically cleaved C-terminal fragment of $Ca_v1.2$ L-type channel can translocate to the nucleus, where it interacts with a nuclear protein to regulate the transcription of multiple neuronal genes.

Voltage-Gated Potassium Channels (Kv10–Kv12)

G A Robertson, University of Wisconsin – Madison, Madison, WI, USA

Introduction

The 1980s and early 1990s witnessed the intersection of molecular genetics with ion channel biophysics to reveal for the first time submolecular details of ion channel structure and function. *Shaker*, cloned in Lily Jan's lab using a genetic approach in *Drosophila*, provided the first insights into the primary structure (amino acid sequence) of voltage-gated potassium (K) channels. Having the gene in hand meant channel structure could be perturbed through genetic engineering to test hypotheses about gating, permeation, and other functions in heterologous expression systems such as *Xenopus* oocytes or mammalian HEK-293 cells. A wave of additional K channels identified based on their homology with Shaker together with mutagenesis and modeling studies revealed a shared architecture of six transmembrane domains and the primary structures underlying voltage sensitivity and K selectivity.

The cloning of *ether à-go-go* (*eag*) provided a very different perspective on K channels. The name *ether à-go-go* was coined by Kaplan and Trout in 1969 to describe spontaneous *Drosophila* mutants exhibiting leg-shaking behavior induced by ether anesthesia. Many years later, Barry Ganetzky and colleagues identified the *eag* gene as a regulator of neuronal excitability at the *Drosophila* larval neuromuscular junction and predicted its gene product was a voltage-gated potassium channel subunit. The gene was cloned, and the translated sequence revealed several similarities to Shaker channels, including a conserved S4 voltage-sensor domain containing the canonical sequence of a positively charged amino acid at every third position, and a six-transmembrane topology (Figure 1). However, instead of the GYGD 'signature sequence' that rigidly define the K selectivity filters of all other known K-selective channels, eag channels had the amino acid sequence GFGN. Another important difference was a region C-terminal to the transmembrane domains that was homologous to the cyclic nucleotide binding domain (CNBD) of kinases and a cyclic nucleotide-gated ion channel, which had recently been cloned. Quantitative sequence analysis revealed that the hybrid-looking eag is more closely related to the non-selective cyclic nucleotide-gated (CNG) cation channels and inward rectifier K channels in plants than the *Drosophila* Shaker channel (Figure 2). Thus, *eag* and *Shaker* evolved from a common ancestral gene that predates the divergence of the plant and animal kingdoms.

Drosophila eag was just the tip of a phylogenetic iceberg. Homology screening and degenerate polymerase chain reaction techniques revealed a rich family tree of ion channel genes extending from *Caenorhabditis elegans* to *Homo sapiens*. Analogous to the Shaker family, the Eag family members fall into distinct subfamilies: EAG (for the original isolate, or Kv10), ERG (Eag-Related Gene, or Kv11), and ELK (Eag-LiKe, or Kv12) (see Table 1 for other nomenclatures). One member representing each subfamily was identified in *Drosophila*, whereas in mammals gene duplication has given rise during evolution to multiple members in each subfamily. Within a subfamily, the primary amino acid sequence is 60–75% identical between the first transmembrane domain and the end of the putative CNBD; for members of different subfamilies, the identity decreases to 40–50%. Diversity is further enhanced in the Kv10 and Kv11 subfamilies by alternative transcripts arising from exon splicing and different promoters. Although the current International Union of Pharmacology 'Kv' nomenclature is used in this article (Table 1), as indicated previously, Eag family members bear less similarity to Shaker and other Kv-type channels than to other families such as the CNG channels, and they are best considered members of a distinct family.

Heterologous expression in *Xenopus* oocytes showed that despite the unusual selectivity filter sequence, all Kv10–12 family members are highly selective for K^+ over Na^+ and other physiological ions. All are gated by voltage and not cyclic nucleotides. They transition from a closed or resting state at negative voltages to an open state at positive voltages. Some progress from the open to a nonconducting inactivated state at maintained positive voltages. Differences in rates of transition between these conformational states give rise to functional differences between family members (Figure 3). Compared with members of the Shaker family, opening is relatively slow. External tetraethylammonium (TEA) and 4-aminopyridine, broad K channel blockers, are relatively ineffective at blocking Eag-type channels.

The members of the Eag family are broadly expressed in the nervous system, but their physiological roles are only beginning to be understood. The focus of this article is on the biophysical and pharmacological properties of α (primary) subunits expressed in heterologous systems, which will ultimately enable us to identify the corresponding currents in native tissues. These studies describe an

unfolding and fascinating diversity of function arising from adaptations of fundamental mechanisms common to voltage-gated ion channels.

The Kv10 (EAG) Subfamily

Two genes encode the mammalian Kv10 (EAG) channels. Expressed in heterologous systems, Kv10 channels exhibit properties characteristic of delayed rectifiers (Figure 3(a)). They open and close with time constants of activation of the order of 40 ms at steps from −80 to 40 mV. They inactivate slowly, as in the case of *Drosophila* eag, or not at all. Kv10 channels are known for their prominent Cole–Moore shift, first described for potassium currents in crayfish axon. The Cole–Moore shift takes place as the holding potential becomes more negative, causing slower activation that is sigmoidal in nature. Like hyperpolarizing prepulses, physiological concentrations of Mg^{2+} slow Kv10 channel activation, reflecting channel occupancy in deeper closed states early in the activation pathway (Figure 4).

Figure 1 Kv10–12/Eag channels are composed of four subunits surrounding an ion conducting pore. Each subunit comprises six transmembrane domains, an S4 voltage sensor domain, a P region mediating ion selectivity, and an S6 domain forming the channel vestibule and gate. The asterisk represents the S4–S5 linker, which interacts with the gate-forming regions in S6.

In *Drosophila*, eag channels are critical in maintaining normal excitability in motor neurons and at the neuromuscular junction, where loss of eag function leads to repetitive action potential firing and prolonged transmitter release. In mammals, the physiological roles of the corresponding Kv10 channels are poorly understood due to a dearth of specific inhibitors, mouse mutants, or human diseases linked to either Kv10 gene. Kv10.2/EAG2 channels activate at particularly negative voltages, approximately −70 to −80 mV, close to the equilibrium potential for potassium. However, their kinetics of activation differ dramatically depending on recent history: Depolarizations closely spaced will evoke rapid Kv10.2

Figure 2 Phylogenetic relationships among Kv10–12/Eag and related channels. The horizontal branch lengths are inversely proportional to the similarity between the sequences. Reproduced from Warmke JW and Ganetzky B (1994) A family of potassium channel genes related to eag in *Drosophila* and mammals. *Proceedings of the National Academy of Sciences of the United States of America* 91: 3438–3442, with permission.

activation, whereas longer repolarizing periods of 3–8 s significantly delay activation due to the Cole–Moore effect. These properties may contribute to activity-dependent plasticity in neurons.

What is the biophysical basis for the Cole–Moore shift in Kv10/EAG channels? The sigmoidal activation reflects conformational changes in the S1–S4 voltage sensor in each subunit. These conformational changes can be monitored by recording gating currents or the quenching of fluorescent moieties attached at locally introduced cysteines. Changes in membrane potential evoke two components of conformational change in the voltage sensor. One carries most of the gating charge and is relatively insensitive to modulation by Mg^{2+}. The other carries little gating current but can be detected by an optical reporter near S4; this component is sensitive to Mg^{2+} and corresponds to rate-limiting movements of S4 in the activation pathway. Moreover, the voltage dependence of fluorescence quenching is indistinguishable from that of the Cole–Moore effect that slows activation at negative voltages. Thus, the activation pathway in Kv10 channels includes transitions from deep closed states that are rate limiting and modulated by Mg^{2+}. This modulation arises from the coordination of Mg^{2+} or other divalent cations between acidic residues in the S2 and S3 transmembrane domains. The modulation occurs noncooperatively, altering the conformational change of each voltage sensor in the stepwise transitions to channel opening first modeled by Hodgkin and Huxley.

The Kv11 (ERG) Subfamily

The Kv11/ERG subfamily contains the single gene *seizure* in *Drosophila* and three members in mammals. *Kv11.2* and *11.3* (*ERG2* and *ERG3*) are primarily expressed in the central nervous system, whereas *Kv11.1/ERG1* is expressed in the central nervous system, the heart, and a wide range of other tissues. There is significant overlap of the encoding mRNA in regions of the brain. The currents exhibit different kinetic profiles but all are blocked by class III antiarrhythmic drugs known to block human Kv11.1/hERG1. Kv11.1–3/ERG1–3 subunits are capable of forming heteromultimers in heterologous systems, providing the possibility of tremendous structural and functional diversity where they are co-expressed in native tissues.

Human Kv11.1/ERG1 and Cardiac Excitability

Of all the members of the Kv10–12 family, the human ERG1 (hERG1/Kv11.1) is by far the most studied and best understood, and because it is widely known by its original nomenclature it will be referred to here as hERG1. The *hERG1* gene encodes the channels underlying cardiac I_{Kr}, a potassium current critical in ventricular repolarization during each beat of the heart. Mutations in *hERG1* or a block of hERG1 channels by a wide range of drugs, often intended for other therapeutic targets, can cause long QT syndrome (LQTS), catastrophic arrhythmia, and sudden cardiac death. Some known hERG blockers still in

limited clinical use elicit life-threatening arrhythmias with an incidence as high as 3–5%. An estimated 50% of lead compounds are dropped from pharmaceutical development because they inhibit hERG channels and thus represent a cardiotoxic risk. Because these problems have significantly hampered new drug discovery efforts for all therapeutic targets, understanding the mechanism of hERG1 block and the constellation of susceptibility factors for acquired LQTS is a goal of enormous clinical importance.

hERG1 Gating in the Cardiac Action Potential

In cells expressing hERG channels, voltage steps to 40 or 60 mV evoke little outward current compared to the large inward current elicited upon subsequent repolarization to voltages negative to the channel's reversal potential, so they are sometimes said to be inwardly rectifying (Figure 3(b)). These properties dictate hERG1's physiological role in the heart but, despite the unusual hERG current profile, the underlying gating transitions are mechanistically similar to those of Shaker and other voltage-gated K channels. hERG1 channels are activated by membrane depolarization but with a slow time course and correspondingly slow movement of the S4 domain; they also inactivate, entering into a state that is nonconducting but distinct in conformation from the closed or resting state. However, because inactivation is approximately 10 times faster than activation, channels spend little time in the open state at positive voltages (Figure 5(a)). Upon repolarization, channels recover from inactivation and revisit the open state. Deactivation is approximately 10 times slower than recovery from inactivation, causing extended dwell times

Figure 5 Human Kv11.1/hERG1 channel characteristics. (a) State diagram for hERG1 gating. (b) hERG1 expressed in *Xenopus* oocytes subject to a two-electrode voltage clamp command signal mimicking a ventricular action potential. From H Sale, J Wang, and G Robertson, unpublished results. (c) The relationship between action potential duration (APD) and the interval between the Q and T waves (QT) of the surface electrocardiogram (ECG). Prolongation of the APD leads to increased QT interval and electrical instabilities triggering *torsades de pointes* arrhythmia, also apparent on the surface ECG.

in the open state. The quantitative relationships between these gating transitions translate into a current that is suppressed at positive voltages but dramatically rebounds upon repolarization, thus bearing little resemblance to Shaker-related currents. The rebounding tail current mediates I_{Kr}'s role in terminal repolarization of the ventricular action potential (Figure 5(b)). When I_{Kr} is reduced by mutations or drug block, ventricular myocytes are slower to repolarize and action potentials are prolonged (Figure 5(c)). The duration of the ventricular action potential (APD) is directly reflected in the QT interval of the surface electrocardiogram, hence the term 'long QT syndrome.' The prolonged APD destabilizes membrane excitability both locally and across the wall of the ventricle, leading in some cases to catastrophic arrhythmias known as *torsades de pointes* ('twists of points'; Figure 5(c)).

hERG1 Activation and Deactivation

Channel activation occurs when charge dipoles in the S1–S4 voltage sensor (Figure 1) move in response to changes in transmembrane potential and trigger opening of the activation gate. This coupling is mediated by the S4–S5 linker, which, based on structural studies of the mammalian Shaker channel Kv1.2, is thought to wrap around and bear down on the S6 domains to close the channel. In hERG1 channels, an electrostatic interaction between the S4–S5 linker and the S6 domain is important in stabilizing the closed conformation at negative potentials; mutations can cause the channel to re-open upon further hyperpolarization. Because of the temporal overlap of the inactivation process, the activation time course must be measured in mutants in which inactivation has been removed by mutagenesis or measured by indirect approaches that determine the numbers of channels that have opened on their transit to the inactivated state.

Nature has solved in different ways the problem of how channels gate access of ions to their pores. For example, Shaker channels gate by a hydrophobic seal at a kink or bend in the S6 transmembrane domain where the subunits overlap, whereas cyclic nucleotide-gated channels gate in the narrow part of the selectivity filter at the other end of the channel vestibule. For hERG1 channels, mutations at several sites in the more C-terminal half of the S6 domain interfere with channel closing and also promote reversal of inhibition by hERG1 blockers. These findings are interpreted to suggest that a single gate regulates ion flux and traps drugs in the internal vestibule. The precise location of the gate is unknown. Given the importance of hERG1 channels as a target for acquired LQTS, it is of great interest to map the activation gate and thus define an important dimension of the drug-binding vestibule.

hERG1 Inactivation Mechanisms

The molecular mechanisms underlying hERG1 inactivation are complex. A faster version of the pore-based C-type inactivation in Shaker, hERG1 inactivation is slowed by elevated external concentrations of potassium and TEA. Mutations at precisely homologous sites in the pore region disrupt inactivation in Shaker and hERG1. However, what distinguishes hERG inactivation is an inherent voltage sensitivity not coupled to channel opening. Efforts to understand the inactivation mechanism have focused on two regions: the S4 component of the voltage sensor and the sequences in and around the K selectivity filter. The overriding hypothesis is that these two regions must be linked to account for voltage-dependent inactivation. As has been shown for other voltage-gated channels, perturbation of residues in the S1–S4 voltage sensor disrupts activation gating. However, also within the S4 domain are residues whose perturbation selectively disrupts inactivation. It is interesting to note that voltage sensor movements exhibit two components, whether observed with gating currents or the quenching of fluorescent labels covalently linked to substituted cysteines neighboring S4. The slow component correlates with activation/deactivation gating. Kinetic analysis suggests the rapid component is consistent with inactivation, but it fails to change with manipulations that alter macroscopic current inactivation. Thus, the location and nature of the voltage sensor for inactivation remain uncertain. An important structural domain in this process is the S5–P linker, where single mutations can disrupt both inactivation and activation gating. This region possesses α-helical secondary structure and is sufficiently long to bridge the distance between S4 and the outer pore in hERG1 models.

Mechanisms of hERG1 Drug Block

The process of inactivation is at the center of an ongoing debate about the mechanism of hERG drug block underlying acquired LQTS. Like most drugs, those that block hERG1 channels are hydrophobic, crossing the plasma membrane to exert their actions inside the cell. hERG1 channels are blocked in a use-dependent manner: The drug enters the open channel, binds, and then somehow prevents ion conduction. Mutation studies show that two aromatic residues, Y652 and F656, are critical for drug block (Figure 6). The sensitivities for three distinct compounds were decreased

Figure 6 Stereo image of a hERG drug blocker docked into the channel vestibule formed by the S6 domains. Y652 and F656 are highlighted. G, glycine; Y, tyrosine 652; F, phenylalanine 656. Reproduced from Mitcheson JS, Chen J, Lin M, Culberson C, and Sanguinetti MC (2000) A structural basis for drug-induced long QT syndrome. *Proceedings of the National Academy of Sciences of the United States of America* 97: 12329–12333, with permission.

by approximately 100-fold, providing good evidence that the mutations disrupt the binding site rather than allosteric gating transitions. Mutations in and around the outer pore region also disrupt drug block but probably do not contribute to the drug-binding site *per se*.

How the binding of drug translates to channel inhibition is the subject of competing hypotheses: a simple pore occlusion, on the one hand, and promotion of inactivation, also known as the modulated receptor hypothesis, on the other. Most mutations that disrupt drug block also remove or dramatically slow inactivation, as if inactivation gating were critical to drug inhibition. However, there is no evidence that the inactivated state exhibits a higher affinity for the drug, which is a prediction of the modulated receptor hypothesis; voltages that drive the channel into the inactivated state were found not to promote block. The problem with a simple pore-block model is that mammalian EAG channels are quite insensitive to the pharmacopeia of hERG1-blocking drugs despite possessing a highly conserved vestibule, including the key drug-binding residues identified in hERG1. What most distinguishes EAG from hERG1 channels, besides insensitivity to drug block, is the absence of inactivation, once again raising the possibility that drug block requires inactivation. Indeed, sensitivity of bovine EAG to the hERG1 blocker dofetilide was increased nearly 30-fold by mutations at corresponding sites to residues critical for inactivation in hERG – S620 and S631. Focused efforts to clarify the structural details of the drug-binding site and its interaction with channel gating mechanisms will be important in facilitating the development of drugs free of cardiotoxic side effects.

Modulation of Gating by the N-Terminus

With the exception of the subunit encoded by the hERG1b alternate transcript (see below), all channels in the Eag family share homology in a region comprising the first approximately 135 amino acid residues sometimes referred to as the 'eag domain.' An X-ray crystallography study of the eag domain revealed a structure from residues 26 to 135 similar to Per-Arnt-Sim (PAS) domains implicated in protein–protein interactions. The first 25 amino acids were unordered in the crystal. Following the PAS domain, the N-terminal structures markedly diverge; the hERG1a N-terminus has a total length of approximately 396 amino acids, much longer than the N-termini of EAG or ELK channels. The hERG1 N-terminus docks to the hydrophobic core via the S4–S5 linker, where three distinct domains respectively slow deactivation and promote activation and C-type inactivation. Deletion of the first 16 amino acids selectively increases deactivation rate, an effect that can be largely reversed by adding the soluble N-terminal 16mer peptide to excised macropatches containing N-truncated channels. Slow deactivation in N-truncated constructs could also be reconstituted by the addition of the entire purified 1–137 amino acid polypeptide to the oocyte cytosol, but it is unknown whether the PAS domain *per se* directly slows deactivation or rather serves as the docking domain for the more N-terminal sequences. Inactivation is unaffected by the 2–16 amino acid deletion, but it is slowed by full N-terminal truncations. Deletion of the 'proximal domain,' residues 137–373, accelerates activation with no effect on deactivation. The N-terminus is thus highly complex and modulates many different components of basic channel function, the physiological ramifications of which remain to be determined.

Two hERG1 Subunits Contribute to I_{Kr}

Much of the work on hERG1 channels has focused on what we now term the hERG1a subunit, which can form functional homomeric channels with properties largely similar to those of I_{Kr}. A second subunit, hERG1b, is identical to hERG1a except that it has a much shorter N-terminus with a very different primary sequence. The two subunits are encoded by alternate transcripts from the hERG1 gene, meaning that they each have their own promoter sequence. Heterologous expression of hERG1b produces currents with extremely low efficiency, but the 1b subunits readily assemble with hERG1a subunits to form heteromeric channels. Together, 1a and 1b form channels more like native I_{Kr}, with reduced rectification and faster deactivation than hERG1a homomeric channels. Both 1a and 1b are expressed in heart, where they exhibit similar T-tubular distribution in cardiomyocytes. The two subunits can be co-immunoprecipitated from heart tissue, supporting the hypothesis that heteromers of hERG1a and-1b underlie cardiac I_{Kr}. The stoichiometric ratio of the two subunits is not known, nor do we know whether all channels are heteromeric or if regional pools of homomeric hERG1a channels exist. The mRNA expression of hERG1b is much higher in the heart than in the brain, but further work is required to determine its distribution there.

hERG Channels and Neuronal Function

Although the *hERG1* gene was originally cloned from the human hippocampus, we know relatively little about its functional role in the brain. In computer models and neuronal-type cells in culture treated with hERG blockers, it is clear that Kv11/ERG channels can regulate firing frequency and cause spike frequency adaptation during a burst of action potentials. Their gating properties seem especially well suited to

modulating slow-wave activity. ERG channels have also been identified in astrocytes and microglia.

Kv11/ERG channels may also be important in the developing nervous system. They are expressed in proliferating neuronal precursors in neural crest, where they are subsequently downregulated in favor of other types of potassium channels as the cells differentiate. In this regard, the neuronal precursors are like neuroblastoma and other tumor-related cells, which exhibit high levels of ERG expression. In both cases, high ERG levels are correlated with a relatively depolarized resting membrane potential and cellular proliferation. Kv11/ERG channels are also important functionally in the developing mouse spinal cord, where they regulate oscillations of GABAergic interneurons.

Despite the widespread expression of hERG1 in the brain, LQTS patients, who are heterozygous for *hERG1* mutations, have not presented with consistent neuropathological phenotypes. Perhaps the heart is less tolerant of reduced *hERG1* gene copy number than the brain, in which the additional expression of *hERG2* and *hERG3* might be expected to compensate for reduced hERG1 channel function. It is also interesting to note that some drugs used to treat mental illness are known to block hERG1 channels in pharmacological assays. Whether their therapeutic benefit is related to hERG1 (or hERG2 or -3) block is an important unanswered question.

The Kv12 (ELK) Subfamily

The Kv12/ELK subfamily comprises three members in mammals, all primarily expressed in the nervous system and in patterns that significantly overlap in the brain. They differ from Kv11/ERG channels in that they are insensitive to E-4031 or the other ERG channel blockers. None of the Kv12 isoforms exhibit the Cole–Moore shift of Kv10/EAG subfamily channels. Overall, we know less about Kv12 channels than all other members of the Eag family.

The functional roles of Kv12 channels in the nervous system are unknown, but we can make certain predictions based on the biophysical properties of these channels expressed in heterologous systems. Kv12.1/ELK1 currents exhibit delayed rectifier characteristics with slow activation and deactivation kinetics, suggesting they may repolarize action potentials or regulate burst frequency. Kv12.2/ELK2 channels are quite different, exhibiting rapid activation and inactivation (Figure 3(c)). Like hERG1 currents, they undergo C-type inactivation; however, because they activate more rapidly and inactivate more slowly, they produce more current (i.e., are less rectifying) at positive voltages. Voltage clamp commands with repolarizing ramps designed to mimic slow-wave neural activity suggest that Kv12.2 channels may play a dual role in membrane excitability (Figure 7). Upon depolarization, the channels activate and inactivate, producing an early peak of current with a duration of the order of milliseconds. However, when the step is followed by a slow ramp repolarization, the channels recover from inactivation and rebound to produce a second phase of current before slowly closing within hundreds of milliseconds or even seconds. Thus, in native tissues, one might expect the 'early' Kv12.2 currents to help repolarize action potentials or regulate short bursts of activity, whereas the 'late' wave could shape slow-wave activity. The subunits encoded by the three Kv12 subfamily members can co-assemble in heterologous expression systems and, given their overlapping patterns in the brain, may generate native channels of considerably diverse composition and function.

The Future: Functional Roles of Kv10–12 Channels in the Nervous System

This article focuses on the structure and function of α subunits of the Kv10–12/Eag channel family; for important work on channel modulation by phosphorylation or β subunits and on the roles of these channels in cell proliferation, smooth muscle activity, endocrine function, and the autonomic nervous system, the reader is referred to the primary literature and

Figure 7 Mouse Kv12.2/ELK2 currents expressed in *Xenopus* oocytes in response to a ramp with a 3-ms rise time and variable repolarization rates. Currents exhibit two phases: The first peak arises from activation and inactivation of the channels, and the slower phase occurs as channels recover from inactivation and slowly return to the closed or resting state. Adapted from Trudeau MC, Titus SA, Branchaw JL, Ganetzky B, and Robertson GA (1999) Functional analysis of a mouse brain Elk-type K^+ channel. *Journal of Neuroscience* 19: 2906–2918, with permission.

excellent reviews on these subjects. Even within the narrow focus of this article there remain many details and fundamental mechanisms yet to be understood. For example, why is the putative CNBD in the cytoplasmic C-terminus so highly conserved if not for gating by cyclic nucleotides? Indeed, what functional roles can be assigned to the otherwise divergent C-terminus, which makes up approximately half of each channel polypeptide and is the least understood region of all? One C-terminal domain is known in Kv10/EAG channels to promote oligomerization and another in Kv11.1/hERG1 is known to make contact along the secretory pathway. A much higher degree of conservation is observed in the N-terminus, including the structurally determined PAS domain, and yet the only known functions of the N-terminus are in gating processes that differ dramatically among channel types. Clearly, far more information remains to be discovered.

One of the greatest challenges for those interested in the Kv10–12/Eag family of K channels is determining their physiological roles in the nervous system, in which they are widely expressed. To accomplish this, we need specific inhibitors as well as approaches that reduce expression of the individual genes, preferably under inducible control to minimize the compensatory expression of other genes. To date, inhibition is limited to toxins and blockers of the Kv11/ERG subfamily and to mutant phenotypes of *Drosophila eag* and *seizure* (*erg*) and human ERG (LQTS patients). Members of the Kv10/EAG and Kv12/ELK subfamilies lack specific inhibitors and correspondingly little is known about their functions. Current efforts to identify scorpion toxins that discriminate among the various channel types should significantly advance our understanding of their roles at the cellular level. Advances at the organismal level are hindered by the absence of links of known inherited neurological diseases with mutations in the Kv10–12/Eag family. Perhaps such mutations go undetected because their loss of function is lethal at very early developmental stages or compensated by the activities of related family members that overlap in cellular distribution and functional properties. A concerted effort to develop disease models, together with ongoing structure–function studies elucidating their unique functional properties, will surely lead to significant advances in our understanding of Kv10–12/Eag potassium channels and their functional roles in the nervous system.

The Accessory Olfactory System

The olfactory system has evolved complex mechanisms to detect a vast range of molecular cues. Mammals possess several chemosensory systems, including the main olfactory system (MOS) and the accessory olfactory system (AOS), which is also known as the vomeronasal system. In addition, several other chemosensory subsystems, such as the septal organ of Masera and the Grueneberg ganglion, have been recognized (Figure 1(a)).The AOS has attracted a great deal of attention because of its involvement in the detection of chemical stimuli of a social nature, such as pheromones. Karlson and Lüscher introduced the term "pheromone" and defined it as "a substance secreted to the outside of an individual and received by a second individual of the same species in which it . . . ."

The AOS consists of (1) the vomeronasal organ (VNO, also known as Jacobson's organ), a chemoreceptive structure situated at the base of the nasal septum and which houses the vomeronasal sensory neurons (VSNs); (2) the accessory olfactory bulb (AOB), a structure located in the forebrain, dorsocaudal to the main olfactory bulb (MOB), that receives input from the VNO and serves as the first processing center of vomeronasal information; and (3) higher olfactory centers, such as the medial amygdala, that receive direct or indirect information from the AOB. The medial amygdala is highly interconnected with the bed nucleus of stria terminalis. Both nuclei project to hypothalamic areas important for controlling neuroendocrine events that, in turn, regulate social and reproductive behaviors.

Basic Anatomical Organization of the VNO

Many mammals possess a bilateral, cigar-shaped VNO (Figure 1) that is located at the base of the nasal septum, anterior and ventral to the main olfactory epithelium (MOE). Each VNO is encased in a cartilaginous capsule, the vomer bone. Chemosensory stimuli gain access to the VNO through its single rostral opening, which in rodents opens into the nasal cavity. The main structural elements of the VNO are best seen in coronal sections and include a central lumen, a medially located crescent-shaped sensory epithelium, and a laterally located nonsensory epithelium, together with an extensive network of blood sinuses surrounded by a band of cavernous erectile tissue (Figure 1(c)). These latter components provide the hardware for a vomeronasal pump that aids in stimulus delivery.

The sensory epithelium consists primarily of three cell types: (1) elongated glia-like supporting cells; (2) bipolar sensory cells, the VSNs; and (3) scarce basal stem cells. VSNs make up the majority of the cells in the sensory epithelium and are responsible for the detection of chemostimuli. VSNs extend a dendritic process to the luminal surface, where the process enlarges into an apical dendritic knob which contains up to 100 microvilli (Figure 1(d)). In rat, these microvilli are 3–6 μm long and approximately 0.1 μm in diameter. The primary chemotransduction events are likely to take place within the microvilli. The axonal process of each VSN emerges from the basal aspect of the soma and exits the epithelium through the basal lamina. The axons coalesce to form the vomeronasal nerves that course along the septum (Figure 1(a)), pass through the cribriform plate, and end in the glomeruli of the AOB, where they synapse onto second-order mitral cells.

An intriguing feature of the mouse VNO is its segregation into two major layers or zones (Figure 1(e)), containing subpopulations of VSNs that display different immunochemical markers and unique patterns of gene expression. For example, the apical, or superficial, zone of the epithelium contains VSNs that project to the anterior aspect of the AOB and express the G-protein Gαi2 and a member of the V1R family of chemoreceptors. The basal or deep zone contains VSNs that project to the posterior aspect of the AOB and express the G-protein Gαo and members of the V2R family of receptors. The functional significance of this zonal segregation is not yet fully understood, but there is increasing evidence that these VSN subpopulations detect structurally and functionally distinct families of molecular cues.

Stimulus Detection Strategies

Differential screening of complementary DNA libraries constructed from single rat VSNs led to the isolation of the first family of vomeronasal, G-protein-coupled receptor genes, the V1Rs (Figure 1(f)). These have a similar structure but relatively low homology compared with the olfactory receptor superfamily expressed in MOE and are weakly related to T2r taste receptors. In the mouse genome, 308 V1R sequences have been identified, of which 191 seem to have uninterrupted

Figure 1 (a) Midsagittal view of the mouse nose and forebrain. The vomeronasal organ (VNO) is located at the base of the nasal septum (S). Axons of vomeronasal sensory neurons (VSNs) project to the anterior (red) or posterior (green) accessory olfactory bulb (AOB). MOE, main olfactory epithelium; SOM, septal organ of Masera; GG, Grueneberg ganglion; MOB, main olfactory bulb. (b) Coronal sectioning through the nasal cavity (NC) reveals the organization of the VNO sensory epithelium: an apical zone (red neurons) that can be distinguished from the basal zone (green neurons) projecting to the rostral (red) and caudal (green) AOB, respectively (see (a)). (c) The cytoarchitecture of the VNO includes a sensory epithelium (SE) containing VSNs and supporting cells (SC), a lumen (L), and the nonsensory epithelium (NSE), together with an extensive network of blood vessels (BV). (d) Electron micrograph of a transverse section through mouse VSNs showing their dendritic process (D), which enlarges into a dendritic tip or knob (DT). From the knob emanate various microvilli (MV). (e) Visualization of the two principal layers of the SE by means of double-label immunohistochemistry with antibodies to phosphodiesterase type 4A (red) and the G-protein Gαo (green). (f) VSNs of the two layers express a unique set of transduction-related molecules: apical VSNs express the G-protein Gαi2 and members of the V1R family of vomeronasal receptors, and basal VSNs express Gαo and members of the V2R receptor family. Both neuron types express TRPC2. Magnification ×90 (c), ×15 000 (d). Scale bar = 100 μm (e). full-length open reading frames. The V1Rs are divided into 12 subfamilies that are considerably divergent from each other. The intrafamily identity is in the range of only 15–40%, probably reflecting a corresponding diversity of ligands. Each individual V1R receptor gene is expressed by only a small subset of apically located VSNs. Evidence for a functional role of V1Rs comes from the finding that mice with a targeted deletion in a cluster of V1R genes fail to detect several small organic pheromones present in urine. Furthermore, green fluorescent protein-tagged VSNs expressing the V1Rb2 receptor respond to 2-heptanone, but this response is absent when V1Rb2 is deleted. High resolution Ca^{2+} mapping studies have revealed an exquisite

sensitivity and specificity of VSNs located in the apical V1R-expressing zone, suggesting that each of these cells detects only one or very few ligands.

A second large family of G-protein-coupled receptors expressed in the VNO is encoded by the V2R genes. With their large extracellular N-terminal domain, V2Rs resemble the calcium-sensing and metabotropic glutamate receptors rather than V1Rs and olfactory receptors (Figure 1(f)). In the mouse, the V2R gene repertoire consists of approximately 280 members, of which approximately 120 exhibit an intact open reading frame. No conclusive evidence is yet available for a functional role of V2Rs. Although each V2R receptor is generally expressed by a small subset of VSNs, one group of V2R receptors, V2R2, is co-expressed broadly across basal VSNs. It remains to be seen whether this results in the formation of functional homo- or heterodimeric receptor proteins. It is interesting that VSNs in the basal layer express yet another multigene family: nonclassical class Ib major histocompatibility complex (MHC) molecules. These seem to form multimolecular complexes with V2Rs and have been proposed to function as escort molecules in the transport of V2Rs to the cell surface. The tuning properties of V2R-positive VSNs are just beginning to emerge. As will be discussed in the next section, a subset of these cells detects MHC peptide ligands at near picomolar concentrations. The fact that these cells can detect multiple peptides exhibiting distinct chemical structures argues against a one cell–one receptor–one ligand coding strategy, but more work will be required to determine the molecular basis underlying their ligand selectivity.

Diversity of Chemosignals Detected by the VNO

The AOS has long been known to play important roles in recognizing species-specific chemosignals (pheromones) that convey information about gender, social status, level of aggression, and reproductive state in conspecifics. However, it is now clear that VSNs detect a much wider range of chemical stimuli, including some molecules that cannot be categorized as pheromones. Furthermore, the VNO is not the only sense organ in the mammalian nose in which pheromones are detected; the main and AOSs detect, at least in part, overlapping sets of sensory stimuli, and both systems play important roles in the regulation of social behaviors and the sensing of pheromonal cues. Given that a functional AOS does not seem to exist in adult humans, the MOS is the most likely pathway for conveying any pheromonal effects in human chemical communication.

The AOS responds to complex natural stimuli such as urine, soiled bedding, vaginal secretion, and seminal fluid. These contain a wide range of molecular cues, from small organic volatiles to nonvolatile peptides and proteins. Recent advances have shown that the mammalian VNO detects all these classes of chemosignals. For example, among the best characterized vomeronasal stimuli are volatile pheromonal compounds such as 2,5-dimethylpyrazine, 2-*sec*-butyl-4,5-dihydrothiazole, 2,3-dehydro-*exo*-brevicomin, E, E-α-farnesene and E-β-farnesene, 2-heptanone, 6-hydroxy-6-methyl-3-heptanone, *n*-pentyl acetate, and isobutylamine.

More-recent evidence has shown that VSNs recognize also some peptides at extremely low concentrations. For instance, mouse VSNs of the basal zone detect a vast range of immune system molecules: antigenic peptide ligands of MHC molecules. MHC/peptide complexes are present at the cell surface and carry information about the genetic makeup of cells. They are shed from the cell surface, and their fragments appear in bodily fluids such as serum, saliva, sweat, and urine. These truncated MHC molecules are thought to have a reduced affinity to their peptide ligands and thus are likely release them into the extracellular space. The finding that a subset of VSNs detects these peptides in an MHC-like fashion suggests that these cells are involved in the sensory evaluation of the MHC genotype of other individuals. Mouse VSNs of the basal layer can also be activated by a male-specific 7 kDa peptide produced by the extraorbital lacrimal gland. This peptide, known as exocrine gland-secreting peptide 1 (ESP1), is encoded by a member of at least 23 related genes in mice. Although the behavioral role of ESP1 is not yet clear, these results indicate that social communication in mammals involves the detection of extended families of peptidergic chemosignals by the VNO.

