Christopher Duggan, for the past 25 years, has been performing clinical trials in the fields of pediatric nutrition, gastroenterology, and global health. His early work centered on the management of diarrheal diseases in children, including trials that demonstrated the feasibility and efficacy of oral rehydration solutions (ORS) for diarrhea management in the United States and globally. In collaboration with colleagues at Harvard TS Chan School of Public Health and Muhimbili University of Health and Allied Sciences in Dar es Salaam, Tanzania, Dr. Duggan and colleagues are evaluating the efficacy of micronutrient supplementation in infants and young children born to women with or at risk of HIV infection. Recent studies include the development of new biomarkers of environmental enteric dysfunction as well as the evaluation of nutritional status on neurodevelopment. With colleagues at St John's Research Institute in Bangalore, India, he is evaluating the efficacy of maternal vitamin B12 supplementation on biochemical and clinical parameters during pregnancy and infancy. He is a course co-director of the Bangalore, Boston Nutrition Collaborative (http://bbnc.globalhealth.harvard.edu). Past and present research support has come from the National Institutes of Health, the Gates Foundation, and the World Health Organization.

In addition to his global health research interests, he is a pediatric gastroenterologist and a nutrition physician at Boston Children's Hospital where he directs the Center for Nutrition (http://www.childrenshospital.org/nutrition). He is a medical director of the Center for Advanced Intestinal Rehabilitation, one of the largest centers in the United States for the care of children with intestinal failure/chronic diarrhea syndromes (http://www.childrenshospital.org/cair). He is also the course co-director of an inaugural Harvard College course "Nutrition and Global Health" and mentors undergraduate, graduate, and postdoctoral students at HMS and HSPH (http://www.hsph.harvard.edu/nutrition-and-global-health/).

He is a professor of pediatrics at Harvard Medical School and a professor in the Department of Nutrition at the Harvard TS Chan School of Public Health (http://www.hsph.harvard.edu/faculty/christopher-duggan/).

Jed William Fahey's current research concerns elucidating the mechanisms of how plants protect themselves against unfavorable and stressful conditions, and how this understanding can be translated to chemoprotection of eukaryotic mammalian systems. This work draws on elements of natural product chemistry, enzymology, nutritional epidemiology, and clinical research in order with isothiocyanates (e.g., sulforaphane) and glucosinolates. His work led to the discovery that broccoli sprouts are an exceptionally rich and consistent source of phytochemicals that induce the detoxification of carcinogens, and to the development of methods for their detection and for assessing their metabolism in humans. He discovered that one of the inducers, sulforaphane, has potent antibiotic activity against *Helicobacter pylori*, a causative agent of peptic ulcer and stomach cancer, and followed up with trials in animals and in *H. pylori*-infected humans. Ongoing collaborations examine the effects of broccoli, Moringa, and the other plants and their phytochemicals against a range of chronic diseases. Dr. Fahey has for years taught courses in chronic disease prevention and nutrition at both medical and public health schools.

Manuel Franco is an associate professor at University of Alcalá in Madrid (Spain) where he leads the social and cardiovascular epidemiology research group (http://www3.uah.es/cardiosocialepi/). He is also an adjunct professor at Johns Hopkins University (Baltimore).

Prof. Franco's work focuses on the social determinants of cardiovascular diseases and its major risk factors as diet. His methodological interests include the measurement of the urban environment and large social and economic changes in relation to cardiovascular health. He is the lead investigator of the Heart Healthy Hoods, study funded by the European Research Council, that will study the urban environment in relation to cardiovascular health in Madrid (http://hhhproject.eu/). This longitudinal study will be collecting neighborhood level data (via audits, Google Street view, photovoice, and qualitative methods) and linking them to clinical outcomes collected from patients enrolled at the City of Madrid primary healthcare clinics. Prof. Franco trained in Spain and Germany to obtain his MD and obtained his PhD from Johns Hopkins Bloomberg School of Public Health working with Dr. Ana Diez-Roux in the MESA study on food environment and dietary patterns. He has published over 30 international high impact articles and collaborates with universities in the United States, Europe, and Latin America.

Maria Glibetic is a research director of Centre of Research Excellence in nutrition research, Institute for Medical Research in Belgrade, University of Belgrade, Serbia, and member of executive board of directors for food data association EuroFIR AISBL. She is an experienced basic and nutritional scientist with over 250 scientific publications and presentations. Maria has considerable experience in leading national and international projects and since 2006, she participated in nine EU funded projects including EuroFIR, EURRECA, BaseFOOD, CHANCE, BACCHUS, and ODIN. Maria and her team are responsible for the creation of the first online national food database, for designing food data management system, and for the development of different nutritional tools for intake analysis. She was a principal leader of many nutrition intervention studies evaluating the plant bioactive component effects on human cardiovascular health. She leads postgraduate department for integrated nutritional sciences at University of Belgrade, where she teaches two courses.

Linda Harvey obtained her PhD from the University of East Anglia, UK. She is currently the head of the Human Nutrition Unit at the Institute of Food Research, Norwich, UK. Her research interests include micronutrient requirements, bioavailability, and metabolism.

Ronald Jackson received his bachelor's and master's degrees from Queen's University and doctorate from the University of Toronto. His time in Vineland, Ontario, and subsequent sabbatical at Cornell University, redirected his interest in *Botrytis* toward viticulture and enology. As part of his teaching duties at Brandon University, he developed the first wine technology course in Canada. For many years he was a technical advisor to the Manitoba Liquor Control Commission, developing sensory tests to assess candidates of its sensory panel, and was a member of its external tasting panel. He is the author of *Wine Science: Principles and Applications, 4th edition* (2014), *Wine Tasting: A Professional Handbook, 2nd edition* (2009), *Conserve Water, Drink Wine*, and chapters and technical reviews in other multiple books and encyclopedia. He is retired in Bronte, Ontario, but remains active writing, cycling, doing yoga, and traveling, as well as being a fellow in the Cool Climate Viticulture and Oenology Institute, Brock University, St. Catharines, Ontario, Canada.

Joe P. Kerry is a senior college lecturer and the head of the food packaging research group in the School of Food and Nutritional Sciences at University College Cork (UCC). He received his doctorate in microbiology at University College Galway in 1995. Prof. Kerry is also a qualified member of the Institute of Packaging. He is very involved in national and international research projects both at fundamental and applied levels. Primary research interests address various aspects of food packaging, shelf-life stability, food composition, and numerous aspects of food quality, particularly in relation to muscle foods. He also has very strong links with industry and his research team assists companies in relation to many aspects of new food product development. He has over 220 publications in peer-reviewed international journals, over 300 presentations at major international conferences, along with several other significant publications. His expertise includes use and manipulation of modified atmosphere packaging systems for use with foods, use of extrusion technology for the manufacture of food products/packaging materials, and applications and sensor/new technology developments within the area of food packaging, especially in the area of smart packaging.

Frédéric Leroy, after studying bio-engineering at Ghent University, obtained a PhD in applied biological sciences at the Vrije Universiteit Brussel in 2002, where he continued his academic career at the research group of Industrial Microbiology and Food Biotechnology (faculty of sciences and bio-engineering sciences). As associate professor, his lecturing activities include courses in food science and technology (i.e., "Nutrition," "Technology of animal products," "Food microbiology and ecology," and "Quantitative and predictive microbiology"). Dr. Leroy's research primarily deals with the ecology and functional roles of bacterial communities in (fermented) foods, in particular with respect to the generation of quality, safety, and/or nutritional and health advantages. Focus is mostly on meat products, but other food systems are also being studied, including fermented milks and sourdough breads. In addition, his research interests relate to elements of tradition and innovation in foods, both from a technological and societal point of view.

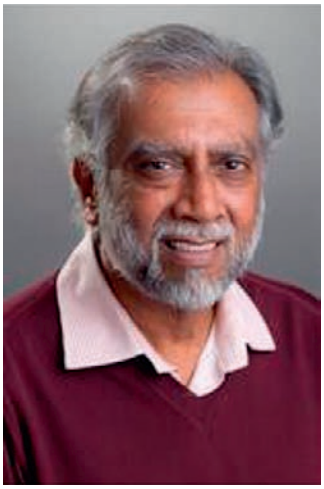
Catherine M. Logue completed her undergraduate and postgraduate degrees in Ireland and earned a PhD in meat microbiology from the University of Ulster, UK in 1996. Dr. Logue was a faculty member at North Dakota State University from 1999 to 2011 rising through the ranks of assistant to associate and full professor. In 2011, she re-located to Iowa State University's College of Veterinary Medicine and is a professor of veterinary microbiology and preventive medicine. Dr. Logue is also the director of faculty and staff advancement and equity for the college. Her research interests focus on foodborne pathogens of food animals and the contamination of meat and meat products destined for human consumption. Her research studies the detection, isolation, and characterization of a range of foodborne pathogens such as *Salmonella*, *Campylobacter*, *Listeria*, *Escherichia coli*, and methicillin-resistant *Staphylococcus aureus* (MRSA) in poultry, bovine, and swine. She also focuses her research on antimicrobial resistance in commensals and pathogens of production animals. She has been an author and a co-author on more than 90 peer-reviewed papers and book chapters as well as more than 150 abstracts and presentations at national and international meetings.

F. Xavier Malcata graduated in chemical engineering in 1986 from the University of Porto (Portugal), received a PhD in chemical engineering/food science from University of Wisconsin, Madison (USA) in 1991, and his habilitation in food science and engineering by Portuguese Catholic University in 2002. He was the dean of College of Biotechnology of Portuguese Catholic University, the chairman of Portuguese Society of Biotechnology, Portuguese representative at VI and VII European Union Framework Programs of research and development, expert for European Food Safety Agency, and a co-ordinator of Portuguese Engineering Accreditation Board in chemical engineering for Northern Region. He is currently a full professor at University of Porto.

His major research interests have focused on technological improvement of traditional Portuguese foods and upgrade of byproducts thereof, development of nutraceutical ingredients and functional foods, design and optimization of enzymatic reactors for edible oil processing, characterization of plant proteases toward cheese and whey cheese manufacture, production of starter and nonstarter cultures from adventitious microflora, and optimized application of unit operations to food processing.

With an academic career of independent research and teaching for more than two decades, Prof. Malcata published more than 450 papers in refereed journals worldwide, wrote 11 books, and prepared more than 45 chapters for edited books. Among many international distinctions, he was

recipient of Ralph H. Potts Memorial Award in 1991 by American Oil Chemists' Society (AOCS, USA), Foundation Scholar Award – Dairy Foods in 1998 by American Dairy Science Association (ADSA, USA), Young Scientist Research Award in 2001 by AOCS, Canadian/International Constituency Investigator Award in physical sciences and engineering in 2002 and 2004 by Sigma Xi (USA), Danisco International Dairy Science Award in 2007 by ADSA, Scientist of the Year Award in 2007 by European Federation of Food Science and Technology (the Netherlands), Samuel C. Prescott Award in 2008 by Institute of Food Technologists (IFT, USA), International Leadership Award in 2008 by International Association for Food Protection (IAFP, USA), Elmer Marth Educator Award in 2011 by IAFP, Distinguished Service Award in 2012 by ADSA, and William V. Cruess Award in 2014 by IFT. He has been elected for the honor societies of food science (Phi Tau Sigma, USA), scientific research (Sigma Xi, USA), and engineering (Tau Beta Pi, USA). He was also elected for fellow of IFT, ADSA, AOCS, and International Academy of Food Science and Technology.



Gopinadhan Paliyath is a professor at the Department of Plant Agriculture, University of Guelph, and the research program director for "Food for Health," under the UG/OMAFRA partnership. Dr. Paliyath is a biochemist and has an interest in various aspects of fruits and vegetables, specifically the nutraceutical components and their mechanism of action. He obtained his BSc Ed degree (botany and chemistry) from the University of Mysore, MSc degree (botany) from the University of Calicut, and PhD degree (biochemistry) from the Indian Institute of Science, Bangalore. Subsequently, he did postdoctoral work at Washington State University, University of Waterloo, and University of Guelph. Dr. Paliyath's research is focused on the biochemistry of plant senescence, specifically pertaining to postharvest biology and technology of fruits and vegetables. Investigations on the role of phospholipase D (PLD) in membrane homeostasis and signal transduction have led to advances in the understanding of the mechanism of membrane deterioration that occur during stress and senescence. Another aspect of his research is focused on understanding the mechanism of action of food components in disease prevention. The efficacy, bio-accessibility, bioavailability, and molecular mechanisms of action of nutraceuticals in fruits and processed products in relation to their cancer-preventive and anti-inflammatory actions are being investigated using mammalian cell lines, and animal model systems.

Dr. Paliyath has developed technologies and products for enhancing the shelf life and quality of fruits and vegetables based on PLD inhibition. R&D activities relevant to the industry sector include: (1) optimization of an enhanced freshness formulation for application to various fruits, vegetables, and flowers; (2) developing methods for nutraceutical carriers that would enhance the functional food quality and delivery (e.g., stabilizing lycopene in tomato juice, sauce, etc., for health beneficial effects); and (3) developing novel technologies to enhance the cancer-preventive ingredients in fruit products, etc. Patents awarded include: (1) # 6,514,914 (US) and 2,298,249 (Canada); (2) #7,198,811 (USA), 4141387-1 (Japan), 260738 (Mexico), 1469736 (Turkey), 028 284763 (China), and 223077 (India). The patents describe the use of nanoformulations based on hexanal and other generally regarded as safe (GRAS) ingredients for enhancing the shelf life and quality of fruits, vegetables, and flowers by pre or postharvest treatments. These technologies are currently being evaluated for extending shelf life and quality of mango in India and Sri Lanka with the assistance of the Canadian International Food Security Research fund. The collaboration involves researchers from Canada, India (Tamil Nadu Agricultural University), and Sri Lanka (Industrial Technology Institute).