Other work indicates that VSNs can also detect larger proteins. In snakes, for example, a 20 kDa chemoattractant purified from earthworm shock secretions has been shown to induce excitatory responses in VNO and AOB. Work in rodents supports involvement of proteins in VNO sensing. Mouse urine contains a class of highly polymorphic proteins known as major urinary proteins that are involved in scent marking. These are 18–20 kDa members of the lipocalin family of ligand-binding proteins that bind volatile pheromonal ligands. It has been suggested that major urinary proteins, devoid of their volatile ligands, function as VSN chemosignals in their own right.

Finally, VSNs can be stimulated by odorants without known pheromonal functions, such as methyl anisole, patchone, indole, helional, butyrophenone,

and fenchone. Functional imaging studies using a mixture of these compounds demonstrate that they stimulate the mouse AOB *in vivo*. These odorants are suggested to be released from plants or other animal species and could signal the presence of a predator or indicate the suitability of a particular site for feeding or nesting.

VNO Signal Transduction: Transient Receptor Potential Channels and Phosphoinositide Signaling

How do VSNs transduce these molecular cues into an electrical membrane signal? Work from several laboratories has demonstrated that VSNs, at rest, maintain a relatively low spiking activity and that chemostimulation produces a transient increase in the rate of action potential firing. This excitation is caused by the generation of a depolarizing receptor potential sufficient in size to activate voltage-gated Na^+ channels. The ionic properties of this receptor potential are not yet fully understood, but it seems to depend critically on the generation of a transient inward current in the distal dendrites and microvilli of VSNs which is associated with an increase in membrane conductance. Recent work has pointed to a phospholipase C (PLC)-mediated second messenger system involving at least one member of the transient receptor potential (TRP) family of cation channels, TRPC2, in the generation of this receptor current (Figure 2). Because TRPC2 encodes a protein that is expressed in all VSNs and is specifically localized to the sensory microvilli of these cells (Figure 2(a)), it was proposed to participate in VSN signal transduction. Indeed, mice with a targeted mutation in the TRPC2 gene exhibit strongly reduced electrophysiological responses to some pheromonal ligands, and these mice also show dramatic defects in the regulation of sexual and social behaviors. However, the recent finding that V2R-type peptide-responding VSNs do not require a functional TRPC2 channel indicates that VNO signal transduction might involve additional, not yet identified, ion channels.

What kind of ion channel is formed by TRPC2? Although this question is still being investigated, evidence indicates that TRPC2 is required for a Ca^{2+}-permeable cation channel that is gated by the lipid messenger diacylglycerol (DAG) or one of its endogenous analogs (Figure 2(b)). DAG is a direct product of the activity of PLC, which hydrolyzes

Figure 2 (a) Expression of a member of the transient receptor potential (TRP) family of cation channels, TRPC2, in the vomeronasal sensory neurons (VSNs). TRPC2 immunoreactivity (red) is clearly seen in the tuft of microvilli at the distal end of the dendrite. (b) Schematic representation of pathways that might regulate the activity of the TRPC2 channel in the dendritic tip of a mammalian VSN. The model refers to VSNs of the apical zone of the vomeronasal organ. Whether this applies also to VSNs of the basal zone remains to be investigated. α, β, and γ, G-protein subunits; DAG, diacylglycerol; GDP, guanosine diphosphate; GTP, guanosine triphosphate; Ins(1,4,5)P_3, inositol 1,4,5-trisphosphate; PIP, phosphatidylinositol-4,5-bisphosphate; PLC, phospholipase C. Scale bar = 5 μm (a). From Liman ER, Corey DP, and Dulac C (1999) TRP2: A candidate transduction channel for mammalian pheromone sensory signaling. *Proceedings of the National Academy of Sciences of the United States of America* 96: 5791–5796, copyright 1999, National Academy of Sciences, USA. (b) Reprinted from Zufall F, Ukhanov K, Lucas P, Liman E, and Leinders-Zufall T (2005) Neurobiology of TRPC2: From gene to behavior. *Pflügers Archiv: European Journal of Physiology* 451: 61–71, with kind permission of Springer Science and Business Media.

phosphatidylinositol-4,5-bisphosphate into two second messengers, namely inositol 1,4,5-trisphosphate (Ins(1,4,5)P_3) and DAG. Excised patch clamp recordings identified a 42-pS DAG-activated cation channel present in high density in the plasma membrane of dendritic knobs of VSNs, and the activation of this channel is strongly defective in TRPC2-deficient VSNs. Furthermore, the functional properties of this channel are consistent with those of the pheromone-evoked conductance. Independent evidence that endogenously produced DAG may be a critical second messenger in the sensory response of VSNs comes from pharmacological blockade of DAG kinase, an enzyme involved in termination of DAG signaling. Thus a direct link between stimulus-induced PLC activity, gating of the TRPC2 channel by DAG, and the sensory current has been established, but several other second messengers, such as Ca^{2+}, Ins(1,4,5)P_3, and arachidonic acid might also be involved in VSN signal transduction.

Functional Organization of the AOB

VSN axons terminate exclusively in the AOB. With respect to the morphological organization, the AOB appears quite similar to the MOB. It can be divided into five layers: (1) the accessory olfactory nerve layer, which contains VSN axons that converge onto glomeruli in (2) the accessory glomerular layer; (3) the accessory external plexiform layer; (4) the accessory mitral cell layer; and (5) the accessory granule cell layer. VSN axons terminate in the accessory glomerular layer, forming glutamatergic synapses with the apical dendrites of mitral cells. Mitral cells form reciprocal dendodendritic synapses with granule cells, a class of γ-aminobutyricacidergic interneurons. Plastic changes at these synapses are hypothesized to play an essential role in the formation of social memories (see the next section and Figure 3). AOB mitral cells have direct projections to the medial and posteromedial cortical amygdaloid nucleus, the bed nucleus of the stria terminalis, and the bed nucleus of the accessory olfactory tract. Together these structures can be called the accessory olfactory cortex.

AOB mitral cell responses in the awake mouse consist of a gradual elevation in firing rate during 2–5 s following contact with a stimulus, such as facial or anogenital investigation. The slowly evolving elevation of firing rate is in sharp contrast to other sensory systems, such as vision, auditory, or somatosensory, in which the precise timing of stimulus-triggered responses is highly conserved. However, the slow evolution of activity in the AOB mitral cells is consistent with the indirect nature of stimulus access. The relatively slow characteristics of sensory responses could allow for significant temporal evolution of local inhibitory feedback and cortical feedback during the detection event.

Figure 3 Hypothetical model for the neural basis of mate recognition in the pregnancy block paradigm. (a) During mating, the disinhibitory effects of increased noradrenaline (NA) and activation of mGluR2 (m2) glutamate receptors enhance stimulation of ionotropic glutamate receptors, resulting in potentiation of those glutamatergic synapses on granule cells that receive input from the mating male's chemosignals (green). (b) Exposure to the mating male's urinary chemosignals during the days following mating activates the potentiated synapses and calls up increased levels of feedback inhibition from the granule cells. This increased inhibitory control of the mitral cells responding to the mating male's chemosignals disrupts their transmission and prevents the activation of the neuroendocrine pathway for pregnancy block, resulting in reproductive success. (c) Exposure to the urinary chemosignals from an unfamiliar male during the days following mating activates a separate population of mitral cells without potentiated synapses. The activation of mGluR2 suppresses inhibition from the associated granule cells, and the signal is transmitted centrally, resulting in pregnancy block. GABA, γ-aminobutyric acid; Glom, olfactory glomerulus; VSNs, vomeronasal sensory neurons. Reproduced from Brennan PA (2004) The nose knows who's who: Chemosensory individuality and mate recognition in mice. *Hormones and Behavior* 46: 231–240, with permission from Elsevier.

The logic of input–output connectivity in the AOB is an area of intense investigation. AOB glomeruli are spherical structures comprised of dense entanglements of mainly axon fibers from VSNs and dendrites from mitral cells. AOB glomeruli are 10–50 μm in

diameter, poorly separated by interneurons, and distributed in a loosely organized layer that is many glomeruli thick. The division of VSNs into two zones is maintained at the level of the AOB, separating it into an anterior and a posterior domain (**Figure 1(a)**). In contrast to the glomerular organization in the mammalian MOB, VSNs expressing the same receptor gene project to multiple glomeruli in either the anterior or the posterior domain of the AOB (6–20 glomeruli per gene have been reported). The distribution of these multiple glomeruli within each domain exhibits a high degree of variability compared with the convergence and position of glomeruli in the MOB, but there is a general similarity across animals. In addition, AOB mitral cells have a structure strikingly different from that of MOB mitral cells. AOB mitral cells possess multiple apical dendrites that each divide into branches ending in different glomeruli. Because at least some of the mitral cell multiple processes innervate glomeruli that receive axons from the same population of VSNs, the divergent pattern of VSN projections into the AOB can be rendered convergent. A recent study using transgenic mouse lines in which projections from multiple populations of VSNs, each expressing a distinct V1R receptor, were differentially labeled revealed that AOB inputs from neurons expressing closely related V1Rs intermingle within shared, spatially conserved domains of the AOB. Individual mitral cells were shown to extend dendrites to glomeruli associated with different, but closely related, V1Rs, suggesting that considerable integration of information might already occur at the level of the AOB.

VNO Sensing and the Modification of Behaviors

A vast literature has established an involvement of the VNO and AOS in a variety of behavioral effects, but very few studies have linked the sensing of defined molecular cues by VSNs to the modification of a specific behavioral response. Initially, researchers used surgical lesions of the VNO in hamsters, voles, mice, rats, farm animals, and reptiles to show that chemosensory signaling via the VNO influences a number of social behaviors, including male aggression to intruder males; maternal aggression in lactating females; male mating behavior; male ultrasonic vocalizations; and the timing of puberty, cyclicity, and ovulation in females. But significant differences occur between species, and the VNO is also involved in the detection of heterospecific stimuli, such as those involved in prey recognition in snakes. More recently, researchers used genetic lesions (i.e., mice with targeted mutations in specific signal transduction molecules such as TRPC2) to investigate the role of the VNO in chemical communication. With respect to male–male aggression and maternal aggression in lactating females, an excellent correspondence exists between the behavioral phenotypes caused by TRPC2 deletion or surgical VNO ablation. However, profound discrepancies occur in the context of male sexual behavior, which may be explained in part by the recent finding of TRPC2-independent responses of peptide-sensing VSNs.

The VNO is also critical for one of the best known examples of olfactory imprinting in adult vertebrates, the selective pregnancy block (or Bruce effect) in the mouse, which depends on the formation and maintenance of a long-lasting odor recognition memory by the AOS. The Bruce effect occurs when a recently mated female mouse aborts if exposed to the urine odor of a male genetically different from the stud male. This unfamiliar male odor results in pregnancy block and return to estrus in the recently mated female. Changes at the dendrodendritic synapse between granule cells and mitral cells in AOB might be crucial for odor memory of the mate in the female (**Figure 3**). The Bruce effect can be abolished if noradrenergic centrifugal input to the female AOB is blocked immediately after mating, presumably before olfactory memories of the mate are formed. Thus, noradrenaline appears to be important in strengthening the memory of the odor of the mating partner. Noradrenergic innervation of the AOB derives from locus coeruleus projections. Granule cells in the AOB are a major target of the noradrenaline input. Thus, noradrenaline's effect on granule cells leading to enhanced inhibition of a subset of mitral cells for several hours following mating may facilitate this selective odor memory.

The MHC peptide ligands are the first identified vomeronasal stimuli that can mediate the Bruce effect. To show that MHC peptides provide a crucial signal among the plethora of other cues present in male urine, peptides characteristic of a disparate MHC molecule were synthesized and added to the urine of a familiar male. Compared with the addition of cognate peptides, which have no effect, disparate peptides cause pregnancy block by otherwise familiar urine, an effect that is absent after surgical lesioning of the VNO. Thus, MHC peptide ligands are recognized as natural odors and convey genotypic information in the context of a distinct social behavior.

Conclusion

Recent developments have shown that vertebrate pheromones come in a wide variety of chemical forms, from small organic volatiles to peptides and

proteins. The AOS is heavily involved in the detection of these pheromones, but the MOE has been found to overlap significantly with the VNO in the social cues it detects. Studies using gene-targeted mice have shown an unexpected diversity of mammalian chemosensory systems and their underlying cellular and molecular mechanisms. Our understanding of mammalian and especially human pheromonal communication is still incomplete, but new insights into ligand–receptor interactions will enable selective ablation of specific receptor systems, followed by investigation of the resulting cellular and behavioral phenotypes. It is hoped that these approaches will ultimately reveal many of the molecular and cellular mechanisms underlying mammalian social behavior.

Vomeronasal System Evolution

T D Smith, Slippery Rock University, Slippery Rock, PA, USA

Introduction

Tetrapods such as snakes, lizards, rodents, and moles can track prey, forage, or receive social signals by detecting chemical stimuli. Not surprisingly, these animals are endowed with 'dual' olfactory systems – the vomeronasal and the olfactory. The components of the main olfactory system are the olfactory neuroepithelium, the olfactory glands (of Bowman), olfactory fila, and nerve fascicles synapsing within the glomeruli in the olfactory bulb and coursing through the limbic system to reach the olfactory cortex. In the periphery, the vomeronasal system (VNS, or 'accessory olfactory system') comprises bipolar vomeronasal receptor neurons (VRNs) with apical microvilli. Together with supporting and basal cells, VRNs comprise the vomeronasal neuroepithelium. The VRN axons coalesce into often ganglionated vomeronasal nerves that extend to glomeruli in the accessory olfactory bulb (AOB), and after synapsing with the mitral cell dendrites project to the hippocampus–amygdala complex. Their onward course to the olfactory cortex, if there is any, is less well known. The vomeronasal organ (VNO) and ancillary structures are shown in Figures 1 and 2.

In strict terms, the vomeronasal organ is the patch of chemosensory epithelium that may take the form of a sac or duct, and may or may not have nonsensory epithelium integrated with the wall. This definition is advantageous in that it acknowledges homology of the neuroepithelium, which differentiates from a medial patch of the embryonic nasal pit in all tetrapods, among vertebrates that possess the VNO. Other definitions are specific to particular taxa (e.g., veterinary terminology for the mammalian VNO). Such definitions should be avoided since nonhomologous elements may serve the same function in different taxa (notably, the cartilaginous versus bony elements that encapsulate the organ).

History

Erroneously, Frederick Ruysch (1638–1731) is credited with the discovery of the VNO. He reported on a grossly observable aperture and passage, visible along the lateral surface of a child's nasal septum. Ruysch did not cross-sectionally evaluate this mucosal structure and canal, so it is not possible to know whether it was indeed the vestige of the VNO later documented in humans. The VNO was first reported in mammals (but not in humans) by Ludwig Levin Jacobson (1783–1843; Figure 3(a)). Rudolf Albert von Kölliker (1817–1905) provided the first microscopic evidence of the VNO in humans. Numerous reports followed on the VNO of other tetrapods.

Distribution across Vertebrates

An anatomically distinct VNS, as defined in the preceding section, is found in most terrestrial vertebrates, a distribution leading some to consider the VNS as a terrestrial adaptation (but, see later). Broadly speaking, a VNS is found in most extant amphibians, reptiles, and mammals, but is absent in extant archosaurs (birds and crocodilians; Figure 3(b)). However, loss of the VNS has occurred within all classes of vertebrates that possess it.

Morphological Diversity

The Vomeronasal Organ

The nasal chambers of amphibians vary in complexity from simple recesses in urodelans (e.g., salamanders) to the series of chambers in anurans (e.g., frogs). The VNO of anurans is found along the medial extent of the inferior recess (Figures 2(a) and 4(a)–4(c)). The VNO, therefore, is unenclosed, and instead is an elongated furrow or pouch that openly communicates with the inferior recess. Most accessory structures are absent, except for some glands found just dorsal to the VNO. In urodelans, the VNO takes the form of a pouch that openly communicates with a single nasal chamber. The VNO of caecilians is an enclosed, ovoid neuroepithelial sac. Unique structures to this group are bilateral sensory tentacles, which are considered modified eyelids/conjunctiva. These communicate with the VNO medially via a central duct.

Among all vertebrates, snakes appear to possess the proportionally largest VNO and AOB, in which the usual proportions relative to the main olfactory system are reversed. In squamates (snakes and lizards) the VNO takes the form of an inverted sac (Figures 2(b) and 4(d)–4(f)). Although the oral and nasal cavities are broadly joined by elongated choanae, the VNO opening is restricted to the oral cavity since it opens only via a narrow palatal duct, oriented ventrally. Aside from the ventrally positioned palatal duct, the 'floor' of the squamate VNO is distinguished by the presence of ciliated epithelium that lines a convex mass termed the mushroom body (Figure 5(c)). Turtles possess an

Figure 2 Schematic illustrations of the vomeronasal complex in different vertebrates (frontal plane), highlighting positional variations of the vomeronasal organ (VNO) and its capsule. In amphibians, the VNO is a recess within a large nasal chamber, or series of chambers (a, *Rana* sp.). In most reptiles (b, *Hemiergis* sp.) and mammals (c, *Microtus pennsylvanicus*; d, *Lemur catta*), the VNO is found along the base of the nasal septum (NS) within a capsule of bone (black-filled) or vomeronasal cartilage (VNC). (e) In some species (e.g., *Pan troglodytes*), the VNO may be displaced from the cartilaginous capsule (PC, paraseptal cartilages). BC, bony capsule; L, lumen; NC, cartilaginous nasal capsule; OE, olfactory epithelium. Scale bar = 500 μm (a, b, d), 150 μm (c), and 1 mm (e).

unencapsulated vomeronasal neuroepithelium – a VNO homologue since its axons transmit to the AOB.

In mammals, the VNO most commonly opens anteriorly into the nasopalatine duct (NPD), representing a potential 'dual-access' channel for oral or nasal chemostimuli. Usually the VNO narrows to a stratified squamous duct on its rostral end, which links to the NPD. Caudal to the VNO duct, the elongated mammalian VNO most commonly takes the form of a crescent when viewed in coronal sections (Figures 2(c), 6(a), 6(b), and 6(c)). Ventromedially, the VNO wall is thicker and convex; dorsolaterally, the VNO wall is thinner and concave (Figures 1(b), 6(c), 7(c), and 7(d)). The dorsolateral wall is usually a ciliated, nonsensory epithelium, termed 'receptor-free epithelium' (RFE).

The Accessory Olfactory Bulb

A miniature, generally disorganized, accessory olfactory bulb is an essential feature of the VNS. An extremely close relationship exists between the

vomeronasal neuroepithelium (VNNE) and the AOB, which receives axons from the former. One is never found without the other. Most commonly, the AOB is situated caudally within the main olfactory bulb, but varies in mediolateral position. The six layers of the main olfactory bulb are also present in the AOB. In mammals, they are very miniscule in size, intermixed, and disorganized. The different parts and cytoarchitectural details of the cellular and fibrous elements have not been reported in most of the species. This is an intense area for future neuroanatomical investigation. Of the six layers, the glomerular layer (II) and mitral and tufted cell layer (IV) are dispersed throughout the AOB. Further projections of the mitral and tufted cells are less well understood.

Glandular Apparatus

Olfactory epithelium appears to have a phylogenetically ancient glandular apparatus that moistens its surface. As these Bowman's glands are nested in the olfactory lamina propria itself, the secretions appear to be sufficient for binding odorants for chemoreception. The VNO of extant tetrapods receives secretions from at least one of two glandular sources: secretions from the ventral nasal septal glands and the Harderian gland. Each of these glands has been implicated as a provider of odorant-binding secretions (herein, the term odorant is used to denote chemical stimuli that the olfactory epithelium and/or VNO can detect).

With few exceptions, Harderian glands are ubiquitously present in tetrapods. It is a medial orbital gland which varies in product and sends its secretions to the nasal cavities via the nasolacrimal duct (NLD). In most amphibians, Harderian secretions are indirectly accessible by the VNO. This has been clearly demonstrated by experimental work that shows NLD-borne substances are transported to the cavum medium of anurans and diffuse to the VNO (the latter is a diverticulum of the cavum inferior; **Figure 4**). Urodelans do not require stimulus transfer via a duct, but appear to have a nasolabial groove in which glandular secretions may be borne, and chemical stimuli may be acquired during 'nose-tapping' behavior. In squamates, the NLD connects to the palatal duct by which the VNO opens orally. It is hypothesized that Harderian secretions facilitate odorant binding in the VNO of squamates. This possibility is bolstered by recent evidence that Harderian secretions have pheromone-binding capacity in snakes.

In mammals, the functional association of Harderian secretions with VNO function is far less clear; in some mammals other (e.g., pheromonal) functions for Harderian secretions are known. A role has been proposed for Harderian secretions in mammalian VNO function. The evidence is indirect and deserves more scrutiny. The putative sequence is elaborate but ultimately testable. In brief, since the Harderian secretions reach the nasal vestibule of most mammals, they may contribute to a blend of fluids that are accessible at

Figure 4 Rostrocaudal series of nasal fossae in an amphibian (*Rana*, a–c) and reptile (*Hemiergis*, d–f). In anurans such as *Rana*, the nasal fossae are divided into a series of chambers on each side. The vomeronasal organ (VNO) is an inferomedial recess of the inferior chamber (cavum inferior, CI). In reptiles that possess a VNO, the organ is found bilaterally at the base of the nasal fossae (NF). Mucosal glands (GI) adjacent to the VNO are absent in squamate reptiles. CP, cavum principal (main chamber); CM, cavum medium; NLD, nasolacrimal duct; NS, nasal septum; PD, palatal duct; RFE, receptor-free epithelium; VNNE, vomeronasal neuroepithelium. either end of the NPD; behaviors such as flehmen, or 'nuzzling,' may aid in stimulus delivery.

All tetrapods except lepidosaurs have a cluster of glands adjacent to the VNO. In mammals, this series of glands enters the VNO at the RFE–VNNE junctions and posteriorly, where the VNO lumen is continuous with a large gland duct that ramifies into multiple gland lobes. The nomenclature often used for these glands, 'vomeronasal glands,' may obscure certain issues of homology, however. For instance, it is not clear that the glandular complex associated with the amphibian VNO is homologous with that of mammals. In mammals, a subset of nasal septal glands empties into the VNO, and such glands appear to be retained in mammalian taxa that lack a VNO. Until the homology of these glands is firmly understood, the term 'vomeronasal gland' should not be used.

The Capsule

In most reptiles and mammals that possess a VNO, a cartilaginous or osseous capsule surrounds the neuroepithelial tube or sac (Figures 6 and 7). Reptiles and mammals possess bilateral paraseptal cartilages that run parallel along the base of the nasal septum. In most mammals, a portion of these cartilages (the 'vomeronasal cartilage') surrounds each VNO (Figures 6(c), 7(c), and 7(d)). Some mammals (e.g., rodents) possess a bony capsule around the organ (Figures 1, 2(c), and 6(a)). In rodents, it is unlikely that the bony capsule represents ossified vomeronasal cartilages.

Figure 5 High-magnification views of the vomeronasal organ in amphibians (a, b) and reptiles show a vomeronasal neuroepithelium (VNNE) comprising numerous layers of nuclei. (a) *Rana*; (b) *Dermophis*; (c) *Thamnophis*; (d) *Hemiergis*. MB, mushroom body; RFE, receptor-free epithelium. Scale bar = 50 μm (a–d).

Figure 6 The location of the nasopalatine duct (NPD) is shown in a rodent (a, *Microtus*) and in an insectivore (b, c, *Tenrec*). In rodents, the NPD is located posterior to the opening of the vomeronasal organ (VNO). In insectivores and most mammalian taxonomic groups, the VNO opens into the NPD via a short vomeronasal duct (VND). (c) The VNO posterior to the level in (b). NS, nasal septum; IP, incisive papilla. Scale bar = 1 mm (a–c).

The cartilage/bone capsule may be related to stimulus delivery in all tetrapods. In mammals, a large venous sinus or multiple sinuses are found adjacent to the VNO, within the capsule (Figure 1(b)). Therefore, autonomic nerves may elicit changes in blood volume adjacent to the VNO, either compressing the VNO lumen (expelling contents) or allowing the lumen to expand (drawing fluids in). As this occurs within the capsule, the effect is to expel contents or (creating a vacuum) draw fluids into the VNO lumen.

Venous sinuses are not found adjacent to the VNO of squamates (Figure 4(e)). In snakes, the suggested mechanism is via pressure of the tongue on the palate, creating a suction force to draw fluids into the lumen.

The Receptor-Free Epithelium

Two types of epithelia may comprise a VNO–neuroepithelium, and receptor-free or nonsensory epithelium. The multiple ducts of the septal ('vomeronasal') glands enter VNO at variable positions (dorsoventrally and

Figure 7 The vomeronasal organ (VNO) of strepsirrhine primates, such as dwarf lemurs (a, *Cheirogaleus*; inset is enlarged in (c)) and bushbabies (b, *Galago*; inset is enlarged in (d)), resembles that of most mammals in possessing two distinct epithelia. The neuroepithelium (*; c, d) comprises bipolar vomeronasal receptor neurons (VRN), which are demonstrated with a *Ulex europaeus*-1 procedure (e, showing the neuroepithelium of *Eulemur*). The axons of VRNs coalesce into vomeronasal nerves (VNN) in the lamina propria. ET, ethmoturbinal I; MT, maxilloturbinal; NS, nasal septum; RFE, receptor-free epithelium; VNC, vomeronasal cartilage. Scale bar = 1 mm (a, b); 150 μm (c, d); 50 μm (e).

rostrocaudally) among mammals. Primates represent an extreme, in that the gland ducts open through the VNNE around the entire perimeter in some species. In some bats and rodents, the gland ducts open dorsally at the RFE–VNNE junction. Of these epithelial types, RFE is the most variable, being patchy (ciliated alternating with nonciliated, microvillar, or nonmicrovillar) or even without surface specializations. A detailed comparison of apical cell processes in the RFE in different species is warranted. Such a study may elucidate special attributes of this portion of the VNO wall.

The Vomeronasal Nerves and Paravomeronasal Ganglia

In the lamina propria surrounding the vomeronasal neuroepithelium and underneath are the axons that coalesce into vomeronasal nerves. These neural bundles are ganglionated (termed 'paravomeronasal ganglia') in at least some mammals. They course posteriorly in the mucosa of the nasal septum toward and through the cribriform plate and the accessory olfactory bulb.

Development

Vomeronasal Organ

The origin for the epithelia of the VNO in all vertebrates is from a medial portion of the embryonic nasal pit, which itself originated from the nasal placode. In squamates and all mammals, this patch of epithelium invaginates to form a sac (in squamates) or tube, which possesses a communication to the developing oronasal cavity (initially) via a short duct.

In mammals, this invaginating mode of development occurs regardless of the final locus of communication for the VNO opening. Subsequently, a short duct of the VNO develops a communication with the NPD (Figure 6(b)) or with the nasal fossa alone (e.g., rodents). The latter is the embryologically primitive condition for amniotes. Differing patterns of craniofacial growth have been suggested to account for variation in supero-inferior position of the VNO opening in primates. Similar lines of study could focus on the different anteroposterior positioning among different taxa. For example, the differing position of the VNO opening relative to the NPD in rodents (Figure 6(a)) compared to most mammals (Figure 6(b)) may relate to the magnitude of growth of the incisive (premaxillary) bone in rodents, the result of which is a more posteriorly positioned incisive fossa compared to other mammals (Figure 6(a)). In other words, the VNO and adjacent supporting tissues may be ontogenetically decoupled during growth. Certainly the cartilaginous capsule is known to lose association with the VNO in hominoids.

Do Humans Have a Vomeronasal Organ?

Controversy concerning the human VNO, spanning decades, has been reviewed repeatedly. Conflicting results concerning the presence versus absence of the VNO in adult humans and the purported prenatal disappearance also have been thoroughly discussed. In recent years, many authors have regarded bilateral epithelial tubes, found 6–11 mm superior to the base of the nasal septum, as vestigial homologs of the VNO found in other mammals. The human VNO is nearly as spatially incongruous with that of most mammals as the cetacean blowhole is with typical mammalian external nares. Yet, in contrast, no good skeletal correlates exist to demonstrate the relationship between the two. The homology of these morphologically incongruous structures is only understood through examination of embryonic and fetal development.

Through comparison of embryos at approximately similar stages of development, developing humans are

found to possess first 'vomeronasal grooves' and then tubular VNOs in the same position as found in other mammals, including some primates. During fetal development, the human VNO becomes displaced from its initial position near the base of the nasal septum. Thus, the fetal and postnatal human VNO vestiges are positioned more superiorly relative to the palate and devoid of a cartilaginous capsule (the cartilage remains inferior to the nasal septum, as in other mammals). The displacement may be related to the magnitude of downward growth of the midfacial region that typifies hominoids (humans and great apes). Indeed, the chimpanzee possesses a positionally identical epithelial tube of the same light microscopic structure, in fetuses and adults (**Figures 2(e) and 8(f)**). Given the developmental link of the human VNO vestige to the VNO of other mammals, this epithelial tube seen in fetal and postnatal chimpanzees most certainly represents a VNO vestige. Despite the developmental link between the human VNO and that of other mammals, a number of lines of data indicate it is a nonfunctional vestige in terms of chemoreception. A transition to this nonfunctional status is discernible prenatally, in terms of second trimester loss of innervation and a conversion of its epithelium to a pseudostratified, ciliated columnar type.

Some erroneous concepts concerning the human VNO have persisted. The human VNO and its capsular cartilage do not disappear during early development. Moreover, the fetal VNO and postnatal human VNO are spatially separate from the palate as well as the incisive canal, which houses an NPD in most mammals. In adult humans, bilateral, ciliated epithelial tubes and the paraseptal cartilages persist as reduced homologs of the VNO and its cartilaginous capsule, respectively (cf. vomeronasal cartilage; **Figures 6(b) and 8(b)**).

Evolutionary Patterns

Presence of elements of the vomeronasal system in fishes is debated. Among extant vertebrate taxa, an anatomically distinct VNS exists in all higher taxa of vertebrates except archosaurs, in which the VNS has been lost. This distribution has two implications. First, an anatomically distinct VNS first developed in a common ancestor of living tetrapods. Second, numerous taxa at all hierarchical levels lost the VNS in evolutionary convergence and perhaps, in some cases, parallelism. The second point has been fodder for much discussion of adaptive aspects of VNS chemoreception (see later). An understanding of adaptive significance of this system has remained elusive, in part, because of the murky evolutionary history of this neural system.

In extant animals possessing a VNS, every functional element is a soft tissue structure, and no osseous features of the skull (foramina or fossae) may be solely related to the presence of peripheral or central elements of the VNS. In the following sections, some indirect clues to the origin and adaptive significance of the VNS are discussed.

Structural Diversity

Though varied in microanatomy, two basic morphologies of VNO are found among vertebrates. In nearly all extant mammals, the VNOs are elongated epithelial tubes that run parallel to the intersection of the palate and nasal septum. This morphology is in strong contrast to the furrow or pouch shape of the VNO that characterizes most extant nonmammalian tetrapods.

Aside from evolutionary loss (see later), the major variation seen in nonmammals concerns the degree to which the VNO is separated from the nasal cavity. In anurans and urodelans, the VNOs are akin to recesses of the nasal cavity in mammals – that is, they bear large ports of communication to the main chamber. This is consistent with two other concepts. First, solvents reach the VNO by diffusion through fluid in connecting nasal chambers in anurans. Second, the common ancestor of tetrapods, in which the VNO is hypothesized to have first occurred, bore characteristics indicating a completely aquatic existence. The simple recess would allow better access than would the ostium of a duct for such a passive delivery system. As already described, the palatal ducts of squamate reptiles or vomeronasal ducts of other vertebrates require stimulus delivery.

The tubular VNO is surely a primitive characteristic of mammals, as it exists in all subclasses. One may speculate that this morphology developed first in therapsid reptiles, yet reliable skeletal clues regarding the VNO shape have yet to be established. The close spatial relationship with the nasal septum and a relatively rostral opening appear to be characteristics that typify most extant amniotes. Less certain is the advent of the NPD opening of the VNO. The timing of evolution of an oral opening for the VNO is uncertain. Even though many extant mammals possess a 'dual-access' opening via the NPD, some therapsids did not. Most lepidosaurs possess an oral opening for VNO entry, but this is considered a derived feature, and the VNO opens into the anteromedial nasal cavity in the most primitive lepidosaur (*Sphenodon*). For these reasons, a nasal-only VNO opening is likely the primitive condition for early therapsids.

An additional consideration has been brought to light regarding the NPD development in extant mammals. Although it would appear that mammals primitively possessed a dual-access opening, during

Figure 8 The vomeronasal organ (VNO) of New World primates, such as marmosets (a–c, *Cebuella*), exhibits vomeronasal neuroepithelium (Δ) both medially and laterally, in contrast to most mammals (cf. **Figures 6** and **7**). In chimpanzees (d–f, *Pan*) and humans (not shown), VNO homologs are found in an atypical position (d, e), displaced superiorly from the base of the nasal septum (NS) and spatially separated from the paraseptal cartilages (PC; homologs of the vomeronasal cartilages). Micrographs (b) and (c) and (e) and (f) are progressive enlargements of the VNO shown in (a) and (d), respectively. The VNO epithelium in chimpanzees (f) and humans is pseudostratified, columnar, with apical cilia (double arrows). ET, ethmoturbinal I; L, lumen of VNO; NLD, nasolacrimal duct (orbital end); NS, nasal septum; VNC, vomeronasal cartilage; VRN, nuclei of the vomeronasal receptor neurons. Scale bar = 1 mm (a, d); 150 μm (b); 50 μm (c, f); and 500 μm (e).

embryogenesis the VNO primitively opens to the nasal chambers in all vertebrates, including mammals. In mammals, eventual communication of the VNO with the NPD is contingent on formation of the secondary palate. Interestingly, some primates that possess a dual-access opening in adults continue after palatogenesis to transiently possess a VNO opening into the base of the nasal cavity. Subsequently, as the palate grows in depth, the VNO duct is incorporated into the palate along with a nasal portion of the NPD. In addition, some mammals with especially pronounced depth of the palate (e.g., great apes, elephants) have ducts that are partially nonpatent or absent, even though the bony canal that encloses it may be present. This raises the possibility that variation in VNO entry among mammals is partially a byproduct of different modes of facial growth, especially as regards the bony palate.

Since the VNO opens anteriorly into the NPD in prototherians, many metatherians, as well as many eutherians, this may well represent the primitive condition for mammals. However, the developmental sequence of VNO duct relative to the NPD, noted previously, makes the issue far less certain. In essence, the bar is raised for clearer criteria regarding osseous correlates of the duct to the VNO, which may in turn augment paleontological interpretation.

Although the VNO itself does not clearly relate to osseous landmarks, some researchers have suggested osseous morphologies of fossils which indirectly relate to VNO function. Hillenius has carefully outlined the potential significance of the septomaxillary foramen to the distal (nasal) end of the nasolacrimal duct in therapsids. In extant mammals, the link between Harderian gland (nasolacrimal duct-borne) secretions and VNO function is more tenuous than for squamate reptiles, but still plausible. It is possible that Harderian secretions may travel to the snout via the septomaxillary foramen, and thus may be involved in odorant binding when drawn into the VNO (indirectly) via the oral or nasal route. If so, this indirect secretory route first appeared in therapsids.

Variations of the Vomeronasal System

There appear to be two extremes among extant tetrapods: (1) snakes and other lepidosaurs have a proportionally large VNS peripherally as well as centrally, and (2) in some extant synapsids (comprising mammals, reptiles, and birds) the VNS is on the path of regression. The subclass Archosauria represents the highest taxonomic group that is characterized by VNS absence. However, the VNS has been lost independently at numerous other taxonomic levels of all classes of tetrapods. Among mammals the VNS is absent, or not intact (i.e., a vestigial VNO with no neural connections as in humans) in all cetaceans, all Old World primates, numerous chiropterans (all sirenians Megachiroptera and some Old World Microchiroptera), and proteid salamanders.