Dr. Paliyath is also the research program director for the food and health theme-related activities under the OMAF/MRA/University of Guelph research partnership. He serves on the editorial board of several journals. He is a member of American Chemical Society and Canadian Society of Plant Biologists.

(Total-refereed publications in journals – 92; patents and intellectual properties – 2; disclosures – 4; chapters in books – 27; nonrefereed contributions – 10; research reports – 28; conference proceedings – 88; edited books – 9; book reviews – 6 (Google Scholar: h index – 31, i10 index – 68, citations – 4332; RG score – 35.63)).

Yolanda Picó is a full professor of nutrition and food science at the University of Valencia since 1998. She is currently the head of the research group on food and environmental safety of the University of Valencia. Her research interests are the development of new analytical methods to determine organic contaminants in food and the environment, identification of unknown compounds by liquid chromatography–mass spectrometry, micro-extraction separations, and environmental and food safety. To the date, she is the author of nearly 200 peer-reviewed papers, 170 scientific papers in journals of SCI, 25 book chapters, and editor of four books on food and environmental safety.

Vieno Piironen is a professor of food chemistry at the Department of Food and Environmental Sciences, University of Helsinki, Finland. She received her PhD in food chemistry at the University of Helsinki in 1987 and has approximately 35 years of experience in food research and education on bachelor, master, and PhD levels. She has participated actively in international research and education projects and networks. Her research has focused especially on chemical and nutritional properties, reactions and analysis of lipids, vitamins, and other bioactive compounds. Research on vitamins has been active from the beginning of 1980s. She has studied both lipid- and water-soluble vitamins; their chemical and nutritional properties and importance in foods and diets as well as factors influencing vitamin levels. In addition, development of analytical methods for different vitamers as well as validation and harmonization of the methods through international collaboration have been among the priorities. Recent collaboration projects have focused on enhancing vitamin contents in cereal-based foods by plant breeding, utilization of vitamin-rich grain fractions, and bioprocessing. Currently, the research focus lies on investigating microbial *in situ* synthesis of folate, vitamin B12, and other B vitamins in cereal and legume matrices as a means to improve nutritional quality of foods and to develop new food applications. In lipid research, different lipid classes and their chemical and enzymatic reactions in food matrices are studied. Diverse methods are used to study proceeding of oxidation from primary products to monomeric oxides, volatiles, and polymerization products and to study possibilities to control oxidation. Controlling enzymatic reactions leading to off-flavors in cereal and legume matrices is also among the interests. Phytosterols and their conjugates have been studied as natural food components belonging to the dietary fiber complex. On the other hand, questions related to sterol enrichment such as oxidation susceptibility and mechanisms as well as factors affecting oxidation reactions have been of interest. She has also studied nutrients and anti-nutrients in legumes and more recently started research on utilization of high value components in microalgae. She has approximately 160 papers in international journals and a number of other publications.

David Rodríguez-Lázaro is a doctor in veterinary medicine (DVM), specialized in food science (BSc and MSc) and molecular microbiology (PhD). He is a senior scientist at ITACyL and an assistant professor of microbiology at the University of Burgos. He has performed research stays in the Danish Institute for Food and Veterinary Research (Denmark), the University of Prague (Czech Republic), the Food and Environmental Research Agency (UK), and the University of Bristol (UK). He was a Leverhulme visiting professor in the Institute of Advanced Sciences in the University of Bristol during the years 2004 and 2005 and Marie Curie research fellow in the faculty of medical and veterinary sciences in the University of Bristol (UK) until 2007.

His research interest is focused on the establishment of reliable, quantitative molecular strategies for detection of important food-borne pathogens from environmental sources and various types of foodstuffs, the characterization of the prevalence of the main foodborne pathogens in food and food-related environments, and the development of emergent food preservation processes and their effects in the microbial virulence. He has participated in a number of coordinated EU-funded projects such as PROMISE, BASELINE, VITAL, FOOD-PCR, SACROHN, and MONI-QA, having established active links with the leading European research groups working in food safety.

He has published more than 100 international scientific papers and book or book chapters regarding food safety. He is currently a member of the editorial board of *Applied and Environmental Microbiology*, *International Journal of Food Microbiology*, *Food and Environmental Virology*, and *International Journal of Food Contamination* and the editor-in-chief of the journal *Food Analytical Methods*. He was awarded with the XV Jaime Ferrán Award in 2013 by the Spanish Society for Microbiology for his promising scientific career in microbiology.

Turid Rustad is a professor and the head of the food science group at the Department of Biotechnology, Norwegian University of Science and Technology. The main research focuses on the biochemistry of marine raw materials, the relationship between biochemistry and quality, and changes in raw material properties during processing. Studies of enzymatic activities in different raw materials have been linked to studies of changes in the biochemistry of these raw materials. She has worked with characterization of composition and enzymatic processes in a wide range of different raw materials, such as fish, fish by-products, and zooplankton in relation to different storage and processing methods such as chilling, heating, superchilling, and frozen storage.

Noel W. Solomons has lived and worked in Guatemala for 40 years. He was born and educated in Massachusetts in the United States. As a young child, he became an amateur naturalist and was a nature counselor at various summer camps; this would guide him to a career in science. In his young adulthood, he would participate in the civil rights and anti-war movements, only to become disillusioned by the intractable nature of the injustice elements in the fabric of American society. As a physician by graduate training, he performed his university studies at Harvard College and Harvard Medical School; it was during overseas electives in his medical training that he visited Peru and Colombia and committed to an expatriate life trajectory outside of his homeland. Clinical training included a residency in internal medicine and infectious diseases at the Hospital of the University of Pennsylvania and specialization in gastroenterology and clinical nutrition at the University of Chicago. He became a resident of Guatemala in 1974 as an affiliated investigator at the Institute of Nutrition of Central America and Panama. He would later commute for eight years to a faculty position in the Department of Nutrition and Food Science of the Massachusetts Institute of Technology. Assuming a full-time Guatemala commitment in 1985, he co-founded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) where he remains its scientific director. Over 40 local university theses have been completed by Central American students in that institution as well as an equal number of master's degree research projects from international students from Europe, and North and South America. He has supervised doctoral dissertations for 12 PhD candidates from the United States, Canada, Germany, Spain, and the Netherlands through CeSSIAM.

Dr. Solomons has 332 publications indexed on Medline. In addition, he has edited two books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection.

Among the honors bestowed upon Dr. Solomons are the International Nutrition Prize of the International Union of Nutritional Sciences and the Kellogg Prize of the Society for International Nutrition Research. He is a fellow of the American Society of Nutrition. He is an academic member of the Guatemalan Academy of Medical, Physical and Natural Sciences and the Spanish Academy of Nutrition and Food Science. He was the awardee of the 2010 National Medal for Science and Technology for Guatemala.

He has been a visiting professor in university courses in Mexico, Peru, Brazil, Indonesia, and Spain. He currently holds adjunct professorial appointments at the Boston University School of Public Health, and the Friedman School of Nutrition Science and Policy and the Department of Community Medicine and Public Health, both at Tufts University. He is a founding board of directors, member of the Hildegard Grunow Foundation in Munich and the Essential Nutrient Foundation of Singapore. Finally, Dr. Solomons is a coordinator for Central America of the Nevin Scrimshaw International Nutrition Foundation in Boston, and an associate editor for the Foundation's *Food and Nutrition Bulletin*. He serves on editorial boards for ten scientific journals.

Maria Tsimidou is a professor of food chemistry and the head of the Laboratory of Chemistry and Technology in the School of Chemistry at the Aristotle University of Thessaloniki (AUTh), Greece. Her teaching is food chemistry, analysis, quality control, and food legislation. Research interests are related to virgin olive oil chemistry, quality and authenticity, saffron chemistry, authenticity and quality, antioxidant activity of plant extracts and constituents, new sources of targeted bioactive compounds (squalene, carotenoids, and phenols), and analytical procedures for their determination. She has published many research papers, review articles, and contributions to scientific books and encyclopedias on the above-mentioned topics. Currently, she is an associate editor in the *European Journal of Lipid Science and Technology* and chairs the COST ACTION FA1101 "Saffronomics."

Jorge Welti-Chanes earned his degree in biochemical engineering (1976) and master of science in food engineering (1978) at Tecnológico de Monterrey (ITESM, Mexico), later he moved to Spain to perform his doctoral studies in chemistry, in the area of food technology, obtaining his degree at the University of Valencia. He is currently the national director of graduate studies at School of Engineering and Sciences at Tecnológico de Monterrey also is professor and researcher in the areas of biotechnology and food at the same institution. He started his academic activity in 1976 as a university professor of ITESM, has additionally been a full professor at the National Polytechnic Institute (IPN, Mexico) and the University of the Americas, Puebla, Mexico (UDLA). He has an experience of 37 years as a teacher and university researcher, 20 of which were spent in combination with the development of administration work in education, science and technology. In the UDLA, he was teaching in the Departments of Chemistry and Biology and Chemical Engineering and Food, in the latter was responsible for the leadership for a period of a year and subsequently became dean of the School of Engineering (1986–1988). From January 1989 to June 2002, he was an academic vice chancellor at UDLA. He has published 14 books and has over 200 scientific publications in refereed journals and books, has given more than 250 presentations at international conferences. He is an associate editor of the journals *Food Engineering Reviews* and *Journal of Food Science* and participates as a member of the editorial boards of *Journal of Food Engineering* and *Current Opinion in Food Science*. In May 2011, he received the Life Achievement Award by the International Association for Engineering and Food (IAEF), for his career as a researcher and academic worldwide, and in January 2014, the Romulo Garza Award from the Tecnológico de Monterrey for the impact of their research work and as recognition for being one of the most productive researchers in the life of Tecnológico de Monterrey. He has been the president of ISOPOW and IAEF and is the currently president of the International Society of Food Engineering (ISFE).

Peter J. Wilde graduated in biophysics at the University of East Anglia in 1985 and has been researching the colloidal and interfacial properties of food systems at the Institute of Food Research (IFR) for over 25 years. IFR is the only publicly funded UK research institute that focuses on the underlying science of food and health to address the global challenges of food security, diet, and health, healthy aging, and food waste. IFR is the one of eight institutes that receives strategic funding from the Biotechnology and Biological Sciences Research Council (BBSRC). It also receives funding from government agencies and departments, the EU, charities, and industry, from the UK and overseas.

Pete's research expertise is the interfacial behavior of proteins and other surface active components in food relevant systems. The aim is to determine how the molecular and interfacial processes control the functionality of foams and emulsions. Currently, the functional aspects of his research have focused on improving the dietary impact of emulsified foods. These include fundamental studies on how interfacial layers control emulsion rheology to develop novel fat reduction strategies; the design of interfacial structures to control lipid digestion to promote satiety or the delivery of fat-soluble nutrients and drugs; and to determine the physico-chemical role played by the salivary film in perceiving fat content in emulsions. The impact of this research will be to aid the rational design of foods with enhanced nutritional benefits to address the global challenges of obesity, type 2 diabetes, and other major diet-related conditions.

HOW TO USE THE ENCYCLOPEDIA

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Contents

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

The majority of articles within the encyclopedia have an extensive list of cross-references that appear at the end of each article, for example:

See also: Anemia: Causes and Prevalence; Anemia: Prevention and Dietary Strategies; Iron: Biosynthesis and Significance of Heme; Iron: Physiology of Iron.

3. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

4. Contributors

A full list of contributors appears at the end of volume 5.

INTRODUCTION

Until a few decades ago, virtually all known health effects of foods were related to their content of essential nutrients. The clinical description of most diet-related illnesses mirrored the signs of essential nutrient deficiencies, such as pellagra, beriberi, and others. Consequently, the key public health concern regarding diet was ensuring that everyone consumed enough food. It was only in the past 50 years that large-scale epidemiological observations began to associate chronic diseases like diabetes and cardiovascular disease with nonessential diet constituents such as saturated fat, fiber, and cholesterol. Taking advantage of the emergence of digital informatics, these studies were able to manipulate increasingly large sets of data and provide, for the first time, a picture of the secular changes in the health of large populations and its association with what they ate regularly. These findings progressively shifted the concern from eating enough to avoiding excessive consumption of certain foods. Eating enough was replaced by eating well.

But it turned out that defining how to eat well is far more complex than defining minimum needs of essential nutrients. First, there is no single paradigm to study those relationships, given the wide variety of biological mechanisms and the long exposures involved. Second, many of the experimental models used to define essential nutrient needs are not applicable to the study of long-term effects of diets in free-living populations. And it is now clear that experiments with isolated dietary compounds do not reflect the actual effects of the complex food matrix we consume daily. Finally, while the discovery of essential nutrients and their role in health was the domain of a few specialties speaking a common language (primarily biochemists and physiologists), the study of the long-term effects of whole diets in humans must of necessity involve epidemiologists, social and behavioral scientists, food scientists, clinicians, policy experts, etc., making far more difficult the development of consensus and foundational concepts.

It is thus not surprising that today we have still not achieved a stable consensus on how to eat 'well.' Furthermore, while few nonscientists would care about the minimum requirement of a vitamin to sustain life, there are plenty of opinions among nonscientists on how to eat 'well.'

Our goal in preparing this encyclopedia has been to contribute to the understanding of that complex diet–health relationship by providing a multidisciplinary, integrative and accurate source of information. We aim to serve the needs not only of established and in-training scientists, but also of the increasingly important group of professionals who are key to disseminate and sustain the practice of science: journalists, science writers, science administrators, fund raisers, donors, and policymakers. In preparing this work, we had the enormous advantage of working with one of the publishers with the most extensive expertise in major reference works, Elsevier. This first edition builds on the impressive breadth of knowledge of over 922 authors and on the tireless work of our editorial advisory board. We are very grateful to all of them.

Smoked Foods: Principles and Production

ZE Sikorski, Gdańsk University of Technology, Gdansk, Poland

Introduction

Smoking belongs to the oldest methods of food preservation. Meat or fish hung by the bonfire lost part of its water and was penetrated by wood smoke. Thus, spoiling of the food was retarded and the sensory properties were changed, especially when the raw material had been presalted. Gradually, most suitable procedures of smoking in local conditions and various types of equipment were developed to treat the different available raw materials. The smoke used in the process is actually mostly produced in separate generators and may be also converted to liquid, powdered, or gel-like smoke preparations by precipitation, distillation, and further refinement. The preservative effect of smoking has lost much of its importance due to developments in refrigeration and canning, while the sensory and safety aspects have became dominant. Nowadays, different smoking procedures are applied to process a large variety of foods, including meats, fish, cheese, and plums.

Smoking involves penetration of the food by a large variety of smoke components, partial loss of moisture and often fat, and enzymatic and/or heat-induced modifications of proteins. The extent of the changes caused by the process depends on the preparation of the raw material, that is, skinning, gutting, filleting, salting, curing, cutting, chopping, mincing, and stuffing into casings; on the duration of the exposure to smoke of controlled density, composition, temperature, humidity, and flow rate; and on the conditions of final handling and packaging of the products.

Wood Smoke Composition

Wood smoke results from smoldering logs, chips, or sawdust. Most often, hardwood is used, predominantly oak, beech, and hickory, although wood of coniferous trees is also applied. Heather, juniper, and coconut husks may serve for imparting special sensory properties to the products.

Smoke occurs due to thermal degradation of the main constituents of the woody material and to partial oxidation of the products of pyrolysis. Thus, its composition is affected by the contents of hemicellulose, cellulose, and lignin of wood, which degrade, respectively, at 180–300 °C, 260–350 °C, and 300–500 °C, and the conditions of oxidation of the liquid and gaseous degradation products, that is, the temperature in the smoldering zone and the concentration and flow rate of oxygen. The main components of wood smoke include air, water vapor, CO_2, CO, nitrogen oxides, phenols, carbonyls, carboxylic acids, alcohols, esters, and hydrocarbons, as well as minute amounts of N-heterocyclic and O-heterocyclic compounds. The number of components of smoke is in the hundreds; about 400 individual chemicals have been unequivocally identified.

The concentration of water vapor in the smokehouse depends on the moisture content of the wood, on the characteristics of the smoked goods, and on the phase of processing, as well as on the temperature and rate of circulation of the smoke. It affects the relative humidity of the environment and thus the evaporation/sorption phenomena, as well as the rate of heat transfer and thermal changes in the products.

At least 250 phenolics, including, among others, polyhydroxy compounds, components containing additional functional groups, and those with long side chains have been separated and at least 85 identified. The phenolic components present in smoke in the highest concentrations include syringol and its derivatives, especially methyl and ethyl syringol and syringaldehyde, 280 mg $(100\ g)^{-1}$ of oak wood used for smoldering; guaiacol and derivatives, predominantly methyl, ethyl, and vinylguaiacol, 240 mg$(100\ g)^{-1}$; pyrocatechin and its derivatives, including metoxypyrocatechin and methylpyrocatechin, 215 mg$(100\ g)^{-1}$; and phenol and its derivatives, about 160 mg$(100\ g)^{-1}$.

The highest yield of different phenols, especially of guaiacol and syringol and their derivatives, compounds that are essential for the sensory and preservative action of smoking, is at 400–600 °C, since they are formed due to thermal degradation of lignin. In the fraction of carbonyls, about 110 aldehydes and ketones have been identified. The group of compounds present in the highest concentrations include acetaldehyde, about 1200 mg$(100\ g)^{-1}$ of wood; furfural, 1000 mg$(100\ g)^{-1}$; acetone, 750 mg$(100\ g)^{-1}$; furanone; formaldehyde; 5-methylfurfural; 3-methyl-2-cyclopenten-1-one; and cyclotene (2-hydroxy-3-methyl-2-cyclopenten-1-one). Other numerous aldehydes and ketones are present in wood smoke in very much lower concentrations, usually in the range of 1–50 mg $(100\ g)^{-1}$ of wood.

The fraction of carboxylic acids is composed of about 65 chemicals, including mono- and dicarboxylic acids as well as ketoacids. Acetic and formic acids are predominant, about 3700 and 800 mg$(100\ g)^{-1}$ of wood, respectively, while the contents of propionic, valeric, 4-oxovaleric, butyric, oxalic, malonic, maleic, fumaric, and succinic acids are about 100 times lower. Among the identified alcohols are methanol, ethanol, allyl alcohol, *n*-amyl alcohol, 2-pentanol, 3-methyl-3-buten-1-ol, 3-metyl-1-butanol, 2-hexanol, 2,4-pentadiol, and 1-heptanol, while the methyl esters of formic, acetic, butyric, acrylic, propionic, 4-oxovaleric, heptanoic, and pelargonic acids are in the ester fraction. Also, ethyl and butyl acetates, ethyl butyrate, and ethyl valerate have been identified.

Wood smoke is rich in hydrocarbons, containing some 20 aliphatic and 100 aromatic compounds. Among the aliphatic components are mainly methane and ethane. The fraction of polycyclic aromatic hydrocarbons (PAHs) comprises at least 61 identified species. They are formed mainly when the temperature of thermal decomposition of wood is higher than 400 °C. Their molecular weight ranges from 116 Da in the case of indene to 302 Da for dibenzopyrenes.

Interactions of Smoke and Meat/Fish

The wood smoke constituents settle on the sausage or fish by absorption in the surface layer. The mixture of hundreds of chemical compounds of the smoke forms an aerosol. Since the boiling point of most of them is higher than the temperature in the smoking chamber, about 90% of their total mass is present mainly as small liquid droplets or solid particles, 0.08–0.15 μm in diameter, dispersed in the gases and vapors. The proportion of specific smoke components in both phases depends on their boiling point and temperature – heating increases the concentration of smoke constituents in the gaseous phase. Coalescence of the droplets and particles due to Brown's motion, as well as deposition caused by gravitational and centrifugal forces in the smoke ducts, on the walls of the kiln, and on the smoked food, regards mainly the dispersed components. The rate of deposition and sorption depends on the wetness/dryness of the surface and the humidity and temperature of the smoke. The settling of smoke components on the surface of smoked goods may be enormously accelerated due to high-voltage electrostatic field, to take only a few minutes instead of hours.

Depending on their physical state and chemical properties, the smoke components settle on the surface and diffuse to different depths of the smoked goods. The rate and extent of diffusion depend also on the barrier properties and reactivity of the surface and deeper layers. A thick skin of fish, for example, eel, efficiently inhibits the movement of smoke components, including PAHs, into the flesh. The concentration gradients of different compounds across the products diameter are not equal. Phenolic and carbonyl compounds may polymerize and interact with thiol groups in proteins, peptides, and amino acids. In model experiments, such reactions were shown to decrease significantly the number of available –SH groups. However, they do not cause any significant loss in nutritive value of smoked foods, since the concentration of phenols and carbonyls in the edible tissues is very low. On the other hand, even in minute quantities, these compounds affect the sensory properties of the products and have antimicrobial and antioxidant activity.

Sensory Effects of Smoking

Smoking is usually just one of several unit processes involved in manufacturing a food product. Generally, the raw material is also salted or cured, often chopped, minced, and mixed with various ingredients. Thus, the sensory characteristics of smoked meats, fish, and cheese result from simultaneous or concerted action of various factors. The smoke components affect mainly the color and flavor of the products, while the drying and heating induce textural changes.

The color of the surface of smoked meat and fish depends on the original pigmentation of the raw material and on the deposited smoke components. The color added by smoking ranges from light yellow to gold to deep brown and increases in intensity with the density and temperature of the smoke and duration of the process. Raising the smoke temperature and the wetness of the product's surface leads to darker color of sausages.

Fish treated with beech, maple, ash, sycamore, or lime tree smoke turn into goldish yellow; oak, nut, and alder smokes impart yellow brownish coloration, while acacia smoke lemon-like coloration. The color is caused primarily by oxidation and polymerization of the deposited smoke components, mainly phenols, but partially also due to the Maillard reaction with the participation of carbonyl compounds from the smoke and amino groups of the food proteins and amino acids. The predominant direct role of smoke components can be shown by exposing a metal sheet to smoking in an electrostatic field – in 2–3 min, the inert metal surface turns yellow or brown due to deposition of a viscous thin film.

The aroma of smoked products comes from the odor molecules present in the smoke and the odoriferous substances generated in various biochemical and chemical reactions in the food matrix. The group of phenols responsible for the typical, desirable smoky aroma comprises mainly syringol, 4-methylsyringol, 4-allylsyringol, guaiacol, 4-methylguaiacol, *cis*-isoeugenol, *trans*-isoeugenol, *o*-cresol, *p*-cresol, and 2,6-dimethoxyphenol. Pyrocatechol adds a burned, phenolic note to the aroma. Various aldehydes and ketones contribute a sweet, caramel-like smell positively modifying the rather harsh phenolic aroma. Cyclotene contributes to the smoky odor of foods. The variations of the smoky flavor result from the additional action of carboxylic acids, alcohols, and esters, as well as of numerous other components of wood smoke, which, although present in minute concentrations, can modify the perceivable aroma of various products. Thus, the attempts to generate a smoky flavor typical for that of, for example, smoked sausage of a particular assortment or fish of a certain species by mixing in different proportions pure wood smoke components have been unsuccessful.

Various phenols, carbonyl compounds, acids, and the products of their reactions with the components of the food matrix are also responsible for the typical taste of smoked foods.

The Preservative Effect of Smoking

The shelf life of smoked sausages and fish depends on the initial characteristics of the raw material, the conditions of smoking, the packaging, and the temperature and humidity during storage. It changes gradually through the high-quality life to the practical storage time and ends at the stage of unfit for consumption. Smoking prolongs the shelf life only if the whole treatment lowers significantly the water activity in the products due to both added salt and partial drying, decreases the pH as the result of lactic acid fermentation, reduces the viable population of spoilage microflora by heating, and impregnates the meat or fish with wood smoke components of antimicrobial and antioxidant properties. Cured and heavy smoke-dried sausages, produced with a yield of 55–60% in relation to the weight of the cured meat, as well as smoke-dried fish with a water content of about 15% keep well up to a few months at room temperature and low relative humidity. On the other hand, mild smoked frankfurters or hot-smoked mackerel have a shelf life of about 2 weeks under refrigeration.

Hot smoking of sausages may decrease the total number of aerobic bacteria by 2 log cycles mainly due to the heating effect. In manufacturing semidry and dry-fermented products, the

important factor increasing the shelf life is the low pH resulting from the activity of lactic acid bacteria, the decrease in water activity, and impregnation with smoke components. Among the compounds mostly responsible for the antibacterial activity are phenols, especially guaiacol and pyrocatechol and their derivatives, as well as some carbonyls. An aldehyde group in a phenolic compound increases the antimicrobial activity. Different smoke components may reduce the number of various species of bacteria on heavy smoked foods by 2–3 log cycles, but generally, smoking is not an effective way of inhibiting the formation of *Cl. botulinum* toxin or elimination of *Listeria monocytogenes* in products stored in conditions favorable for the growth of food poisoning microflora. Thus, in order to control the proliferation of *Cl. botulinum* in hot-smoked fish, the products should be immediately chilled below 4 °C and kept under refrigeration.

The shelf life of foods, especially those containing fats rich in polyenoic fatty acid residues, is also limited by oxidative rancidity. Smoking has an antioxidant effect due to the activity of phenols, especially pyrogallol, resorcinol, and guaiacol and syringol and their derivatives. Many smoke phenols have an antioxidant activity equal to or higher than that of the well-known antioxidants butylhydroxyanisole and butylhydroxytoluene. Phenols, being true antioxidants, inhibit lipid oxidation even in low concentrations by inactivating the free radicals, which initiate the chain reaction of lipid autoxidation, as well as the secondary radicals, and thus are able to terminate the reaction.

Food Safety Aspects

Smoked foods are perfectly safe for the consumer provided that they have been produced according to good manufacturing practice from fresh raw material free of natural toxins, chemical contaminants, pathogens, and parasites and that the storage conditions do not lead to microbial proliferation or production of toxins.

Health hazards for the consumer resulting from smoking may be caused by carcinogenic PAHs, *N*-nitroso compounds, and heterocyclic aromatic amines contained in the products in too high concentration. It is practically not possible to totally eliminate some harmful compounds from our foods to below the concentration detectable by contemporary analytic techniques, which may be as low as even pg/g. However, national and international regulations limit the residues of these compounds to levels that do not cause health hazards.