What does VNO loss or reduction imply? Several ecological correlates have been offered. Tetrapods of terrestrial stock that secondarily became aquatic or semiaquatic have no VNS or have a putatively reduced VNS. The underlying basis for VNS reduction in these taxa has not been explained in terms of selective pressures. However, it was recently observed that the ratio of two families of vomeronasal receptor genes is inverted in terrestrial tetrapods compared to aquatic tetrapods and teleost fish. An interesting implication is that terrestrial tetrapods may no longer utilize the VNS in the same manner as did their fully aquatic ancestors. One well-reasoned basis for VNO loss concerns catarrhine primates, which all lack an intact VNS (extant strepsirrhines, New World anthropoids, and tarsiers have retained an intact VNS). It is argued that loss of VNS function coincided

with the acquisition of trichromatic vision in catarrhines. The loss of VNS has been related to the replacement of pheromonal signaling via the VNS with social signals of a visual nature (e.g., perineal coloration). More proximally, VNS loss is related to reduced selection pressure and an accumulation of pseudogenes related to signal transduction in the VNS. The accumulating evidence that the VNS is not exclusively involved in pheromonal communication makes the preceding argument a bit more tenuous. However, it remains the most potent hypothesis offered to explain the evolutionary loss of a special sensory system.

Bats rival or exceed primates in the degree of inter- and intrataxonomic variation of the VNS. Only one family, Phyllostomidae, is endowed with an intact VNS. In the other 17 families of bats, the VNS remains either variable or untraceable. Chiroptera remains an attractive mammalian group for developing a second hypothesis for VNO loss, which might also be related to sensory ecology. On the other hand, it is unclear why certain taxa of chiropterans have retained a well-developed VNS. One might be tempted to speculate the functional relationship between the long, highly extensile and pointed tongues and the VNO, as in snakes, lizards, and phyllostomid bats (many of the latter have elongated muzzles, large VNOs, and highly extensile tongues, as in glossophagine bats). In these cases, there is a chance for the tongue to be introduced into the VNOs, as in snake tongue-flicking, after receiving the chemostimulus from the environment.

Historically, an understanding of VNS loss was complicated by false generalizations that entire taxonomic groups (e.g., cles, bats) lack the VNO, generalizations that were subsequently corrected. Another hindrance to our understanding of VNS loss is our preconception of VNO functions. Whereas it is well established that the VNO is critically important for sociosexual interactions in rodents, and equally important for food detection in snakes, few studies have considered that the VNO may function for multiple purposes among or within taxa. Renewed focus on dietary, ecological, and other factors may explain the VNO loss in various taxa.

Conclusions

The VNO in Extant Tetrapods

A functional dichotomy of the 'dual' olfactory systems (VNS and main olfactory system) has been reassessed in recent years. Evidence now exists that molecules of differing characteristics (volatile or nonvolatile) or functions (social or food odorants) may stimulate the VNO. It has been observed that odorant volatility seems irrelevant to animals with a fully aquatic lifestyle (e.g., urodelans). In amniotes, morphological variations of the VNO suggest considerable evolution since the initial appearance of the VNS. The extent to which the VNS of amniotes has diverged functionally from the main olfactory system would appear to relate to a terrestrial evolutionary history, quite removed from selection pressures encountered by their aquatic ancestors. Recent work has shown potential importance of the VNO to feeding in a marsupial, suggesting functional flexibility closer to that known for squamate reptiles. Thus, the VNS may ultimately be understood as serving for redundant chemosensory functions, perhaps specializing only at the level of odorant molecules.

An Elusive Ancestral Function

The ancestral function of the VNS remains unknown and difficult to deduce, due to the indirect nature of fossil evidence (see earlier). Therefore, reconstructions of VNS evolution in relation to the lifestyle of tetrapod ancestors vary greatly. For instance, the VNS was considered an adaptation of terrestrial tetrapods until recently. The first appearance of the VNS also has been linked with amphibian metamorphosis. Since proteid salamanders do not metamorphose, Eisthen concluded that the VNS was lost in proteid salamanders, and rejected the hypothesis that the VNS originated in conjunction with metamorphosis in amphibians. Eisthen brings to bear a more basic argument as well: since the VNS likely evolved in the common ancestor of lissamphibians and amniotes, and this ancestor was fully aquatic, it was not an adaptation for terrestriality. So, what novel selective pressures were encountered by prototetrapods that were not already acting on all aquatic vertebrates? Conceivably, the advent of air breathing in tetrapod ancestors was associated with odorant detection in different mediums, and/or at the air/water interface itself.

Clues to the primitive function of the VNS might still be derived from extant tetrapods. It has been hypothesized that an ancient relationship exists between the VNO and the Harderian gland of the orbit, and that the gland secretions may have served as solvents for vomeronasal chemoreception. This scenario may also relate to the functional diversity of the VNO across amniotes. The ancient connection between the Harderian gland and VNS, if correct, is unstable in amniotes, in which other secretions (septal glands) may suffice for some taxa.

Hillenius and Rehorek suggested that odorant molecules may have been "inadvertently 'trapped' on the cornea of aquatic tetrapod ancestors, specifically

when the eyes breach the water surface. Such molecules could travel through the nasolacrimal duct, along with Harderian secretions, to the VNO. The notion that odorants may enter the nasal chambers indirectly via an orbital entry is fascinating in conjunction with the image of ancestral tetrapods that lived in shallow water and evolved adaptations for air breathing. These creatures may have been the first vertebrates to encounter a novel array of chemical stimuli. In tandem with changes in the respiratory system, ancestral tetrapods may have evolved adaptations for sensing chemicals at the air/water interface.

Voxel Based Morphometry

J Ashburner and K J Friston, Functional Imaging Laboratory, London, UK

Introduction

Since the advent of magnetic resonance imaging (MRI), neuroscientists have been able to measure structures in living human brains. A large number of automated or semiautomated approaches for characterizing differences in the shape and neuroanatomical configuration of different brains have emerged due to improved resolution of anatomical scans and the development of new image processing techniques. There are many ways of identifying and characterizing structural differences among populations. Voxel-based morphometry (VBM) is one such method, which has been used widely during the past decade. Its applications range from the study of progressive supranuclear palsy to neurogenetic studies of polymorphisms and age-related changes. Unlike other approaches to morphometry, VBM does not refer explicitly to anatomy; it treats images as continuous scalar measurements and tests for local differences at the appropriate spatial scale. This scale is controlled by the smoothing. Smoothing is critical for VBM because it sets a lower bound on the anatomical scale at which differences can be expressed. It does so by removing fine-scale structure that is not conserved from subject to subject. Effectively, VBM is a scale-space search for anatomical differences. There are several reasons why VBM has proved so popular. First, in contrast to conventional analyses of anatomical structures, it tests for differences anywhere in the brain. Second, VBM can be applied to any measure of anatomy – for example, gray matter density, compression maps based on the Jacobian of deformation fields, or fractional anisotropy from diffusion weighted imaging. By choosing the data and their transformations carefully, a large range of anatomical attributes can be analyzed in a simple and anatomically unbiased way.

In summary, VBM is a simple procedure that enables classical inferences about the regionally specific effects of experimental factors on some structural measure. These effects are tested after discounting the large-scale anatomical differences removed by spatial normalization. Because these differences have been removed, VBM is not a surrogate for classical volume analysis of large structures or lesions. Furthermore, it will not replace shape analysis; VBM infers on smooth scalar fields, where constructs such as 'edges' or 'shape' have no meaning. VBM represents an established and effective complement to shape and volume analyses that is used widely in many basic and clinical contexts.

This article discusses the various stages involved in preparing data for VBM and then considers modeling and inference on these data.

Preparing the Data

VBM relies on good quality high-resolution MRIs from different subjects and uses these to identify correlations between disease severity and the spatial deployment of different tissue types. Many researchers assume that VBM can only be implemented within the SPM package; this is not the case. There are many software tools that could be used to perform the requisite sequence of operations. The MRIs are segmented, producing images that reflect the spatial distribution of a tissue type or attribute (e.g., gray matter). To compare brains of different subjects, all gray matter segments are warped to the same stereotaxic space. A correction can be applied to the data that accounts for expansion and contraction during this nonlinear spatial normalization. The normalized segments are then smoothed. This makes each voxel a measure of the proportion of the brain, in a region around the voxel that is gray matter (i.e., gray matter density). Statistical analysis using the general linear model (GLM) is used to identify regions that are significantly related to the effects under study. The GLM is a flexible framework that allows many different tests to be applied. The output is a statistical parametric map (SPM) showing regions where tissue density differs significantly among the groups. A voxel-wise SPM comprises the result of many statistical tests, so it is necessary to correct for multiple dependent comparisons using the theory of random fields.

Segmentation

The images are typically partitioned into different tissue classes using one of a number of segmentation techniques. Usually, VBM involves an analysis of gray matter, but it is possible to work with other tissue classes or any other scalar measure of anatomy (e.g., fractional anisotropy). To accurately segment an image, the image needs to show clear differentiation among tissue types. Usually, high-resolution T1-weighted MRIs are used, although multispectral images may allow more accurate tissue classification (Figure 1). Different segmentation models have different requirements. For example, many approaches take smooth intensity inhomogeneities into account, so they can deal with some of the artifacts that arise in MRIs.

Figure 1 The result of segmenting the gray matter from a T1-weighted MRI. Note that toward the top of the brain, the segmentation is less accurate because the gray matter is hardly visible in the original image. Similarly, in gray matter regions such as the thalamus, the intensity is closer to that of white matter, resulting in incorrect segmentation. Some partial volume voxels can be seen around the ventricles. These arise because voxels containing signal from both white matter and CSF have intensities that are close to those of gray matter.

Most automated segmentation algorithms assume that the intracranial cavity contains only gray matter, white matter, and cerebrospinal fluid (CSF), so they may be confounded by lesions. However, there are some that have been specially designed for dealing with such pathology, although they generally require multispectral images (e.g., aligned T1- and T2-weighted scans).

Many segmentation approaches use prior spatial information in the form of tissue probability maps, which inform the segmentation algorithm about the approximate spatial distribution of the various tissues. In most cases, the tissue probability maps need to be registered with the image to segment, but the segmentation framework of SPM5 combines this registration with the tissue classification.

Spatial Normalization

Spatial normalization involves warping all the gray matter images to the same stereotaxic space, which is achieved by matching to a common template image (Figure 2). There are many nonlinear registration methods that can be used for this. The unified segmentation–normalization approach in SPM5 is a robust procedure because it accommodates conditional dependences among the segmentation and normalization parameters. It is a low-dimensional method which uses approximately 1000 parameters to describe the deformations. Other approaches have many more degrees of freedom and may be more accurate. However, just because a method can warp anything to anything else does not mean that it furnishes the most likely registration (high-dimensional procedures generally overfit the data). For example, the evaluations of Hellier et al., which compared registration accuracy of different approaches, found that the simple spatial normalization of SPM2 was as accurate as other methods with more degrees of freedom.

The objective of VBM is to localize regions (in stereotaxic space) where there are significant differences. Accurate spatial normalization and segmentation ensures regional differences can be attributable to local effects rather than systematic, pathology-induced misregistration artifacts. However, registration can never be perfect because there is no correspondence between one subject and another at a fine spatial scale. For example, many sulci are shared between brains, but this is not the case for all. Generally, the primary sulci, which are formed earliest and tend to be quite deep, are conserved over subjects. Sulci developing later are much more variable. Therefore, some sulci can be matched objectively, whereas others cannot. VBM accommodates the fact that the scale of anatomical correspondence, and implicitly the scale of differences in anatomy, has a lower bound by smoothing the segments.

Jacobian Adjustment

Nonlinear spatial normalization changes the volumes of brain regions. This has implications for the interpretation of what VBM tests. The objective of VBM is to identify regional differences in the composition of

Figure 2 An image (top left) is warped to match a template (top right) to produce a spatially normalized version (top center). For clarity, the original image was approximately aligned with the template, and the warping was only done in two dimensions. The bottom row shows the difference between the template and image, both before and after the warping.

brain tissue. To preserve the actual amounts of a tissue class within each voxel, a further processing step can be incorporated that multiplies (modulates) the partitioned images by the relative voxel volumes before and after warping. These relative volumes are simply the Jacobian determinants of the deformation field (Figure 3). In the limiting case of extremely precise registration (using very high-dimensional registration), all the segments would be identical. The adjustment preserves the differences in volume of a particular tissue class (Figure 4).

The deformations from spatial normalization map points in a template (x_1, x_2, x_3) to equivalent points in individual source images (y_1, y_2, y_3). The derivatives of the deformation field can be thought of as matrix at each point. These are the Jacobian matrices of the deformations and are defined by

$$J = \begin{Bmatrix} \partial y_1/\partial x_1 & \partial y_1/\partial x_2 & \partial y_1/\partial x_3 \\ \partial y_2/\partial x_1 & \partial y_2/\partial x_2 & \partial y_2/\partial x_3 \\ \partial y_3/\partial x_1 & \partial y_3/\partial x_2 & \partial y_3/\partial x_3 \end{Bmatrix}$$

The determinant of this matrix encodes the relative volumes of deformed and undeformed structures.

Smoothing

The warped gray matter images are now smoothed by convolving with an isotropic Gaussian kernel. This makes the subsequent voxel-by-voxel analysis comparable to a region of interest approach because each voxel in the smoothed images contains the average amount of gray matter from around the voxel (where the region around the voxel is defined by the form of the smoothing kernel; Figure 5). This is often referred to as gray matter density, but it should not be confused with cell packing density measured cytoarchitectonically. Critically, smoothing removes finescale structure from the data that is not conserved from subject to subject. This increases the sensitivity of VBM to differences that are expressed at a larger spatial scale. The smoothing conforms to the matched filter theorem, which states that the smoothing should match the scale of the difference in question. Normally, the smoothing kernel is Gaussian with a full width at half maximum (FWHM) of between 4 and 16 mm. By the central limit theorem, smoothing also has the effect of rendering the data more normally distributed, thus increasing the validity of parametric statistical tests.

Statistical Modeling and Inference

Voxelwise statistical tests are performed on the preprocessed images using standard linear models (GLM). The results of these tests are an SPM showing significant regional effects. The GLM allows many different tests to be applied, ranging from group comparisons and identification of regional correlates of disease severity or age to complex interactions among

Figure 3 Warping an image results in some regions growing and others shrinking. The top left image is a spatially normalized image with deformations overlayed (the same data as in Figure 2). Beside it is a map of Jacobian determinants, in which darker regions indicate regions where the deformation lines are closer together. The bottom left image is the original undeformed image, with the deformations that would spatially normalize it overlayed. This deformation field is the inverse of the one shown above it. Beside it are the Jacobian determinants showing expansion and contraction.

Figure 4 The image on the left is a warped gray matter image. In the center is a map of the Jacobian determinants from the warp (see Figure 3). The image on the right is the result of multiplying them together, such that the amount of gray matter is preserved.

these effects. In the GLM, the model is expressed as a design matrix. Each row of this matrix corresponds to a scan, whereas each column is some effect that is modeled. At each voxel, the optimal linear combination of effects is computed in terms of parameter estimates. Statistics are then based on the parameter estimates at each voxel. Standard statistics (t tests and F tests) are used to test the hypotheses and are valid providing the residuals, after fitting the model, are normally distributed.

Figure 5 Smoothing effectively converts the images to maps containing a weighted count of the number of gray matter voxels within each region. The top row shows three unsmoothed images. The middle row shows these images after they have been convolved with a circular-shaped kernel. It should be clear that the result is a count of the values within each circular region. The bottom row shows the images after convolving with a Gaussian-shaped kernel. The result is a weighted count of the values around each point, where values in the center are weighted more heavily.

Occasionally, researchers want to mix images from different scanners or data acquired using different sequences. The effects of different types of images can generally be modeled by including confounds in the design matrix. Note that for a comparison of one group versus another, where one group is collected on one scanner and the other group is collected on another, modeling the scanner effect will explain away all group differences. An important confound is the global or whole measure.

Global Normalization and Other Confounds

Global normalization is a generic issue in neuroimaging. SPM is used to identify regionally specific (i.e., nonglobal) effects. This can be ensured by treating the global signal as a confound, which is explained away during inference. Because the global effect is the sum of all regional effects, this means that the sum of all regional effects, over the brain, is zero. Global normalization therefore partitions effects into regional and global components. In the context of gray matter–VBM density, this involves modeling the global gray matter as a linear confound (or by scaling each segment by its global mean). The implicit partitioning into regional and global effects finesses the characterization of anatomical differences. For example, a regional increase in gray matter density can indicate one of two things: it could be due to local hyperplasia, or it could be a local sparing of the region in the context of diffuse cortical atrophy everywhere else. The resolution of this ambiguity rests on inference about the global measure. In the first instance, there will be no global difference, but it would be significant in the second.

There are other confounds people include in statistical models that remove variance in gray matter density that could have been caused by nonspecific mechanisms (in relation to cohort selection or experimental factors). These can be expressed in a regionally selective fashion (e.g., age or experimental factors) or globally. For example, larger brains have proportionally more white matter than gray, leading some researchers to treat total intracranial volume as a confound.

Inference

Following application of the GLM, the significance of any regional difference is ascertained using the parameter estimates and their associated statistics. A voxelwise SPM comprises the results of many statistical tests, so it is necessary to correct for multiple dependent comparisons. Without any correction, the number of false-positive results would be proportional to the number of independent tests. A Bonferroni correction would be applied if the tests were independent, but this is not the case because of the inherent spatial smoothness of the data. In practice, the effective number of independent statistical tests is determined using random field theory (RFT). RFT provides a correction for multiple dependent that controls the rate of false-positive results. Parametric statistical tests are based on assumptions about the data. In particular, they assume that the residuals after fitting the model are normally distributed. There is a special caveat for VBM concerning the normality assumption: gray matter segments contain values between 0 and 1, where most of the values are close to either of the extremes. In this case, smoothing is essential to render the residuals sufficiently normal. For group comparisons, normality can be ensured with smoothing at or above 4 mm FWHM. For single-case comparisons, numerical studies suggest that at least 12 mm should be used. An alternative for unbalanced designs (e.g., single-case studies) is the nonparametric methods.

The t or F fields produced by SPM are thresholded at some value. Regions of the field that survive the threshold (called clusters, excursion sets, or simply blobs) are then examined further. SPM allows inferences to be made based on the spatial extent of blobs, under the assumption that large blobs are less likely to occur by chance than small blobs. In the SPM software implementation of RFT, inferences on the extent of a cluster (but not the height of a peak) assume that the smoothness of the residuals is roughly the same everywhere. This is ensured for data that have been smoothed. However, without smoothing, large blobs that occur by chance in smooth regions may be declared significant, whereas smaller true blobs in rough regions may be missed.

Nonstationary behavior of error terms can also misdirect the interpretation of true positive results. Spatial changes in error variance can cause blobs to move toward regions with low variance and away from regions with high residual variance. This explains the occasional finding of significant differences outside the brain (because the residual variance approaches zero as one moves away from the brain). Accurate localization of differences should not use the SPM. As with all applications of SPM, interpretation rests on looking at the parameter estimates that subtend the significant effect. In this instance, the gray matter difference maps provide the veridical localization.

Frequentist statistical tests cannot be used to prove a hypothesis, only to reject a null hypothesis. Any significant differences that are detected could be

Figure 6 Significant differences determined using VBM can be explained in many ways.

explained by a number of different causes, which are not disambiguated by the inference *per se*. When the null hypothesis has been rejected, it does not impute a particular explanation for the difference if there are several causes that could explain it (Figure 6). The preprocessing employed by VBM manipulates the data so that the ensuing tests are more sensitive to some causes relative to others. In particular, VBM has been devised to be sensitive to systematic differences in the density of a particular tissue class, but significant results can also arise for other reasons. A critique of VBM is that it is sensitive to systematic shape differences attributable to misregistration from the spatial normalization step. This is one of a number of potential systematic differences that can arise. This does not mean that VBM is invalid but the explanation for the significant result may be complicated. VBM will only detect systematic group differences. This applies to misregistration. Because the registration is driven by anatomy, any difference must be due to anatomical differences, but these may not be meditated locally (e.g., misplacement of the cortex by subcortical lesions). Some explanations can be trivial (e.g., some patient groups may have to be positioned differently in the scanner) and it is important to identify confounds of this sort. In short, there may be real differences among the data, but these may not necessarily be due to reductions in regional gray matter.

VBM in Clinical Research

Neurodegeneration involves regional loss of tissue over time. Volumetric changes can be inferred on voxel compression maps from high-resolution warping algorithms applied to longitudinal data. This approach has shown that the rate of tissue loss, rather than tissue distribution, has a better predictive validity in relation to disease progression. Comparisons of these maps between subjects requires some kind of regional averaging, either in the form of parcelation or spatial smoothing, as in VBM. Regions of compression and dilation often lie close to each other, so simple regional averaging approaches may cause differences to cancel. The most straightforward approach involves partitioning the compression maps into different tissue classes (cf. the RAVENS map approach). VBM with simple intrasubject rigid registration of longitudinal data is a simpler way of achieving similar results. Although it is useful for research, VBM may not be the most sensitive approach for diagnosing a disease in an individual. For example, VBM may be able to state that Alzheimer patients have smaller hippocampi than controls, but it is difficult to state for certain that an individual is in the early stages of the disease simply by examining hippocampal volume. We have contrasted generative models of regional pathology and recognition models for diagnosis and classification. Classification approaches are generally not interested in regionally specific differences but try to find the best nonlinear function of the data, over the entire brain, which predicts diagnosis. Multivariate kernel methods, such as support vector machines, relevance vector machines, or Gaussian process models, are established recognition models that may be useful in diagnosis and endophenotyping.

Walking in Invertebrates

F Delcomyn, University of Illinois, Urbana, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

A major advancement in the evolutionary history of invertebrates was the development of a hard external skeleton such as that found among the arthropods (insects, spiders, crustacea, etc.). This was important because a skeleton allows for the development of segmented legs, and legs make possible efficient walking. With two exceptions, all invertebrates with true legs are arthropods. The exceptions are the soft-bodied Onycophora and Tartigrada, evolutionary relatives of the arthropods.

From a neurobiological perspective, an important question is how arthropods are able to coordinate their legs as they walk. Although neurobiologists have identified general principles that seem to apply to walking coordination in all arthropods, the application of these principles in different arthropods can lead to rather different patterns of walking because body shapes and sizes, number of legs, and living conditions are dramatically different in different groups of these animals. For example, the long and slender millipedes and centipedes have large number of legs, upward of 100 pair in some species. The more compact spiders and scorpions typically have eight pairs, and insects only six. Some crustacea have more than a dozen pairs of legs, but the better known crabs, crayfish, and lobsters have only ten, with the front pair usually modified structurally into claws that are not used in walking. In addition to these differences in body plan and number of legs, the terrestrial arthropods have different mechanical requirements for walking than do the aquatic crustacea, which, since they walk underwater, have water's buoyancy to assist them.

Although there are more species of arthropods than all other animals combined (entomologists estimate well over a million species of insects alone), walking has been studied in only a handful. Furthermore, the study of walking in invertebrates is itself a rather minor subfield of neurobiology. Nevertheless, such studies have contributed to neurobiology out of all proportion to their numbers. Contributions have come mainly in the field of motor control, especially in relation to the problem of how repetitive movements can be generated and coordinated, and also in bioengineering.

This article covers the main gait patterns observed in arthropods, the ways in which these patterns are generated and maintained, and how animals modulate their gaits. It concludes with an overview of recent work on robots.

Gaits

All invertebrates whose walking has been studied exhibit what is called a metachronal rhythm in the movements of their legs. Such rhythms have the appearance of a traveling wave of leg movements usually moving from the rear to the front of the animal. This is easiest to see and visualize in the many-legged myriapods (centipedes and millipedes). In most of these animals, each leg on one side of the body lifts for its forward swing a little later than the leg behind it, producing the wavelike appearance that gives the motion its name. Legs on the other side of the body are out of phase such that as a leg on the left side is in the air swinging forward, its partner on the right side is on the ground moving backward.

Aquatic crustacea also exhibit a metachronal wave, but it is not so obvious in these animals because the water provides sufficient buoyancy that the animals need only support a small fraction of their body mass on their legs. This allows the legs to move in ways that on land would result in unbalanced positions. The result is that coordination between legs in a crab or crayfish is much less tightly coupled than it is in arthropods that walk on land. Furthermore, evidence from trace fossil tracks of extinct arthropods suggests that at least some of these walked using a swimminglike pattern of leg movement in which the two legs of a pair on opposite sides of the body moved forward and backward together rather than alternately, a pattern not seen on land.

Insects and spiders, the other terrestrial arthropods, also exhibit a metachronal wave of leg movement during walking, but with only six (insects) or eight (spiders) legs, a metachronal sequence is not usually obvious in these animals. Nearly all insects use one simple gait most of the time. This gait, the alternating tripod or alternating triangle gait (Figure 1), consists of stepping in which the front and rear legs on one side of the body move forward together with the middle leg on the other side. The tripod of legs thus formed alternates in its movements with the other three legs, hence giving the gait its name.

The metachronal underpinning of this gait was first pointed out by Don Wilson about 40 years ago. Wilson saw that occasionally an insect will walk very slowly, moving only one leg forward at a time. When it does this, the order of movement is rear, middle, front leg

on one side of the body, followed by rear, middle, front on the other side, an obvious metachronal sequence. Wilson's insight was to notice that if a second metachronal wave were to start before the first one had finished, the overlap of the waves could result in the swing of a rear leg to start a second metachronal wave coinciding with the swing of the front leg that represents the last part of the previous wave. Because the two legs of a pair on one body segment move essentially in the opposite direction, the effect is to have a rear and front leg on one side step together with the middle leg on the other side to form a triangle (Figure 2).

Figure 1 The alternating tripod gait of an insect. The front and rear legs on one side of the insect move together with the middle leg on the other side of the body (arrows). The legs forming one tripod alternate in their movements with the legs forming the other tripod so that as one triplet of legs is lifted to swing forward the other triplet is put on the ground and pushes back. Reproduced from Adelmari G and Smith BH (eds.) (1999) *Encyclopedia of Neuroscience*, 2nd enlarged and revised edition, p. 966, with permission from Elsevier.

The alternating triangle gait is the most common gait among insects, but other gaits may be seen. Some rather slow-moving insects such as the stick insects may employ other gaits, and even fast-moving ones like cockroaches may occasionally walk so slowly that the alternating triangle gait breaks down. Furthermore, when grasshoppers and some of their relatives with extremely long legs walk very slowly, they may take only one step with a rear leg for every two steps of the front and middle legs. Praying mantises sometimes walk as quadrupeds, holding up the two front legs ready to capture prey as they walk. Under some conditions, spiders may also walk with the two front legs held up, in which case they use an alternating tripod gait.

An essential feature of an alternating triangle gait is that each leg moves oppositely from each of its nearest neighbors. For example, in an insect, if a left middle leg is in mid-swing, then its nearest neighbors, the left front and rear and the right middle, are all on the ground in mid-stance. The nearest neighbors of a right rear leg in mid-stance, the right middle and left rear legs, will both be in the swing phases of their stepping cycles. This pattern of adjacent legs being in opposite phases of their stepping cycles occurs in spiders and crustacea as well as in insects but not as regularly as it does in insects. In spiders, the resulting pattern is called an alternating tetrapod gait. When ten or more legs are involved, as with crabs or crayfish, no special name is given to the gait.

Neural Control

Generating Rhythmic Movement

A full understanding of how animals walk must include an understanding of how the sequences of

Figure 2 Metachronal rhythm of an insect during walking. The diagram represents the stepping of an insect, with time running from left to right. The numbers and letters represent the legs of the insect (left), L1 for left front, R2 for right middle, and so forth. The black bars represent swings of each leg and the dots between bars represent periods when each leg is on the ground. For example, during the walking sequence shown in the diagram, the right rear leg (R3) begins with a swing and ends with a swing, whereas the right middle leg (R2) begins on the ground and ends on the ground. The solid-line ellipses show metachronal sequences of swings, rear, middle, and front legs on the right side. Note that the last swing of the first metachronal sequence (the swing of R1) overlaps the first swing of the next (the swing of R3). The dashed-line ellipses enclose the swings of the three legs that form each tripod, R3, L2, R1 and R2, L3, L1. The tripods form due to overlap between successive metachronal waves of movements. Reproduced from Wilson DM (1965) Proprioceptive leg reflexes in cockroaches. *Journal of Experimental Biology* 43: 397–409, with permission.

leg movements that animals use is generated. Legs move in a specific sequence because the muscles that control the legs are activated in a particular sequence. Muscles are made to contract by the activity of the motor neurons that innervate them. Hence, to understand how a particular sequence of leg movements is generated, one must understand how the nervous system is able to generate an appropriate sequence and pattern of motor nerve impulses in the neurons that control leg muscles.

Reaching such an understanding has been a major goal for neurobiological research for decades. The problem is not confined to invertebrates – the walking of vertebrate animals must also be understood in terms of the sequential activation of motor neurons. Hence, research on invertebrate animals has had an impact on our understanding of walking in vertebrates as well. In fact, some of the most fundamental ideas about how walking is coordinated and controlled have come from work on invertebrate animals.

The common feature of all locomotion, and indeed of any behavior involving repetitive, rhythmic movements, such as flying, swimming, or scratching, is an alternating extension–flexion sequence of a limb or other body part. Research on a variety of animals and many different kinds of rhythmic behavior has shown that in all cases the rhythm is generated in the nervous system by a small network of neurons dedicated to this task. The neurons are interconnected in such a way that, once activated, they will generate trains of nerve impulses that are directed first to extensor and then to flexor muscles. These neural networks are often referred to as central pattern generators (CPGs).

Two features of pattern-generating neural networks are noteworthy. First, although feedback from sense organs activated by the movement being generated plays a critical role in shaping the final movements in virtually all rhythmic behavior, it does not appear to be necessary for the generation of the basic rhythmic neural output. Instead, the alternating rhythm is produced as an emergent property of the neurons that together form the network. It is this property of a 'centrally' generated pattern, that is, one generated by the central nervous system without the necessity of external timing cues, that gives CPGs their name.

Second, among all the CPGs that have been studied, most are functionally based on reciprocal inhibition between some of the neurons in the network. Neurons are said to be reciprocally inhibiting if each neuron forms an inhibitory synapse on its partner. Although modeling studies have shown that a single pair of reciprocally inhibitory neurons can generate an alternating output when they receive some constant stimulation, no such simple network has been found in any animal, and it appears likely that more than a single pair of neurons is necessary in order to ensure the stability and robustness of the network's output.

Since CPGs generate alternating output to two sets of muscles, such as flexor and extensor muscles in a leg, it seems reasonable to assume that a single CPG generates the basic rhythmicity of each leg of a walking invertebrate. If this were the case, the output of the CPG during one phase of its activity would be to all the flexors of a limb, and the output during the other phase of its activity would be to all the extensors. Such an arrangement would require that all the flexor muscles and all the extensor muscles act synergistically, contracting essentially together. Kinematic studies of the movements of legs in walking insects suggest that the different segments of each leg do move in synchrony. Nevertheless, research has also shown that in some insects (stick insects), there is a single and separate CPG for each leg segment, meaning that at least three CPGs are necessary to control the movement of each leg. Multiple CPGs controlling a single limb have not yet been described in other arthropods. Simple observation suggests that they may well exist. Insects, for example, will move a leg rhythmically while grooming and searching for a foothold, but these movements are not identical to the movements that legs adopt during walking, indicating that there must be some way for the animal to flex and extend the segments of each leg in combinations other than those used during walking.

Coupling Rhythmic Generators

An important question in the field of motor control is how the different CPGs are coupled together functionally. Some sort of communication between the neural networks must be present to ensure that the different parts of the animal move with proper timing relative to one another. For CPGs that reside in the same ganglion of the nervous system (a single ganglion generally controls a single pair of legs in many insects and crustacea), neurons of one CPG may send branches directly to another CPG. Hence, it is believed that the multiple CPGs thought to control the movements of different segments of each single leg of an insect are able to communicate directly with one another without necessarily involving intermediary interneurons in order to ensure proper coordination.

The question of how movements of different legs are coordinated with one another is not so easily resolved, however, on both morphological and functional grounds. In some arthropods, such as flies, spiders, and crabs, the separate ganglia that control the movements of separate pairs of legs have fused into a single ganglionic mass. In these cases there could

be direct communication between CPGs, although such communication has not been demonstrated experimentally. In other arthropods, such as crayfish and cockroaches, each ganglion that controls movements of a single pair of legs is anatomically separate from its neighbor ganglia and connected to it by bundles of neurons. This means that in order for CPGs in these different ganglia to communicate with one another, they must do so via interneurons, neurons that travel from one ganglionic mass to another. There is physiological evidence in cockroaches and crayfish for the presence of interneurons that provide information to one CPG about the activity of another. However, this evidence provides little information about the detailed properties of such interneurons and how they might interact with CPGs to help ensure proper coordination.

Sensory Feedback and Rhythm Generation

The discussion so far has concentrated on coordination mechanisms that depend on information carried from one CPG to another within the central nervous system. But this is not the only way that coordination could in principle be achieved, and experiments show that in some arthropods coordination between legs does not depend at all on neuronal connections between the CPGs. Instead, coordination is achieved indirectly, through the influence of feedback from sense organs in the legs. The legs of all arthropods are heavily invested with sense organs, including many that provide information about leg position and movement and about the strains that are experienced by a leg. During walking, signals from such sense organs are directed back into the nervous system, where they can interact with CPG networks to ensure proper coordination of the legs.

The role of this sensory feedback varies from animal to animal, and in some cases it varies with the speed at which the animal walks. In the American cockroach, for example, which has an enormous range of walking speeds, sensory feedback is critical in ensuring the proper sequence of leg movements during slow walking but appears to have little influence when the insect is moving fast. At high speeds of walking, coordination appears to be achieved entirely via internal central nervous connections. Stick insects, on the other hand, which are generally slow moving, use sensory feedback extensively. Experiments on these insects have shown that without sensory feedback very little coordination between the movements of different legs is possible.

Control of Walking

By far the bulk of research on the walking of arthropods has focused on the problem of coordination, that is, on how the nervous system is able to generate the appropriate sequence of neural commands that allow the legs to move in a coordinated fashion. However, researchers also want to understand how the behavior is regulated. For example, how is walking started and stopped? How are the speed and direction of walking determined? These processes are controlled by the brain.

In insects, different regions of the brain interact to regulate starting and stopping. Cutting off the head of an insect, a procedure that severs the connections between the head and the rest of the body, essentially eliminates spontaneous locomotion altogether. Cutting the nerve trunks that connect the superesophageal and subesophageal ganglia (the two parts of an insect brain) produces an insect that walks nearly constantly, even continuing to move its legs after bumping into a wall. Recent studies of the effects of specific mutations of restricted areas of the brain have strengthened the view that the superesophageal ganglion contains centers that inhibit walking. Disruption of the mushroom bodies in the brains of *Drosophila* by targeted mutations tend to lengthen the durations of episodes of walking in these insects. Hence, the mushroom bodies may help provide the inhibition that the superesophageal ganglion typically exerts on the locomotor centers in the subesophageal ganglion. Mutation-induced lesions in other parts of the insect brain may also affect walking. Lesions of the central complex, for example, have been shown to disrupt coordination between legs on the two sides of the body, showing that not all coordination is a function of the ganglia in the thorax.

Regulation of speed and turning is also a brain function, but little is known about it. Speed of walking is hypothesized to be controlled by the level of excitation provided by the brain to the locomotor centers in the thorax, but how this is done is unknown. As for turning, it has been shown that electrical stimulation of specific brain regions in an insect can induce turning in one direction or another. Such observations have led researchers to infer that the direction and tightness of a turn are determined in the brain.

Behavioral observations of insects show that turns are accomplished mainly by differences in stride length. Strides on the side of the body toward which the insect is turning (the inside of the turn) are significantly shorter than those on the side away from the direction of the turn (the outside). Shorter steps for legs inside a turn has been seen in turning crayfish as well. Stride length may not be the only factor in turns. Studies in cockroaches have shown differences in the way in which muscles in the leg segments are used in legs inside and outside a turn. Furthermore, during sharp turns (turns with a very short radius), insects

may uncouple legs on the two sides of the body, in extreme cases even moving some legs backward while others move forward.

Modulation of Walking

Most studies of walking in arthropods have concentrated on the behavior with little regard for the context in which it is expressed. However, arthropods walk for many different reasons and under many different circumstances. Insects and spiders, for example, may walk on the stems of plants or on the ground. Some may seek sheltered areas under or along which they walk, and many use walking or running as a means to escape from predators or to capture prey.

Study of insects walking along narrow surfaces have shown that an alternating tripod gait may still be used by an insect walking along the stem of a plant but that the legs are adjusted so the feet can contact the stem under the insect's body. This indicates that the locomotor system can be quite flexible in the exact placement of the feet during walking.

A number of insects seek out a solid surface under or along which to walk. Cockroaches, for example, will maintain a more-or-less constant distance from a wall along which they are walking. If the wall curves, they turn along with it. If the wall is made jagged like the folds of an accordion and the insect is allowed to walk along it, the insect will follow the folds in the wall most of the time, weaving in toward and out away from the wall as appropriate. Studies suggest that the insect uses its antennae to assess the distance it is from the wall and adjusts its walking as necessary. Hence, although it is easy to think of straight walking on a smooth, level surface as being highly stereotyped, it is nevertheless true that the animal has excellent dynamic control of its locomotion and can modulate it as needed according to circumstances.

This can especially be seen in the case of escape running. Most insects avoid a disturbance by jumping or flying (or jumping and then flying). However, even though they have wings, some insects use walking as their primary means of escape. Cockroaches, for example, react to disturbances that may be airborne or delivered via touch to the body. Irrespective of the stimulus, the result is that the insect turns away from the stimulus, then begins to run. The turn has been analyzed both behaviorally and physiologically. If the stimulus strikes the animal from one side, the turn is effected mainly by a pivot around one or two feet on the side of the body away from the stimulus. Which feet are used depends on how the feet are positioned relative to the body when the stimulus is detected. The rear foot on the stimulated side provides most of the thrust for the turn. Once the insect has turned to the desired direction, leg movements transition into a typical tripod gait.

Physiological study of escape turns suggests that they are controlled by activation of neural centers in the ganglia containing the leg motor neurons. There the signal from the sense organs that have detected a disturbance activates the locomotor system, first effecting a turn if that is necessary. At the same time, neural signals are sent to the brain, which effectively takes over control of the subsequent forward running. Although rapid escape is usually considered an innate response that cannot be modified, a cockroach initiating an escape response toward a wall can turn away from the wall as soon as it senses it with its antennae even if the wall is so close that the insect can detect it after only a single step. This is another indication that the locomotor control system can be extremely flexible.

Practical Ramifications

Readers might expect that studies of walking in invertebrate animals, a rather esoteric subject, would have no practical impact. Certainly, study of the mechanisms by which insects and crustacea coordinate their legs has been important scientifically by showing how rhythmic movements of any kind are generated and coordinated. The demonstration by Pearson and Fourtner more than 30 years ago that a small network of nonspiking interneurons could generate the alternating flexion–extension movements of cockroach legs, for example, stimulated much research into the cellular makeup of CPGs in various animals.

However, the study of walking has had a significant practical impact as well. For centuries, engineers have been interested in constructing walking robots. Wheeled vehicles are superior for traveling on defined pathways like railways or roads. Modern off-road vehicles can also traverse unprepared ground. But if the ground is steep or rugged, wheels lose their advantage, and legs are more effective. In this context, the rapid and agile locomotion of many insects has long served as an inspirational model for engineers as they designed legged vehicles.

Early attempts at building walking robots used animals as models only in the sense that animals have legs and it was legs that engineers were trying to emulate. However, in recent decades, engineers collaborating with biologists have taken a further step. By carefully identifying salient features of the physical structure or locomotor control system of an animal and incorporating them into a walking robot,

engineers attempt to emulate the biological system in hardware. The resulting biomimetic robots generally have performance abilities that are not common in robots designed in more conventional ways. Among walking invertebrates, insects (cockroaches, stick insects) and crustacea (crayfish) have successfully been used as models for such robots. The features of the animal that have been emulated include the physical structure of the legs (cockroaches), the neuromuscular system (cockroaches, stick insects), the neural system used to coordinate walking (stick insects), and even some of the behavioral repertoire of the animal (cockroaches, crayfish).

Although biologists and engineers have collaborated to produce some remarkable robots, it is nevertheless true that even the best of these are not able to emulate the enormous agility, speed, and flexibility exhibited by many arthropods as they walk. There is little doubt, however, that we will see continued progress in the development of biomimetic robots, and what seems like science fiction today may well be reality tomorrow.

Wallerian Degeneration

S L Carroll, The University of Alabama, Birmingham, AL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The term Wallerian degeneration refers to a series of stereotyped, synchronized changes that occur in the distal segment of a peripheral nerve after this structure has been separated from its associated neuronal cell bodies by trauma or, less commonly, an ischemic event. Wallerian degeneration is named after Augustus V Waller, the scientist who first described this process in 1850. Over the decades since its initial description, it has been recognized that Wallerian degeneration shares many features with axonal degeneration, a common form of axonopathy that can be produced by numerous diseases, drugs, and toxins. Given these similarities and the fact that Wallerian degeneration is initiated by a single, precisely timed event (the severing of the nerve), Wallerian degeneration has proven to be an extremely useful experimental model that has provided valuable new insights into the mechanisms underlying axonal degeneration. Below, the morphological events that occur during Wallerian degeneration, the biochemical alterations that accompany these morphological changes, and how these changes prepare the nerve for subsequent regeneration, are considered. Then, the Wallerian degeneration in the peripheral nervous system (PNS) is compared to Wallerian degeneration in the injured central nervous system (CNS), highlighting the similarities and differences in these processes. Finally, the recent studies of the Wallerian degeneration slow (*Wld*^{s}) mouse, a spontaneously arising mutant that has fundamentally altered our understanding of axonal degeneration by demonstrating that this process is actively mediated by an axon death program distinct from apoptosis, are discussed.

Morphologic Changes during Wallerian Degeneration of Peripheral Nerve

The majority of studies of Wallerian degeneration have been performed using rodents (primarily rats and mice) as experimental models. Consequently, the timing of events described below is that observed in these animal models unless otherwise indicated. Wallerian degeneration has been studied in man and the findings compared to observations made in rodent models. The primary difference noted between Wallerian degeneration in man and in rodents is that many of the morphologic alterations described below take significantly longer to develop in human nerves, a feature that may be related to their much larger size. Other than these differences in timing, Wallerian degeneration in humans, rats, and mice is highly similar.

Axonal Changes Following Nerve Transection

For a short period after nerve transection, axon segments distal to the injury site remain intact. Although separated from the cell body of the neuron, these distal axon segments also remain capable of transmitting electrical impulses for 48–96 h (4–10 days in man, with the ability to conduct current typically lasting longer in lengthier distal nerve segments). Despite this continuing electrical responsiveness, morphologic changes begin to appear in the distal axon segment quite rapidly. Within hours, membranous organelles, glycogen, and atypical swollen mitochondria, which are normally transported along the axon, begin to accumulate in paranodal regions and adjacent to the lesion site on both the proximal and distal sides. Lysosomes also begin to accumulate in the paranodal and lesional regions by 2 h after injury. The accumulation of organelles in severed axon segments adjacent to the cut site is of a magnitude sufficient to enlarge the axon, thereby stretching and thinning the adjacent myelin sheath; however, this dilatation is typically of a lesser degree than is characteristic of the axonal spheroids that develop following interruption of a CNS axon. Within 12–24 h, axonal microtubules begin to become disorganized, heralding the dissolution of this portion of the axonal cytoskeleton. One to two days post injury, calcium ions enter the axon segment via calcium-specific channels and activate calcium-dependent calpain proteases which degrade the axonal neurofilaments. As these morphologic changes, which are known as granular disintegration, progress, the normal axonal cytoskeleton, axolemma, and axonal organelles are degraded, converting the axoplasm into a watery fluid filled with amorphous and granular debris. At the time granular disintegration occurs, the myelin sheath surrounding the axon, although stretched, is still intact.

Although the sequence of morphologic changes described above is widely accepted, the spatiotemporal pattern with which the final breakdown of the axon occurs has long been controversial. In large part, this reflects the technical difficulty of reliably distinguishing individual axons within a nerve during a prolonged period of observation and the fact that when axonal degradation occurs, it occurs quite rapidly. Early studies produced contradictory results, with some investigators reporting that distal axon segments degenerate in a proximal-to-distal direction

and others reporting that degeneration occurred either distally to proximally or simultaneously throughout the entire length of the axon. It was also suggested that the type of experimental injury used affected the pattern, with crush injury reported to produce degeneration that proceeded proximally to distally and cut injury resulting in simultaneous degradation of the entire distal axon segment. These issues have recently been clarified by studies performed with transgenic mice that express either yellow fluorescent protein (YFP) or green fluorescent protein (GFP) in small subsets of axons. When nerves in these animals were transected and axonal degeneration followed by imaging of nerve segments, it was found that axons transition from a fully intact state to a fully degraded state quite rapidly, with axons identifiable in a partially degraded state for less than an hour. Sequential imaging of the partially degraded axons indicated that degeneration occurred in a distal to proximal direction after a cut injury, while axon degeneration after a crush injury proceeds proximally to distally.

Schwann Cell Changes Following Nerve Transection

In noninjured peripheral nerve, myelinated and unmyelinated Schwann cells are mitotically quiescent differentiated elements whose primary function is to facilitate axonal conduction. Following injury, however, these glia dedifferentiate, proliferate, and activate a genetic program that enhances and guides the growth of regenerating axonal sprouts through the distal nerve segment and back to their original peripheral targets. It has long been believed that these changes in the post axotomy phenotype of Schwann cells are initiated by a positive signal sent from the injured axon. At this time, however, the nature of this axon-derived signal is unknown.

In the early stages of Wallerian degeneration, myelinated Schwann cells mediate the initial breakdown of their myelin sheath and associated distal axon segments. Minutes after nerve transection, widening of Schmidt–Lanterman incisures (channels in Schwann cells that run transversely across spiraled compact myelin layers and allow these layers to communicate with one another) can be observed in myelinated Schwann cells immediately distal to the injury site; by 24–36 h after injury, this same alteration is evident in Schwann cells throughout the more distal portions of the nerve segment. As the Schmidt–Lanterman incisures open up, the cytoplasm of myelinated Schwann cells begins to swell and compress associated axons. Twenty-four to forty-eight hours after nerve transection, myelin destruction begins. By light microscopy, the initial sign that myelin destruction is underway is the fragmentation of the myelin sheath into myelin ovoids that are contained in compartments in the Schwann cell cytoplasm known as digestion chambers (Figure 1). As Wallerian degeneration proceeds, digestion chambers are often found to also contain fragments of axoplasm. In subsequent days and weeks, myelin ovoids are further fragmented and cleared as macrophages begin to assist in the clearance of myelin and axonal debris (see below). Degeneration in unmyelinated Schwann cells occurs in a similar fashion except, of course, that myelin ovoids are not seen.

During development, Schwann cells that do not establish axonal contact undergo apoptosis. However, at least during the first few weeks post axotomy, apoptosis is not evident in the population of adult Schwann cells within denervated nerve segments.

Figure 1 Morphologic changes in peripheral nerve undergoing Wallerian degeneration. (a) Noninjured rat sciatic nerve. Note the relatively low cellularity and the orderly alignment of axons and their associated myelin sheaths. (b) Rat sciatic nerve distal to a site of crush injury performed 5 days previously. Cellularity is now increased relative to the noninjured nerve illustrated in (a) as the result of macrophage infiltration and Schwann cell proliferation. The arrow indicates one of the numerous Schwann cell digestion chambers evident in this field. A myelin ovoid is present within the indicated digestion chamber (the red roughly oval mass).

Indeed, adult Schwann cells, which heretofore have been mitotically quiescent, begin to proliferate rapidly within the confines of their original basal lamina. In rodents, Schwann cell mitogenesis peaks 3–4 days post axotomy and gradually declines thereafter, with only scattered proliferating Schwann cells evident in the distal nerve segment by 18 days after injury. As a result of this Schwann cell proliferation and accompanying macrophage infiltration (see below), the distal nerve segment becomes obviously hypercellular when examined by light microscopy. The proliferating Schwann cells layer upon one another within their basal lamina to form structures known as bands of Büngner or bands of von Büngner. The bands of Büngner are critically important for subsequent axonal regeneration as they form a substrate that will provide both structural and biochemical support for newly elaborated axonal sprouts as they elongate (see below).

Macrophage Recruitment and Action Following Nerve Transection

Injuries occurring at most sites in the body elicit an acute inflammatory response involving polymorphonuclear leukocytes which is subsequently replaced by a chronic inflammatory infiltrate rich in lymphocytes. Distal nerve segments undergoing Wallerian degeneration, however, typically contain only occasional polymorphonuclear leukocytes and lymphocytes. Instead, macrophages are the primary inflammatory cell type found in degenerating peripheral nerve. Studies using chimeric rats in which the grafted marrow cells have been GFP-tagged have demonstrated that resident macrophages are normally present in the endoneurium and that these cells become activated during Wallerian degeneration. Indeed, resident tissue macrophages are more abundant in peripheral nerve than is commonly appreciated, representing an estimated 2–9% of the endoneurial cell population in noninjured nerve. The action of the activated resident macrophages is complemented by an influx of large numbers of hematogenous macrophages that are recruited into degenerating distal nerve segments by a variety of signals including degenerating myelin (likely the most important signal), complement components, adhesion molecules, and factors derived from injured axons. Macrophage infiltration is also facilitated by opening of the blood–nerve barrier; this is triggered by the release of histamine, serotonin, and other substances from resident mast cells, which proliferate *in situ* during Wallerian degeneration. Magnetic resonance imaging studies following the fate of circulating macrophages tagged with superparamagnetic iron oxide particles and analyses of chimeric mice with GFP-tagged bone marrow cells demonstrate that hematogenous macrophages begin to infiltrate distal nerve segments 1 day after injury, with infiltration peaking 4 days post axotomy and markedly declining by 8 days after injury. Macrophage infiltration begins at the lesion site and proceeds in a proximodistal direction, paralleling the breakdown of the myelin sheath.

Once in the distal nerve segment, macrophages replace Schwann cells as the primary phagocytes. Unlike Schwann cells, whose phagocytosis of myelin is lectin mediated and opsonin independent, macrophage phagocytosis of myelin debris is dependent upon their expression of complement receptor type 3 and the presence of complement component C3 on degenerating myelin sheaths. Macrophages can phagocytose myelin debris lying free in extracellular spaces or they can remove this debris directly from the Schwann cell's cytoplasm via a poorly understood mechanism. Macrophages also facilitate the clearance of myelin debris by synthesizing and secreting apolipoprotein E, which scavenges lipid products for future reutilization. After macrophages finish clearing myelin and axon debris from the distal nerve segment, they are eliminated from the nerve both by local apoptosis and by re-entering the circulation and then migrating to regional lymph nodes and the spleen.

Neuronal Regenerative Responses Following Nerve Transection

In contrast to development, where loss of neuronal contact with its peripheral target frequently results in neuronal apoptosis, adult neurons that have undergone axonal transection most commonly survive. Shortly after nerve transection, the neuronal Nissl substance (rough endoplasmic reticulum) begins to disperse (a process known as chromatolysis), heralding a fundamental shift in their metabolism as they prepare for regeneration. Then, as the bands of Büngner and their associated supportive microenvironment form, neurons begin to put out regenerative sprouts from the stump of the axonal segment still associated with the neuronal cell body and from nearby nodes of Ranvier. Neurons typically put out many more sprouts than will be needed, with up to 25 sprouts arising from a single axon. These sprouts will, if possible, extend across the gap in the injured nerve to establish contact with the bands of Büngner in the distal nerve segment. Once this contact is established, the axonal sprouts begin to elongate along either the surface of Schwann cells within the band of Büngner or along the inner surface of the basal lamina that forms the boundary of these structures. It is clear that Schwann cells play an important supportive role in this process; irradiating distal nerve segments so as to kill Schwann cells within the bands of Büngner markedly impairs axonal regeneration. On

the other hand, it is also evident that Schwann cells are not the sole element within the distal nerve segment that promotes axonal regeneration. Regenerating axons do continue to grow along the basal lamina in irradiated nerve segments, albeit with a reduced rate of extension. Furthermore, *in vivo* imaging of GFP- and YFP-tagged axons regenerating after a crush injury (a injury which minimally disrupts the basal lamina) has provided an elegant demonstration that physical cues, likely provided at least in part by the basal lamina, allow regenerating axons to precisely retrace their original pathway and reform appropriate synaptic contacts with skeletal muscle.

As axonal sprouts re-establish contact with Schwann cells, the Schwann cells respond to axonal cues by beginning anew to elaborate myelin sheaths. Since multiple axonal sprouts are initially present and elongating along the band of Büngner, this results in the formation of groups of small, thinly myelinated axons (regenerative clusters) within a single basal lamina. With time, one of these axons will become dominant and the other sprouts will regress. The mechanisms responsible for precisely matching axon-Schwann cell numbers during regeneration are not understood.

Molecular Alterations Occurring during Wallerian Degeneration of Peripheral Nerve

Although it may seem paradoxical for a process that is described as a degeneration, Wallerian degeneration is accompanied by the increased expression of a number of molecules in the distal nerve segment. Over the last three decades, a variety of techniques have been used to identify transcripts whose expression is altered by nerve injury, including direct examination of individual candidate mRNAs, subtractive and differential hybridization and, more recently, microarray analyses. When examined at the tissue level, changes detected by these techniques reflect the sum of multiple alterations in gene expression occurring in multiple cell types endogenous to the nerve such as Schwann cells, fibroblasts, resident tissue macrophages, mast cells, and perineurial cells. Many of the apparent alterations in gene expression occurring during the first 7–8 days post axotomy also reflect the increase in the number of hematogenous macrophages migrating into the distal nerve segment. However, the majority of the axotomy-responsive genes identified to date are of Schwann cell origin. Axotomy-responsive genes expressed by Schwann cells encode multiple functional classes of proteins. These proteins include factors that promote demyelination, macrophage recruitment and macrophage activation, molecules that encourage axonal regeneration such as neurotrophic factors and cell adhesion molecules, and, as remyelination begins to occur, proteins necessary for myelin structure and synthesis.

By 2 days after nerve transection, myelinating Schwann cells have markedly decreased their expression of mRNAs encoding myelin proteins such as peripheral myelin protein-22 (PMP-22), myelin protein zero (P_0), myelin basic protein, myelin-associated glycoprotein (MAG), periaxin, and proteolipid protein (PLP). Following this decrease in the expression of myelin protein transcripts, Schwann cells in the distal nerve segment dedifferentiate to a state characterized by increased expression of the low affinity neurotrophin receptor ($p75^{LNTR}$), the intermediate filament glial fibrillary acidic protein, and the cell adhesion molecules L1 and neural cell adhesion molecule (NCAM) and decreased expression of Pax3, a transcription factor that represses myelin gene expression, and the transcription factor Krox-20. The phenotype of these dedifferentiated Schwann cells is similar to that of premyelinating and nonmyelinating Schwann cells. Because of this, the phenotype of dedifferentiated Schwann cells is often equated with that of Schwann cells during development. Such comparisons are potentially hazardous. While it is true that these cell types demonstrate many similarities, it is also clear that there are some important differences between dedifferentiated adult Schwann cells and developing Schwann cells (e.g., the ability of adult Schwann cells to survive when axon contact is lost).

As Schwann cells in the distal nerve segment dedifferentiate, they also begin to elaborate a variety of cytokines capable of recruiting macrophages such as interleukin-1β (IL-1β), stromal cell-derived factor 1 (SDF-1), tumor necrosis factor-α (TNF-α), macrophage inflammatory protein-1α (MIP-1α), and monocyte chemoattractant protein-1 (MCP-1). As macrophages are recruited into the injured nerve segment, they too begin to elaborate TNFα, interleukin-1α (IL-1α), and IL-1β. Injecting neutralizing antibodies that inhibit the action of MCP-1 or MIP-1α both reduces macrophage recruitment into degenerating peripheral nerve and impairs phagocytosis of myelin debris. Although IL-1β neutralizing antibodies do not effectively inhibit macrophage recruitment, they do similarly interfere with myelin phagocytosis. The role played by other cytokines expressed in degenerating nerve is still incompletely understood.

Dedifferentiated Schwann cells in degenerated peripheral nerve also begin to express a variety of neurotrophic factors such as nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), leukemia inhibitory factor, fibroblast growth factor-2 (FGF-2), insulin-like growth factor I (IGF-I) and its receptor,

and glial cell-derived neurotrophic factor (GDNF) and its GFRα receptor subunit. These molecules are thought to provide trophic and tropic support for regenerating axons, enticing and guiding them along the bands of Büngner so that physiologic function can be restored. Dedifferentiated Schwann cells likewise begin to express increased levels of cell surface molecules such as NCAM, L1, ninjurin-1, ninjurin-2, tenascin, and N-cadherin. These cell adhesion molecules mediate intercellular interactions and thus likely play a role in guide elongating axons along the length of denervated nerve segments.

Some recent observations have provided insight into the identity of the molecules that trigger demyelination in axotomized peripheral nerve. Proteins in the neuregulin-1 (NRG-1) family of growth and differentiation factors potently regulate the proliferation, survival, migration, and differentiation of developing Schwann cells *in utero* and during early postnatal life. Schwann cell expression of class II NRG-1 isoforms (also known as glial growth factors; GGFs) and their erbB receptors (erbB2 and erbB3) is induced in injured sciatic nerve beginning at 3 days post axotomy, a time that coincides with the onset of Schwann cell proliferation induced by nerve injury, and continuing to at least 30 days post axotomy. Tyrosine phosphorylation (an indirect indication of activation) of erbB2 and erbB3 becomes evident in nerve with a similar time course. Based on these observations, it was initially suggested that increased class II NRG-1 expression and erbB receptor activation promoted Schwann cell mitogenesis in injured nerve and potentially had other effects such as triggering demyelination. Consistent with these observations, transgenic mice overexpressing the class II NRG-1 isoform GGFβ3 in myelinating Schwann cells demonstrate Schwann cell hyperplasia and develop a demyelinating hypertrophic neuropathy. While GGFβ3 clearly is promitogenic for Schwann cells in adult nerve, it may not be required for proliferation as transgenic mice with an inducible genetic ablation of erbB2 in adult Schwann cells do not demonstrate a decrease in post axotomy Schwann cell proliferation. However, it is quite clear that treating myelinated Schwann cell–neuron co-cultures with GGF induces demyelination in a concentration-dependent manner, consistent with the phenotype of GGFβ3 overexpressing mice. Intriguingly, the effects that NRG-1 exerts on Schwann cells may be distinct for different NRG-1 subfamilies. In contrast to the demyelination observed in transgenic mice overexpressing class II NRG-1 in Schwann cells, transgenic mice overexpressing class III NRG-1 in neurons develop hypermyelination rather than demyelination. In further support of the hypothesis that NRG-1 effects on myelination are subfamily specific, transgenic mice overexpressing class I NRG-1 in neurons show no abnormalities of myelination. These latter studies have focused on NRG-1 effects on myelination during development; it remains to be determined whether class III NRG-1 isoforms are critical for the re-establishment of myelination in regenerating nerve.

A Comparison of Wallerian Degeneration in the PNS and CNS

Transection of axons whose length lies entirely within the CNS also results in degeneration of the distal nerve segment. However, both the specifics of this CNS process and the ultimate outcome are clearly distinct from those seen with Wallerian degeneration in the PNS. Because of this, purists argue that it is not appropriate to refer to posttraumatic axonal degeneration in the CNS as Wallerian degeneration. In contrast to this perspective, a growing body of evidence indicates that the mechanisms underlying the active degeneration of transected axon segments (see below) are similar in the PNS and CNS. Consequently, it is increasingly clear that there are at least some important similarities between Wallerian degeneration in the PNS and in the CNS.

In both the PNS and the CNS, degeneration of the severed distal axon segment occurs before the destruction of myelin sheaths associated with the degenerating axon. However, thereafter these processes diverge. Wallerian degeneration in the CNS is slower than Wallerian degeneration in the PNS. Furthermore, oligodendrocytes, unlike Schwann cells, do not form structures equivalent to the bands of Büngner and thus fail to establish a microenvironment supportive of axonal regeneration. This latter difference clearly reflects the distinct nature of the relevant glia (and the presence of inhibitory molecules such as Nogo in the CNS) rather than differences in the PNS and CNS neuronal populations; in a classic set of experiments, Aguayo and colleagues showed that CNS neurons will extend processes readily into peripheral nerve grafts transplanted into a CNS injury site. Myelin debris is also removed more slowly during Wallerian degeneration occurring in the CNS. This may be because the macrophages responding to CNS Wallerian degeneration are not hematogenously derived and thus likely differ functionally from the macrophages responding to nerve injury. Given these differences, it seems most appropriate to equate the similarities in axonal degeneration seen in CNS and PNS Wallerian degeneration and to be extremely cautious when comparing other aspects of Wallerian degeneration in the PNS and CNS.

Recent Findings Indicating that Axonal Degeneration Results from Active Self-Destruction Rather than Simple Atrophy of Severed Axons

For decades after the initial description of Wallerian degeneration, it was thought that degeneration of distal axon segments occurred because axonal transport had been interrupted, resulting in atrophy that was secondary to the disruption of metabolic communication between the axon and the neuron cell body. This notion was challenged by the unexpected discovery of a spontaneous mouse mutant that demonstrated abnormal Wallerian degeneration in both the PNS and the CNS. In these Wallerian degeneration slow mice (*Wld*^{s} mice, previously known as C57BL/Ola mice), the distal segments of transected axons remain viable and capable of conducting action potentials for up to 3 weeks. Experiments with bone marrow chimeric and sciatic nerve chimeric mice have demonstrated that prolonged axon survival in *Wld*^{s} mice results from an alteration intrinsic to the axon itself. The *Wld*^{s} mutation is inherited as an autosomal dominant trait that maps to the distal arm of chromosome 4. An 85 kb tandem triplication present at this site encodes a chimeric nuclear protein in which the NH_2-terminal 70 amino acids of the 1173-residue-long E4b ubiquitination factor (UbE4b; also known as ubiquitin fusion degradation protein 2a (Ufd2a)) is fused in frame to the entire coding sequence of the NAD+ synthesizing enzyme nicotinamide adenylyltransferase 1 (NMNAT1). Expression of this chimeric gene under the control of a β-actin promoter confers the *Wld*^{s} phenotype on wild-type mice. Considered together, these findings indicate that axonal degeneration results from the action of an active axon death program rather simply a passive atrophic process. The localization of the UbE4b/NMNAT1 fusion protein to neuronal nuclei implies that this mutant protein acts indirectly via other as yet unknown molecules that are localized to axons.

In addition to its intriguing effects on Wallerian degeneration, the phenotype of the *Wld*^{s} mutant mouse also has important implications for the mechanisms underlying other nervous system disease states in which the axon of a diseased neuron progressively degenerates from the distal portions of the axon toward the cell body. These dying back axonal degenerations occur in a variety of medically important peripheral neuropathies (e.g., diabetic neuropathy) and have been suggested to contribute to neurodegeneration in a variety of CNS diseases such as Alzheimer's disease, Parkinson's disease, and motor neuron disease. Consistent with this latter hypothesis, dying back axonal degeneration is delayed in progressive motor neuronopathy (*pmn*) mice crossed to *Wld*^{s} mice. Similar results have been obtained by crossing *Wld*^{s} mice to gracile axonal dystrophy (*gad*) mice or mice with a null mutation of the P_0 gene (a model of hereditary motor and sensory neuropathy IB/Charcot–Marie–Tooth disease type 1B), two other models thought to involve a dying back axonopathy. The *Wld*^{s} gene also confers resistance to peripheral neuropathy induced by vincristine toxicity. The ability of the *Wld*^{s} mutation to inhibit the progress of these PNS and CNS diseases thus provides a clear mechanistic link between Wallerian degeneration and dying back axonopathies.

Several lines of evidence indicate that the axon death program is distinct from the apoptosis program typically associated with neuronal cell death. Culture systems in which the distal axons of wild-type sympathetic neurons are locally deprived of NGF results in degeneration of the distal axon while the remainder of the axon and the cell body survive. In contrast, in *Wld*^{s} sympathetic neurons deprived of NGF, axons remain viable long after the cell body has undergone an apoptotic death. These observations are consistent with the finding that inhibitors of caspase action do not prevent Wallerian degeneration and that activated caspase-3 and cleavage products resulting from caspase action are not found in transected axons. In addition, mutations that prevent apoptosis such as overexpression of the anti-apoptotic molecule Bcl2 or genetic ablation of the pro-apoptotic molecules Bax and Bak do not prevent axonal degeneration. Finally, the UbE4b/NMNAT1 fusion protein encoded by the *Wld*^{s} gene bears no structural similarity to any of the known anti-apoptotic proteins.

At present, little is known about the mechanism or the downstream molecules involved in the axon death program. Initial attempts to establish the function mediated by the UbE4b/NMNAT1 fusion protein essential for delaying Wallerian degeneration focused on the possibility that this protein modulates the action of the ubiquitin–proteasome system. Consistent with this hypothesis, inhibiting the action of the ubiquitin–proteasome system pharmacologically or by overexpression of the ubiquitin protease UBP2 has been found to delay Wallerian degeneration in cultured sympathetic neurons and in transected optic nerve *in vivo*. However, it was subsequently found that overexpressing the UbE4b fragment from the UbE4b/NMNAT1 fusion protein in dorsal root ganglion neurons was not sufficient to delay axonal degeneration following transection or vincristine treatment. In contrast, both overexpression of NMNAT1 and administration of NAD prior to injury delays axonal degeneration induced by both of these

treatments. Both NMNAT1 overexpression and pretreatment with NAD seem to act through the NAD-dependent deacetylase SIRT1 as inhibiting the action of this deacetylase by RNA interference or with a small molecular inhibitor blocks the delay in Wallerian degeneration; enhancing SIRT1 action with a specific activator similarly delays Wallerian degeneration. Of note, SIRT1, like the UbE4b/NMNAT1 fusion protein, is expressed in the nucleus. Consequently, the axonal effectors cooperating with the UbE4b/NMNAT1 fusion protein to delay Wallerian degeneration are as yet completely unknown.

Wilson's Disease

J A Ghika, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland

© 2009 Published by Elsevier Ltd.

In 1912, Kinnier Wilson described with some detail a disease previously recognized by Frerichs (1861) and Westphal (1883) characterized by various neurological manifestations, such as tremor, rigidity, spasmodic contractions, emotionalism, and mental symptoms, which he concluded were related to lesions of the lenticular nucleus. Four years later, Bramwell reported the case of seven children, four of whom died of liver failure, and proposed that the neurological manifestations of the disease could be preceded by liver dysfunctions. The disease is now referred to as Wilson's disease, or hepatolenticular degeneration, and it is known to be a disorder of copper metabolism. It is inherited as an autosomal recessive trait, lethal if not treated and reversible if treated early enough with chelation of copper. The gene responsible for the defect has recently been isolated and found to code for a copper-transporting protein referred to as ATP7B (WDNP), a P-type ATPase on chromosome 13q14.3-q21.1. The prevalence of the disease is low, between one and four cases in 200 000, and only individuals homozygous for the abnormal gene suffer from clinical manifestations, but the prevalence of heterozygotes is 1 in 100.

Pathogenesis

One of the major alterations observed in this disease is an accumulation of copper in the body tissues. Copper, which is a component of an ordinary diet (2–5 mg day^{-1}), is, after Zn and Fe, the third most important trace element in the body with a mean amount of 75–150 mg. Seafood, nuts, mushrooms, cereals, and liver are the main sources. It is found essentially in muscles, bones, liver, and pigmented nuclei of the brain, mostly in glial cells, where it is used as a cofactor of different mitochondrial, cytoplasmic, or nuclear metalloenzymes (cytochrome oxidase, superoxide dismutase, tyrosinase, dopamine beta hydroxylase, monoamine oxidase), but it also plays a role in the synthesis of hemoglobin and melanin, absorption of iron, energy production, collagen and elastin bridges, and mitochondrial function. In the brain, the highest concentrations of copper are found in locus coeruleus and substantia nigra, where copper is associated with dopamine beta-hydroxylase, the enzyme that catalyzes the conversion of dopamine to noradrenaline, followed by the striatum, pons, thalamus, cerebellum, and spinal cord. Over 90% of the copper absorbed in the intestinal epithelial cell under the regulation of hepatic ATP 7B, bound to metallothionein, is transported in the blood associated with ceruloplasmin, a 151 kDa protein synthesized by the liver, that binds up to six atoms per molecule. Other copper-binding proteins include albumin, apoceruloplasmin, and cuprophilin. Copper is removed from the blood by hepatic uptake and then partially excreted in the bile. Normal plasma concentrations are 0.05–1.10 mg dl^{-1}. In Wilson's disease, copper accumulates at toxic levels by deficient intracellular access and biliary and urinary excretion in various organs.

Recent progress achieved by combining genetic analyses and molecular biology techniques has made it possible to identify and clone the gene responsible for the disease, located between markers q14 and q21 on chromosome 13. Interestingly, the DNA sequence of this gene was found to have marked homologies with that responsible for Menkes disease, another recessive but X-linked disturbance of copper metabolism associated with abnormal hair and severe, progressive neurodegeneration. The symptoms observed in Menkes disease have been attributed to a lack of important copper enzymes, probably because of copper deficiency in specific intracellular organelles. It must be noted, however, that copper deficiency in Menkes disease occurs despite excessive accumulation of the metal in various tissues. In both diseases, the affected genes appear to code for copper-transporting proteins referred to as ATP7A (for Menkes disease) and ATP7B (for Wilson's disease), which are P-type ATPases with metal-binding regions similar to those found in prokaryotic heavy metal transporters. Many patients suffering from Wilson's disease or Menkes disease have now been reported to have deletions or mutations within the coding region of these homologous genes. More than 300 different mutations of the gene ATP7B have so far been described, and 80 polymorphisms and the mutations that affect more severely the gene or protein are also responsible for earlier and more dramatic hepatic disturbances. Based on these new findings, Wilson's disease can be attributed to the expression in liver, but probably other organs as well, of a defective transporter for copper. This results in abnormal metabolism of copper by the hepatocyte and reduced excretion in the bile. It is also interesting to note that a usual finding in patients suffering from Wilson's disease is a reduced level in serum ceruloplasmin, a finding that remains unexplained.

In Wilson's disease, hepatic copper accumulation starts very early during the first years of life. This

process begins asymptomatically until hepatic copper-binding sites are saturated. Then hepatic insufficiency and hepatocellular necrosis may develop, and copper accumulates in other tissues. The most affected organs are the brain, erythrocytes, and kidneys. Copper deposition also usually occurs in the Descemet's membrane of the cornea, forming a golden-brown pigment ring known as the Kayser–Fleischer ring. This constitutes one of the most pathognomonic signs of the disease.