PAHs in wood smoke and smoked foods are a reason for concern, since many heavy species, of a molecular weight higher than 216 Da, have been recognized as mutagenic and/or carcinogenic. Most of the PAHs contained in wood smoke, however, belong to the low-molecular-weight species. The group of PAHs recognized as potentially genotoxic and carcinogenic for humans consists of 15 compounds. In the human organism, PAHs are metabolized by various enzymes to form promutagenic and carcinogenic DNA adducts. These metabolic changes are affected by the chemical structure of the aromatics; thus, the carcinogenicity of various PAHs is different. Initially, benzo(a)pyrene (BaP) was used as an indicator of carcinogenic PAHs in wood smoke and smoked products. Earlier data regarding the contamination of foods with carcinogenic PAHs refer to the concentration of this hydrocarbon. However, it was found later that in many smoked commodities, the content of BaP was negligible, while higher levels of other carcinogenic PAHs were detected. Thus, the European Food Safety Authority decided in 2008 that a more realistic indicator should be the sum of the concentration of BaP, benz(a)anthracene, benzo(b)fluoranthene, and chrysene (PAH4) or even better the sum of PAH4 plus the concentration of benzo(k)fluoranthene, benzo(g,h,i)perylene, dibenzo(a,h)anthracene, and indeno(1,2,3-cd)pyrene (PAH8). Therefore, in the Commission Regulation (EU) of 2011, a maximum level of BaP in smoked meat and meat products has been maintained ($5\ ng\ g^{-1}$ until 31 08 2014 and $2\ ng\ g^{-1}$ later) to make possible future comparisons with earlier experimental data, and additionally, the upper limit for PAH4 has been introduced ($30\ ng\ g^{-1}$ from 1 09 2012 to 31 08 2014 and later $12\ ng\ g^{-1}$). These limits can be easily observed if the foods are smoked in modern kilns supplied with smoke generated at not too high temperatures. Hot-smoked sausages produced in such conditions contain usually not more than 1 ng BaP per g. On the other hand, some products smoked traditionally above a pile of smoldering sawdust in the kiln may contain even 50 times higher amounts of BaP. Furthermore, in many products, the concentration of PAHs in the outer layers is up to ten times higher than in the inner parts, for example, in the skin of smoked eel.

Smoked foods are also contaminated with minute amounts of the environmental pollutants nitro-PAHs, ubiquitous in urban air and in many agricultural commodities. Among them are 1-nitropyrene, 2-nitronaphthalene, and 2-nitrofluorene. The concentration of the sum of various detected nitro-PAHs in different foods, in $ng\ g^{-1}$, is about 1.5 in olive oil, 3 in grilled meat, 15 in smoked meats, 30 in smoked sausages, and 35 in roasted coffee beans. No nitro-PAHs were detected in the inner parts of smoked cheese. In tea leaves of different brands, the nitro-PAHs were found in amounts from about 10 to several hundred $ng\ g^{-1}$.

Cured meats and bacon, as well as smoked meat and fish products, contain also different *N*-nitroso compounds, since the reactions of aldehydes with cysteamine and cysteine in the tissues lead to thiazolidine precursors, which can be nitrosated by the nitrogen oxide of the smoke. Among these compounds, *N*-nitrosothiazolidine, *N*-nitrosothiazolidine-4-carboxylic acid, 2-(hydroxymethyl)-*N*-nitrosothiazolidine, and 2-(hydroxymethyl)-*N*-nitrosothiazolidine-4-carboxylic acid were found. In smoked fish, *N*-nitrosodimethylamine, *N*-nitrosodiethylamine, *N*-nitrosodibutylamine, *N*-nitrosopiperidine, and *N*-nitrosopyrrolidine were determined in amounts up to about $5\ ng\ g^{-1}$. In various smoked meat products, different *N*-nitroso compounds occur in concentrations reaching several hundred $ng\ g^{-1}$. Smoking traditionally in kilns with logs of wood or sawdust smoldering below the hanging rows of meats or fish leads to heavier contamination than processing in a modern smokehouse.

In different smoked meats, fish, and cheese, various heterocyclic aromatic amines have been found, although generally in very small concentrations of about $1\ ng\ g^{-1}$ or lower. Smoking, especially at low temperature, does not favor the pyrolytic reactions of amino acids and proteins and nonenzymatic browning, which lead to the formation of these compounds.

Smoking Procedures

Smoking is either the main unit process in manufacturing a typical smoked product, for example, smoked eel or smoked cod, or just one of several links in an often long chain of treatments applied to produce, for example, canned smoked sprats in oil, smoked sturgeon balyks, or smoked bacon. Thus, different conditions of smoking are applied in various processes, that is, cold, when the smoke temperature is 12–25 °C, warm at 25–45 °C, and hot up to 90 °C.

Cold smoking lasts several hours or days in manufacturing various assortments of raw sausages made from cured meats, for example, salami and mettwurst, or of cured cuts of bacon. In producing raw, cured, fermented sausages, several phases of slow drying and cold smoking contribute to developing the sensory properties typical for such assortments and bring the intended decrease in water activity. The smoke components do not inhibit the lactobacilli, which by producing lactic acid increase the shelf life by controlling the growth of putrefactive and pathogenic organisms.

Drying and cold smoking in different stages for several hours or up to days are applied in producing smoked fish like Finnan haddocks, salmon fillets, or sturgeon balyks. Red herring smoking may last even up to 3 weeks. The preparation of the fish prior to smoking differs depending on the raw material and assortment of the product but includes always brining or other way of salt curing. In proper conditions, brining may lead to enzymatic changes in the flesh. The shelf life of these products depends on the loss of moisture during the whole process and on the contents of salt.

Cold smoking at about 20 °C for 2 h up to about 2 days is used for various assortments of cheese in order to add the desirable flavor and increase the shelf life by forming a dry surface and impregnating it with smoke components.

Hot smoking for 1–1.5 h in dense smoke is one of the processing steps in manufacturing frankfurters. The sausages, after reaching a core temperature of 60–68 °C and the desirable smoky color and flavor, are cooked under a hot-water spray or by steam. In producing jagdwurst, the procedure is more complicated. The sausage batter consisting of a mixture of cured pork, beef meat, and spices, in natural casings, has first to settle up to 12 h at 2–6 °C, or 2–3 h at room temperature. This is followed by 80–90 min of smoking at 80 °C, dry heating at 85 °C for 25 min, the second phase of smoking at 24–32 °C for 12 h, drying for 6–8 days at 14–18 °C and relative humidity of 75–80% to a water content of 55–57%, final smoking at 24–32 °C for 2–3 h, and cooling.

Kabanos, a delicatessen-type, spicy cured pork sausage in natural casings of small diameter, is made by settling for 12 h at 2–6 °C, hot smoking for 50–60 min, followed by 20 min dry heating to a core temperature 69–70 °C and dark reddish brown color, cooling, and drying at 12–18 °C for 5–7 days.

Among the hot-smoked fish products, very popular are smoked sprats. When prepared for canning, they are smoked for about 1 h to attain light color and lose 20–25% of water. Whole sprats prepared for the market, Kieler Sprotten, are smoked to golden brown and to a higher yield in order to make the product succulent. Hot smoking of whole herring, very popular in Northern Europe under the name of buckling, lasts about 2.5 h. Smoking of gutted mackerel takes about 3 h. Fish like large herring or middle-sized cod, threaded on speats through the gills and mouth or through the eyes, may tear under their own weight. Such droppers may cause considerable financial loss to the producer. This happens when at high temperature and humidity, the thermal changes in the collagenous elements of the fish head precede the strengthening of the tissues due to drying and impregnation with smoke components. In smoking of gutted eels, the temperature in the first stage of processing should be high enough to cause thermal shrinkage and curling of the collagen of the belly flaps to expose the abdominal cavity to the smoke. Otherwise, the penetration of the smoke into the flesh only through the thick skin would be very slow. The same can also be attained by dipping the fish in hot water before smoking. Curling is also characteristic for the German specialty Schillerlocken made by hot smoking of the belly flaps of dogfish.

Equipment

A large variety of equipment can be used for smoking of foods, generally classified as traditional kilns and mechanical smokehouses. Numerous types of kilns and tunnels are available both for industrial use and for home smoking.

In traditional kilns, the smoke and heat are generated by burning/smoldering the woody material on the floor below the sausages or fish hanging on speats or rods or placed on wire meshes. The temperature, humidity, and density of the smoke depend significantly on the weather conditions and must be skillfully controlled manually by the operator. He may change the moistness of the wood chips or sawdust and open or close the air inlets to the kiln and the shutter on the chimney. In contemporary traditional-type kilns, the material to be smoked is placed on trolleys. Because of differences in temperature and draft in various parts of the kiln, the smoked goods must in some cases be shifted and rearranged during smoking.

Mechanical smokehouses are usually heated by steam or electricity and are supplied by smoke from external generators. They may be also equipped for vaporization or nebulization of liquid smoke preparations. The distribution, the flow rate, and the parameters of the smoke, as well as the process time, are controlled automatically according to programs for the different assortments of food. The meats or fish to be smoked are transported on trolleys or conveyers into the kilns or tunnels. In an electrostatic smoking unit, the fish or sausages are carried on a grounded metal transporter between two flat high-voltage electrodes at about −40 kV. Due to corona discharges, the ionized smoke particles and droplets, as well as the components of the dispersing phase carried by the 'electrical wind,' are forced towards the material on the grounded conveyor. In the smokehouses used in manufacturing cooked sausages, the cooking can be carried out under hot-water showers or by steam.

Smoke generators with a grated fire bed or heated plate are supplied with chips or sawdust of standardized water content and mesh size. The parameters of smoldering are controlled so as to favor the formation of desirable smoke components and prevent generation of PAHs. In a friction-type machine, the smoke develops due to heat generated in the thin layer of a wood log pressed against a rotating drum or disk.

The temperature in the friction zone is controlled by the rotation rate of the rotor and the pressure exerted on the log, while the access of air depends on the construction of the apparatus. Several other types of smoke generators have been proposed, one of them being that using overheated steam at 250–390 °C for heating the sawdust or chips.

The smoke may be filtered or conditioned under a water spray to control its temperature and humidity and to separate undesirable tar fractions and soot. The exhaust gases from smokehouses should be neutralized in order not to pollute the atmosphere. This can be accomplished by using electrofilters, fibrous filters, or activated charcoal. Afterburners may also be used to oxidize the organic components of the spent smoke at 800–1500 °C or at about 600 °C in the presence of catalysts.

Snack Foods: Role in Diet

JS Tumuluru, Idaho National Laboratory, Idaho Falls, ID, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The human body needs the right food and regular maintenance to achieve its health potential. Healthy eating plays a major role in keeping fit for day-to-day activities. The body cannot deliver its full potential if nonnutritional foods are consumed. Various advantages of eating balanced diet are that it (a) promotes energy, (b) maintains and improves the body weight, (c) enhances the immune system, (d) keeps oneself active and fit and helps overcome tiredness, and (e) reduces serious health diseases like diabetes and hypertension and other cardiovascular disorders. Table 1 indicates advances in food and nutrition research in the last 100 years.

Food and Nutrition

Food by definition consists of macronutrients like protein, carbohydrate, and fat and micronutrients like vitamins and minerals, which sustain and support vital processes in a human body. Table 2 indicates the various macro- and micronutrients and their function in a human body. Two decades ago, the US Department of Agriculture (USDA) created Food Guide Pyramid to convey the elements of healthy diet (Figure 1). This food pyramid helps a person to make healthy food choices from a recommended variety of foods, suggested serving sizes that can help you control the amount of calories, trans fat, saturated fat, cholesterol, sugar, or sodium. According to nutritionists, foods are considered healthy if they have fewer fats contained in fried foods, butter, cream, margarine, and certain oils (e.g., saturated and trans), but at the same time, some fats are essential for health and are recommended in prescribed daily amounts (monounsaturated fat, polyunsaturated fat, and omega-3 fatty acids). Foods with lower unhealthy fat content can reduce heart-related diseases. Fiber is the indigestible part of the food and is considered to be very good for the health. It helps to lower cholesterol, prevents gallstones and bowel cancer, and helps to maintain the body weight. Some of the examples of the fiber-rich foods are whole meal, grain breads, brown rice, barley, lentils, beans, and vegetables. Vegetables, fruits, and grains carry an abundance of vitamins, minerals, and numerous other natural substances like phytochemicals. These phytochemicals act as antioxidants and help to prevent the free radical formation and damage in cells, membranes, and DNA. Many scientific studies indicated that vegetables and fruits help lower heart disease and cancer. Sugar adds flavor; however, excessive amounts of sugar can lead to diseases. Higher amount of salts in the food can result in heart-related problems. Most of our salts come from everyday commercial foods (including bread, biscuits, cereals, butter, deli meats, and snack foods), and it is recommended to buy foods that are lower in salt. Water is an important component for keeping the body hydrated and at least 2 l is recommended for efficient functioning of the kidneys.

Processing can help improve the nutritional value of food. Refining and separation of the antinutritional components increase the vegetables nutritional quality, and processing of fresh tomatoes into ketchup increases the bioavailability of the carotenoid lycopene. If the foods are overprocessed, they lose their nutritive value. During processing both micro- and macronutrients can be added to increase its nutritional value. For example, many products are fortified or enriched with vitamins and minerals (e.g., orange juice fortified with calcium for bone health and margarine enriched with plant stanols and sterols for heart health).