The clinical manifestations of Wilson's disease seem to be directly related to a toxic effect of copper in the different regions where it accumulates. If copper is removed, a recovery from both the hepatic and neurological signs results. The mechanisms of copper toxicity are, however, not yet clearly understood. In the brain, lesions predominate in the basal ganglia, although they may also be seen in the subthalamic nucleus, thalamus, claustrum, myelinated fiber bundles, or even brain stem, spinal cord, and cerebral cortex. An enlargement of ventricles is usual, as well as an atrophy of cerebral cortex. Histological findings include an increase in the size and number of protoplasmic astrocytes, many of which become multinucleated, and a degeneration of neurons and glial cells, a process which may lead to cavitations. Cell death is not restricted to a specific type of neurons, but it is more important in basal ganglia than in cerebral cortex. Vascular changes may also be seen, consisting of capillary swelling and proliferation. These lesions are not specific for Wilson's disease and may also be seen in cases of hepatic encephalopathy. Thus, they probably reflect general suffering of neurons, and their distribution might be related to regional differences in vulnerability. Copper toxicity could result from different mechanisms, including severe mitochondrial dysfunction, production of free radicals, and increased oxidation, which all could affect energy metabolism and membrane integrity.

Clinical Picture

Wilson's disease generally starts during the second decade (range between 6 and 35 years; cases over age 40 are extremely rare), as a liver disease (50–60%) or with neurological symptoms (30%), and sometimes with both. Patients may present with other systemic manifestations such as osteoarticular (10%; osteoarthropathy, osteomalacia), cardiac (1–2%; cardiomyopathy), ophthalmological (2%), or hematological (2%; hemolytic anemia) symptoms. Isolated cases starting with endocrinological (hypoparathyroidism, pancreatitis) or renal (Fanconi syndrome) symptoms have been reported. Asymptomatic cases can be found by serendipity, but fulminant hepatocerebral forms, generally with hemolytic anemia, are most dramatic. Genotype–phenotype correlations start to be reported in some detail, but nonsense and frameshift mutations seems to be associated with an earlier and more severe course of disease.

The liver dysfunction in patients with Wilson's disease is either an asymptomatic high level of transaminases or a chronic, recurrent hepatitis with icterus, nausea, vomiting, and asthenia which may rapidly progress to cirrhosis with hepatic failure and portal hypertension. At this stage of the disease, copper deposition will occur in extrahepatic organs.

Neurological symptoms are essentially an atypical cortico-bulbar syndrome and dystonic syndrome with important dysarthria, potentially dangerous dysphagia, hoarseness of the voice, drooling, emotional lability, and a strange 'vacuous or sardonic smile.' Other symptoms include slowness of distal motility, corticospinal signs, parkinsonism (bradykinesia, rigidity, posture, and gait abnormalities), tremor or involuntary movements (choreo-athetosis, dystonia, or exceptionally myoclonus), and, rarely, epilepsy. Psychiatric symptoms are very frequent. In 10–15% of the cases they precede the neurological symptoms and are essentially personality changes, mood disorders or behavioral changes (aggressivity, disorders of impulse control, asocial behavior, depression, suicide, anxiety, emotional lability, bipolar mood disorders, mania, obsessive-compulsive disorders, apathy, mental anorexia, social withdrawal, psychosis such as paranoia, delusions, hallucinations, catatonia, or confusion), or sleep disorders. Cognitive deficits (slowing of cognitive processes and dysexecutive syndrome) up to dementia or loss of school performance are exceptional. Supranuclear oculomotor disturbances (slow saccades, gaze distractibility, apraxia of lid opening, recurrent ophthalmoplegia, accommodation, or acute blindness) are sometimes found. Brown-yellow Kayser–Fleischer rings at the corneal limbus are present in almost 100% of the cases with neurological symptoms. Sometimes, however, they are only unilateral or can only be seen with a slit lamp. Sunflower cataract can also be found.

Due to the variability of the clinical picture, diagnosis is sometimes difficult and usually delayed. It can be confirmed by decreased serum ceruloplasmin ($<20\,\mathrm{mg\,dl^{-1}}$) and copper levels ($<80\,\mu\mathrm{g\,dl^{-1}}$), high 24 h copper urine excretion ($>100\,\mu\mathrm{g\,24\,h^{-1}}$), high transaminase levels, and slit lamp eye examination, but the gold standard remains the quantitative determination of copper in liver tissue from biopsy by mass spectrometry with values between 250 and 3000 $\mu\mathrm{g\,g^{-1}}$ dry tissue. An atypical form with apoceruloplasmin deficit has been described. Glucosuria, aminoaciduria, phosphaturia, and bicarbonaturia (Fanconi syndrome) may also be present. High levels of copper in hepatic

biopsy can be found. Brain atrophy and hypodensities or low signals are usually found in the basal ganglia on computed tomography (CT) scans. Studies carried out using magnetic resonance imaging (MRI) have typically reported high T2 weighted signals in the basal ganglia (caudate and lenticular nuclei, thalamus), but also in the hemispheric and cerebellar white matter. Abnormal high intensity signals have also recently been found in the midbrain ('face of the giant panda' sign with high intensity signals in the tegmentum, but not in red nucleus, preservation of signal intensity in the lateral portions of the substantia nigra and hypodensities in the superior colliculus, pons, and dentate nucleus). Definitive diagnosis of the disease as well as prenatal diagnosis can now be made by genetic analyses.

Treatment and Perspectives

The major objective of treatment is to reduce the accumulation of copper in liver and other tissues. This may be achieved in two ways: by using chelating agents, such as D-penicillamine or trientine, which remove copper from tissues, or by inhibiting the absorption of copper from the intestinal tract using potassium sulfide, zinc salts, tetrathiomolybdate, or a low-copper diet (no liver, cacao, chocolate, nuts, mushrooms, shellfish). Hepatic graft, hemofiltration, and plasmapheresis are reserved for fulminant or end stage presentations.

The first method is most commonly used. Treatment usually results, after an initial worsening of the symptoms, in a significant improvement of both hepatic and neurological manifestations. Cases of successful pregnancies under treatment have been reported. Occasionally recovery of organic lesions may be observed. Kayser–Fleischer rings as well as hypodensities or hyposignals in the basal ganglia will eventually disappear on CT scans. Improvement of high signal intensities seen on MRI scans as well as of striatal dopamine D2-receptor binding has also recently been reported following treatment. Techniques such as MRI, positron emission tomography, and recording of sensory evoked potentials are thus very helpful not only for the diagnosis of the disease, but also to assess the extent of structural alterations of the brain and the efficacy of treatment. Another interesting aspect concerns results obtained with positron emission tomography using 2-deoxy-2-fluoro-D-glucose or F-6-fluorodopa, which may show metabolic dysfunctions before lesions are seen on CT or MRI scans. This will certainly help clarify the sometimes poor correlations observed between clinical pictures and structural alterations.

The very important progress achieved in the last years with the identification of the Wilson's disease gene has opened new perspectives concerning the introduction of new therapies for this disease, among which gene therapy will probably represent an important goal.

Wilson's disease can be confounded clinically with hereditary hypoceruloplasminemia, paraneoplastic copper accumulation, acquired hepatocerebral degeneration (parenteral nutrition, hepatopathies, hemochromatosis, Nieman–Pick C disease, sea-blue histiocyte or mitochondrial diseases, schizophrenia, Reye syndrome, pantothenate kinase-associated neurodegeneration (PKAN) or other generalized dystonias, cerebellar degeneration, Huntington's disease, or atypical Tourette syndrome).

Wnt Pathway and Neural Patterning

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

The Wnt pathway is a complex signal transduction pathway triggered by secreted ligands of the Wnt family, named after its two original members, the products of the *wingless* gene from *Drosophila melanogaster* and the mammalian gene *Int-1* (now known as *Wnt-1*). Wnt signaling is involved in many different embryonic processes, including the fundamental pattern-forming stages that establish the nervous system in insects and vertebrates. Many of the components of the these developmental pathways were first identified in *Drosophila* and in the African clawed frog *Xenopus laevis* and have since been extrapolated to other organisms, including mammals. Wnt signaling is also involved in many later processes in the nervous system, including synaptic specialization, microtubule dynamics, synaptic protein organization, modulating synaptic efficacy, and regulating neuronal gene expression.

There are at least 20 distinct Wnt genes in vertebrates, organized into 12 conserved subfamilies. Not all vertebrates have orthologs of all members of the Wnt family. At the time of writing, 19 Wnt genes have been found in humans and mice and 16 in *Xenopus*. Only six of the vertebrate Wnt subfamilies have counterparts in *Drosophila*, while at least 11 are present in sea anemones, indicating selective evolutionary loss of different Wnt classes during the branching of the animal lineage.

The vertebrate Wnt proteins can be grouped by biological activity using functional assays. The overexpression of some Wnt proteins induces secondary axis formation in early *Xenopus* embryos and transforms C57MG mammary epithelial cells, while other Wnt proteins do not act in this way and can even antagonize the transforming Wnt proteins, hinting at the existence of different, competing signaling pathways. Currently, five different pathways are known to be activated by Wnt proteins: a canonical Wnt/β-catenin cascade, a divergent canonical pathway involved in synapse modeling and axon growth, the noncanonical planar cell polarity (PCP) pathway, the Ca^{2+} pathway (which is involved in the control of cell migration), and a microtubule-dependent pathway.

Secretion of the Wnt Protein

Wnt proteins are secreted from the cell and therefore carry an N-terminal signal sequence targeting them for cotranslational import into the endoplasmic reticulum. During their journey through the secretory pathway, they undergo several forms of posttranslational modification, including N-linked glycosylation and palmitoylation of specific cysteine residues. Not all Wnt proteins undergo both types of modification, but when palmitoylation occurs the added lipid moiety appears essential for Wnt function. The presence of a lipid group also makes the Wnt protein hydrophobic and insoluble, which contributes to the difficulty in purifying many Wnt proteins from cell culture media. In *Drosophila*, the product of the *porcupine* gene is required for Wnt palmitoylation and has been identified as an acyltransferase. Another gene, *wntless*, encodes a transmembrane protein which co-localizes with the Wingless protein inside the cell and is required for trafficking through the Golgi apparatus. Vertebrate orthologs of both proteins have been identified.

One of the main characteristics of Wnt proteins is their ability to function as developmental morphogens – that is, molecules that establish long-range concentration gradients that enable them to influence cell fates differently, according to the cell's position along the gradient. It has been unclear how Wnt proteins achieve such a gradient given their poor solubility, although it has been proposed that the proteins remain tethered to the plasma membrane, or to intercellular transport vesicles or lipoprotein particles. Alternatively, Wnt proteins may travel along cytonemes, which are long, thin filopodial processes that can bridge several cells. A further possibility is that extracellular heparan sulfate proteoglycans (HSPGs) may be involved in the transport of Wnt proteins and the establishment of morphogen gradients. As soon as they are secreted, Wnt proteins interact with glycosaminoglycans in the extracellular matrix and bind tightly to the cell surface, another factor which makes them difficult to isolate in cell culture. In *Drosophila*, the Wingless protein is found in specialized membrane vesicles called argosomes that are thought to be derived from lipid raft microdomains, and the incorporation of the protein into these vesicles requires HSPGs. Mutations in genes such as *dally*, which encodes components of this HSPG system, cause phenotypes similar to those resulting from mutations in *wingless*. Six HSPGs have been identified in vertebrates, and mouse knockouts confirm that Wnt signaling is disrupted in such animals.

Canonical Pathway – Wnt Receptors and Alternative Ligands

Wnt proteins bind to the cysteine-rich extracellular domain of seven-pass transmembrane receptors of the

Frizzled (Fz) family, named after the founder member identified in *Drosophila*. There are at least four Fz family genes in *Drosophila* and at least ten in vertebrates, but the complexity of signaling is much greater since different Wnt proteins can interact with more than one receptor and different Fz proteins can bind more than one ligand. Promiscuous as it is, the interaction between Wnt and Fz requires a number of additional factors, including a membrane-bound protein encoded by the *arrow* gene in *Drosophila*, and represented by two homologous lipoprotein receptor-related proteins (LRPs) called LRP5 and LRP6 in vertebrates. Wnt proteins can bind directly to LRPs and there is evidence that Wnt, Fz, and LRP form a ternary complex. Delivery of the Arrow protein depends on the presence of a molecular chaperone encoded by the *boca* gene, and in vertebrates this function is fulfilled by the homologous mesoderm development (Mesd) protein. Mutations in *arrow/Lrp* genes and in *boca/Mesd* result in phenotypes similar to those of *wingless/wnt* mutants.

The Fz/LRP receptor complex interacts not only with Wnt proteins, but also with alternative ligands that can act as agonists or antagonists to Wnt signaling. An example is Norrin, which binds to Fz4/LRP5. This is a cysteine knot protein identified through investigation of the human developmental disorder Norrie disease, which is characterized by major eye vascular defects. Another example is the family of proteins known as R-spondins. In *Xenopus*, R-spondin-2 is a Wnt agonist that synergizes with Wnt signaling to activate β-catenin in muscle development. In contrast, proteins of the Dickkopf family inhibit Wnt signaling by sequestering LRP5/LRP6 and then cross-linking them to an unrelated class of transmembrane proteins known as Kremens, thus promoting internalization. The sclerosteosis-associated SOST/sclerostin family of Wnt antagonists also acts by sequestering LRP5/LRP6. The soluble Frizzled-related proteins (SFRPs) are also Wnt antagonists, but these work by sequestering the Wnt proteins. This is possible because the SFRPs contain cysteine-rich domains that mimic the genuine Fz protein. They may either bind Wnt proteins in isolation, or form inactive complexes along with Fz. However, certain combinations can promote rather than inhibit Wnt signaling, perhaps by stabilizing the Wnt signal in a manner that preserves its ability to interact productively with Fz/LRP.

Canonical Pathway – Events in the Cytosol

The formation of a stable Wnt/Fz/LRP complex facilitates the phosphorylation and activation of a cytosolic protein called Dsh (from the *Drosophila* gene *disheveled*), which interacts with the cytosolic face of the complex. The activated Dsh protein is then able to disrupt a so-called destruction complex comprising three additional proteins: glycogen synthase kinase-3 (GSK-3), axin, and adenomatous polyposis coli (APC) protein. In the absence of activated Dsh, these three proteins would normally phosphorylate β-catenin, leading to its ubiquitinylation and proteasomal degradation. When the destruction complex is disassembled, β-catenin is stabilized and some of it can be imported into the nucleus, where it interacts with transcription factors of the T cell factor/lymphoid enhancer factor (TCF/LEF) family to activate the transcription of target genes (Figure 1).

The receptor complex Wnt/Fz/LRP interacts not only with Dsh but also with axin, one of the components of the destruction complex. Axin is the scaffold for the destruction complex, so all of the other components bind directly to it. The interaction between axin and the cytoplasmic tail of LRP is mediated by direct contacts with phosphorylated residues. Axin will not interact productively with LRP unless the tail is phosphorylated on multiple serine/threonine residues, and phosphorylation occurs only when Wnt binds to the receptor complex. The phosphorylation of these residues is carried out by GSK-3 and another kinase called caseine kinase I (CKI), which is also anchored to the

plasma membrane. These two kinases phosphorylate different sets of serine/threonine residues on the LRP tail and both are required for transduction of the Wnt signal. The remaining component of the complex, APC protein, is an essential protein, but its precise role is unclear. It has been proposed that APC protein is required for efficient shuttling and loading/unloading of β-catenin onto the cytoplasmic destruction complex. Both APC protein and axin can be phosphorylated by their associated kinases, changing their affinity for other components of the destruction complex.

In the absence of Wnt, β-catenin is phosphorylated by CKI and GSK-3, and in its phosphorylated state it can be recognized by a transducin repeat-containing protein (β-TrCP), a component of a dedicated E3 ubiquitin ligase complex. The β-catenin protein is thus ubiquitinated and destroyed by the proteasome. In the presence of Wnt, the kinase activity of CKI and GSK-3 is inhibited, and β-catenin is able to translocate into the nucleus. Certain protein phosphatases may antagonize CKI and GSK-3, thereby promoting β-catenin stability.

Canonical Pathway – Events in the Nucleus

It is presently unclear how β-catenin is imported into the nucleus, although the process is dependent on a nuclear localization signal and β-catenin has been shown to interact with nuclear pore components. It is possible that β-catenin may shuttle from nucleus to cytoplasm in concert with axin and/or APC protein, and may be retained in the nucleus by associating with anchor proteins such as Pygopus. The role of β-catenin in the nucleus is to interact with transcription factors in the TCF/LEF family and prevent the formation of a repressive complex with proteins of the Groucho family via physical displacement. The TCF/LEF family is represented by a single protein in *Drosophila* and four paralogs in vertebrates. The replacement of Groucho with β-catenin facilitates TCF/LEF binding to the minor groove of DNA at highly conserved target sites characterized by the presence of purines on one strand and pyrimidines on the other. The binding results in the introduction of a tight kink into the DNA backbone, and allows β-catenin to bind to chromatin components such as Brahma-related gene 1 (Brg-1) protein – part of the mating-type switch/sucrose nonfermenting (SWI/SNF) chromatin remodeling complex – and histone acetylase cAMP response element-binding (CREB)-binding protein (CBP), to promote transcriptional initiation. TCF/LEF is also regulated via other pathways, and phosphorylation via the activation of mitogen-activated protein (MAP) kinase reduces its affinity for β-catenin.

The Canonical Pathway in *Xenopus* Axis Specification

Wnt signaling is critical for the establishment of dorsoventral polarity in the early *Xenopus* embryo and for laying down of the primitive anteroposterior neuraxis. The dorsal side of the embryo gives rise to a structure called the organizer, through which cells migrate to establish the anteroposterior axis. In 1989, McMahon and Moon injected mouse *Wnt-1* mRNA into the ventral blastomeres of a four-cell *Xenopus* blastula and generated an embryo with two organizers, which developed into tadpoles with a duplicated body axis. Axis duplication was also induced by Dsh, β-catenin, and a dominant-negative version of GSK-3.

In normal *Xenopus* development, the Wnt pathway is activated opposite the site of sperm entry in what becomes the future dorsal side of the embryo following cortical rotation after fertilization. It is thought that maternal Dsh protein, initially located in the vegetal region of the egg, is translocated by cortical rotation to a discrete zone of the fertilized egg, where it stabilizes β-catenin. As the embryo undergoes cleavage, cells incorporating this β-catenin-enriched cytosol activate specific genes, leading to the formation of a structure called the Nieuwkoop center, which induces the formation of the organizer in the overlying mesoderm. The ventral injection of Wnt, Dsh, β-catenin, or an inhibitory form of GSK-3 artificially activates the same genes, resulting in the formation of a duplicate organizer.

Wnt signaling is also important for the establishment of anteroposterior polarity in the neuroectoderm. The organizer expresses several Wnt antagonists, such as those encoded by *dickkopf-1*, *cerberus*, and *frzb-1*, while several Wnt proteins are expressed in the remainder of the embryo. Injection of mRNA for the antagonists leads to enlarged head development, whereas injection of wnt mRNA at this developmental stage inhibits neural induction and head induction. Although long elusive, the specific Wnt signal that triggers axis induction in *Xenopus* was identified as Wnt11 in 2005.

Wnt Signaling in Synapse Development – Divergent Pathways and Diverse Mechanisms

A number of Wnt proteins and their downstream signaling components are expressed in the developing synapse, and investigations in *Drosophila*, *Xenopus*, and mammals have revealed a previously unknown and surprisingly diverse range of signaling pathways activated by Wnt proteins. To further add to the

complexity, it appears that the same Wnt proteins can activate different downstream pathways in different parts of the central nervous system (CNS) and that different Wnt proteins can activate the same pathway in a given region of the CNS, providing scope for functional redundancy. Perhaps most exciting of all, the prominent roles of Wnt proteins in synapse formation appear to involve retrograde signaling, but there is also evidence that Wnt proteins can act as anterograde or autocrine signals.

In the mammalian CNS, various Wnt proteins are expressed during synapse development, including Wnt-3 in Purkinje cells and motor neurons, and Wnt-7a in cerebellar granule cells. These Wnt proteins can regulate axonal remodeling and presynaptic differentiation retrogradely, and do so by influencing the architecture of the cytoskeleton. For example, the addition of Wnt-7a proteins to cerebellar granule cells in culture can increase axonal branching and the clustering of synaptic vesicle proteins, and *wnt7a* knockout mice show transiently decreased axonal complexity and limited synapsin I levels. Wnt-3 is also expressed in motor neurons during synapse formation with sensory neurons, and increasing the levels of this protein results in growth cone enlargement, increased axonal branching, and increased clustering of synapsin I.

Investigation of the role of Wnt proteins in axonal remodeling has shown that a divergent form of the canonical pathway is involved (Figure 2). Some of the components are familiar (GSK-3, the Disheveled family protein Dvl1, and axin), while a significant role is also played by the microtubule-associated protein MAP1B. The phosphorylation of MAP1B by GSK-3 alters its affinity for microtubules and facilitates the regulation of microtubule dynamics. Wnt signaling reduces the availability of phosphorylated MAP1B and increases microtubule stability, a process mimicked by the ectopic expression of Dvl1, which is also known to be physically associated with microtubules. Therefore, it appears that Dvl1 antagonizes the effect of GSK-mediated destabilization. These effects are independent of β-catenin (i.e., the divergent canonical pathway acts directly upon the structural elements of the axons without requiring new gene expression).

Figure 2 The divergent canonical pathway with no β-catenin and regulation of microtubule (MT) organization by the destruction complex through phosphorylation of microtubule-associated proteins 1 B (MAP1B). Fz, Frizzled; Dvl, Disheveled; APC, adenomatous polyposis coli protein; GSK-3β, glycogen synthase kinase-3β. Reproduced from Speese SD and Budnik V (2007) Wnts: Up- and-coming at the synapse. *Trends in Neuroscience* 30: 268–275, with permission from Elsevier.

A further manifestation of the Wnt signaling pathway has been identified in the hippocampus, where Wnt-7b is expressed during dendrite maturation. Experiments have shown that Wnt and Dvl1 can each increase dendritic complexity, and *dvl1* knockout mice have fewer dendritic branches. The key difference between this and the canonical pathways described earlier is that the pathways operate independently of both β-catenin and GSK-3. Instead, the Wnt/Fz/LRP complex acts through a c-Jun N-terminal kinase (JNK) signaling protein to affect cytoskeletal architecture, using the small GTPase Rac, and to regulate both actin and microtubule dynamics, in a manner similar to the planar cell polarity signaling pathway in *Drosophila* (Figure 3(a)).

Although Wnt proteins appear to function as retrograde signals to regulate the differentiation of the presynaptic compartment, there is also evidence that they might operate as anterograde or even an autocrine signals to modulate postsynaptic differentiation. Studies of the *Drosophila* neuromuscular junction show that Wingless is secreted by presynaptic boutons, and the receptor Fz2 is localized in both presynaptic and postsynaptic compartments. The release of Wingless from synaptic boutons initiates an anterograde signaling cascade, which involves yet another divergent signaling pathway in which the receptor is internalized, cleaved, and trandslocated into the nucleus in a manner dependent on the *Drosophila* homolog of the mammalian glutamate receptor-interacting protein (dGRIP), well known for its role in α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor and ephrin B receptor trafficking in mammals. Postsynaptic disruption of the so-called Frizzled nuclear import (FNI) pathway (Figure 3(b)) alters the development of both presynaptic and postsynaptic specializations, suggesting that anterograde Wingless signaling might trigger

Figure 3 Three β-catenin-independent pathways: (a) planar cell polarity, (b) Frizzled nuclear import, and (c) Ca^{2+}. further retrograde signals or even an autocrine loop to regulate presynaptic differentiation. Similar roles for Wnt proteins in postsynaptic development have been identified in vertebrates; for example, the regulation of acetylcholine receptor clustering by agrin and by muscle-specific receptor tyrosine kinase (MuSK) has been identified, the latter of which has now been shown to interact with Dvl1, linking this regulation to the Wnt pathway. However, since agrin has no effect on β-catenin accumulation, it appears that the canonical pathway is not triggered.

Wnt Signaling and Ca^{2+}

A further β-catenin-independent Wnt signaling pathway has been identified that modulates cell movements (e.g., during embryonic gastrulation), and it also plays a role in the definition of cell fate. In this pathway, the binding of Wnt to Fz/LRP leads to an increase in intracellular Ca^{2+} concentration and nuclear import of the transcription factor NF-AT (nuclear factor of activated T cells; Figure 3(c)). The mechanism depends on the ability of specific combinations of Wnt and Fz proteins to activate Ca^{2+}/calmodulin-dependent kinase II (CaMKII) and protein kinase C (PKC). Some Fz proteins also have the ability to activate phospholipase C (PLC) and phosphodiesterase (PDE), acting through heterotrimeric GTP-binding proteins. The ability of different Wnt ligands to activate the β-catenin and Ca^{2+} pathways may reflect the preferences of different Fz proteins (e.g., rat Fz1 does not increase Ca^{2+} release or stimulate CaMKII or PKC in zebra fish embryos, whereas Fz2 does) and preferences for different coreceptors (e.g., LRP-5/LRP6 stimulates the β-catenin pathway, whereas alternative coreceptors such as Knypek and Ror2 stimulate the Ca^{2+} pathway).

Summary

Wnt signaling plays a pivotal role in the development and function of the nervous system, being required to establish the major body axes and compartment polarity in vertebrate and insect embryos, orchestrating cell migration, polarity, and fate, and controlling synaptic bouton development, axonal growth cone remodeling, and dendrite maturation, as well as a host of other processes. The canonical signaling pathway (Figure 1) involves the protection and subsequent nuclear import of β-catenin (Armadillo in *Drosophila*), although there is a divergent pathway, using many of the same components, that is β-catenin independent and acts directly on the organization of microtubules (Figure 2). There are also at least three pathways which involve Ca^{2+} as a second messenger, one involving the activation of CaMKII and protein kinase C, one involving the recruitment of heterotrimeric GTP-binding proteins to activate phospholipase C and phosphodiesterase, and, finally, one involving the planar cell polarity pathway, which signals through JNK (Figure 3). The particular pathways activated in any given cell, and their consequences, reflect the availability and abundance of different pathway components, particularly the Wnt ligands and Fz receptors and coreceptors, which all impact on the downstream events.

Word Learning

J Snedeker, Harvard University, Cambridge, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Word learning is often considered the simplest and least controversial aspect of language development. Although theorists fiercely debate the ontogenetic and phylogenetic origins of grammar, everyone agrees that words must be learned by observing the contexts in which they are used. No other theory can explain how English-speaking children come to use 'shoe' to label footwear, whereas young French speakers use the same sequence of sounds to label cabbage. However, this self-evident truth masks a host of questions about how learning occurs and the knowledge that children bring to the problem.

Defining the Problem

To understand word learning, we need to know both what a word is and which aspects of words are learned. Surprisingly, neither question has a clear answer. There are two difficulties in defining what a word is.

The first is determining what information is included as part of a word. By all definitions, each word (or lexical entry) consists of a symbol that is paired with a concept. In the case of spoken languages, these symbols consist of phonological representations. For example, my lexical entry for 'cat' includes the phoneme sequence /kæt/ which is linked to some conceptual representation of catness. Literate individuals also store the written form of words they are familiar with. In addition, language users have other knowledge of words that could be a part of the lexical entry. Much of this knowledge is related to the grammatical environments in which a word appears. For example, our knowledge of English allows us to recognize that "I have a cat" is a grammatical sentence, whereas "I like to cat" is not. In dictionaries, we capture these facts by assigning words to grammatical categories which are listed with each definition (e.g., 'cat' is a noun and not a verb). Many have argued that grammatical categories are also stored in the mental lexicon. However, our knowledge of the relation between lexical items and grammatical structure extends beyond syntactic categories. For example, we know that a verb such as 'roll' can appear in a transitive sentence ("I rolled the ball"), whereas a verb such as 'fall' cannot ("I fell the ball"). This has led many to propose that individual lexical entries contain detailed grammatical information about the contexts of word use. Others have argued that the concepts with which words are associated allow us to derive these structural facts, eliminating the need for their storage.

The second definitional difficulty is determining how to individuate words: Which chunks of linguistic material are entered in our mental lexicons? How large are these chunks, and where does one entry end and the next begin? Clearly, words such as 'cat' that consist of a single morpheme (meaningful unit) will have to be stored because they cannot be derived in any way. However, we also store morphemes that are not whole words (-ness or-ed), some words that are made of multiple morphemes (e.g., 'walked' or 'happiness'), and idioms that consist of multiple words ('kick the bucket'). The fact that many phonological forms have several meanings creates further uncertainty about what constitutes a lexical entry. In the case of homonyms, these meanings are not related and clearly must be stored separately (e.g., river bank vs. savings bank). However, in the case of polysemes, the different meanings are related (e.g., line up vs. telephone line), and it is unclear whether the alternatives are two separate words, two ways of thinking about a single lexical entry, or two subentries of a single lexical item. Problems of this kind have led some theorists to reject the metaphor of the lexicon as the list of entries and to argue instead that the lexicon is a generative system for linking forms to meanings.

Once we have defined a word, we can ask what it means to learn one. Which aspects of a lexical entry are learned and which can be derived? Which parts of the entry precede word learning and which are the result of it? All theorists agree that children must learn the mapping between the phonological form and the concept. Although there are some minor islands of systematicity (e.g., in English words beginning with *sn-* are related to the nose), these mappings are largely arbitrary and vary across languages; thus, they must be learned. There is more controversy about the role of learning in our ability to represent the phonological form of the word or to represent the concept with which it is associated.

Adults and older children clearly represent speech in terms of stable phonological categories and thus simply have to learn the sequence of phonemes that is linked to a particular concept. The nature of infants' phonological representations has been more controversial. Because infants sometimes fail to distinguish between two novel words that are similar but phonologically distinct (e.g., 'bim' and 'dim'), it has been suggested that infants have less precise, gestalt representations of words and only develop phonological

representations as their lexicons grow. However, infants can succeed in learning phonologically similar words in more supportive contexts and have more difficulty comprehending a known word when a single phoneme has been altered. One possible interpretation is that infants represent word forms in the same way as older children but have difficulty attending to and encoding these forms when the task is challenging.

Many developmental psychologists have argued that word learning involves concept acquisition. Children do not merely map words to existing concepts; instead, they use the recurring word form as a cue to form a new category. This theory is compatible with the Whorfian hypothesis because the concepts that the learner acquires depend on the concepts that are lexicalized in the learner's language. This theory could potentially explain why children learn concrete words early and more abstract words later, or why labels for objects generally appear before predicates. However, theories of this kind face two challenges. First, it is unclear how a child could learn what a word means if he or she did not already have access to the concept that the word encodes. To recognize that a word reliably co-occurs with a particularly category of entities, one must be able to represent those entities as a class. In other words, you cannot not learn that /kæt/ means cat unless you already have a representational arsenal that allows you to distinguish cats from non-cats. Second, the course of lexical development in cognitively advanced learners suggests that conceptual limitations play little role in early word learning. Children who are internationally adopted as preschoolers must learn a new language in context similar to that of infant language learners. If the course of infant word learning is shaped by the conceptual limitations of babies, then we would expect that older children, free from such limitations, would be able to learn more verbs and abstract words during the initial phases of lexical development. However, internationally adopted preschoolers acquire words in approximately the same order as infant learners, suggesting that early vocabulary development is largely independent of cognitive development.

Figure 1 Vocabulary growth throughout development. The vocabulary estimates for 12- to 30-month-olds are from Fenson L, Dale PS, Reznick JS, Bates E, Thal DJ, and Pethick SJ (1994) Variability in early communicative development. *Monographs of the Society for Research in Child Development* 59: 1–173. The estimates for 6- to 10-year-olds are from Anglin J (1993) Vocabulary development: A morphological analysis. *Monographs of the Society for Research in Child Development* 238: 1–166. The estimate for adults is based on the figure cited by Aitchinson J (1994) *Words in the Mind: An Introduction to the Mental Lexicon*, 2nd edn. Oxford, UK: Blackwell.

Word Learning across Development

Children learning both signed and spoken languages generally produce their first word at approximately 12 months of age. By adulthood, the typical person knows approximately 60 000 words. Although this averages out to approximately 9 words a day, the actual pace of word learning varies across development. As Figure 1 illustrates, the initial pace of word learning is quite slow, with the average child learning approximately 2 words a week between 12 and 16 months of age. Until recently, many observers believed that there was a sudden acceleration in word learning at approximately 18 months of age (often called the vocabulary spurt). However, closer examination has revealed that the pace of word learning increases gradually throughout the toddler and preschool years. In literate societies, this steady acceleration continues into the school years as children encounter new words while reading. The pace of word learning begins to decelerate sometime between 8 and 18 years, presumably because older children encounter fewer unknown words. There is no evidence for a critical period in word learning: Adults do as well or better than children in most experimental word learning tasks and we can readily learn new words throughout our lives.

As children's vocabularies grow, they also change. The first words that children learn are typically labels for people ('mommy' or 'daddy'), animal names ('kitty'), social words ('hi' or 'uh-oh'), or utterances used in common routines ('peek-a-boo'). Although verbs, prepositions, and other relational words

appear in early vocabularies, they may have more limited meanings for infants than they do for adults and older children. For example, many 1-year-olds say 'more' to request the recurrence of an event or object, but there is no evidence that children of this age understand that 'more' is a term that quantifies the amount in one set relative to another.

The early vocabularies of children learning English are dominated by nouns, most of which label people, animals, or objects. Even though adults speak to young children in full sentences, complete with verbs and grammatical words, these elements are massively underrepresented in children's early vocabularies. The proportion of nouns in the child's lexicon varies from language to language depending on whether subjects and objects are mandatory and whether the verb appears in a perceptually salient position (e.g., at the beginning or end of the utterance). Nevertheless, in every language that has been systematically studied, nouns are overrepresented in children's vocabularies relative to their rate of occurrence in the input, whereas verbs are underrepresented. This suggests that nouns, particularly those that label objects or people, are easier for children to learn than verbs or other relational words. Some theorists have attributed this to the greater conceptual complexity of verbs, whereas others attribute it to the nature of the information needed to identify the meanings of nouns and verbs.

There is considerable variability in how rapidly children learn words. At 16 months of age, the median vocabulary size for middle-class children in the US, is approximately 40 words. However, 10% of children produce no words, whereas another 10% produce more than 150 words. Early in development, vocabulary size is a better predictor of vocabulary composition than age. As the child's vocabulary grows from 50 to 200 words, the proportion of these words that are nouns increases. Verbs and adjectives begin to appear in greater numbers between 100 and 400 words. Grammatical words (such as articles, pronouns, prepositions, and auxiliaries) increase in frequency at approximately 400 words. Between 16 and 30 months, the size of a child's productive vocabulary is tightly correlated with the grammatical complexity of the child's speech. Initially, children primarily produce one-word utterances. When their productive vocabulary reaches 50–200 words, they begin combining words into short phrases. From 300 to 500 words, grammatical morphemes appear and the child's utterances increase in length and complexity. These relations are preserved in internationally adopted preschoolers, suggesting that the correlation is not a side effect of global maturational or cognitive changes. In bilingual children, these relations hold within a language but not between languages, suggesting that lexical development facilitates grammatical development or vice versa. During the school years, lexical development and reading are closely linked. A child's vocabulary when he or she enters school is a strong predictor of later reading achievement, and subsequent vocabulary development is correlated with the amount that the child reads.

Word Learning as Induction

How do children learn the meanings of words? Most people who have thought about the problem long enough have come up with essentially the same solution: Word learning is a form of induction. Learners generate hypotheses based on the situation in which the new word occurs. As the learner observes new instances of the word, hypotheses are eliminated or strengthened, allowing him or her to close in on the correct meaning.

Although this mechanism clearly plays a role in word learning, it cannot be the entire story. First, even very young children can learn some words after hearing them used in just one context. Second, many words, particularly verbs and other relational terms, are often used in the absence of the event being labeled (e.g., when parents tell children to "go to sleep," both parties are typically awake).

Finally, the account of word learning given previously is subject to the mid-century critiques of empiricism voiced by philosophers such as W. V. O. Quine and Nelson Goodman. Learning simply cannot be unconstrained induction because any finite set of observations is consistent with an infinite set of hypotheses. To take Quine's example, the set of observations that would allow one to learn that a word ('gavagai') means rabbit is also compatible with the hypothesis that it means undetached rabbit parts (or temporal rabbit slices). Thus, a full account of lexical development requires more than merely stating that word learning is induction. In the past 25 years, developmental psycholinguists have begun to flesh out this story by identifying three ways in which children and adults can tame the induction problem and learn the meanings of words.

Constraints and Biases on Hypothesized Meanings

The first way to tame induction is by limiting the range of meanings that are considered as possible hypotheses. Many theoretically possible meanings may be ruled out simply because children cannot or do not think of them – for word learning or any other purpose. Quine's example of undetached rabbit parts

is presumably ruled out by cognitive constraints of this kind. However, such constraints cannot explain how the learner rules out more plausible alternatives such as white, fluffy, hopping, tail, animal, or Flopsie. All these hypotheses are plausible ones, meanings which the learner could eventually link to some other phonological form. Children, however, are biased learners who privilege some of these hypotheses over others.

The nature of these biases has been explored with an experimental paradigm called the word extension task. In this task, children are shown a novel object (e.g., a blue kidney-shaped piece of plaster) which is labeled with a novel word ("This is my dax"). Then they are given a small set of test objects (e.g., a blue circular piece of plaster and a red kidney-shaped piece of wood) and asked to find another example of the target word ("Can you give me the dax?"). The child's response allows the experimenter to infer how the child is interpreting the novel word.

Through tasks such as this one, researchers have discovered that children (and adults) have a strong bias to assume that a new word refers to a whole object rather than one of its parts, its properties, or the relations that it is involved in. When children have mapped a word to an object, they will extend it to other objects of the same kind rather than to other objects that are involved in the same event (e.g., extending from a birthday cake to other cakes rather than to birthday presents and birthday candles). In the case of novel artifacts, they typically extend the word to objects of the same shape rather than to objects of the same material or same color. However, when a word is applied to a novel animal, children are more conservative, preferring referents that have the same color or texture and the same shape.

These biases should aid the child in learning count nouns (such as 'cat,' 'book,' or 'car'), but they might hinder the acquisition of adjectives, verbs, relational nouns, and labels for substances and parts of objects. For example, if little Johnny were to hear the word 'silver' applied to Mommy's car, his bias to map words to whole objects could lead him to incorrectly conclude that 'silver' means car. One additional constraint, often called mutual exclusivity, may help learners overcome this bias. Young children are reluctant to map a second label to an object for which they already have a label. Thus, if little Johnny has already learned that cars are called 'car,' he is likely to reject the hypothesis that 'silver' means car and consider other possibilities.

The existence of these biases is uncontroversial, but their origins are not. Current research in this area focuses on two issues. The first is domain specificity. Are these biases unique to word learning or do they reflect more general properties of cognition? Perhaps the bias to link words to whole objects reflects the centrality of objects in early cognition rather than any preconceptions about the nature of words. Similarly, mutual exclusivity in word learning could result from a more general principle of communication which leads learners to assume that speakers will use known forms of reference whenever possible. The second issue is whether these biases are available at the onset of word learning. Some theorists suggest that these biases are learned as the child acquires words and notices the properties that are typically used in word extension. For example, children may learn their first artifact labels by trial and error. After learning many of these words, a child may notice that these labels are generally extended by shape and develop a bias to extend new words in this way. Several pieces of evidence support this account. The shape bias for novel artifacts increases as vocabulary size grows, and toddlers who are taught categories that are extended on the basis of shape develop this bias more quickly and are more successful at learning count nouns.

Social Cues to Reference

Children can also tame the induction problem by using their implicit understanding of social interactions to make inferences about the communicative intentions of the speaker. These inferences can help the child identify the object or event to which the speaker is referring, thus simplifying the problem of word learning. The best studied social cue to word meaning is the speaker's direction of gaze. When speakers are talking about objects that are visible, they often look at that object at roughly the same time as they are mentioning it. By approximately 18 months of age, children will map a word to the object that the speaker was looking at, even when they themselves were examining a different object when the word was spoken. Infants can also identify the referent of a word when the speaker points at the object or moves it as it is labeled.

Other abilities appear to require a more complex representation of the interaction. When a speaker labels an action before performing it, young children prefer to link the label to an intentional action rather than an accidental one. When a speaker uses a novel label, children assume that she is referring to an object that was introduced while she was gone rather than an object that she saw before.

Research on the use of social cues has explored two questions. First, what role do these cues play in word learning? Are they necessary or merely facilitory? Several lines of evidence demonstrate that children can learn words in the absence of any single social cue. For example, infants can learn the mapping

between an object and a word from a videotape in which the person who is producing the word is never visible. The ability of blind children to acquire words at approximately the same age as sighted children provides further evidence that visual access to social cues (such as pointing or gaze direction) is not necessary for successful word learning. Of course, it is possible that these learning contexts contain other cues that allow the child to infer the referential intentions of the speaker. A second and related question is whether infants' use of social cues reflects an understanding of the mental states of the speaker rather than simple associations or low-level attentional processes. Do infants make use of eye gaze because they know that it reflects the speaker's knowledge and communicative intentions, or have they merely learned that gaze is a reliable predictor of which object a word will be associated with?

Sentential Contexts as Cues to Word Meanings

The final way in which children tame the problem of word learning is by using the sentential context in which a word occurs to narrow down the set of possible hypotheses. Sentential contexts provide three kinds of information. First, they identify the syntactic category of a novel word. Because syntactic categories are systematically (but imperfectly) linked to semantic categories, they provide information about the kind of meaning that the word is likely to have. For example, 1-year-olds who are shown a doll and told that 'this is a zav' interpret the novel word as a common noun and extend it to other similar dolls. In contrast, those who hear 'this is Zav' interpret it as a proper noun and refuse to extend it. Similarly, by approximately 2½ years of age, young children have learned to extend mass nouns ('this is some dax') to entities that are made of the same substance and to extend adjectives ('this is a daxy one') to objects that share a common property.

Second, sentential contexts provide information about the number and kinds of arguments that a predicate can take which constrain the kind of meaning that the predicate has. For example, verbs of self-generated motion (e.g., 'dance') often appear with just one argument (the subject); verbs of contact (e.g., 'hit') or caused motion (e.g. 'push') usually appear with a subject and a direct object; and verbs of transfer (e.g., 'send') appear with three arguments (subject, direct object, and indirect object). Young children use these connections between syntax and semantics to learn the meanings of unknown words. For example, 2-year-olds who hear a transitive utterance such as "She is blicking her around" expect the verb to have a meaning such as 'push,' whereas those who hear an intransitive utterance such as "They are blicking around" expect the verb to have a meaning such as 'dance.'

Finally, sentential contexts contain known words which provide information about the other entities or relations that are involved in the event under discussion. For example, if children hear an utterance such as 'John is eating a dax,' they can infer that a dax is probably a kind of food, and they can direct their attention to John to ascertain precisely what kind of food it might be. Although cues of this kind tightly constrain word learning, their availability depends on the child having already learned some of the other content words in the utterance.

Current research on the role of sentential contexts centers on two issues. First, when do children begin to use each of these cues? Some cues have an influence on infants as young as 13 months of age (e.g., use of word in count noun syntax), but other cues appear to have little effect even in preschoolers. For example, in several studies 2- and 3-year-olds have failed to use verbal morphology ("Look gorping!") to map the word to the action (e.g., waving) that is being performed. The second active area of research explores how these cues are acquired. One possibility is that by learning words from particular categories, children discover a direct association between specific grammatical contexts and particular aspects of word meaning. The second possibility is that children's word learning is guided by universal linkages between syntax and semantics. Children must learn the grammatical morphemes that mark each syntactic category (e.g., that 'a dax' is a count noun in English and 'une dax' is a count noun in French) but the connection between particular syntactic categories and patterns of word extension comes for free. These theories make different predictions about when these cues should be learned and whether the semantic relations in question are likely to be linked to observable properties (e.g., count nouns pick out shape-based categories) or more abstract properties that are tightly linked to the syntax (e.g., count nouns pick out individuated entities).

Final Words

During the past 25 years, researchers have demonstrated that young children make use of all three of the previously discussed strategies to learn words. The challenge in the future will be to understand how these strategies work together throughout development. It may be useful to think of constraints, social cues, and structural contexts as complementary mechanisms rather than competing hypotheses. The three strategies account for different aspects of word learning. For example, social cues allow children to

identify the referent of the phrase, whereas constraints on hypotheses and structural cues provide guidance about how this referent is being construed.

The order in which these abilities emerge during development may explain why early vocabularies are dominated by nouns but contain few verbs, and why children's mastery of verbs coincides with the emergence of grammar. Many social cues and constraints may be available at the onset of word learning. These abilities do not necessarily depend on prior linguistic knowledge, and their use extends well beyond the linguistic domain (e.g., knowledge of object kinds constrains reasoning as well as word learning, and eye gaze provides information about a person's knowledge outside of the linguistic domain). These abilities would primarily facilitate the acquisition of nouns: Most word learning constraints and biases apply to object categories and most social cues function to pick out objects in space. In contrast, the use of structural contexts necessarily requires some grammatical knowledge and thus can only be used after language acquisition is underway. This information source is particularly useful for learning verbs and other predicates (which occur in richer structural contexts). Thus, efficient verb learning may emerge only when children have acquired enough grammatical and lexical knowledge to make use of sentential contexts during word learning.

Word Production

Introduction

Please say the name of the item pictured in Figure 1.

Research on word production is concerned with the mental processes and representations that are involved during the 1000–1200 ms that it probably took from seeing the picture to uttering the word 'banana.' In picture naming, this involves the initial process of visual processing, followed by core processes of identifying the concept, retrieving the appropriate word from memory, determining the word's phonological structure (e.g., the word has three syllables) and content (e.g., the first speech sound is a /b/), and planning a speech motor program, which controls articulation.

Historically, language production has been the subject of less research than language comprehension, and this holds for both research studying the word level and the sentence level. However, in recent years there has been an increase in interest in production. This increased interest is accompanied by important methodological innovation. Until fairly recently, the main source of data informing the field of word production research was corpora of spontaneously occurring speech errors. Although this work has allowed the development of influential production theories, in particular Merrill Garrett's theory of language production, observational methods suffer from important problems, such as collector biases, the infrequency of errors, and the issue of whether the corpus is representative of the language as a whole. Methodological improvements have made it possible to study word production under laboratory conditions, considering normal, fluent production as well as the production of errors and allowing researchers to focus on the time course of the production process. Moreover, despite methodological obstacles (e.g., the need to control for movement artifacts), word production can now be studied while registering the speakers' eye-movements, event-related potentials, or Bold signals.

The Functional Architecture of Word Production

Word production is a multistage process. That is, given the intention to say something, representations need to be selected or constructed in a sequence of processing levels. Each of these processing levels is specialized and represents a particular type of knowledge, such as meaning or form. Although there is consensus in the field about this hierarchical organization, there is considerable debate about whether the processing stages are strictly sequential or whether they interact to some degree (see below). This multistage nature of word production is sometimes overlooked. For example, some studies of word recognition use the task of word naming, neglecting the fact that this task also recruits production.

A blueprint of word production is provided in Figure 2. The figure shows the core processing levels (against the blue background) and several sources of input to this system. Imagine that a speaker will produce the word 'banana,' perhaps so as to name a picture or, in a more naturalistic situation, because the person is thinking about a banana and wants to say something about it. The following sections describe the route that processing takes from seeing to saying, excepting details of articulation.

Conceptual Preparation

The first core processing level is the conceptual level. Here, a representation referring to a banana becomes activated, and representations of related concepts (e.g., 'apple,' 'pear,' 'fruit,' 'peel' (part of a banana), 'canoe' (looks like a banana)) are also somewhat activated. There is no consensus on the precise nature of the conceptual representations used for production. Some researchers argue for distributed conceptual representations, so that a given concept can be characterized by a constellation of features (either 'macrofeatures' that carry meaning themselves, such as 'yellow,' 'sweet,' 'long,' or in certain connectionist models, 'microfeatures' without any intrinsic meaning). In these views, similarity among concepts is determined on the bases of features that are shared across concepts and features that are instead specific for a given concept. Other researchers, however, argue for localist concepts, so that there would be a single, indivisable representation for each concept. On such 'semantic network' accounts, concepts are connected via meaningful links that indicate category membership (e.g., a banana is a fruit) and properties (e.g., a banana has a yellow color). Similar concepts have links to the same categories and properties.

Do speakers of different languages activate identical concepts when they are preparing to say a word? Probably not. Languages differ in what they require their speakers to think about. For example, English often captures the manner of motion in a verb, whereas Spanish needs to add such information in

Figure 1 Picture of an everyday object. From the picture set presented in Rossion B and Pourtois G (2004) Revisiting Snodgrass and Vanderwart's object set: The role of surface detail in basic-level object recognition. *Perception 33: 217–236.*

Figure 2 Overview of core word production processes (against the blue background) and lead-in stimuli, such as pictures, words, and thoughts.

an additional phrase. Research has shown that such differences influence the type of information speakers recall from a description (e.g., of a cartoon) they recently provided, suggesting that when verbalizing events, conceptual information is activated in a language-specific way.

Lexical Processing

The activated concept will send activation to the lexical level, and if all goes well, the lexical representation for banana will become the most active representation at this level. If there was always a one-to-one relation between concepts and words, it would not be necessary to postulate different processing levels for them. However, there are many situations in which there is no one-to-one relation between concepts and words. For example, there are concepts such as 'the actions of two people maneuvering for one armrest in a movie theater or airplane seat' for which we do not have a word. Moreover, as discussed above, which concepts are verbalized can differ across languages.

At the lexical level, the word activated by the concept (the 'target word') enters into a competition with other activated words, usually words with a similar meaning. The word with the most activation will be selected, and the time to select the correct word and the chance of making a lexical selection error depend on the activation level of competitor words. This mechanism of selection by competition is nicely illustrated by results from the picture–word interference paradigm, one of the most frequently employed paradigms in word production research. In these experiments, participants are instructed to name pictures with single words while ignoring a 'distracter word' that is presented either simultaneously with the picture or shortly (e.g., 150 ms) before or after the picture. A consistent finding is that semantically related distracters (e.g., 'apple' for the picture of a banana) delay picture-naming onsets compared with unrelated distracters (e.g., 'chair' for the picture of the banana). This delay can be explained as follows: Both the written words 'apple' and 'chair' directly activate their corresponding representations at the lexical level (Figure 2). However, the picture's concept (for banana) activates the related concept (for apple) but not the unrelated concept (for chair). Therefore, the lexical representation of 'apple' receives additional input from and is a stronger competitor for 'banana' than is 'chair.' Computer models of word production that incorporate this mechanism can mimic the temporal costs caused by semantic relatedness.

How many lexical levels are there? Some researchers argue that the lexical level should be subdivided into two levels, namely, a lemma level and a word form level, whereas others postulate only a single lexical level. In the two-level view, lemmas are lexical representations containing or pointing to lexical-syntactic information (e.g., gender) and semantic information, but not phonological information. Furthermore, there are different versions of two-level theories. Thus, in his seminal book *Speaking*, Willem Levelt suggested that the lemma representation of a word contained semantic and syntactic information and pointed to the word form representation that contained morphological and phonological information. But in a more recent version of Levelt's theory, the lemma is considered void of content; it connects the conceptual level to the level of word forms and is connected to (rather than contains) syntactic information.

There is much evidence that appears to support a division into a lemma level and a word form level.

One source of observational evidence concerns the occurrence of word substitution errors. These are related to the intended word either in its meaning or in its form, suggesting that there are two types of retrieval processes that can derail: (1) lemma selection, which is driven by semantic information and can lead to semantic errors, and (2) word form selection, which can lead to phonologically conditioned errors. For example:

1. I want whipped cream on my mushrooms. (intended: strawberries)
2. I've got some whipped cream on my mushroom. (intended: mustache)

In addition, picture–word interference studies show distinct effects of semantically related distracters, which slow down picture naming (see above), and phonologically related distracters, which speed up picture naming. The difference in polarity of these effects is consistent with the notion of different processing levels.

Further evidence comes from the so-called tip-of-the-tongue (TOT) phenomenon. This phenomenon, strikingly described by William James in 1890, entails the inability to produce a word one is certain to know. Studies that have elicited this phenomenon in the laboratory demonstrated that speakers in a TOT state reliably know syntactic information about a word (e.g., whether an Italian noun's grammatical gender is masculine or feminine) while being unable to retrieve phonological information about the word. This suggests that speakers have succeeded in retrieving the lemma (and can therefore activate the syntactic information associated with it) but have failed to retrieve the word form. It is interesting that brain-damaged patients who suffer from an inability to name objects or events likewise demonstrate syntactic knowledge of the words they cannot name.

A final source of support for the distinction between lemmas and word forms comes from studies of morphological processing. A model with two such levels rather naturally lends itself to the representation of morphologically complex words. For example, a Dutch complex verb like *opgeven* (to give up) would have a separate lemma from a simplex verb like *geven* (to give). This is syntactically motivated as these verbs are syntactically different. At the word form level, however, overlapping inflectional forms of *geven* and *opgeven* would be shared, for example, *geeft* in the third-person, present-tense forms *geeft op* and *geeft*. In line with this hypothesis, Dutch speakers have a naming latency advantage when saying *geeft op* compared with *veegt op* (sweeps up), although these verb–particle combinations occur equally frequently. The advantage is that *geeft op* shares a word form with a very frequent verb, whereas *veegt op* shares a word form with an infrequent verb.

Figure 3 Lexical representations according to Levelt and colleagues (left panel) and Caramazza and colleagues (right panel).

This subdivision into lemmas and word forms has been challenged by Alfonso Caramazza and colleagues, who proposed that the conceptual level is directly connected to the level of word forms and that both these levels are independently connected to syntactic information (Figure 3). In addition to a network of phonological word forms (employed in speaking), there would be orthographic word forms (used in writing). Much evidence that supports the distinction between lemmas and word forms is also consistent with Caramazza's framework.

Phonological Processing

Most theories assume a level of word forms, at which words are represented in terms of their speech sounds. It is conceivable that an error at this level leads to a malapropism, a phonologically governed word substitution error, like the Dutch error *ondergoed* (underwear) instead of *onderzoek* (research). Perhaps surprisingly, the next processing step involves breaking up the word form into its constituents, such as its phonological segments and metrical structure. Why doesn't the processor simply use the just-retrieved complete word form to guide articulation? An important reason is that speakers normally do not produce words in their citation forms. Rather, in connected speech, words are merged, and syllables can cross word boundaries. For example, in natural speech, one does not say "and Oliver" but "n doliver."

An influential model of the processes involved in phonologically encoding words was proposed by Gary Dell (Figure 4). This model, analogous to McClelland and Rumelhart's seminal Interactive Activation Model of word recognition, postulates

Figure 4 Gary Dell's 1986 model of word production.

Figure 5 The WEAVER++ model's architecture of phonological encoding.

localist representations for different phonological units (such as words, syllables, and phonological clusters); processing proceeds by spreading activation from a target unit. Selection takes place at the phoneme level, so that after a given number of time steps of activation spreading (determined by speech rate), the most highly active phoneme unit is selected in separate pools of units. These pools correspond to the onset (initial consonants), nucleus (vowel), and coda (final consonants) of the syllable.

If all goes well, phoneme units corresponding to the intended word are selected, but whenever a competing phoneme has a higher activation level than the intended one, a speech error occurs. There are several reasons an unintended phoneme can win the competition. It may have residual activation because it has been recently selected and the activation has not decayed yet. It is also possible that the unit needs to be selected in an upcoming syllable but is activated too early. Finally, a phoneme may be randomly active because the system is intrinsically noisy.

Dell's model successfully accounts for naturalistic speech error data. For example, the model simulates effects of speech rate on the number of errors; the so-called lexical bias effect (by which errors tend to form existing words more often than chance would predict); and the distribution of speech errors, so that anticipations (in which a phoneme is said too early; e.g., 'bake my bike' (intended: take my bike)) outnumber perseverations (in which a phoneme is repeated in a subsequent word; e.g., 'she pulled a pantrum' (intended: she pulled a tantrum)), which in turn outnumber exchanges (in which phonemes from different words are swapped; e.g., 'waple malnut' (intended: maple walnut)).

However, Dell's model has two limitations. First, the model is restricted to accounting for the outcome of phonological encoding (correct or error) but not for the time course of processing. Another limitation is that the model does not have a mechanism for the resyllabification processes that take place in connected speech: it produces words in citation form only. Ardi Roelofs, Willem Levelt, and colleagues therefore extended their theory of lexical access to phonological encoding. This new model, WEAVER++ (Figure 5), complements Dell's: it provides an account of reaction time data (e.g., results from picture–word interference experiments) but does not account for speech errors.

WEAVER++ assumes that the word form is broken down into its parts in two parallel processing streams, one that retrieves individual phonemes and one that retrieves the metrical frame. The latter frame specifies the number of syllables of the word and the location of stress. These processes take place in parallel for all constituent syllables of the phonological word, which is usually defined as a content word (like 'banana') and any function words (e.g., 'a,' 'the,' 'it') that are phonologically 'glued' to it. Based on these representations and on the language's resyllabification rules (not shown in the figure), a syllabified, phonological plan for the phonological word is constructed. Finally, information now associated with syllable representations (e.g., that the onset of the first syllable is /b/ and its rhyme is /a/) serves as input to the 'syllabary,' a repository of motor programs that guide the articulation of individual syllables.

This model has successfully simulated reaction time data, mostly from experiments that used the picture–word interference paradigm or the implicit priming

paradigm (a task in which speakers produce blocks of words with (experimental condition) or without (control condition) phonological overlap). Note, however, that some assumptions of the WEAVER++ model are controversial. In particular, there is no compelling evidence in support of the mental syllabary.

Self-Monitoring

Speakers monitor whether the words they produce conform to what they wanted to say. This verbal self-monitoring system inspects not only a speaker's overt speech but also speech before articulation (internal speech). That internal speech is monitored is evident from data on self-interruptions. Speakers can interrupt their errors so quickly that they could not have detected the error in their overt speech. Despite recent attempts to formulate precise computational models of the monitoring process, it is still unclear how monitoring establishes that something is an error. This issue has important theoretical repercussions, in particular with respect to the question of whether the processing levels in production have the characteristic of modular stages or whether there is cross-talk between different levels (see the next section).

Information Flow in the Functional Architecture: Modularity versus Interactivity

A debate that has divided the word production literature for decades concerns whether processing levels are modular (i.e., encapsulated from other levels) or not. There are two aspects to this issue. First, models differ in whether they assume that only the selected representation at level $n-1$ activates representations at the next level, n (the modular stance), or whether processing at these levels overlaps somewhat in time so that all representations activated at level $n-1$ send some activation to level n. The latter mechanism is usually referred to as 'cascading of activation.' Second, models differ in whether they assume that activation flow is unidirectional (from level $n-1$ to level n), or whether there is also a return flow of activation (from level n to level $n-1$). The latter mechanism is usually referred to as 'feedback of activation.' Note that even theorists who propose full interactivity (cascading and feedback) limit it to local interactivity. There appears to be no direct (cross-) talk between level $n-2$ and level n.

In contrast to conclusions of several studies in the early 1990s, there is now overwhelming evidence for cascading of activation. For example, picture–word interference studies using homophone targets (e.g., a picture of a (toy) ball) showed facilitation when the distracter was related to the other meaning of the target name (e.g., 'dance'). This demonstrates that the distracter activated the lemma for the 'dance' meaning of 'ball' and that this lemma cascaded activation to the word form 'ball,' thereby speeding up selection of this word form.

The existence of feedback remains disputed. Data from speech errors appear to support feedback. For example, the lexical bias effect on phonological speech errors suggests that feedback from the phonological level activates representations of existing words, increasing the probability that they are selected. It is important that Dell's model, which incorporates feedback links, simulates the lexical bias effect, as well as effects of speech rate on the magnitude of this bias. However, a competing account of the lexical bias assumes unidirectional activation flow and explains the effect as the result of covert error repair. On that story, the monitoring system uses criteria such as, is this a word? and is therefore more likely to detect and intercept nonsense errors than errors that form existing words. It is difficult to reject such accounts, because the mechanisms of error detection remain underspecified. Note that recent evidence suggests a third possibility, one by which monitoring biases interact with an underlying pattern of errors, which is shaped by feedback.

Neural Correlates of the Functional Architecture

What are the neural systems engaged in word production? It has long been known from patient studies that language processing takes place in a brain network that is largely left-lateralized and surrounds the perisylvian fissure. Modern brain imaging techniques allow for a more fine-grained localization of brain areas involved in production, although only very recently have studies begun to address overt production, thanks to the advent of data acquisition and analysis techniques that reduce susceptibility to movement artifacts.

A recent meta-analysis considered 85 imaging studies (mostly positron-emission tomography and functional magnetic resonance imaging) in which participants were engaged in tasks like picture naming, verb generation (e.g., "Generate as many verbs as you can applying to a particular noun"), word naming, pseudoword naming, and so on. These tasks differ in the extent to which they involve different processing components (Figure 2). The logic of the meta-analysis was that if a certain brain region genuinely subserves a certain process, then this region should be active

Figure 6 Proposed localization of brain regions involved in word production processes. The numbers refer to Indefrey's and Levelt's estimates of the moments of time during which these areas would be active, given the task of picture naming. Adapted from *Cognition*, 92, Indefrey P and Levelt WJM, The spatial and temporal signatures of word production components, pp. 101–144 (2004), with permission from Elsevier.

in all tasks that involve this process. That study suggested several localizations of production processes (Figure 6).

Conceptual processing and lemma selection are subserved by an area in the middle of middle temporal gyrus. Word form retrieval is localized in the posterior part of the middle and superior temporal gyri (Wernicke's area). Phonological encoding is localized in the left posterior inferior gyrus (Broca's area). Articulation is subserved by several regions, including bilateral sensory and motor areas. Finally, self-monitoring is localized in the superior temporal gyri of both hemispheres.

A more detailed neuroanatomical hypothesis concerning the brain network(s) subserving word production has been proposed by Hanna Damasio and colleagues on the basis of imaging and lesion data. In this view, word naming is achieved in the following manner: Conceptual retrieval corresponds to engagement of intermediary regions in higher-order association cortices. The brain network subserving conceptual activation can differ (at least partially) depending on the semantic category of the stimulus (e.g., animals vs. famous people) and recruits regions outside the 'language' network, for example, in left inferior temporal areas. Once conceptual activation is achieved, naming a stimulus from a particular conceptual category is dependent on intermediary structures for 'words.' These intermediary structures correspond to the neural substrate of semantic representations. Finally, structures which support the implementation of word forms (the classical language areas located in the left perisylvian region, including Broca's and Wernicke's areas) are engaged. These structures correspond to the neural substrate of phonological word forms and the processes engaged in their retrieval.

Consider Figure 7. When an individual is shown a picture of a cup or a picture of a familiar person (e.g., John F. Kennedy) and is asked to name the item, there will be activation of the appropriate 'concept' intermediary regions, which will promote concept retrieval. Activation in the concept intermediary regions leads to activation in the corresponding 'word' intermediary region, which in turn promotes the retrieval of lexical knowledge required for word production. This is likely to require auditory structures (areas 41/42; 22), which overlap in part with Wernicke's area. This step can be considered to closely correspond to the retrieval of word forms. Finally, somatomotor (3/1/2; 40; 44/45) structures are engaged for the phonetic sequencing and production of the actual spoken name; these structures overlap in part with Broca's area.

Summary and Future Directions

There is broad consensus in the literature on the functional architecture of word production, and recent imaging and patient studies have led to suggestions about the localization of global processing components in the brain. However, important lacunae in our knowledge remain. These include the nature of conceptual representations, the number of levels of lexical representation, the existence of a mental syllabary, the workings of the self-monitor, and the existence of direct feedback between processing levels.

It is important to note that word production research studies the production of isolated words, neglecting that words are usually parts of sentences and that sentences are parts of conversations. A consideration of these higher levels raises important further questions. For example, one debate in the literature concerns the scope of planning in language production: Do we produce one word at a time, or can the production system plan multiple words in parallel? Another debate concerns the interface between words and sentence level syntax: Do words constrain the syntactic structure of the rest of the sentence, or do syntactic planning mechanisms recruit words that fit the syntactic requirements?

It is also important to note that word production has concentrated mainly on production of spoken words. However, people have several modalities at hand for word production, including typing, handwriting, and signing. Issues regarding the number of levels that are shared or separate between modalities remain largely unexplored. Finally, with bilingualism being the rule rather than the exception

in Earth's population, many speakers have two or more lexicons to choose from, which raises important new questions about the functional organization and processing mechanisms in bilingual people.

Word Recognition

J Zevin, Weill Medical College of Cornell University, New York, NY, USA

© 2009 Published by Elsevier Ltd.

It is intuitive to think of the word as a basic unit of language. Dictionaries, for example, list the definitions of individual words. But in fact, they list multiple definitions for most, because what a word means is determined in large part by its context. Consider, for example, that the phrases 'a chocolate bar,' 'a sports bar,' or 'to bar entry' each use the word 'bar' to refer to very different things. Furthermore, words are not even the smallest unit at which regularities between sound and meaning are encoded: new words can be created generatively by a process of 'derivational morphology.' For example, once we know what a 'blog' is, we have little difficulty guessing what a 'blogger' does or what the 'blogosphere' might be, even on first hearing. Thus, although it is natural to think of words as representing a stable correspondence between a linguistic form (spoken or written) and a meaning or concept, in fact, both the status of words as units of linguistic form and their relationship to particular meanings are something of an oversimplification. Fortunately, despite these definitional issues about what a word is, and what one is actually doing when one 'recognizes a word,' much is known about how words are recognized in both spoken and written language.

Factors That Influence Word Recognition

The recognition of individual words presented in isolation is arguably not very representative of typical language use. Nonetheless, it has formed the basis for a vast empirical literature, in part because various properties of words are readily quantified, manipulated, and controlled. Large databases of text called corpora can be used to determine how frequently words occur in the language and to quantify their similarity to other words. These properties can then be used to develop experimental materials used in studies that test how rapidly and accurately words can be recognized and whether there is an effect of a particular measurable factor.

Frequency

The more frequently a word occurs in the language, the more rapidly it is recognized. This is true of both written and spoken words, across a wide range of psycholinguistic tasks. The relationship between frequency and response efficiency is consistent with the power law of practice such that, for example, a word that is seen only 10 times per million is processed much less efficiently than a word that is seen 50 times per million, whereas the difference between a word that is seen 110 times and a word seen 150 times is much smaller. This power law holds for a wide range of psychological phenomena, and its role here suggests an important role for domain-general learning mechanisms in vocabulary acquisition.

A factor related to frequency is age of acquisition. Unlike other aspects of language, word-learning ability is not thought to decline during development. There is evidence, however, that the age at which words are learned has an influence on word recognition: Words learned earlier in life are processed more efficiently than words learned later in life. One difficulty in establishing this effect, however, is that words learned earlier in life tend to be easier for a host of reasons that also influence adult processing. Nonetheless, a number of carefully controlled studies have shown independent effects of age of acquisition in some aspects of word recognition.

It has been suggested that the number of times a word occurs is less important than its 'contextual diversity' – the number of different discourse contexts in which it occurs. Whether as a result of frequency or contextual diversity, it is clear that factors regarding the number and context of experiences with a word predict performance in a manner consistent with general models of learning and memory.

Neighborhood Effects

The 'neighborhood' of a word is the set of words that can be made by changing one or more speech sounds (for spoken words) or one letter (for written words). 'Neighborhood size' is thus an index of similarity to other words. Interestingly, this factor influences auditory and visual word recognition differently. In auditory word recognition, similarity to other words slows down response latency, but larger neighborhood size results in faster responses to written words. This difference is likely due to the task constraints of reading and listening. Because spoken words unfold over time, spoken word recognition under time pressure seems to involve activating multiple candidate words that are consistent with the auditory input at a given time. Therefore, if the goal is to identify a specific word, similarity to many other words will result in greater confusion.

In visual word recognition, in contrast, the facilitatory effect of having many neighbors is related to the fact that written words are processed in parallel – that is, all of the letters of the word are seen at once. Words with common combinations of letters are, all else being equal, more visually familiar than words with unusual combinations of letters and therefore easier to recognize. Neighborhood effects for pseudo-words, such as GLORP, that can be read aloud but do not correspond to real written words are highly task dependent. When subjects are asked to read pseudo-words aloud, neighborhood size has a facilitatory effect, just as it does with words. However, in a lexical decision task, large neighborhood size slows down responses to pseudo-words. That is, people find it more difficult to determine that an item such as BREN, which has at least 15 neighbors, is not a word than an item such as FNER, which has none.

Mapping from Spelling to Sound in Visual Word Recognition

Visual word recognition depends in large part on being able to determine the pronunciation of a word from its written form. One factor that influences how easily this can be done is the regularity of the mapping from spelling to sound. Consider a word such as DOLL. Arriving at the correct pronunciation benefits from experience with words such as DOT and GOLF, in which the O is pronounced in the same way. On the other hand, DOLL is very similar to words such as ROLL, TOLL, and KNOLL, in which the letter O is assigned a different pronunciation. The fact that similar written forms map onto disparate phonological forms makes mapping difficult, and in fact words that contain such inconsistent mappings between spelling and sound are more difficult to read than words that contain entirely consistent mappings.

Interestingly, regularity in spelling-to-sound mappings varies greatly among languages. Some, such as Korean and Serbo-Croatian, employ perfectly regular mappings from spelling to sound, such that each sound in the language is represented by a single character. Chinese characters, at the opposite extreme, contain only highly probabilistic information about pronunciation. English – the language in which by far the most research has been conducted – represents something of an intermediate case. This has consequences for how visual word recognition is accomplished in these languages and even for how reading disorders manifest. In English, it is common for dyslexic children to have trouble with 'decoding' (i.e., being able to read novel pseudo-words), whereas in Italian (a highly regular writing system) the main deficit in dyslexia is slow reading speed.

Word Recognition Influences Lower Levels of Processing

In both spoken and written language, words can be described as composed of parts. For example, the word KNEW is written with four letters and pronounced with two or three phonemes (a 'phoneme' is the linguistic term for a single speech sound, and KNEW can be pronounced /nu/ or /nju/ depending on one's dialect). The ease with which these parts can be identified, particularly in print, makes it tempting to assume that word recognition proceeds in a strictly serial fashion, starting with the identification of individual parts and proceeding to the identification of the whole word. In fact, there is abundant evidence that knowledge of whole words has a strong influence on recognition of smaller units.

Fluent comprehension of language frequently depends on making decisions based on incomplete information. For example, most telephones carry a signal that discards much of the information carried in speech, and yet we are rarely aware of the ambiguities this introduces, for example, between the first sounds in the words 'think' and 'fink.' In fact, a great deal of early research on speech perception was done at Bell Labs to address this kind of issue. One reason we are so good at word recognition is that we are able to engage what are called 'top-down' processes – for example, guessing what the next word will be or using our knowledge that some patterns are more consistent with a specific context or even general properties of our language. The influence of our knowledge of words on perception of smaller 'grain sizes,' or units of information, is part of a general pattern: Sentence and even discourse-level context can influence how we recognize individual words, and knowledge of the speech sounds of our language influences how we perceive particular sounds. As discussed later, however, there is some controversy regarding whether top-down influences affect perception directly or are implicated only when we make decisions about what we have heard.