Role of Snacks in Diet

By definition, a snack is a small portion of food that is smaller than a regular meal, generally consumed between meals. Snacks are defined as smaller, less structured meal that are not eaten during regular meal times, such as breakfast (morning), lunch (midday), and dinner (evening). Snacks come in a variety of forms including fresh ingredients and packaged and processed foods. Some of the common snack products include tortilla chips, corn chips, potato chips, extruded products (direct expansion and pellets), pork rinds, pretzels, popcorn, nuts, and seeds. Beverages are considered a snack if they have substantive amounts of fruits like strawberries, banana, and kiwis. Processed snack foods are designed to be more satisfying, less perishable, and more durable and portable than prepared foods. Snacking is more common today as snacks and fast food are more readily available and are quick substitutes for regular meals. Consumption of fast food in the United States has increased significantly starting from 1977–78 to 2005–08 (Figure 2). Currently, snacks are eaten as part of main meals and this trend is expected to grow in popularity by 5% by 2018. A typical consumer in the United States takes about 2.12 snacks per day, and children in the United States consume snacks on an average of six times a day, approximately twice as often as in the 1970s. According to Mintel Group report, in 2013, the dollar value of the salty snack category was estimated at $21.8 billion. The report also concluded that potato chips are the largest snack purchased with the maximum sales of about $7.6 billion with an estimated market share of about 34.8%. Figure 3 indicates the revenues of various salty snacks in the United States from 2011 to 2015. The figure clearly indicated chips and crisps are the most consumed compared to others. Recent marketing research data indicated that 47% of Americans purchase salty snacks and dips for snacking throughout the day and 35% are buying more snacks while eating fewer regular meals. Increased snacking frequency and higher revenues from snack products indicate that the role of snacks in the diet has increased significantly.

Snacks are generally categorized as healthy or unhealthy. Snack foods with less or little nutritional value are considered as junk food and do not contribute to general health and

Table 1 Evolution of nutrition research in the past 100 years

Year	*Name*	*Discovery*
1925	Edwin B. Hart	Trace amounts of copper are essential for iron absorption
1927	Adolf Otto Reinhold Windaus	Synthesized vitamin D and won the Nobel Prize in Chemistry
1928	Albert Szent-Györgyi	Isolated ascorbic acid (vitamin C). In 1932, he proved that vitamin C prevents scurvy. In 1937, he synthesized vitamin C and won the Nobel Prize
1930	William Cumming Rose	Identified essential amino acids that the body cannot synthesize, but are necessary protein components
1935	Eric John Underwood and Hedley Marston	Discovered the necessity of cobalt
1936	Eugene Floyd Dubois	Linked school and work performances with caloric intake
1938	Erhard Fernholz	Discovered the structure of vitamin E, synthesized later by Paul Karrer
1940	Elsie Widdowson	Developed nutritional principles for rationing in the United Kingdom during and after World War II. Coauthored book with Robert McCance in 1940 titled 'The Chemical Composition of Foods.' This book is the basis for modern nutritional thinking
1941	The National Research Council (the United States)	First Recommended Dietary Allowances (RDAs)
1968	Linus Pauling	Introduced the term orthomolecular nutrition. Proposed that the body should get right molecules in right concentration. This work eventually led to large intravenous doses of vitamin C to improve survival times and quality of life of some terminal cancer patients. Awarded with the Nobel Prize in Chemistry
1992	The Department of Agriculture (the United States)	Set up the Food Guide Pyramid
2002	Natural Justice Study (the United States)	Revealed the link between violent behavior and nutrition
2005		Researchers identified adenovirus is the cause for obesity, and bad nutrition

Source: Medical News Today-Knowledge Center.

Table 2 Micro- and micronutrients, minerals, and vitamins and their importance

Macronutrients
- Carbohydrates: Monosaccharides, disaccharides, and polysaccharides. The molecules consist of carbon, hydrogen, and oxygen atoms. Nutritionally, polysaccharides are more favored because of complex molecular sugar chains. Due to its complexity, it takes the body more time to break down and absorb into the bloodstream
- Proteins: Nitrogen, carbon, hydrogen, and oxygen atoms. Simple proteins like monomers are used to create complicated proteins. Nitrogen in protein is eliminated by the kidneys
- Fats: Carbon, hydrogen, and oxygen atoms. Fats are triglycerides – three molecules of fatty acid combined with a molecule of the alcohol glycerol. Fatty acids are simple compounds (monomers), while triglycerides are complex molecules (polymers)
- Fiber: Consists of carbohydrates. Less sugars and starches get into the bloodstream due to less absorption
- Water: About 70% of the nonfat mass of the human body is water. It is unknown how much water the human body needs – approximately 1 and 7 l per day is recommended to avoid dehydration

Micronutrients

Minerals
- Sodium and potassium: systemic electrolyte, required in coregulating ATP
- Chloride: produces hydrochloric acid in the stomach
- Calcium: builds bones and is important for muscle, heart, and digestive health
- Phosphorus: bones and energy processing
- Magnesium: healthy bones
- Zinc: necessary for several enzymes
- Iron: required for proteins and enzymes, especially hemoglobin
- Manganese: cofactor in enzyme functions
- Copper: part of several redox enzymes
- Iodine: biosynthesis of thyroxin
- Selenium: required for activity of antioxidant enzymes
- Molybdenum: uric acid formation and iron utilization, carbohydrate metabolism, and sulfite detoxification

Nutrients
- Vitamins – A, B1, B2, B5, B6, B7, B9, B12, C, D, E, and K
- Vitamins are called supplements, because the human body cannot produce enough of them and should be obtained from the foods consumed
- Vitamins are classified as water-soluble (dissolve in water) or fat-soluble (dissolve in fat). There are 4 fat-soluble (A, D, E, and K) and 9 water-soluble (8 B vitamins and vitamin C) vitamins
- Water-soluble vitamins should be consumed more regularly because they are removed quickly from human body and are not readily stored.
- Fat-soluble vitamins are absorbed through the intestines with the help of fats (lipids). They accumulate in the human body and are harder to eliminate quickly

nutrition. Typically unhealthy snacks have a high content of refined sugars, saturated fat, and salt, whereas healthy snacks are lower in fat, sugar, sodium, and calories. The increasing chronic illness and health-related problems in developed countries can be partially attributed to the consumption of processed foods especially snack-based products, which are high in sodium, sugar, and fat. Most of the Western countries have obesity problem and it is more severe in the United States. The journal of the American Medical Association has reported that 65% of the adults $\geq$20 years in the United States are either overweight or obese and about 280 184 deaths are attributed to obesity. According to the American Heart Association, more than 64 million Americans have cardiovascular disease, which is a major case of mortality (about 38.5% of all deaths). The other prominent health-related problems in the United States include hypertension (50 million), type II diabetes (11 million), and high-risk total cholesterol concentrations (37 million). One of the reasons for the increased diseases in

Figure 2 Processed food consumption in the United States.

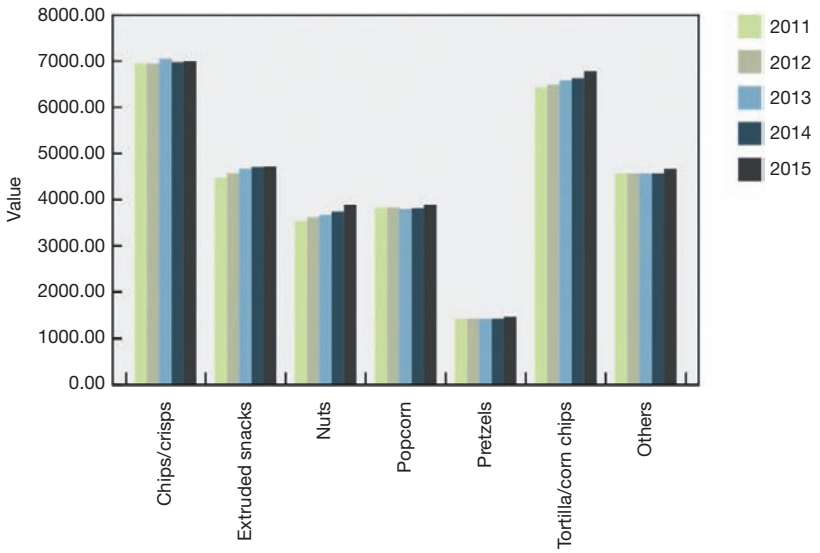

Figure 3 Consumer trends: Salty snack food in the United States (value: US millions). (Source: Agriculture and Agri Food Canada.).

the United States can be due to the exponential increase in commercial food outlets, which started selling processed foods high in sugar, fat, and sodium. Also, the food outlets started selling bigger portion sizes (supersizing) for salty snacks, desserts, soft drinks, and hamburgers. For example, potato fries sold by fast food outlets used to provide about 200 calories in 1960, whereas in 2002 they provided about 600 calories. Research indicated that this trend is similar in most of the Western countries. The increase in consumption of processed food and snacks as a replacement for regular meals resulted in increased carbohydrate consumption in the form of sugar and fat in the form of saturated and trans fat, whereas protein and healthy fat (mono- and poly-saturated and omega-3 fatty acids) intakes have lowered. Figures 4 and 5 indicate the increase in consumption of sugar in the United States and United Kingdom and macronutrients (protein fat and carbohydrates) in the United States. This increased consumption of carbohydrates, harmful fats, and sugars majorly contributed to obesity-related diseases like hypertension, diabetes, and cardiovascular diseases. Growing health-related problems have alerted the consumers, as they are now more conscious of the nutritional value of the snacks they consume. Also, many health organizations are advising consumers to be more vigilant on the calorie count of the snack they are consuming. Cutting the unhealthy snack and replacing them with healthy snack can have a positive impact on consumer's health. Research has indicated that replacing an unhealthy snack with a healthy snack every day can help to reduce nearly 4 g of

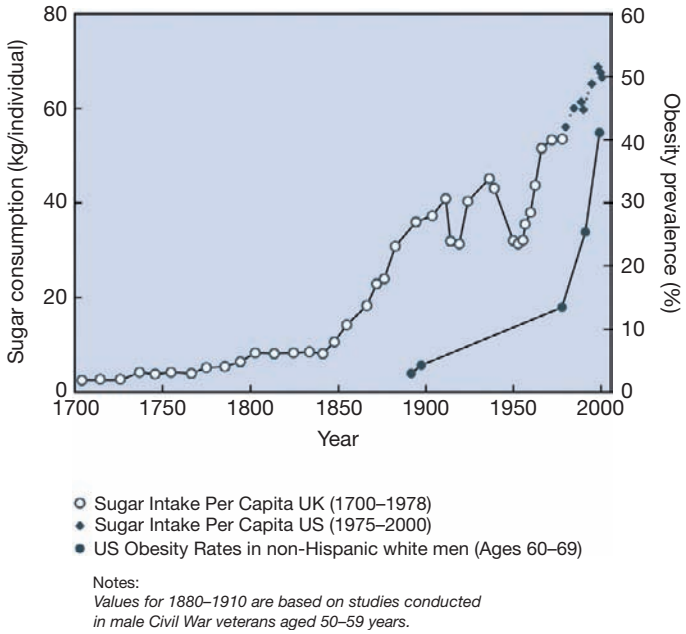

Figure 4 Increase in sugar consumption with time in United Kingdom and United States. (Source: Johnson et al., 2007.).

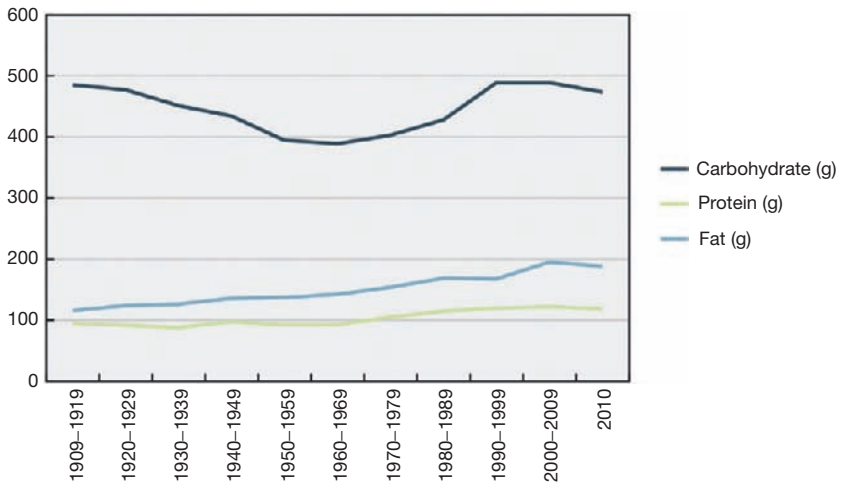

Figure 5 Nutrient content of the U.S. Food Supply: macronutrients per captia per day, 1909–2010. (Source: USDA.).

saturated fat and 0.5 g of sodium consumption. Both sodium and saturated fats are major contributors for obesity-related diseases. At present, potato chip manufacturers have started using healthier fats (olive or avocado oil) for frying. These oils that are rich in antioxidants and monounsaturated fats are good for heart health. Right now, there is an urgent need to reduce the role of unhealthy snacks in the current diet. The diseases caused by unhealthy snacks can lead to poor health for aging individuals and require higher costs in medical care, which leads to economic issues for the nation. Snack food manufacturers should focus on developing processes, technologies, and nutrient-rich ingredients to produce healthy snacks. This can reduce the obesity-related diseases in developed countries and malnutrition issues in developing and underdeveloped countries.