Phoneme Restoration and the Ganong Effect

Lexical effects on phoneme perception can, in appropriate circumstances, result in rather compelling auditory illusions. For example, when presented with a sentence in which a consonant has been replaced with white noise, people readily identify all words in the sentence and furthermore are frequently unable to determine which sound was manipulated. This is termed the 'phoneme restoration effect' because it is as if the manipulated speech sound were restored by the listener. A similar effect is named after its discoverer,

William F. Ganong III: When ambiguous speech sounds are presented as stimuli in categorical perception experiments (e.g., an utterance halfway between 'pink' and 'bink'), people are more likely to identify the stimulus as a word. This is interesting because unlike the tasks typically used to study the phoneme restoration effect, in this case the experiment explicitly requires participants to pay attention to individual speech sounds, and yet there is a strong influence of lexical knowledge.

Although these effects clearly demonstrate that lexical knowledge influences how speech sounds are perceived, there is also abundant evidence that fine phonetic detail has an influence on how rapidly words are recognized. To some extent we hear what we are somehow 'prepared' to hear, but there is also an effect of what is actually impinging on our ears. Manipulations much subtler than replacing an entire phoneme with white noise – for example, splicing in the same sound from a different word – result in slower performance in a wide range of word recognition tasks. Furthermore, the strength of both the Ganong and phoneme restoration effects can be influenced by various stimulus parameters. Finally, there is some question as to whether or not identification of these 'smaller units' is a necessary precursor to identifying spoken words. In fact, a number of distinct theories share the assumption that identification of individual speech sounds is epiphenomenal to the goal of distinguishing words from one another.

The Reicher–Wheeler Effect and 'Interactive Activation'

In the late 1960s, GM Reicher and Daniel D Wheeler each independently discovered the 'word superiority effect.' In a series of experiments, they consistently found that people were much better at identifying letters that appeared in words than when they appeared in random letter strings or when they appeared by themselves. The interactive activation model was developed in 1981 by David Rumelhart and James McClelland in part to explain these phenomena, and it remains influential in current research. It was one of the first models of a psychological process that was implemented on a computer and made quantitative predictions based on an architecture loosely inspired by facts about information processing in the brain.

The interactive activation model simulates human word recognition with a set of interconnected nodes that represent increasingly large 'grain sizes' or units from visual features that make up letters, to letters themselves, to whole words. Processing in the model is simulated as passing activation – an analogy to electrochemical impulses transmitted across synapses in real neural systems – forward from levels representing smaller units and, critically, backward from larger levels to smaller. The feedback connections were critical to capturing the word superiority effect: When the visual features for a known word were activated, this would partially activate the corresponding letters, which in turn would partially activate all of the words in which they were contained. When the active letters were consistent with a known word, the feedback from the word level would be stronger and more coherent than when they were not, resulting in a word superiority effect. This remains the dominant explanation of the word superiority effect in reading, although the role of feedback in perception of spoken words is more controversial.

Word Recognition Models and Controversies in Cognitive Psychology and Neuroscience

Word recognition is often a paradigmatic case for cognitive psychology and cognitive neuroscience because it provides a setting in which phenomena of clear relevance to larger theoretical issues can be readily observed. Many issues of theoretical debate are relatively abstract, and so pursuing computational models of increasing sophistication and addressing specific phenomena in word recognition has been one important way these debates have moved forward. Thus, although they remain largely unresolved, no discussion of word recognition would be complete without touching on these issues.

Interactive Processing with Feedback or Autonomous, Feed-Forward Processing?

The necessity of feedback touches on a long-standing issue of contention in cognitive psychology: Is the architecture of cognition correctly described as a set of modular, domain-specific processing units dedicated to particular tasks? Or is it more of an interactive system in which processing units at multiple levels influence one another bidirectionally? Spoken word recognition is an area of research in which this question is being actively pursued.

The influence of lexical knowledge on perception of smaller units of speech is well characterized. One model that addresses these phenomena, the TRACE model, is based on the interactive activation model. In fact, TRACE uses the same principles as the interactive activation model, but instead of visual features and letters, this model identifies words based on auditory features and phonemes. In this model, the

influence of lexical knowledge on speech perception is the result of feedback from the word level to lower levels of representation.

An alternative model, the MERGE model, argues that such feedback is never necessary for word recognition and could, in fact, prevent the hearer from being able to detect mispronunciations. As noted previously, lexical effects can result in compelling auditory illusions under some conditions, but it is more usual for so-called 'bottom-up' processes to drive perception. The MERGE model addresses lexical influences on phonological perception by attributing these effects to a phonetic decision stage that is task specific. That is, when asked to make a decision about which speech sound was presented, people pool information from both phoneme-level and word-level representations in a third, decision stage that is not used in typical spoken word recognition.

Both models can explain much of the relevant data, and in fact it remains controversial which is more accurate or complete. The distinction between these two models reflects a division between interactionist and modular theories of cognition that is found throughout the cognitive psychology. Interactionist theories stress the role of feedback because it is consistent with a particular view of brain function – specifically that information processing involves pooling multiple, interacting sources of information, and that 'partial products' of processing at one level can influence processing at other levels. In contrast, modular theories emphasize the autonomy of processing subsystems because this is thought to be critical for rapid, automatic processing.

'Words and Rules' or 'Constraint Satisfaction'?

One point of consensus among theorists who study visual word recognition is that there are at least two pathways involved in word reading: One that links written words directly with their pronunciations and another that links them with their meanings. The two dominant theoretical frameworks in the field differ sharply, however, in the mechanisms they propose to underlie these pathways. The contrasts are very revealing with respect to the differences between two rival schools of cognitive psychology (especially psycholinguistics) and their differing approaches to interpreting data and elaborating theories of language processing.

In the 'words and rules' view (this moniker is taken from a popular book by Steven Pinker that describes a similar debate – with many of the same participants – regarding morphological processing; the most important example of this approach to reading is Max Coltheart's 'dual route' model), reading is accomplished by two separate mechanisms with entirely different computational properties. The 'lexical route' is an associative network of words similar to the interactive activation model. The 'sublexical route' comprises a set of rules for translating letters into sounds. Whereas the lexical route is activated in parallel, and is sensitive to fine-grained statistics of the lexicon such as the frequency of individual words, the sublexical route operates in serial and applies spelling-to-sound rules that, though based on statistics of the lexicon, are discrete and categorical in their application (so that no matter how many times it has seen the word MIND, it will always arrive at a pronunciation that rhymes with PINNED by applying the rules for M, I, N, and D in serial).

An important feature of this view is that the different pathways are conceived as entirely distinct processing mechanisms. This reflects a theoretical commitment to the notion of modularity, with an emphasis on the assertion that cognitive functions are subserved by highly specialized processing units. Note, however, that this model differs from MERGE in that it permits both feedback and cascading activation, albeit only in the lexical route. This model also reflects the influence of cognitive neuropsychology in its early development. The distinction between lexical and sublexical routes was initially motivated by a series of neuropsychological observations of double dissociations. Some stroke patients present with specific difficulty reading exception words that do not follow typical spelling-to-sound correspondence patterns, such as PINT, but are relatively unimpaired at reading novel pseudowords, such as GLORP. Other patients present with a complementary pattern of deficit: relatively spared performance on exception words and gross impairment on pseudowords.

The constraint satisfaction approach views the division of labor in visual word recognition differently. (This approach is often referred to as the parallel distributed processing approach, after the style of computational model that is used to implement the theory; the most recent version of this model by Harm and Seidenberg directly addresses the notion of division of labor.) In this view, mappings from spelling to sound and spelling to meaning are acquired and processed by the same basic mechanism, operating over different types of information. Mappings from spelling to sound are not conceived as a set of categorical rules abstracted from the statistics of the input but, rather, as a set of probabilistic constraints that reflect these statistics. In this way, consistency effects resulting from multiple grain sizes – letters, combinations of letters such as PH that map onto single sounds, and still larger possible units – can be accounted for (e.g., the influence of ROLL and POLL on DOLL discussed previously). Mappings from spelling to

meaning are acquired with the same learning mechanism. However, because associations between spelling and meaning (in English, at least) are more arbitrary than associations between spelling and sound, the result of this learning process tends to be more word specific. That is, different factors influence the mapping from spelling to sound and the mapping from spelling to meaning as a result of the same learning mechanism applied to different types of problem, not as a result of different processing mechanisms in the two pathways.

In this view, observed dissociations between nonword and exception word reading are the result of damage to regions involved in mapping from spelling to sound and spelling to meaning, respectively. This further predicts that patients who lose the ability to read 'exception' words may also have difficulties with word meanings more generally, and that patients who have difficulty with decoding are likely to have difficulties with more general aspects of speech sounds. These associations are found throughout the neuropsychological literature, and in fact, the cases of dissociation are, despite their importance in theory building, relatively rare. Furthermore, because constraint satisfaction models are implemented as systems that learn, they have been able to provide an explanation of the link between phonological deficits and reading difficulties observed in developmental dyslexia.

Neuroanatomy of Word Recognition

Aside from modality-specific sensory regions engaged by particular stimulus types – visual regions involved in perceiving text and auditory regions involved in perceiving speech – a number of brain regions have been consistently shown to be involved in word recognition. Data from both neuropsychological studies of patients with brain lesions and studies using neuroimaging techniques such as positron emission tomography, functional magnetic resonance imaging, and electroencephalography provide insights into the network of brain regions involved in perceiving and understanding words.

Superior Temporal Gyrus and Superior Temporal Sulcus

Superior temporal gyrus (STG) is the site of auditory association cortex (and a site of multisensory integration) and thus necessarily plays some role in spoken word recognition. Evidence that its role extends beyond that of higher-level perceptual processing was found as early as 1871 by Karl Wernicke. He discovered that lesions in the posterior portion of the left STG were associated with the loss of the ability to comprehend and produce spoken words. More recently, it has been found that this phenomenon of 'Wernicke's aphasia' is observed to result from brain damage to a broad variety of sites; furthermore, damage to traditional Wernicke's area does not always result in aphasic symptoms.

Neuroimaging studies of healthy subjects have found evidence for a role in processing of word meanings for both anterior and posterior STG as well as superior temporal sulcus (STS; the sulcus that divides the STG from the middle temporal gyrus). The STS, in particular, responds more strongly to interpretable speech than to a range of stimuli matched on lower level acoustic dimensions. The STS is also a likely site of integration between print and sound in visual word recognition.

Inferior Frontal Gyrus

Although the involvement of inferior frontal gyrus in language processing was initially described by Paul Broca in 1861, its precise function is the subject of continuing research even today. This region is known to be involved in multiple aspects of word recognition, including both semantic and phonological processing. Critically, it is not thought to be involved in purely perceptual or bottom-up processes involved in word recognition. Instead, activity in this region is thought to reflect effortful processing, as in tasks that require comparing the meanings or pronunciations of multiple words. One active area of investigation concerns whether subdivisions of the inferior frontal gyrus are functionally distinct with respect to their role in word processing; because this region also plays a role in many forms of working memory, its activity is also related to general task difficulty.

The 'Visual Word Form Area'

A region of left ventral temporal cortex, on the fusiform gyrus, is involved in processing the printed forms of words. Evidence that this region plays a role in early visual processing of written words comes from studies using a wide range of techniques. Within less than 200 ms after a stimulus is presented, electrophysiological responses in this region differentiate words from nonlinguistic visual stimuli. Patients with brain damage in this region present with alexia – an inability to read, often with a spared ability to write. Furthermore, metabolic neuroimaging techniques consistently show a role for this region in reading. Whether activity in this region is specific to words is under debate, as is its specific function, although anatomical and functional evidence suggests that it intermediates among lower level visual information and the phonological and semantic processes

involved in recognizing visual words. Bilateral ventral temporal cortex has been implicated in many tasks involving perceptual expertise for visual stimuli. Specialization for text in this region may thus be understood as an example of perceptual expertise.

Summary

Behavioral research has established a number of key phenomena in word recognition: Many factors that influence the efficiency of computing meaning from sound – and both meaning and sound from text – have been discovered. Sophisticated computational models have provided mechanistic explanations for these findings while, largely in parallel, research in cognitive neuroscience and neuropsychology has revealed gross aspects of the neuroanatomy of word recognition and has begun to explore finer-grained detail of how these processes are accomplished in the brain. Although serious controversies remain, these multiple different avenues of research together have provided important insights about the word recognition and about many broader issues in the study of cognition.

Working Memory: Capacity Limitations

T Drew and E K Vogel, University of Oregon, Eugene, OR, USA

© 2009 Published by Elsevier Ltd.

Working Memory System

Working memory (WM) has been proposed to be a cognitive system that temporarily holds a limited amount of information in an active state so that it may be quickly accessed, integrated with other information, or otherwise manipulated. This type of memory is thought to underlie our ability to perform a wide range of basic tasks such as assigning meanings and syntactic roles to the interdependent words of a complex sentence, understanding the relationships among the ideas within a complex argument, performing mental rotation, and tracking the trajectory of a moving object when the visual input to the brain is continually disrupted by eyeblinks and saccades. Many cognitive processes that require information to be held in an online state are thought to use the WM system as a form of mental workspace to perform their requisite operations. As a result of its central position within cognition, the limited capacity of the WM system reflects one of the more significant processing limitations for human cognition.

Capacity Limits: Central or Modality-Specific?

One of the most notable characteristics of WM is that its storage capacity is highly limited. Most of the early models of short-term memory implicitly or explicitly assumed that it was a unitary memory store, irrespective of modality. In the 1970s, however, Baddeley and his colleagues proposed a multimodal model of WM in which the memories for visual and verbal information are stored separately with independent capacity limits, both controlled by a central executive process. Early support for this model came from dual-task experiments in which little or no interference was found when verbal memory tasks were performed concurrently with visual memory tasks but substantial interference was found for two concurrent verbal tasks or two concurrent visual tasks.

Nelson Cowan, on the other hand, proposed that the capacity limits of WM reflect a more central limit, irrespective of modality. Specifically, his model proposes that WM is not an entirely separate system but is a part of the long-term memory system. Consequently, representations of information in WM are proposed to be the activated portions of long-term memory within two embedded levels. The first level consists of activated long-term memory representations, which are memory representations that have recently been accessed. Although a large number of these representations can be active simultaneously, the highly accurate retrieval of this information is fairly limited as a consequence of interference. By contrast, the second level consists of a small subset of these active long-term memory representations that are held within the focus of attention, which has a capacity limit of approximately four items, irrespective of modality. That is, although there may be independent passive maintenance of information in modality-specific stores, the true capacity limits arise from the central limitation of the focus of attention.

Overview and Approach

At present, the evidence is somewhat mixed with regard to whether WM capacity limits are modality-specific or a single central limitation. Therefore, in the following sections, we consider the capacity limitations of WM separately for the verbal and visual modalities. Where appropriate, however, we also describe how these results can be alternatively accounted for within the Cowan framework. After discussing the common behavioral approaches to measuring WM capacity, we then describe more recent attempts to use neurophysiological methods to measure these capacity limits. In the final section, we summarize work that examines individual differences in WM capacity and how these differences relate to broader cognitive constructs such as intelligence and attentional control.

Verbal Working Memory Capacity – Memory Span Tasks

For over a century, the most common approach to measuring WM capacity has been with variations of the digit span task. In the standard version of this task, subjects are given a randomized list of numbers that they must immediately repeat back in the order of presentation. Subjects are initially presented with lists of two or three digits and if they repeat a list of numbers without making a mistake, the size of the list is increased until they cannot accurately complete the list. On average, most individuals can accurately report approximately seven items, although this number varies substantially across individuals. Similar estimates are typically observed when letters and words are used as the to-be-remembered stimuli.

Although the results of span tasks are often interpreted as reflecting the capacity of WM for verbal material, there are two important constraints that shed light on the nature of storage capacity in this context.

Chunking of Information

Recently, *Psychological Review* named George Miller's 1956 article, "The magical number seven, plus or minus two: Some limits on our capacity for processing information," as its most influential paper. Although many agree that the author intended the title of the paper to be taken as a tongue-in-cheek statement, the meme of short-term memory being limited to "seven plus or minus two" items has permeated the popular literature in psychology for the last 50 years. However, one of the primary ideas expressed in Miller's paper is that the exact number of items that can be held in WM depends heavily on whether the items can be grouped into meaningful units, or chunks. That is, chunking exploits preexisting information about concepts already stored in long-term memory so that new information can be more efficiently held in WM. For example, consider the letter string:

FBICIAFDRJFK

Memory span for this series is generally fairly poor because the 12 letters exceed the typical seven-item limit. However, consider the same items when broken into the following clusters:

FBI CIA FDR JFK

Performance is greatly enhanced under this condition because the units for memory span are four meaningful and familiar concepts rather than 12 independent letters. Thus, the precise number of items that can be held in WM is strongly dependent on what type of information is to be held, whether those items can be clustered into a smaller number of meaningful units, and finally whether the subject attempts to strategically code the incoming information into clusters. Indeed, efficient chunking of information is thought to be a pervasive aspect of daily cognitive life, and it may greatly underlie our ability to perform complex tasks such as reading and playing chess.

Phonological Coding of Verbal Information

The remaining constraint on estimates of verbal WM capacity is derived from studies that have examined the nature of how information is coded in verbal WM. One of the more popular characterizations stems from Baddeley's model of WM. In particular, information maintained in verbal WM is thought to be stored in a phonological loop. Essentially, information is thought to be stored as a phonological or sound-based code within a structure (e.g., a tape loop) that can hold a limited amount of information for a very short period of time. However, this information can be held for much longer durations when the subject subvocally rehearses the phonological information repeatedly to keep it from being lost. There are several pieces of evidence that support the notion of phonological storage in verbal WM. For instance, fewer phonologically similar words (e.g., cap, slap, trap, map) can be held in WM than phonologically dissimilar words. However, memory span is not affected if the words are similar in meaning (e.g, big, tall, huge, wide) or similar looking (e.g., bough, dough, cough, through), which indicates that the phonological properties of the to-be-remembered items are a primary factor for the storage limit. In addition, many studies have shown that memory span is considerably smaller for phonologically longer words (e.g., alimony, Mississippi, testosterone) than for phonologically short words (e.g., hat, boy, up), which indicates that storage capacity is determined by how long it takes to pronounce the information to be remembered. Moreover, an individual's rate of speech also has a direct impact on how many items he or she can hold in a span task, with fast-speaking individuals capable of holding more items than slower-speaking individuals. On the basis of results such as these, many researchers agree that the capacity of verbal WM is determined by how much the individual can say in approximately 2 s. Thus, it appears that the capacity limits of this system are much better understood in terms of time (i.e., 2 s of speech) rather than by numbers of items (e.g., seven plus or minus two). Interestingly, when subjects are prevented from engaging in rehearsal, individuals can accurately report only three or four items accurately. This could be explained by Cowan's central capacity limit theory, in that the phonological loop is a domain-specific storage mechanism and the true capacity limit of attention can be observed when rehearsal is prevented.

Visual Working Memory Capacity: Whole Report

The initial measurement of the capacity of WM for visual information is often credited to George Sperling. In this influential series of experiments, subjects were presented briefly (50 ms) with arrays of 12 random letters and were asked to immediately report as many letters as possible. Across several experiments, subjects could accurately report between four and five items, irrespective of how many total letters were in the array, how they were configured, or how

long the array was presented (ranging from 15 to 500 ms). The results of these and other similar experiments suggest that subjects' ability to apprehend information from a brief display is extremely limited and that they are capable of maintaining information about only a relatively few items in memory.

Sperling's estimate of visual WM capacity has two potential limitations as an estimate of visual WM capacity. The first is the possibility of output interference. Subjects were asked to name or write each of the letters they remembered. This may have underestimated WM capacity because the process of transforming the visual input into a reportable form may be too slow to capture the fleeting sensory information before memory capacity is fully exhausted. Furthermore, Sperling used alphanumeric characters as the memoranda, which calls into question whether the items were being held strictly in a visual memory store or whether both verbal WM and visual WM contributed to the capacity estimate. Indeed, because the subjects had to report the identity of the letters at the end of the trial, they must have transformed the visual image into verbal labels. Thus, although suggestive, results from whole report tasks such as these do not provide definitive estimates of the capacity of WM for visual information.

Visual Working Memory Capacity: Features and Objects

In an attempt to measure the capacity of visual WM more directly, we and others developed a variation of Philips' sequential comparison paradigm that is commonly known as the change detection paradigm. In this task, subjects are shown a brief array of simple objects that they must remember (see **Figure 1**). The objects disappear for a short retention period and afterward reappear in the same locations as before. On half the trials, the first and second arrays of objects are identical; on the other trials, one of the objects changes its identity (e.g., shape or color). Subjects make a single button-press response regarding whether the two arrays are the same or different. To examine capacity limitations in this task, the number of items in each array is manipulated to find when performance starts to decline. Luck and Vogel used this task to examine the capacity of visual WM for simple single-featured objects. These objects were bright, suprathreshold colors that were chosen to be highly discriminable from one another so that the task would be limited primarily by memory storage capacity rather than by perceptual and decision factors. Performance was near-perfect for arrays containing one, two, or three items, but declined at higher set sizes. They estimated visual WM capacity to be approximately three to four items, and this was unchanged even when subjects performed a concurrent articulatory suppression task to keep them from verbally labeling the visual items. They also tested whether visual WM capacity is determined by the number of features that must remembered or whether it is determined by the number of objects that must be remembered. To do this, they asked subjects to remember arrays of objects that each possess two features (e.g., color and orientation) to determine whether the additional features consumed more memory capacity. Surprisingly, they found that subjects could remember the same number of multifeatured objects as they could single-featured objects. Indeed, in one experiment, they found that subjects could remember four four-featured objects (i.e., color, orientation, size, and a stripe) just as well as they could remember just four colors. That is, they could retain up to sixteen features as long as they were distributed across four separate objects. Although there are some limitations to the strength of this object advantage, these results have been taken as strong evidence in favor of visual WM capacity being determined by the number of objects to be remembered.

Units of Capacity: Objects or Information Load?

A recent challenge to the object-based visual WM capacity proposal was provided by Alvarez and Cavanagh, who tested whether visual WM capacity was also determined by the information load engendered by various complex object categories. To examine this, they measured visual WM capacity for several object categories of varying complexity (e.g., simple colors, Chinese characters, and three-dimensional shaded cubes) and found that, as the complexity of the remembered objects increased, the memory capacity likewise decreased (see **Figure 2**). That is, subjects could remember approximately 4.5 colored squares (the least complex items), but they could accurately remember only 1.6 shaded cubes (the most complex items). They described these results as indicating a direct trade-off between the required resolution of the items in memory and the number of items that may be maintained in visual WM; complex items that require a high resolution cause a decrease in how many objects can be held in memory.

Recently, Awh, Barton, and Vogel examined whether the lower capacity estimates for complex objects may have been due to an increase in similarity between items in the complex categories. That is, change detection performance depends not only on the number of representations that can be maintained in working memory but also on the observers' ability

Figure 1 Estimating visual working memory capacity: (a) change detection paradigm using color; (b) memory performance in (a); (c) change detection paradigm using color and orientation; (d) memory performance in (c). In (a), subjects are asked to remember the colors in the memory array across the retention interval. At test, subjects judge the colors to be the same or different as the memory array. As shown in (b), performance in this task is near-perfect for 1, 2, or 3 items and quickly declines at higher set sizes. A concurrent articulatory suppression task has no effect on performance of the visual memory task. In (c), subjects are asked to remember both the color and orientation of the items. As shown in (d), memory performance is equivalent irrespective of the number of features. Adapted from Luck SJ and Vogel EK (1997) The capacity of visual working memory for features and conjunctions. *Nature* 390: 279–281.

to discriminate between these stored representations and the new items that are presented during change trials. If the similarity is high, then changes can be missed in this procedure even though the changed item was stored in memory. Along these lines, Awh and colleagues found that for the object categories used by Alvarez and Cavanagh there was a strong positive correlation between complexity and within-category similarity. Moreover, they found that when within-category similarity was decreased (by using cross-category changes) memory capacity estimates were equivalent for both simple and complex objects (i.e., three to four items). These data suggest that visual WM represents a fixed number of items, regardless of object complexity. These results do not contradict the important observation that change-detection performance is strongly influenced by object complexity. However, it may be that the relationship between object complexity and change detection has more to do with the resolution for making discriminations than with the number of representations that can be maintained in memory.

Neural Measures of Working Memory Capacity

Neuroimaging Since the 1990s, numerous studies using neuroimaging in humans have found increased blood-oxygen level-dependent (BOLD) activation during the retention interval of various WM tasks. This activity is thought to be analogous to delay activity observed in monkey single-unit studies. The sustained BOLD activity is primarily observed in the prefrontal, posterior parietal, and inferotemporal cortices. Although there have been several demonstrations that the magnitude of the activity increases as memory load increases, it is often difficult to

Figure 2 Information load and working memory capacity. As the information load for a type object increases, the estimated number of items that can be accurately remembered decreases from a high of 4.4 objects for color squares to a low of 1.6 for three-dimensional cubes. The search rate for each object type was found by asking subjects to perform a visual search for a specific object among other objects of that type. Search rate is a proxy for the amount of information load for a given object. Adapted from Alvarez GA and Cavanagh P (2004) The capacity of visual short-term memory is set by both the visual information load and by number of objects. *Psychological Science* 15(2): 106–111.

determine whether it necessarily reflects WM storage demands *per se* or whether other, more task-general activity is responsible for the load-related increase in activity. Consequently, it is often difficult to determine whether the increasing activation is due to more memory representations being held in WM or if it is simply the result of the increased difficulty in the high-load conditions.

Within the verbal WM domain, there is one notable functional magnetic resonance imaging (fMRI) study that appeared to distinguish between patterns of neural activity for subcapacity memory loads and supra-capacity loads. Specifically, Rypma and colleagues used a letter WM task and found increased activation in the left ventrolateral prefrontal cortex for loads of three items, compared to only one item. This region is in the vicinity of Broca's area, and it is plausible that the increased activity reflects the additional subvocal rehearsal demands for the additional items in verbal WM. Interestingly, when the load was increased from three items to six items, a wide range of prefrontal areas became active. These results suggest that when the verbal WM capacity was exceeded, many additional executive processes are recruited to assist in performing the task.

In the visual WM domain, there are two recent studies that suggested that activity in the posterior parietal cortex is sensitive to WM capacity limits. Todd and Marois used the change detection paradigm for colored items and found that retention period activity in the intraparietal sulcus (IPS) increased as a function of the number of items in memory, but this increasing activity reached asymptote at approximately four items (see **Figure 3**). These results suggest that the activity in the IPS reflects the number of item representations that can be successfully maintained in visual WM because it reaches a ceiling at the known storage-capacity limit of visual WM. Xu and Chun recently replicated and extended this finding by showing evidence that there are three primary areas that show this sensitivity to visual WM capacity limits: the superior IPS, the lateral occipital complex (LOC), and the inferior IPS. Interestingly, they found that the activity in the superior IPS and LOC reached asymptotic levels for smaller array sizes when the memory items were complex than when they were simple. However, the inferior IPS activity reached asymptote at arrays of four items, irrespective of whether the items were simple or complex. Together, these results suggest that a suite of posterior cortical areas underlie visual WM capacity limits and that distinct mechanisms may be sensitive to the necessary resolution and the number of items that can be held in visual WM.

Electrophysiological measures Our laboratory used event-related potentials (ERPs) to observe the storage and maintenance of object representations in visual WM. To do this, we used a modified version of the change detection paradigm in which we presented simple objects in both the left and right hemifields and asked subjects to remember the items in only a single hemifield using an arrow cue (see **Figure 4(a)**). This bilateral stimulus task design allowed us to isolate the ERP activity that is specific to the memory items by dividing electrodes in terms of whether they were contralateral or ipsilateral with respect to the side of the display the subjects were remembering on a given trial. Approximately 250 ms following the onset of the memory array, we observed a large negative wave at posterior electrode sites that were contralateral to the position of the memoranda for a given trial. This activity persisted throughout the retention period until the test array arrived, and we refer to it as the contralateral delay activity (CDA). An important property of the CDA is that its amplitude increases as a function of the number of items that are being held in visual WM. However, like the fMRI studies in the IPS, this amplitude increase reaches asymptote at approximately four items,

Figure 3 An fMRI measure of visual working memory capacity: (a) a statistical map of activation in the intraparietal sulcus (IPS) during the retention interval overlaid on a structural scan; (b) activation in the IPS as a function of number of memory items. The green arrow represents the time of presentation. Activation in this area increases until there are three items and then asymptotes for four to eight items. fMRI, functional magnetic resonance imaging; L, left; R, right; VSTM, visual short-term memory. indicating that this activity is sensitive to visual WM capacity limits and may reflect the active representations that can be held in memory. Indeed, the precise point at which it reaches asymptote is different for each subject depending on his or her specific memory capacity (see Figure 4(c)).

Individual Differences in Working Memory Capacity

Although the capacity of WM is known to be highly limited, these limitations have long been known to vary substantially across individuals. In fact, because WM is thought to play a central role in a wide range of cognitive processes, it is not surprising that an individual's WM capacity is positively correlated with performance on a wide range of cognitive and aptitude measures such as intelligence, reasoning, scholastic performance, math abilities, and ability to acquire a second language. Thus, WM capacity appears to be a core mental construct that underlies an individual's general cognitive ability in a variety of situations. Next, we review two primary correlates of WM capacity: intelligence and attentional control.

Intelligence and Working Memory Capacity

The relationship between WM capacity and intelligence has been well known and studied for over a century. For example, Binet and Simon observed that cognitively impaired children have sharply smaller digit spans than normal children, which prompted the view that WM capacity could provide a window to intelligence. Indeed, to this day, almost all intelligence battery tests include at least some form of memory span component. In the last few decades, researchers began to move away from using digit span as an individual difference measure because it is highly susceptible to strategic performance differences, such as chunking, that often weaken the relationship to intelligence measures. Instead, many use WM measures of processing capacity rather than simple span as a predictor of cognitive performance. For example, Daneman and Carpenter demonstrated strong positive correlations between WM reading span tasks and cognitive aptitude. Their reading span task asked subjects to read sets of random sentences and to remember the last word of each sentence, which they were tested on at the end of the session. Performance on this task was strongly correlated with SAT verbal scores and reading comprehension scores. One currently popular method used to measure WM capacity is operation span (OSPAN). A subject's OSPAN is measured by asking the subject to read a simple mathematical equation, judge the accuracy of the equation, and then read a random word aloud. For example:

$$\text{Is } (3 \times 4) - 6 = 7? \text{ Dog}$$

After the task has been repeated several times, the subject is asked to recall as many of the words as possible. Both reading span and OSPAN show strong positive correlations with language comprehension and intelligence measures. However, the relationship between WM capacity and intelligence is not limited to measures of verbal WM, but can also be observed with visual WM measures as well. For example, Cowan and his colleagues recently found

Figure 4 An event-related potential (ERP) measure of visual working memory capacity: (a) a bilateral change detection trial; (b) ERPs time-locked to the memory array; (c) mean amplitude of contralateral delay activity (CDA) during the retention interval; (d) correlation between an individual's memory capacity and the asymptote of the CDA (r =0.78). In (a), subjects are cued to remember the items in one hemifield. After a retention interval, subjects judge whether objects on the cued side of the test array are the same or different than objects in the memory array. In (b), note that negative voltage is plotted upward in the graphs, which show grand-average ERP waveforms time-locked to the memory array and averaged from occipital and posterior parietal electrodes. Ipsilateral and contralateral are defined with respect to the side of the screen that subjects are cued to attend. Gray rectangles represent the time of the memory and test array. As shown in (c), CDA amplitude increases up to approximately three items and then asymptotes at the point when the mean behavioral capacity (approximately three items) is exceeded. In (d), subjects with low memory capacity showed little increase from two to four items compared to high-capacity subjects. Adapted from Vogel EK and Machizawa MG (2004) Neural activity predicts individual differences in visual working memory capacity. *Nature* 428: 748–751.

that individual differences in capacity in change detection paradigms are also strongly predictive of intelligence and scholastic measures, including reading comprehension. This finding is consistent with Cowan's proposal that there is a single central WM capacity because measures that purport to quantify verbal and visual WM capacity are equally predictive of general cognitive ability, suggesting that the same central capacity limit underlies both visual and verbal WM tasks.

Attentional Control and Working Memory Capacity

More recently, researchers have begun to further examine the nature of the relationship between WM capacity and cognitive performance. However, rather than emphasizing the advantages of additional memory storage space, they have proposed that the benefits of a high WM capacity may actually be due to more efficient attentional control, that is, to how the WM system is used to determine the flow of information into WM and reduce the interference from distracting information. To date, there have been many demonstrations of a strong relationship between performance on various attentional control tasks and WM capacity. For example, in the antisaccade task, subjects are asked to look away from the position of a target that abruptly appears on the screen. This task is thought to require attentional control to override the prepotent response to look directly at the new object location. Interestingly, low-capacity individuals are much worse at avoiding eye movements toward distractors than high-capacity subjects. Moreover, WM capacity has also been shown to predict cocktail party effects in which subjects sometimes notice their own names when they are embedded in an unattended auditory channel. Surprisingly, Conway and colleagues found that low-WM-capacity subjects were three times more likely to detect their name than high-capacity subjects. Results such as these question whether the differences between high- and low-capacity individuals are due strictly to storage or processing

abilities; it demonstrates that low-capacity subjects may often be processing more information than the high-capacity subjects but that this information may be detrimental to the task at hand. Along these lines, Vogel, McCollough, and Machizawa examined whether there are differences in the ability to voluntarily control what information is stored in visual WM. To do this, they presented subjects with arrays of objects that contained a mixture of relevant and irrelevant objects, and they measured the CDA component to determine how many total objects (including distractors) were stored in visual WM. They found that high-memory-capacity subjects were extremely efficient at keeping the irrelevant distractors from being stored in memory, whereas the low-capacity subjects were highly inefficient at excluding the distractors from being stored and held in memory (see Figure 5(b)). Thus, the low-capacity subjects actually held more information in memory than the high-capacity subjects, but this ancillary

Figure 5 Attentional filtering and working memory: (a) attentional filtering test; (b) mean contralateral delay activity (CDA) amplitude waveforms split between high- and low-memory-capacity subjects; (c) correlation between filtering efficiency and working memory capacity. In (a), subjects were instructed to remember the orientations of only the red items and to ignore the blue items. There were three trial types: two red items alone, four red items alone, and two red items intermixed with two blue distractors. In (b), the CDA amplitude indicates that low-capacity subjects encoded the irrelevant items along with the red items, whereas high-capacity subjects encoded only the red items. In (c), the filtering efficiency measures how similar the CDA amplitude in the distractor condition is to the amplitude in the conditions without distractors. Perfectly efficient attentional filtering would result in equivalent amplitudes for the distractor condition and the two-item condition, resulting in an efficiency score of 1. As memory capacity increases, filtering efficiency also increases ($r = 0.69$). Adapted from Vogel EK, McCollough AW, and Machizawa MG (2005) Neural measures reveal individual differences in controlling access to working memory. *Nature* 438: 500–503.

storage was for irrelevant information. Together, these results suggest that individual differences in WM capacity may actually be the consequence of the attentional control process that determines what information is stored in memory and whether distractions can be resisted rather than the consequence of how much information can be held at one time.