Extrusion Technology for Healthy Snack Food Processing

Snack industry is one of the fastest-growing division of the food industry, and extrusion technology is commonly used to produce new and creative products. The use of extrusion technology to produce novel snack food products holds great promise for future snack industry. Extrusion is one of the most versatile techniques available to the food processing industries for transforming ingredients into intermediate or finished products. In extrusion process, the material is exposed to temperature, pressure, and shear forces and is pushed through a constricted hole to give a desired shape and texture. During extrusion cooking, the material undergoes mixing, cooking, and shearing. Major advantages of extrusion cooking of foods are it (a) reduces the antinutritional factors and (b) converts insoluble dietary fiber to soluble dietary fiber. This technology helps to develop new products using both traditional and novel ingredients. Some examples of extruded snack foods are corn curls, chips, crackers, chewing gum, chocolate, and soft/chewy candy. Snacks with a wide variety of shapes (pillows, tubes, bars, triangles, and stripped products), structure and texture, color, and flavor can also be produced. A recent advance in extrusion cooking is supercritical fluid injection, coupled with the continuous twin-screw extrusion, which helps to create new engineered products. This process resulted in new product developments in cereals, confectioneries, pastas, flavorings, and snacks. The major advantages of this new process are (a) little or no loss of micro- and macronutrients and (b) expanded structure of the extruded products that are free of oxygen, which prevents oxidative rancidity during storage and increases snack product shelf stability.

Third-generation snacks

The snack food industries are looking for technologies that can help to produce healthier snacks to attract the consumer market. Extrusion technology is widely used to produce multidimensional third-generation snacks or pellets. The preparation of these snacks includes blending of ingredients and passing through a cooking extruder to form a dense pellet. The extruded dense pellets or extrudates are dried to a stable moisture content to increase the shelf stability. Extrudates can be further sold as is or puffed by immersion in oil or heating in microwave. They can also be seasoned with salt and/or various spices, packaged, and sold to the consumer as a ready-to-eat snack. This type of snack adds a new dimension to its marketing potential resulting in a cost-competitive product because of its shelf stability and high bulk density, making transportation to longer distances economical. A major advantage of multidimensional third-generation snacks is that they can be prepared using traditional, novel, low-cost locally available nutritional ingredients and nutrient-rich by-products from food processing industries, which can be blended to make excellent recipes. These recipes can significantly reduce the cost of the snacks without comprising the quality and nutrition. Different types of proteins and protein supplements such as meats (whole fresh shrimp, chicken, and beef), dairy products (cheese, yogurt, and milk solids), and legume proteins (soy, pea, and bean) can be added to third generation snack recipes. Further, it is important to consider the ingredients available locally because ingredient cost is a major expense in snacks production. For example, in the United States, corn and wheat are major starch sources, while in Europe, potato is a major source, and Asia uses tapioca or rice as a major starch source. Major cereal grain starch options for extruded third-generation snack production include rice, wheat, corn, barley, and oats. The bland flavor of these cereal flours can be overcome by extruding with other ingredients. Rice and wheat flour when extruded with meat and fish gives nutritional products with good textural and sensory properties. Similar nutritional products can be produced by extruding corn, oat, and barley with animal, fish, or dairy proteins. These types of low-moisture third-generation extruded products that can be prepared using locally available ingredients can significantly reduce the cost of the snack products and are particularly advantageous in food-insecure and low-income countries. Also, these products have high shelf stability and amenable to easy handling and storage at room temperature.

Reduced Salty Snacks

Currently, sodium reduction in snacks is gaining importance. Researchers from Deakin University, Burwood, Australia, found that children who eat salty foods will have an increased craving to drink sugary beverages. The combination of salty foods and sugar-sweetened beverages has potential to increase weight and lead to obesity in consumers. But reducing sodium in the snacks impacts the flavor of the products. Currently, ingredient manufacturers offer sodium replacements to reduce the total sodium content of the snack. Cargill's salt products division, Minneapolis, introduced FlakeSelect in 2011, which is produced by combining sodium chloride and potassium chloride using a roller. According to the company, the flat crystal produced using this process provides better flavor utilization than ordinary salt. FlakeSelect, and other products like Soda-Lo from Tate & Lyle, Hoffman Estates, Ill., depend on physical modification of salt crystal shapes. Sensient Flavors LLC, Hoffman Estates, Ill., developed natural flavor for healthier salty products. The natural flavor products which are made from yeast extracts can help the snack manufacturers to reduce sodium content in their products.

Enrichment and Fortification of Snacks

Enrichment or fortification of snacks with micro- and macronutrients can produce healthier snacks. In the developing world, feeding the vast population is a major challenge, and protein malnutrition remains to be a major issue. Public health problems related to deficiency in vitamins and iron are real issues. Enrichment and fortification are two ways that food processing can restore or raise nutrient levels of the snacks. Enrichment is a process where nutritional value is increased by mixing low nutritional value ingredients with high-quality and nutritional-rich ingredients to make new products. For example, wheat and other legume flour can be mixed with meat-based products to make them rich in protein. These products make up the nutritional deficiencies that regular snacks have. Currently, many foods are fortified (e.g., cereals, snack bars, and orange juice). The process of fortification is adding nutrients during processing. According to the FDA, the addition of a nutrient to a food may be appropriate if it corrects a dietary insufficiency and restores the level of the nutrient lost during processing or storing. Fortified snack foods can help children achieve a desired healthier intake of key nutrient. Studies indicate that children have lower levels of calcium and vitamin D even after taking supplements. Kids between ages 2 and 18 get only 40–45 mg of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), while the recommendations range from 100 to 250 mg. The other limitations of taking fortified snacks can be overdosing the nutrients. According to an Environmental Working Group, a lot of cereals and snack bars are fortified at levels that are considered very high for young children.

Healthy Snacks

With the growing concerns on snack food influence on general health, government bodies like Health Canada and the US FDA suggest people make a conscious effort to eat healthier, natural snacks like fruit, vegetables, nuts, and cereal grains while avoiding high-calorie, low-nutrient junk food. A healthy snack is high in nutritional value (protein, vitamins, minerals, and fiber) and relatively low in calories, total fat, saturated fat, sugar, and sodium. Increase in nut consumption led manufacturers, such as Blue Diamond Growers and Roll International, experiencing significant growth in their sales, which can be attributed to high nutritional content in the nuts and trail mix recipes. Nuts have more protein, fiber, fat, and nutrients and are considered as a healthy snack. For the period of 2008–13, Mintel's report recorded 53% growth in better-for-you snacks such as nuts and trail mix. Blue Diamond Growers, Sacramento, California, sells almonds with flavors like wasabi soy, caramel macchiato, and raspberry. Fresh fruits and vegetables also make a very healthy snack. Additionally, crackers made from whole grains are considered healthy. Kashi Original 7 Grain Sea Salt Pita Crisps, from Kellogg, is considered a healthy cracker as it provides 5 g of fiber from the Kashi seven-grain flour and 3 g of fat and 180 mg of sodium. **Table 3** indicates healthy fruit, cereal and nut based snacks recommended to grab and go.

Table 3 Recommended snacks to grab on the go

Fruits, Vegetables, and Cereal based products
Fresh or individually packed fruit containers
Raw vegetables (carrots, peppers, zucchini, and tomatoes) and fruits (cherry and grapes)
Baby carrots and whole wheat pita triangles with hummus
Pumpernickel bagel with peanut butter and banana
Sweet peppers (red, yellow or green) and bread sticks with salad dressing or low fat dip
Whole wheat tortilla wrap with salmon or tuna, salad dressing, onions, celery and green peppers
English muffin (with melted cheese) and apple slices
Dry mixed cereal and container of milk
Plain popcorn
Nuts and Seeds
Almonds, orange slices with dark green leafy salad
Nuts, pumpkin or sunflower seeds
Fruit Juices and Dairy Products
Fresh, frozen or canned fruit with low fat yogurt or smoothie
100% fruit juice popsicles or yogurt
Fortified soy beverage, 100% fruit juice, milk, and water

Snack Foods: Types and Composition

SO Serna Saldivar, Centro de Biotecnología-FEMSA, Tecnológico de Monterrey, Monterrey, México

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Snacks are convenient items commonly high in oil and flavored with salt or salty flavorings. Snacks can be manufactured by a wide array of processes. The simpler snacks are those produced from popcorn, dehydrated fruits, peanuts, and nuts and the most complex are those obtained by thermoplastic extrusion.

Snack foods have always been an important part of life, and these products represent an important segment of the food industry worldwide, especially in developed countries. Snacking is increasing from factors such as increases in one-person households, higher proportion of working mothers, and more school age children. On a worldwide basis, the United States is by far the leading snack food-consuming country followed by England, Germany, and France.

Classification of Snacks

Snacks are classified according to the manufacturing process (Table 1). The simplest category, also named first-generation snacks, is the easiest to produce and consists of natural products such as popcorn, nuts, peanuts, and dried fruits. Most of the snacks consumed today fall into the second-generation snack category. These include simple formed products mainly obtained after direct extrusion processes (such as corn chips, puffed or expanded corn products, balls, and curls) or by cutting/sheeting/forming (such as both regular and fabricated potato chips, tortilla chips, and pretzels). The most elaborated category in terms of ingredients and processing is third-generation snacks produced by extrusion processes aimed toward the production of pellets or half products. Extrusion commonly consists of two sequential steps: cooking and forming. The forming extruder yields dense pellets that require drying and further processing to reach the consumer. Frying the pellets produces most third-generation snacks although conventional baking or microwaving fabricates a number of low-calorie items.

First-Generation Snacks

Popcorn

Popcorn is one of the oldest and most popular snacks worldwide obtained after popping a special kind of flinty or vitreous maize, which contains an endosperm with tightly packed starch granules and test weight at least 10–12 kg higher compared to regular corn. Popcorn is merchandized in three kernel types: white, small yellow, and large yellow. Color differences in popcorn kernels result from genetic differences in the pericarp, aleurone, and endosperm. Kernels of white popcorn are usually rice-shaped, while small and large yellow popcorns are pearl-shaped. The integrity and soundness of the bran is critically important to optimize popping volume because it acts as the lid of a pressure cooker.

In order to produce the best-quality popcorn, farmers should harvest kernels when they reach full maturity and contain approximately 17% moisture. The harvesting operation is critical and should be aimed to minimize kernel damage. After harvesting, kernels are cleaned and dried to lower the moisture to around 13–13.5%. Kernels must be dried slowly to prevent the formation of stress cracks but fast enough to prevent mold development. Kernels should not be dried below 11% moisture; otherwise, the popping expansion will not be realized.

Expansion volume is the most critical quality factor for popcorn. The popped volume is important because the commercial buyer purchases the popcorn by weight and sells it by volume. Most commercial popcorns have 30–40-fold expansion.

Popping occurs at about 177 °C, which is equivalent to a steam pressure of 2.5 ton cm^{-2} inside the kernel. The water in the grain is superheated and at the moment of popping converts to steam, which provides the driving force for expanding the endosperm after the kernel ruptures. Popping occurs when the internal vapor pressure exceeds the sum of the burst pressure of the pericarp and atmospheric pressure. Hybrids or varieties with high proportions of translucent, flinty, or vitreous endosperm attain higher expansion rates.

Basically, there are two types of popcorn configurations: mushroom or butterfly. Popped kernels with a spherical shape are called mushroom or ball type. Due to its configuration, it is preferred in the confection industry because it is less susceptible to breakage, more resistant to handling, and more efficiently coated with flavorings and confectionery syrups. The butterfly type has a higher expansion or lower apparent bulk density and better mouthfeel; it is preferred for on-premises popping where it is sold by volume. For production of mushroom or ball popcorn, more heat should be applied during popping. Temperatures of 215 and 235 °C are recommended to favor the production of butterfly- and mushroom-shaped flakes, respectively. The highly expanded or butterfly-shaped popcorn is more tender and contains fewer partially popped kernels that are hard to chew.

There are basically two types of popping methods: wet and dry. Most processors employ wet popping because it produces better flavor. However, dry popping is ideally suited for production of low-fat products. Normally, popcorn, oil, and salt are placed into a heated pan for production of wet-popped product. At the moment of expansion, the oil is absorbed and the salt sticks to the flakes. The most frequent popcorn/oil ratio is 3:1 and the popping cycle varies from 2.5 to 3 min.

Dry poppers come in two basic types. The older method consists of a rotary wire drum and the modern method of a steel auger. The rotary type heats popcorn kernels over an open flame, whereas in the steel auger, kernels are thermally treated

USDA (2014).

while traveling along the screw. Oil, salt, flavorings, or sugar-based flavorings are directly applied or sprayed onto the product.

Microwavable popcorn has increased in popularity for its convenience for in-home popping. Most microwave bags contain 75 g popcorn mixed with 25.5 g partially hydrogenated vegetable oil and 1.5 g salt. The mixture is placed in pillow-style microwave bags with a 15 cm susceptor plate and a heat seal band on the inside of the lip. The expansion volume of microwave popcorn should be in the range of 34.2–43.9 ml g^{-1}, the percentage of unpopped kernels from 2.1 to 6.8, and flake size from 4.6 to 7.1 ml.

Peanuts and Other Nuts

Peanuts, almonds, and various sorts of nuts (pecans, walnuts, hazelnuts, and macadamia) are widely used to produce snacks. These snacks are rich in fat and are considered as one of the most nutritious snacks because of their fat-soluble vitamin content, dietary fiber content, high antioxidant activity, and protein quantity and quality. These are considered minimally processed snacks because kernels are roasted or heat-treated and sometimes fried prior to flavoring and packaging. Roasting and/or frying often intensifies and improves the organoleptic properties of the nuts.

Among nuts, peanuts are by far the most important snack. There are three major types of peanuts: Spanish, Valencia, and Virginia. The Spanish varieties produce thin-shelled pods with one or two elliptical flesh-colored kernels. The Valencia and Virginia types produce thick-shelled pods and are the preferred by the snack food industry. The three types have similar chemical and nutrient composition. The timing of the peanut harvest is critical since it can greatly affect quality. If peanuts are harvested too early, many of the pods will be immature, yielding shriveled kernels, whereas if harvesting is too late, many of the pods may be contaminated with molds. Peanuts are usually picked at an average kernel moisture content of 18–30% and dehydrated to lower it to about 5–10%. For marketing, the desired moisture content of shelled peanuts is about 7–8%.

Dry roasting and oil roasting are the two general processes to obtain peanuts. Regardless of the process, selected and mycotoxin-free peanuts are blanched. Blanching is considered one of the most important operations because it affects color, flavor, and overall acceptability.

Second-Generation Snacks

Potato Chips

The traditional potato chip processing method involves deep fat frying thin slices from raw potatoes followed by seasoning. However, there are many variations to this process; some include the use of different processing equipment to achieve a different shape (such as sticks) or additional unit operations to obtain a crispier product with a lower fat content. In recent years, other potato snacks have been introduced to the market; some are made from expanded pellets produced by extrusion. Other potato snacks of commercial relevance are those that imitate potato chips also named fabricated chips. Their processing method consists essentially of making potato dough from dehydrated potatoes mixed with other ingredients; the slices are then mechanically formed and fried.

Starch is the major component of the potato tuber and comprises 65–80% of its dry weight and is the main responsible for the desirable crispiness of potato chips. A direct correlation between starch and dry matter content in potatoes is well documented. Medium to large tubers with specific gravities above 1.085 (~22% dry matter) are optimum for chip manufacture.

Potato cultivars are constantly being improved for specific gravity, low reducing sugar content, and storability. Among the quality tests commonly performed to evaluate a particular cultivar for potato chip processing are slicing, frying, moisture, yield, oil absorption, defects such as blisters, hash, and bulking. High-gravity potatoes absorb lower oil during frying. Better yields are obtained with increasing specific gravity.

In commercial operations, tubers with specific gravities above 1.085 produce chips with oil contents in the range of 35–40% and with yields of finished product ranging between 28% and 36%. The characteristic flavor and yellow color of potato chips are a consequence of the Maillard reaction during frying. The main potato reducing sugars are glucose and fructose, which are used by the processing industry as quality indicators. Upon harvest, the amount of reducing sugars should be below an upper limit range of 2875–3300 ppm fresh weight (equivalent to 0.29–0.33% w/w); above these levels, potato slices will fry too dark for acceptable quality. Tubers with elevated free amine content are also more susceptible to Maillard browning and bitterness development during frying due to pyrazine formation.

Potato chip manufacturing process

The basic flow diagram for the original potato chip process contains nine major operations: peeling, trimming, slicing, washing, draining, frying, inspecting, seasoning, and packaging.

Peeling and trimming

The most widely used method for peel removal is abrasive peeling consisting of rotating drums coated with carborundum. Approximately 10% of the initial potato weight is lost by this peeling method.

Slicing

Crucial to the characteristic crispiness of potato chips is the slice thickness, which allows for rapid moisture loss and crust formation during frying. Raw potatoes are generally sliced to a thickness that varies in the range of 1.27–1.78 mm for straight-cut slices and between 2.54 and 3.05 mm for crinkle-cut chips. Slicing can be performed in continuous or batch slicers.

Slice washing

During slicing, the potato tissues are disrupted, releasing cell wall contents such as starch and internal water. If unwashed slices are placed directly into the fryer; they tend to stick together retaining moisture and oil between the slices. To prevent these defects, potato slices are washed in mesh tumblers by immersion and/or with high-pressure water sprayers. The washing step produces the second largest dry matter losses after peeling. It is estimated that between 10% and 20% of the initial potato weight is lost during this operation.

Preheating

Rinsing the potato slices in warm water at a temperature below potato starch gelatinization (55–60 °C) is an optional unit operation referred to as 'preheating,' and it can be applied to lower reducing sugars or to improve the texture of stored potatoes. Warm water increases the solubility of glucose and fructose, thus preventing browning defects. The mechanism for texture improvement is different; it involves increasing the activity of the endogenous potato enzyme pectin methylesterase (PME). Temperatures of 50–70 °C have been reported to increase PME activity, which strengthens the cell wall–middle lamella complex.

Slice draining

In order to minimize oil uptake during frying, excess washing water should be removed usually by continuous motion that in some instances also includes air injection or vibrating mesh conveyor belt with vacuum suction. Centrifugal devices are also very effective and may also include hot air injection in order to dry the slice surface and reduce frying time and oil uptake.

Frying

After the previous processing operations, raw potato slices, either peeled or unpeeled, washed or not, are ready for deep fat frying. The key for manufacturing a crispy potato chip is rapid moisture loss; the slice goes from a moisture content of 78–1.5% in ~2 min. The characteristic crispiness can be achieved if the drop in temperature caused by the cold product entering the fryer (ΔT) can be maintained below 5 °C. A typical initial temperature for frying oil would be 177 °C. Any hydrogenated or nonhydrogenated fat can be used and may include one or a mixture of oils such as corn, olive, soybean, palm, cottonseed, canola, rapeseed, sunflower, and peanut oils, among others. With the emerging changes in food labeling, which includes the declaration of trans fatty acid content, the snack industry has been moving to the use of nonhydrogenated oil to eliminate trans fats in their products as a health-related marketing strategy.

Seasoning

Most potato chips are salted or seasoned before packaging. The salt and/or seasoning is generally applied when the product is still hot in order to help them adhere to the surface. Commercial equipment for the application of seasonings consists of a unit that applies the seasoning by sprinkling it over the potato chips as they pass below in a conveyor belt or while tumbling in a rotating drum. The salt is generally added in very fine crystals and usually constitutes 1–2% of the finished product weight. Seasonings are generally spice mixtures with other ingredients and additives. Many flavors can be found in the market, with barbecue, cheddar cheese, sour cream and onion, and vinegar, among others, being the most common ones. The flavoring usage levels vary but may comprise from 5% to 10% of the finished product weight.

Packaging

Packaging is the last step of the potato chip manufacturing process. Modern potato chip packages are complex laminates of synthetic polymeric materials. The most commonly used is metalized polypropylene manufactured by the aspersion of aluminum to a polypropylene ply. Each packaging component has a different functionality; the polypropylene contributes mechanical strength, good sealing, good moisture barrier properties, low oxygen permeability, and protection against light, which accelerates oxidative reactions. Potato chips are packaged at a moisture content of 1.5%, and when the moisture increases to 4%, they become soft and stale.

Corn and Tortilla Chips

Corn and tortilla chips are the fastest-growing market within the salted snack category. Extruded corn chips are produced from coarsely ground lime cooked *masa* that is formed and deep-fat-fried, whereas tortilla chips are produced from pieces of baked tortillas that are deep-fat-fried. Baking of tortillas prior to frying greatly affects organoleptic properties and caloric density of these snacks. Tortilla chips have a stronger alkaline-cooked flavor and a crispier texture than corn chips. In addition, tortilla chips are less energy dense because they absorb about 12% units less oil during frying.

Maize kernels, lime, oil, salt, and flavorings are the basic ingredients for the production of these snacks. Product quality and processing parameters greatly depend on the kernel characteristics. However, the oil, salt, and seasonings used for the preparation of maize snacks have a profound effect on flavor, mouthfeel, and overall acceptability.

The nixtamalized snack food process involves several unit operations such as grain cleaning, lime cooking and steeping, stone grinding, kneading, sheeting/molding, cutting, baking, frying, and seasoning. Extruded corn chips are made from coarsely ground *masa* from either fresh *nixtamal* or dry *masa* flour, which is extruded and cut into *masa* chips with different configurations, deep-fat-fried and salted/seasoned. Key operations are the extrusion of the *masa* into different configurations and the deep fat frying. During the 60–90 s frying, the *masa* exchanges water for oil and the product exits the fryer at moisture and oil contents of about 1.5% and 36%, respectively. Resulting chips are usually seasoned with 2% salt and various types of cheese, citric acid, or chili flavorings.

Tortilla chips are generally manufactured from coarsely ground *masa* from either fresh *masa* or dry flour that is sheeted, formed, and cut in preparation for the subsequent steps of baking, equilibrating, frying, and salting/seasoning. Tortilla chips are usually formed by two rotating smooth Teflon-coated rolls that automatically press the *masa* into a thin sheet. The newly formed *masa* disks are baked into tortilla pieces commonly in a three-tier gas-fired oven at temperatures ranging from 350 to 480 °C for 40–60 s. The resulting baked tortilla pieces are cooled for 3–30 min through a series of open tiers that discharge into the fryer. Frying of tortilla chips is characterized by further starch gelatinization and formation of a yellow crust and the characteristic flavor as a result of Maillard reactions. Immediately after frying, the hot chips are salted and seasoned in rotating tumblers equipped with liquid sprayers and/or auger or electrostatic powder dispensers. After seasoning, fried products are cooled and immediately packaged in moisture-proof or aluminized bags to avoid rancidity and loss of crispiness. There are basically two types of low-fat tortilla

chips: fried and toasted. The first type usually contains 1/3 less oil compared with regular counterparts, and the second type does not contain any added oil although some products are sprayed with cooking oil to increase fat content to 7–8% to enhance flavor and texture. For production of reduced oil snacks, moisture is removed from the baked tortilla chip by further baking or toasting or baking/flash frying to yield a crispy product.

Extruded Snacks

Most second- and third-generation snacks are produced by extrusion cooking. Production of snacks with cooking and forming extruders saves space in the processing plant, offers more versatility, adapts to highly productive continuous plants, and saves labor and energy when compared with expenditures of traditional processes. There are basically two types of snack items obtained with thermoplastic extruders: the direct-expanded snacks and the third-generation snacks produced from pellets or half products obtained after sequential cooking and forming extrusion steps. The direct extruded types are subdivided into bake puffs and fried puffs.

Production of direct-expanded baked products

The raw material for collets should be highly refined and properly conditioned. In most instances, refined grits conditioned to moisture contents from 14% to 19% produced the best-quality products. The conditioned grits enter single or twin extruders set at high temperature (90–120 °C) and a screw design that favors compression. The combination of heat and pressure converts the grits into plastic dough that melts and becomes a viscous fluid. At the very instant that the viscous fluid exits the die orifice, it will instantaneously equilibrate with the external atmospheric pressure causing the expansion and setting of the collet structure. During this time, most of the moisture instantaneously vaporizes, so the extrudate drops its moisture to about 5–8%. The puffed collet is cut and sized to the proper length with a rotating knife. The collet expansion rate is generally between 6 to 8 and the bulk density of 50–65 $g l^{-1}$. Resulting puffs are conveyed into a rotary dryer or oven to drop their moisture to around 1–2%. The driers, set to 130–150 °C, dehydrate the low-density collets in only 4–10 min. The baked expanded collets are finally flavored in a rotary tumbler generally with salt–oil–cheese slurry that is sprayed onto the extrudates. The amount of coating applied ranges from 34% to 42% based on the final puff weight. The product is finally cooled and immediately packaged to avoid loss of texture or crispiness. The puffs generally contain from 27% to 36% oil and about 2% salt. Fried expanded curls are still widely accepted among snack consumers because they possess a different flavor and configuration. These snacks have been produced for more than 60 years and are manufactured using a special type of extruder that generates most of the heat by friction. Technically, this extruder falls into the medium shear category and works similarly as the direct-expanded high-shear extruders. The major difference is that the fry-type snack extruder does not extrude the product through a typical die. Instead, it uses a set of plates: one rotating and the other stationary. These plates shape and expel the extrudate that is internally cut by rotor fingers.

Tempered refined cereal grits are introduced and transported into the barrel section of the stator, and the shear applied by the screw movement increases both the pressure and internal temperature so the starch gelatinizes, melts, and plasticizes. The rotor fingers cut the extruding material, which are then immediately extruded radially between the two plates. As the material exits from between the plates, the pressure drops from 48 Atm to atmospheric pressure and the water superheats and vaporizes expanding the extrudate. The resulting extrudates are generally fried to reduce the moisture level from around 8% to 1.5% for texture and stability, and the fried curls pick up 20%–25% oil. After frying, the collets are seasoned with a two-stage seasoning system where an oil-based slurry is first applied followed by dry seasoning generally consisting of cheddar cheese. Ten to fifteen percent of seasonings containing 10–15% salt are usually dosaged onto the extrudates. This brings the total fat content to a level of around 30–35%.

Third-Generation Snacks

Third-generation snacks are produced from half products or pellets. Pellets are obtained after extrusion cooking and forming and dehydration to yield a shelf-stable product that could be stored for long periods of time. For snacks, the key additional process is frying and less frequently conventional or microwave baking. During these heat treatment operations, pellets expand and lose moisture so a crisp snack is produced. Pellets are cooked in an extruder and forced through a die at temperatures below 100 °C. The lower temperature prevents expansion and favors the production of a high-density pellet that is further dried to yield a shelf-stable intermediate product. Pellets, in contrast to the directly expanded puffs, offer the advantage of being distributed with high weight and low volume. The basis for the wide variety of these snacks is their shape imparted by the die design and configuration. Most common shapes are flat, tube, shell, ring, screw, and wheels.

Most pellets are manufactured from mixtures of starch-rich raw materials that include dehydrated potato products and/or potato starch, modified starches, wheat flour, and refined cereal grits. The starch content of the blends approximates 90% of the dry matter. Key operations for the production of third-generation snacks are extrusion, pellet drying, and frying. These snacks are usually flavored with powdered seasonings generally applied with a belt-type flavor depositor or in a revolving tumbler. After seasoning, fried products are cooled and immediately packaged in moisture-proof bags to avoid rancidity and loss of crispiness due to moisture uptake.