Writer's Cramp

M J Nirenberg, Weill Cornell Medical College, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Background

Dystonia is a syndrome of sustained muscular contractions that cause twisting and repetitive movements or abnormal postures of the affected body parts. It can be focal (involving a single body part), segmental (involving adjacent body parts), hemidystonic (affecting one side of the body), multifocal, or generalized. Some focal dystonias selectively impair the performance of a specific task. These focal, task-specific dystonias (FTSDs) most commonly affect the hands. They usually develop after chronic, repetitive, stereotyped performance of a specific task such as writing (writer's cramp; WC) or playing a musical instrument (musician's dystonia). Of these, WC is the most common FTSD. It is characterized by co-contraction of agonist and antagonist muscles in the affected limb that occurs selectively with writing, with overflow to muscles that are not normally involved in this task.

Clinical Presentation

Demographics

WC occurs in both genders, but is slightly more common in men than in women (1.3:1 ratio). It typically develops in the third to fifth decades, with a slightly younger age of onset in women. The estimated prevalence in the United States is 69 per 100 000, whereas in a study of eight European countries it was only 14 per 1 000 000. These figures are likely underestimates, given that many patients never seek medical attention, and some who do so may not receive the correct diagnosis.

Clinical Features

Patients may initially present with dull pain in the absence of other visible symptoms. Over time, any combination of twisting movements, abnormal postures, muscle cramps, incoordination, or dystonic tremor may occur. The dystonia manifests itself when the writing instrument is picked up, or very soon thereafter. The characteristics of the involuntary movements differ between patients, but are highly stereotyped within an individual. Exaggeration of the usual grip of the pen is common; involuntary hyperextension of the fingers; flexion, hyperextension, supination, or pronation of the wrist; or other abnormal hand, forearm, arm, or shoulder movements may also occur. Disability results from impairment of fine motor control of the hand such that handwriting becomes sloppy or illegible; in some cases, patients are unable to write more than a few words at a time. A characteristic feature of WC and other focal dystonias is the presence of a 'sensory trick' (geste antagonistique), whereby tactile stimulation in the affected region can reduce the dystonic spasms.

When WC first develops, it usually spares other actions with the affected hand (simple WC). In about one-third of cases, the dystonia eventually goes on to affect other actions performed with the symptomatic hand (dystonic WC). The dystonia may also spread to adjacent body regions (segmental dystonia) or involve writing with the contralateral hand. Tremor is present in about one-third of patients and may be either a dystonic tremor (triggered by writing) or a bilateral postural tremor that resembles essential tremor. The remainder of the neurological examination is usually normal, though there may be other subtle abnormalities such as reduced arm swing or mild dystonic posturing of the hand when the patient is not writing. Secondary carpal tunnel often occurs, and should be suspected when there is significant pain, which is otherwise uncommon in WC.

Differential Diagnosis

The differential diagnosis of primary WC includes organic writing disturbance in the absence of dystonia, primary writing tremor, psychogenic dystonia, and secondary dystonia related to another underlying neurological disorder. Outside of the medical literature, the term WC is often used nonspecifically to describe the occurrence of discomfort or handwriting impairment that occurs with excessive writing. This differs from true WC in that pain is often a major symptom; the 'cramp' usually occurs after prolonged, continuous writing; and abnormal involuntary movements, overflow, dystonic tremor, and sensory tricks are absent. Primary writing tremor is a task-specific tremor with clinical features that may resemble tremulous WC, but it has a distinct pathophysiology. Psychogenic hand dystonia is usually not task specific and is often accompanied by other clinical features that suggest a nonorganic etiology (e.g., fixed posturing, sudden or posttraumatic onset, other unexplained somatic symptoms). True WC may also occur as the initial, exclusive, or most prominent symptom of generalized dystonia, or as part of a 'dystonia plus' syndrome due to a metabolic or neurodegenerative disorder.

Etiology

Environmental factors WC and other FTSDs are often regarded as sporadic disorders resulting from a specific environmental factor – the repetitive performance of attentionally demanding, stereotyped movements. Other environmental factors have been implicated in the development of WC in a minority of patients; these include prior trauma (reported in 5–10% of cases), medications (e.g., lithium), or structural lesions (e.g., cervical spine degeneration, arteriovenous malformations, tumors, stroke, or cerebral hemorrhage).

Genetic factors Although repetitive use and other environmental factors are clearly involved in the pathogenesis of WC, there is an underlying genetic predisposition in at least a subset of affected patients. There is a known family history of WC in 5% of patients with this disorder. With careful clinical examination, however, 25% of patients with FTSD were shown to have affected family members in one study. WC can occur as a forme fruste of DYT1 and has also been reported in other genetic dystonias, including DYT5 (dopa-responsive dystonia), DYT6, DYT7, and DYT13. These differences in genetic susceptibility may explain the fact that only a small percentage of people who perform frequent, attentionally demanding writing go on to develop WC.

Diagnostic Workup

The diagnosis of WC is based on the history and examination findings and does not usually require confirmatory testing. If the diagnosis is uncertain, then electrophysiological studies can be used to demonstrate presence of co-contraction of agonist and antagonist muscles and overflow into muscles not normally involved in writing. When there are clinical findings suggestive of a 'dystonia plus' syndrome, laboratory testing or neuroimaging studies can be used to exclude the possibility of Wilson's disease, stroke, multiple sclerosis, or other structural lesions; in the appropriate clinical setting, the possibility of Parkinson's disease, corticobasal ganglionic degeneration, progressive supranuclear palsy, spinocerebellar ataxia, or spinomuscular atrophy should also be considered. If there is a family history of dystonia, or if there is dystonia affecting more than one body region, then genetic testing should be considered to rule out DYT1 or other inherited forms of dystonia.

Pathophysiology

The inappropriate muscle activity that occurs in WC is secondary to diffuse central nervous system dysfunction that affects motor and sensory systems and sensorimotor integration. Although dystonia has been largely associated with dopaminergic dysfunction and abnormalities in the basal ganglia and thalamus, much of the research has focused on the cerebral cortex, because this region is more accessible to study.

Motor System

WC is characterized by a variety of abnormalities in the motor system, including increased excitability, abnormal plasticity, and decreased inhibition. These physiological abnormalities are believed to underlie many of the clinical features of WC, including the presence of abnormally long electromyography (EMG) bursts of activity, agonist-antagonist co-contraction, and overflow of movements into muscles not normally involved in writing.

Task specificity One of the characteristic features of WC is its task specificity. The muscles that are affected in WC function properly to perform other tasks, indicating that the basic control mechanisms are preserved. Writing can be performed normally on the contralateral side, demonstrating that the motor program for writing is also largely intact. Thus, it has been postulated that the main problem in WC is a failure to link a motor program to the appropriate effector. This hypothesis is supported by the fact that WC patients have deficient activation of the premotor cortex, an area that is involved with the overlap between motor and effector function.

Increased excitability One of the major underlying pathophysiological abnormalities in WC is a widespread increase in cerebral motor excitability. Stimulation-induced facilitation of motor-evoked potentials (MEPs) in the primary motor hand area is stronger in WC patients than in controls. During writing, there is hyperactivity of the lateral premotor cortex evident on fluorodeoxyglucose positron emission tomography (FDG-PET) and of the ipsilateral cerebellar hemisphere and contralateral thalamus, basal ganglia (particularly the putamen), primary motor cortex, supplementary motor cortex, and premotor cortex on functional magnetic resonance imaging (fMRI). These changes have been attributed to the failure of normal homeostatic mechanisms, whereby abnormal increases in synaptic strength and the excitability of the motor cortex may occur.

Abnormal plasticity In WC and other FTSDs, cerebral motor excitability is not only abnormally increased but also loses its spatial specificity. In normal subjects, stimulation of the median nerve produces

selective facilitation of the muscles that it innervates. In WC, however, stimulation of the median nerve also produces inappropriate facilitation of ulnar-innervated nerves. These abnormalities in the spatial properties of associative plasticity may underlie both the overflow phenomenon and the tendency for symptoms to spread to involve adjacent body segments.

Decreased inhibition Another major physiological abnormality in WC is the reduced excitability of central inhibitory circuits. In subjects with focal hand dystonia, there is a loss of short intracortical inhibition (SICI) in the bilateral motor cortex, consistent with decreased function of cortical interneurons. The normal prolongation of the cortical silent period after median nerve stimulation is also absent. In WC specifically, there is a decreased long intracortical inhibition (LICI) in the affected hemisphere with voluntary wrist extension, and task-specific shortening of the cortical silent period with pincer grasp but not power grip. There is also bilateral loss of reciprocal inhibition in the upper extremities in patients with unilateral WC. On fMRI, patients with focal hand dystonia have abnormal persistence of basal ganglia activity after a finger tapping task, consistent with loss of inhibitory control of the basal ganglia.

Together, these findings suggest that WC is characterized by a failure to suppress unintended movement of neighboring muscles with writing – a deficiency in the motor equivalent of 'surround inhibition.' This inhibitory circuitry is largely mediated by γ-aminobutyric acid (GABA); SICI appears to be primarily related to GABA-A receptor function, whereas LICI and the cortical silent period are more closely associated with GABA-B receptors.

Motor changes as an endophenotype Many of the abnormalities in the motor system that occur in WC and other focal dystonia are present bilaterally in patients with unilateral WC. In addition, they involve the arm of patients with focal dystonia of other body regions. At least some of the observed changes in the motor system are therefore believed to represent preexisting physiological state (endophenotype), rather than a secondary consequence of the dystonia.

Sensory System

The sensory system also plays a key role in the pathophysiology of WC and other types of focal dystonia. As in the motor system, there appears to be increased and abnormal plasticity, as well as decreased surround inhibition. There are also abnormalities in sensorimotor integration, the interplay between sensory and motor systems.

Clinical and subclinical sensory impairment Patients with WC and other focal dystonias have subtle sensory loss that may reflect abnormal central sensory processing. There are mild deficits in graphesthesia and stereognosis that can be appreciated with detailed clinical testing. Spatial and temporal sensory discrimination is also impaired, with a reduction in the integration of tactile and visuotactile stimuli that is proportionate to the severity of the dystonia.

Abnormal cortical sensory representation Repetitive peripheral sensory stimulation has been shown to produce abnormal functional organization of the primary sensory cortex, with degradation of cortical hand representation. Comparable disorganization of the somatosensory cortex occurs in WC, presumably also as a consequence of repetitive, abnormal sensory input. There are also gross structural abnormalities in the primary sensory cortex in patients with focal dystonia, as demonstrated by the presence of increased gray matter in this region on voxel-based morphometry.

Increased excitability and reduced inhibition On FDG-PET, WC patients have abnormally increased activation of the sensory cortex with writing that increases when the patient is experiencing more severe dystonia. On fMRI, there is also increased task-related activity in the bilateral putamen, caudate, globus pallidus interna, and lateral thalamus during discrimination of the orientation of gratings with the affected index finger. Repetitive transcranial magnetic stimulation (TMS) to the somatosensory cortex attenuates short-latency afferent inhibition in WC patients but not controls, indicating that somatosensory inhibition is also reduced.

Abnormal sensorimotor integration In addition to problems specific to the sensory or motor system, WC is characterized by abnormalities in sensorimotor integration. This is clinically evident as sensory tricks, in which subtle tactile input can dramatically modulate motor symptomatology. Vibratory muscle stimulation can elicit typical dystonic spasms in WC patients, likely also reflecting abnormal sensorimotor integration.

A number of studies have demonstrated abnormalities in the interplay between the sensory and motor systems in WC and other focal dystonias. The normal decrease in amplitude of MEPs after vibratory or electrical stimulation, for example, is attenuated or absent in focal hand dystonia, indicating a failure of the sensory system to appropriately modulate the motor system. Premovement gating is also abnormal in WC, as demonstrated by the absence of the normal

decrease in amplitude of the frontal N30 somatosensory evoked potential after median nerve stimulation. Accordingly, widespread impairment of central sensory integration at spinal, brain stem, and cortical levels has been demonstrated in WC and other types of focal hand dystonia.

Sensory changes as an endophenotype Although some of the observed changes in the sensory system and sensorimotor integration may be secondary phenomena, at least some appear to reflect a preexisting physiological state (endophenotype). This is suggested by the presence of bilateral sensory impairment and disorganization of cortical sensory representation in patients with unilateral hand dystonia and of bilateral sensory abnormalities related to the hands in focal dystonia that affects other parts of the body (e.g., blepharospasm and torticollis). Thus, there appear to be preexisting abnormalities in both sensory and motor systems in subjects who later develop WC.

Prognosis and Treatment

Spontaneous remission of WC may occur in 5% of patients, usually within 5 years of disease onset. For most patients, however, WC is a chronic condition for which the treatment options are largely unsatisfactory.

Behavioral Changes

By the time that patients seek medical attention, they may have already learned to adjust their writing technique to reduce the impact of the WC. Some patients may find it helpful to grasp the pen differently, use a pen with a different (e.g., thicker) grip, make use of a sensory trick, or stabilize the wrist with the contralateral hand. Some may learn to write with the nondominant hand (though 25% of those who do will eventually develop WC on the contralateral side). Biofeedback, hypnotherapy, and relaxation therapy have all been used, though there is limited data regarding their efficacy. Workarounds such as typing or dictation may help to alleviate the functional disability. Physical therapy does not appear to be helpful.

Oral Medications

Oral medications may be used to treat WC but often have significant side effects and limited benefit. Anticholinergic medications are generally the most efficacious oral medications for treating dystonia, but are often poorly tolerated at the high doses that may be required to improve symptoms. Medications that increase GABAergic tone (e.g., benzodiazepines and baclofen) can also be helpful, presumably due to activation of inhibitory circuits. A trial of levodopa is indicated when there is suspicion of dopa-responsive dystonia.

Botulinum Toxin Injections

Botulinum toxin injections can be used to selectively weaken the muscles that produce the dystonic spasms; they are generally the safest and most effective treatment for focal dystonia. EMG guidance can be used to ensure that the toxin is selectively delivered to the affected muscles. The benefits of botulinum toxin are mainly or exclusively attributable to the peripheral actions of the botulinum toxin, rather than a secondary reduction in motor excitability. The major limitation of botulinum toxin therapy for WC is that the associated muscle weakness may produce more disability than the WC itself.

Surgical Treatment

Stereotactic thalamotomy and deep brain stimulation (DBS) of the globus pallidus and thalamus have been used with great success to treat medically refractory primary generalized dystonia. These techniques – pallidal DBS in particular – are also under investigation for treatment of segmental and focal dystonia. There are only a few cases in the literature, however, in which surgical techniques have been used to treat focal hand dystonia. Thus, further investigation is needed to evaluate whether these interventions are a viable treatment option for patients with medically refractory WC.

Disease Modification

With increasing knowledge of the physiological basis of WC, new treatment approaches have been developed that attempt to modify the underlying motor or sensory dysfunction. TMS to the primary motor or premotor cortex has been used on an experimental basis to increase the cortical silent period and reduce abnormal cortical excitability. Sensorimotor retraining has been used with mixed results; approaches have included immobilization of the affected arm followed by motor retraining, and sensory discrimination training in which patients are taught to read Braille with each of the affected fingers. Alteration of sensory input through muscle afferent block (e.g., with lidocaine) or transcutaneous electrical nerve stimulation (TENS) also produces short-term improvement of symptoms. Unfortunately, the benefits provided by these treatments are generally modest and transient. Future investigation is warranted to determine whether these or other types of disease-modifying therapies can induce long-lasting changes in cortical plasticity and enduring symptomatic benefit.

Herpes Zoster

Historical Background

The herpes virus has been reported in the literature since ancient times. Records indicate that it was described by the ancient Greeks as sores that seemed to 'creep' over the surface of the skin. In fact, the term 'herpes' is derived from the Greek word meaning 'to creep.' It is also evident that 2000 years ago, Roman Emperor Tiberius attempted to curb an epidemic of herpes labialis by outlawing kissing during public ceremonies and rituals.

Richard Bright (1831) was the first to suggest that the herpes virus spread along a nerve distribution. Later, Frederich von Barensprung identified involvement of the gasserain ganglion in herpes of the face. In 1892, Von Bokay noted a connection between chickenpox (varicella) and cases of herpes zoster (HZ). In 1900, Head and Campbell studied those afflicted with 'shingles,' noting that the disease was limited to one spinal ganglion. Their work also led to the first published maps of the dermatomes that are still used today.

Netter and Urbain (1926) showed that there was antigenic similarity between fluid vesicles of zoster and varicella. They implied that zoster is a recurrent form of the disease known as chickenpox.

Hope-Simpson (1965) explained that a latent virus could be reactivated from the dorsal root ganglion. The fact that reactivation occurs later in life and in immune-compromised patients supports the role of immunity in suppressing reactivation.

Incidence

An estimated 4 million cases of primary varicella zoster virus (VZV) infection occurred annually in the United States prior to the start of widespread vaccination. Infection was nearly universal by the end of the teenage years, with studies showing only 4% of adults aged 20–29 remaining susceptible to infection. Cumulative over a lifetime, up to 20% of those with primary infections went on to manifest episodes of HZ. High-risk groups, such as elderly populations and immunocompromised people, may experience cumulative incidences as high as 50%. Age is the most significant risk factor, with the disease being relatively uncommon in those younger than age 40 years. The incidence may be as high as 50% in patients older than age 60 years.

According to one epidemiological study, the overall incidence of zoster was 215 cases per 100 000 person-years and did not vary by gender. The incidence, however, did increase sharply with age. Only 5% of cases occurred among children younger than 15 years, whereas the incidence increased tenfold over the age of 50 years. Infection with human immunodeficiency virus was documented in 5% of the people, with incident HZ and cancer in 6%.

The recorded incidence of HZ is 64% higher than that reported 30 years ago; the age-standardized rate is more than twofold higher.

It is unclear what role the varicella vaccine will play in a future reduction of cases. According to Seward, in a study by the Centers for Disease Control and Prevention, varicella disease has declined dramatically in surveillance areas with moderate vaccine coverage. One may conclude that as VZV infections decline, the incidence of postherpetic neuralgia will show a similar reduction. Since the vaccine has been licensed only since 1995, it will take many decades to realize a significant decrease in cases of postherpetic neuralgia.

Pathophysiology

Chickenpox (varicella) virus is usually acquired by the inhalation of respiratory droplets from an infected host. It is highly contagious at this stage. After initial inhalation, the virus infects the conjunctiva and the mucosa of the respiratory tract. The virus replicates in regional lymph nodes of the upper respiratory tract 2–4 days after initial infection and is followed by primary viremia on days 4–6. This initial phase is also known as the prodromal phase, which is clinically manifested as fever, malaise, and headache with stinging, burning, or stabbing pain in the dermatomal distribution. On days 14–16, a second round of viral replication occurs. This secondary viremia is characterized by invasion of capillary endothelial cells and the epidermis. HZ (shingles) is an acute papulovesicular eruption in a dermatomal distribution caused by the reactivation of VZV. VZV infection of cells of the epidermis produces intracellular edema, resulting in the characteristic vesicle. Once formed, the vesicles of chickenpox have high viral titers, and transmission may occur through direct contact. The rash eventually heals by crusting over, and it is no longer infectious. After infecting the skin, the virus travels anterograde

along the sensory neuron, where it lays dormant in the ganglion.

When reactivation occurs, the virus is believed to undergo retrograde transport to the skin. Lesions erupt due to inflammation and accumulation of edema. As the virus replicates in the neural and epithelial nuclei, it can produce intranuclear inclusion bodies. Destruction of the dorsal root ganglion may be observed, as well as peripheral nerve fibrosis and demyelination.

Clinical Symptoms

In the vesicular stage of shingles, the vesicular rash of HZ usually manifests in a dermatomal distribution. Development of the rash may be preceded by paresthesias or pain along the involved dermatome. Ocular involvement and zoster keratitis may result if reactivation occurs along the ophthalmic division of the trigeminal nerve.

Involvement of the geniculate ganglion may produce the Ramsay–Hunt syndrome, which is characterized by development of pain in the ear and transitory unilateral facial paralysis with herpetic vesicles of the external ear or tympanic membrane. Rarely, zoster symptoms may occur without the rash, known as zoster sin herpete. Obviously, this can be difficult to diagnose, but an increase in antibody titer is diagnostic.

Involvement of the gasserian ganglion and trigeminal nerve may cause paroxysmal pain in the area around one or more divisions of trigeminal nerve. The involvement of ocular division may cause conjunctivitis, keratitis, and even loss of vision.

The vesicular stage of the disease is usually limited to one or two dermatomes. The widespread and generalized disease occurs mainly in severely immunocompromised patients. Cases of motor paralysis have been reported in the literature. Most commonly, the facial nerve is involved, but spinal nerves may also become affected resulting in paralysis of an extremity.

Patients with HZ will usually present with one or two of the following pain descriptions: (1) spontaneous, constant, deep, burning, and aching pain; (2) intermittent, sharp, stabbing, and shooting pain; or (3) dysesthesia and hypersensitivity to light touch (i.e., allodynia). Allodynia may be an ominous sign because 90% of postherpetic neuralgia (PHN) cases report this as a symptom. In addition, complaints of clothing irritation and unbearable itching may be elicited.

Physical Exam

When the rash resolves, pale scarring may be seen on the skin. The scarred areas are usually hypoesthetic, but they may also exhibit increased sensitivity to stimulation (hyperesthesia), increased sensitivity to pain (hyperalgesia), and pain that is elicited with nonpainful stimuli (allodynia). These findings may often be present over a wider area than the scar itself. A possible explanation for this phenomenon may be summation of central neurons in response to deafferentation and hypersensitivity of the infected ganglion.

Therapy

Topical applications Acute pain from zoster may be treated with a compress of Burow's solution of aluminum acetate in water. It is used as an astringent wet dressing to relieve inflammatory conditions of the skin. Calamine lotion or petroleum jelly are commonly used.

Symptomatic treatment Symptomatic treatment with a nonsteroidal anti-inflammatory or acetaminophen may be indicated if the pain is significant. Narcotics may be used for cases refractory to nonnarcotic analgesic treatment. Adequate analgesia is important because the conversion to PHN directly correlates with higher pain scores in the acute zoster stage.

Antivirals Acyclovir and valaciclovir are the most studied antiretroviral medications for the treatment of acute HZ. Aggressive early treatment has shown promise in reducing the incidence of PHN

Early analysis of acyclovir studies supported the finding that a dose of 800 mg five times daily for 7–10 days is effective in reducing the incidence of PHN and the duration of pain. The duration of pain was shortened from an average of 86 to 49 days, and the incidence of PHN was reduced to 42%.

Valaciclovir, a prodrug of acyclovir, is almost completely converted to acyclovir *in vivo*. It gives a three- to fivefold increase in acyclovir bioavailability. Given at 1000 mg three times daily for 7 days, valaciclovir accelerates the resolution of pain and offers simpler dosing while maintaining the favorable safety profile of acyclovir. Patients on valaciclovir had a significantly accelerated resolution of HZ-associated pain compared with acyclovir; median pain duration was 38 days versus 51 days for acyclovir. Treatment with valaciclovir also significantly reduced the duration of PHN and decreased the proportion of patients with pain persisting for 6 months (19.3 vs. 25.7%).

Regional anesthetics and corticosteroids Literature reviews including case reports and small series have purported success in treatment of both HZ and PHN using local anesthetic field blocks and sympathetic blocks. Overall, the literature shows a positive outcome with these blocks. The use of sympathetic and epidural blocks with local anesthetic and steroid for pain of HZ was supported by good evidence in the literature. Some studies have suggested that use of

steroids may be able to reduce the early phase of PHN. If given within 2 months of HZ, epidural local anesthetic and steroid may reduce the incidence of PHN after 1 year.

Postherpetic Neuralgia

Definitions

PHN is defined as pain along the distribution of a nerve that has been previously infected by HZ. Significant pain or dysesthesia present after healing of HZ may be considered PHN. Often, symptoms may subside in the first several months. Pain more than 3–6 months after HZ can be classified as an established neuralgia.

Incidence

Overall, the incidence of PHN is low compared to the frequency of HZ seen in the community. Pain 1 month after HZ has been estimated to occur in 9–14% of cases. Predictors of the development of PHN are greater age, pain during acute stage, severity of rash, prodromal pain, viral load in peripheral blood, and adverse psychosocial factors.

Disease Course

Age appears to have the strongest correlation with progression to PHN. According to data from the 1950s literature, the chance of pain persisting at 1 year was 48% for patients older than age 70 years. A 20-year-old had only a 2% chance of persistent pain at the same time point. Recent data indicates that the 1-year incidence is 7.8% for patients older than age 60 years and less than 0.6% for those younger than age 60 years. Perhaps more aggressive early management can account for the decline in chronic unremitting cases during the past 50 years. Nevertheless, for patients younger than the age of 60 years, the vast majority will have improvement of symptoms over time.

Pathophysiology

PHN results from damage and secondary changes within components of the nervous system. Autopsy data have demonstrated atrophy and scarring at the dorsal horn of affected spinal segments. The exact mechanism for hypersensitivity after dorsal horn destruction is not known. Noordenbos postulated that selective loss of larger fibers leaves an excess of small unmyelinated fibers behind which are more sensitive to depolarization. In other words, there is a loss of large fiber inhibition in the dorsal horn. The relief of pain with dorsal root entry zone lesions in some patients may support the hypothesis of local hyperexcitability.

Preventing Conversion from Acute Herpes Zoster to Postherpetic Neuralgia

Prevention is the best treatment of PHN. As many as 40% of patients with PHN are poor responders to currently available treatment options. Established cases of PHN are notoriously difficult to treat because most therapies only provide partial relief of symptoms. True prevention of disease may be possible to achieve by vaccination against the varicella virus. Live attenuated varicella vaccine elicits protective immunity against VZV in children and adults. However, the long-term outcome of this effort remains to be seen.

Evidence supports the early use of antiviral medication and judicious use of opiate medication with adjuvant medications such as tricyclic antidepressants as the best means of preventing disease progression. A number of uncontrolled studies with small sample sizes have suggested a reduction in PHN with use of corticosteroids. Sympathetic blockade may provide symptomatic relief of acute pain of HZ; however, more evidence is needed.

Management of Chronic Cases

Topical applications The 5% lidocaine patch is effective for treatment of neuropathic pain in PHN. The topical application of capsaicin cream has shown a significant improvement from capsaicin cream. Burning or stinging is the main side effect with capsaicin cream. Burning sensations diminish after the first week with regular application of the cream. Usually, 0.075% cream of capsaicin should be applied four times daily.

Antidepressant medications

Tricyclic antidepressants The role of tricyclic antidepressants (TCAs) has been well studied in PHN. PHN has been the prototype for many neuropathic pain studies because it occurs with a significant frequency and the disease course is usually unremitting if left untreated. The use of tricyclics dates back to 1960 for the treatment of trigeminal neuralgia. In 1965, Woodforde et al. first reported the beneficial effects of amitriptyline in PHN. The literature supports good pain relief with use of TCAs in patients with PHN. It should be noted, however, that the analgesic effects of antidepressants are independent of the presence of depression or improvement in mood, and orthostatic hypotension and cardiac arrhythmias represent major limitations to its use.

Research suggests that the analgesic effect of antidepressants is mediated by inhibition of reuptake of norepinephrine and serotonin. Elevated levels are associated with activation of descending inhibitory pathways.

A systematic review comparing amitriptyline or desipramine with placebo in relieving pain showed a statistically significant benefit to using a TCA over placebo. In the studies reviewed, the dosages of TCAs started at 12.5–25 mg daily and increased by 12.5–25 mg every 3–5 days to a maximum of 250 mg daily. The range of effective dosages for desipramine was 12.5–250 mg daily, with the average effective dosage being 167 mg daily. The range of effective dosages for amitriptyline was 12.5–150 mg daily, with the average dosage being 70 mg daily. The most common side effects were dry mouth, constipation, and sedation. The side effects profile is better with nortriptyline, a by-product of amitriptyline, and desipramine, a by-product of imipramine.

In addition to side effects, treatment with amitriptyline and other TCAs in general is limited by the fact that although they provide significant relief, it is often not complete relief in the long term.

Selective serotonin reuptake inhibitors versus selective norepinephrine reuptake inhibitors Selective serotonin reuptake inhibitors (SSRIs) and selective norepinephrine reuptake inhibitors (SNRIs) produce weak antinociceptive effects in animal models. In human clinical trials, the efficacy of SSRIs has been variable and inconsistent. The SSRIs and SNRIs are not recommended as first-line agents for the treatment of post herpetic neuralgia.

Duloxetine, a potent 5-HT and norepinephrine reuptake inhibitor, may find a role in the treatment of PHN. Currently, however, it is only Food and Drug Administration (FDA) approved for painful diabetic neuropathy.

Anticonvulsant medications Gabapentin (Neurontin) and pregabalin (Lyrica) remain the only FDA-approved drugs for PHN, other than Lidoderm and TCAs. Gabapentin and pregabalin are structural analogs of γ-aminobutyric acid and have anxiolytic, analgesic, and antiepileptic properties. Pregabalin is structurally related to gabapentin, but pregabalin has shown greater potency than gabapentin in pain and seizure disorders. Pregabalin reduces neuronal calcium currents by binding to the $\alpha_2\delta$ subunit of calcium channels, and this particular mechanism may be responsible for effects in neuropathic pain, anxiety, and other pain syndromes. The exact mechanism of analgesic effect for gabapentin has not been defined.

Two randomized controlled trials support the use of gabapentin (Neurontin) to treat PHN. The dosage was started at 300 mg daily and titrated over 2 weeks to a maximum of 3600 mg daily or until intolerable side effects occurred (e.g., sedation and dizziness). In one study using smaller doses, 1800 mg daily was as effective and better tolerated than 2400 mg daily.

Pregabalin has been extensively studied for its use in PHN. In one study, pain was significantly reduced in the pregabalin-treated patients after the first full day of treatment and throughout the study. Significant improvement on the McGill Pain Questionnaire total sensory and affective pain scores was also found.

Opioid medications Use of narcotic medications for nonmalignant pain has increased during the past several decades. The available evidence suggests that there is probably a select subpopulation of patients with chronic nonmalignant pain who may obtain sustained partial analgesia without the development of toxicity or the psychological and behavioral characteristics of addiction. The use of opioids should be considered as individualized treatment plan.

Several studies support the use of opioid medications in the treatment of PHN. When sustained-release oxycodone (Oxycontin) was compared with placebo, moderate or better pain relief was achieved in 58% of patients taking oxycodone versus 18% of patients taking placebo. The dosage was titrated from 10 mg twice daily to effect or a maximum of 60 mg twice daily or intolerable side effects. Common side effects included constipation, sedation, and nausea. Another study showed that sustained-release morphine (MS Contin) and nortriptyline (Pamelor) provided better and equivalent pain relief, respectively, than placebo (decrease in baseline pain by 33%). Side effects for opioids included nausea, constipation, decreased appetite, and sedation. Anecdotal reports support the increased use of methadone, a potent anti-NMDA receptor opioid, in the treatment of PHN due to its usefulness for neuropathic pain. Our group has had more success with methadone than with other opioids in treating PHN. However, randomized controlled trials are required to draw definitive conclusions.

A study of sustained-release tramadol showed modest benefit at an average dose of 275 mg day^{-1}. According to the study, patients in the tramadol group required less rescue medication than patients in the placebo group.

Transcutaneous electrical nerve stimulation Transcutaneous electrical nerve stimulation (TENS) works by activating Aβ fibers peripherally. According to the gate control theory of pain by Wall and Melzack, these larger fibers inhibit the nociceptive C and Aδ fibers peripherally. As a result, the feeling of pain can be replaced by a tingling or pulsing sensation.

Review of the literature supports the use of TENS for the treatment of PHN; however, overall, evidence

is conflicting. Some studies have reported TENS to be unsuccessful in this patient population. Regardless, TENS is rarely used alone in pain relief but instead should be part of a larger management program that may include other modalities.

Regional blocks As mentioned previously, if given within 2 months of HZ, epidural local anesthetic and steroid may reduce the incidence of PHN after 1 year.

One interesting study investigated intrathecal steroids administration for treatment of refractory PHN. Compared to the control group, patients who received intrathecal methylprednisolone with lidocaine had significant improvement in burning pain, lancinating pain, and allodynia. Patients who received local anesthetic alone did not experience the same benefit. There were no cases of arachnoiditis reported in the study. Patients who have PHN unresponsive to oral and topical therapy may be considered for intrathecal methylprednisolone treatment based on risks versus benefits ratio.

There have been various other reports of repeated nerve blocks, interspinous injection of hypertonic saline, and subcutaneous injection of local anesthetic with variable benefits. However, due to inconsistencies in the studies and lack of data reporting and follow-up, no conclusions can be drawn from these claims.

Surgical treatment

Rhizotomy of the dorsal root entry zone No surgical techniques have proven to be consistently beneficial in the treatment of PHN. After the dorsal root entry zone is lesioned, no sensory information enters the brain from the area of the ipsilateral side. This includes two-point discrimination, vibration and proprioception, pain and temperature, and crude touch. Although there is some reported success in cases of brachial plexus neuralgias, the postoperative results in patients with postherpetic pain were disappointing.

Cryotherapy Cryotherapy involves freezing peripheral nerves. Review of the literature does not conclusively support use of cryotherapy. A small, unblinded study of cryotherapy for facial pain was unable to show a significant benefit in patients with PHN. In contrast, a second trial reported considerable relief with cryotherapy to the intercostal nerves for PHN. In most cases, however, the duration of relief was less than 2 weeks.

Spinal cord stimulation. This is a nonmedicinal option of treating the pain of PHN. The mechanism of pain control is based on the gate-control theory of Wall and Melzack. Several trials of spinal cord stimulator implantation have been published. Overall, 75% of patient with PHN treated with electrical spinal cord stimulation (SCS) reported better pain control and 50% of patients with acute HZ reported pain relief. Spinal cord stimulator is more effective in postherpetic neuralgia than acute herpes zoster. A smaller study retrospectively analyzed ten patients who received spinal cord stimulators for PHN. It reported relief in six of ten patients, with a mean analgesia of 52.5% during the stimulator trial. All six underwent a permanent implant. At a mean follow-up of 15 months, all six patients reported satisfactory pain relief of 74% of mean analgesia.

Given the limited nature of the evidence available for surgical and interventional techniques, one can only recommend these therapies as salvage techniques in patients who have failed conservative treatment. The decision to use SCS as one treatment modality should be based on careful analysis of the ratio of risks versus benefits. SCS involves surgical procedures, and the risks of infection, bleeding, and other device-related complications cannot be overemphasized.

Alternative medicine

Acupuncture There are very few large, randomized controlled trials of acupuncture therapy for PHN available to draw any conclusions. One randomized controlled trial of acupuncture versus mock transcutaneous nerve stimulation did not show a difference in pain relief recorded in the two groups during or after treatment. Interestingly, patients in both groups experienced significant improvement in their pain at the end of treatment.

Herbal therapy Aside from capsaicin cream, there is little published evidence of herbal treatment in PHN. Two studies have reported that administration of hot water soluble extracts of *Ganoderma lucidum* (36–72 g dry weight day^{-1}) decreased pain dramatically in PHN recalcitrant to standard therapy and other patients with severe pain due to HZ infection. According to the authors, they were able to achieve complete pain relief in 10 days.

Conclusions

As children continue to be immunized, the prevalence of this debilitating disease will likely decrease. In the meantime, PHN will continue to be one of the most challenging pain entities we encounter.

Systematic reviews of the literature have concluded that the treatments shown to be more effective than placebo for PHN include TCAs, opioids, gabapentin, tramadol, pregabalin, topical capsaicin (0.075%), and topical lidocaine. The long-term benefits of most therapies are uncertain, and side effects are common. Intrathecal methylprednisolone may be of benefit

in patients refractory to the previously mentioned measures.