Wheat-Based Snacks

Wheat flour is extensively utilized to produce snacks such as crispbreads and pretzels. The industrial manufacturing process to obtain toasted bread is practically identical to production of fresh bread with the additional operation of bread toasting or drying. There are many bread formulations generally produced to form refined wheat flour, whole wheat flour, or composite flours produced from mixtures of wheat flour with oat, rye, or various crushed grains. Sesame is frequently used as topping. Toasted bread or crispbreads have prolonged microbial shelf life because they generally contain approximately 6% water

equivalent or an a_w of less than 0.5 and a pH below 5. The dehydration toasting process enhances staling and the crispy and brittle texture that characterize crispbreads. Fresh bread normally contains 32%–35% moisture, and this moisture should be carefully removed to produce top-quality crispbreads. The rate of product dehydration depends on the oven settings and product volume or dimensions. Toasting is different from baking because the baked product is dehydrated at lower temperature. Alternatively, crispbreads are produced with extrusion technology into the traditional rectangular-shaped crisps, but new filled forms such as U-shaped and hollow tubes are becoming more important.

Production of Pretzels

A pretzel is a wheat-based snack food with 800 years of history. The typical pretzel configuration clearly shows a cross in the middle representing the crossed arms of a Christian prayer. Pretzels are very popular in the European community and the United States. Pretzels are manufactured from fermented wheat flour dough that is treated with a covering of a sodium hydroxide or other alkali salt solutions prior to baking. Pretzels are unique because of its characteristic flavor and color due to the sodium hydroxide wash. The typical flavor profile is also affected by the products yielded during fermentation, nondiastatic malt and salt. Wheat flour is mixed with about 42% water, 0.25% oil, 0.25% sugar, and 0.027% yeast to form a coarse dough that is rested for 20 min before mechanical rolling and forming into cylinders that are molded into traditional configuration. Pretzels are fermented with yeast for a short time (30 min), formed, and washed for 25–30 s with a 1% sodium hydroxide solution heated to approximately 93 °C. Next, they are immediately salted, flavored, and baked. Baking is performed in three sequential steps: the first step lasts approximately 10 min at high temperature and is aimed toward the formation of the typical dark brownish crust. The other two baking stages are to dehydrate the product and produce the typical crisp texture. Hard pretzels are usually packaged in laminated or coextruded materials with an inert gas to protect the flavor and decrease the rate of product breakage during handling.

Nutritional Value of Snack Foods

Snack foods are one of the most concentrated forms of food energy because the majority contain large quantities of oil and starch and are practically free of water (Table 1). The dietary fiber, vitamin, mineral, and protein content and quality of most snacks are low because they are generally manufactured to form refined cereal grits and/or starches. Furthermore, the various thermal operations decrease the availability of vitamins. All these reasons explain why snacks are considered as 'empty foods' and have bad image among dietitians. Most snacks are salted or flavored with salt-based flavorings and therefore contain large quantities of sodium.

Today, food scientists are including in their research and product development equations for production of snacks with minimal fat calories and fat decomposition products known to have adverse effects on human health and production of snacks with similar sensory properties (flavor, texture, and overall acceptability) compared with their regular counterparts. A healthful balance of fatty acids and the production of snacks free of *trans* fatty acids are taken into consideration.

Sodium: Properties and Determination

R Moreno-Rojas, F Cámara-Martos, and MÁ Amaro López, Universidad de Córdoba, Córdoba, Spain

© 2016 Elsevier Ltd. All rights reserved.

Properties and Determination

Sodium, prepared for the first time by the British chemist Humphry Davy in 1807, is the eleventh element of the periodic table (atomic number 11). Its symbol is Na, and it is included in group 1 (or IA), thus corresponding to the alkali metals. It is an extremely soft silvery metallic element and even can be cut with a knife (hardness of 0.4). It is a very reactive element that tends to be used extensively in the chemical industry. It rusts very quickly when exposed to air and reacts violently with water, forming sodium hydroxide and hydrogen and producing a yellowish flame. It has a fusion point of 98 °C, a boiling point of 883 °C, an atomic weight of 22.98977, and a relative density of 0.97 g cm^{-3}.

Sodium has an electronic structure of [Ne] $3s^1$, and consequently, it always acts with valence 1. It has only one external electron, in orbital 3s, and so the degree of attraction that it suffers with respect to the nucleus rivals the repulsion of the lower orbitals, making it very easy for this electron to disappear, forming the Na^+ cation, its most common state.

Two percent of the Earth's crust comprises sodium, making it the sixth most abundant element in nature, where it is always found in a combined state. Sodium is currently manufactured by electrolytic procedures on melted sodium chloride. Its combining facility yields numerous compounds; with oxygen, it forms Na_2O, Na_2O_2, and even NaO_2, an important whiting and rusting agent. However, the most abundant form and one of the main sources for human use is in combination with chlorine in the form of sodium chloride (NaCl), which is usually extracted from the sea and salt lakes, or in mineral form as rock salt. Sodium can also be found in the form of sodium carbonate (Na_2CO_3), sodium bicarbonate ($NaHCO_3$), and sodium sulfate (Na_2SO_4). Also worth mentioning is sodium hydroxide, known as caustic soda, which is used throughout industry, from the manufacture of soap to the manufacture of rayon, paper, rubber, and oilskin, in petrol refineries, or in the textile industry. Sodium fluoride (NaF) is used as an antiseptic, as a poison for rats and cockroaches, and in the manufacture of ceramics. Nitrate from Chile (sodium nitrate) is used as a fertilizer. Sodium thiosulfate ($Na_2S_2O_35H_2O$) is used in photography as a fixing agent and is even used in the nuclear power industry as a cooling agent.

All these specific uses of sodium are only a few examples, since this cation is one of the most common companions of different molecules, both in nature and when created by man for different purposes.

In terms of the nutritional characteristics of sodium, 90% of sodium provided in the diet is obtained from the sodium chloride consumed. The rest of the sodium is from other sources such as bicarbonate and sodium glutamate. Of the total sodium intake, it has been shown that only 10% originates naturally from foods, around 15% from salt added to cooking or to season food once cooked, and the remaining 75% from the processing and manufacturing stages of foods.

Given the physiological need to supply the human body with sodium in order to maintain extracellular osmotic pressure, and as a result of the obligatory losses through urine and sweat, a regular intake of sodium is required. In ancient times, this meant a dependence on salt deposits, and a huge value was placed on what is now common salt, so much so that this gave rise to the Latin word salarium, corresponding to the payment in the form of salt made to soldiers in ancient Rome, and it was also used as money in Tibet and Ethiopia, as a tax in Asian countries, and as a ritual element in Greek, Roman, Hebrew, and Christian religions.

This physiological need for sodium may explain why the tongue contains specific receptors for the taste of salt. For this reason, in addition to the tradition of preserving certain foods in salt, although culturally and gastronomically unnoticeable, salt is consumed in developed societies.

Over the last few years, there has been a growing trend in some international organizations in collaboration with food industry to recommend a reduction of sodium levels in foods as a consequence of processing (e.g., in bread), due to the high incidence of some pathologies such as hypertension and coronary diseases. The World Health Organization (WHO) has estimated that reducing dietary sodium intake by 50 mmol $\cdot day^{-1}$ (2.9 g salt) would lead to a 22% reduction in the number of deaths from strokes and a 16% reduction in deaths from coronary heart disease. However, fulfillment of this objective is not easily achieved since sodium chloride has several important technological properties such as flavor improvement, structuring, preservative, and modulating water activities. The replacement of salt with potassium chloride does not result in any significant production disadvantages but has an adverse impact on the flavor, due to the production of metallic taste, when it rises above a certain percentage.

Preparation of Samples for Sodium Analysis

The determination of sodium in foods may be achieved using a variety of sample preparations, ranging from noninvasive methods, such as those used for determining sodium by selective electrodes, to complete incineration of the sample and subsequent solubilization of the ash in acid solutions. Each analytic technique requires specific preparation of the sample, since the instrumental requirements in each are very different.

As sodium is usually found in soluble form in foods, the simplest method of preparing samples involves washing and then analyzing the sodium from the solution sample; for this purpose, the food often only has to be crushed, solvent-added, homogenized, and filtered or centrifuged. Solvents to be used may be simple water or slightly acidic or alkaline solutions.

Some methods even propose the direct use of food (particularly liquids) in the detection equipment. Although these may yield good analytic results, other food components such as fats, sugars, or proteins can also deteriorate or stain the instruments.

Given the stable character of sodium, the most aggressive techniques usually yield very good results in terms of the recovery of analyses; hence, the use of incineration at around 500 °C overnight and subsequent recovery in weak acid solutions can be used as a standard sample preparation method for a wide range of foods, modifying temperature and time according to the food in order to obtain soft ash, evidence of good interaction.

Other methods for destroying organic matter, such as acid hydrolysis, can also be used without significantly affecting the detection of sodium content, and a wide range of acids may be used in variable concentrations.

The use of incineration or acid hydrolysis is particularly recommended, due to the possibility of obtaining solutions in which other cations of interest for food can be analyzed, such as K, Ca, Fe, Cu, and Zn.

Methods of Analysis

Although sodium may be determined by a wide variety of instrumental techniques, the recommended and most often used technique is atomic spectroscopy, either by emission or by absorption. This technique is based on the atomic properties of the elements and more specifically on their capacity to react in response to specific stimuli, modifying their orbital distribution, for which purpose they absorb light at a specific wavelength for each element, passing on to a state of higher energy, or lower energy if passing from the previous stage, emitting light at the same wavelength. In the case of sodium, the recommended specific wavelengths are 589.6 and 589.0 nm.

In order to achieve atoms and the passage of electrons to a state of higher energy, it may be necessary to increase the temperature, usually by means of a flame, and the incidence of a beam of light of a specific wavelength. The latter technique enables the determination of the analytic concentration by determining the difference between the energy supplied to the sample and that that remains after crossing – this is generically known as flame atomic absorption spectroscopy (FAAS).

In contrast, if the energy of the element is increased by another method (flame), what is usually measured in order to determine the concentration of the analyte is the emission of characteristic wavelength light when returning to the state of lower energy; this technique is known as atomic emission spectroscopy (AES).

Atomic Absorption Spectroscopy

Although the basis of the technique is the same as that for atomic emission and, in many cases, the same equipment is used for both analyses, this technique is only favored by fewer analysts, due to partly the concentrations of sodium in foods that may be calculated for emissions with limited need of dilutions and to the added cost of using a hollow cathode lamp for analysis, without evident analytic improvement. However, the existence of multielement lamps can reduce further costs. This technique is more suitable for low concentrations as a lower detection limit may be obtained. Several official methods for sodium by FAAS exist, such as AOAC Official Methods 985.35 for infant formula, enteral products, and pet foods and ISO 8070:2007 method for milk and milk products. Standard working conditions for analyzing sodium by atomic absorption spectroscopy are listed in Table 1.

Table 1 Standard conditions for sodium analysis by atomic absorption spectrometry

Spectrometer's setting	*Sodium*
Wavelength/slit (nm)	589.0/0.2
Nebulizer	Spoiler
Oxidant	Air
Fuel	C_2H_2
Flame condition	Oxidizing
Optimum concentration range in solution (μg ml^{-1})	1–20
Interferences	Ionization

Atomic Emission Spectroscopy

The determination of sodium in biological and food samples, as in the case of potassium, may be performed using flame photometers and atomic absorption spectrophotometers (with the option of working in emission conditions). In both cases, a sample in a liquid state is introduced into a fuel carrier (acetylene or propane) and combined with atomized or nebulized N_2O_2 air or oxygen. This dispersion is led to a burner where the fuel combusts. The heat of the flame prompts an increase in the energy of the sodium atoms, which, upon returning to their fundamental state, emit a light beam of characteristic wavelength that is quantified by a detection system. The amount of light emitted is proportional to the concentration of the analyte in the sample.

With this technique, the optimum gain is adjusted to the highest standard of sodium used, and an attempt is made to keep the burner free of sodium impurities emitted by the actual samples and standards analyzed, since these impurities may introduce undesirable emissions or obstruct the passage of fluids through the burner; when the flow decreases, the signal obtained will also decrease. Avoiding samples with high concentrations of sodium (such as undiluted seawater) is considered good practice.

A further potential problem lies in small fluctuations that may occur in the flame or in the carried mixture; these may lead to inaccurate and variable results. To correct this problem, some devices are equipped with a second detector that enables the emission of a second element (usually lithium) to be estimated, with a different wavelength to that of sodium. This second element must be added to solutions of both samples and patterns in a stable and known concentration. When there is a variation caused by the flame or the flow, both detectors must reflect this simultaneously, distinguishing this from variations in the analyte.

Another precautionary step involves the adjustment of the calibration line since, in most cases, this is not linear; instead, it displays a decrease in the slope when concentrations increase due to the fact that the area of linearity between the analytic concentration and the atomic emission is exceeded. The simplest solution involves diluting the samples until the standards

Table 2 Accuracy and precision of the sodium analysis by flame emission

Accuracy	*Certified ($g\ kg^{-1}$)*	*Found ($g\ kg^{-1}$)*	*IC (95%)*[a]	*Rec (RSD)*[b]
Citrus leaves SRM-1572	0.16 ± 0.02	0.17 ± 0.03	0.11–0.24	108 (18)
Nonfat milk powder NIST-1549	4.97 ± 0.10	5.17 ± 0.14	4.90–5.46	104 (2.8)
Precision	Relative standard deviation			
Plant food	1.15			
Dairy food	1.20			

[a]Intervals of confidence (95%).
[b]Recovery percentages and relative standard deviation (RSD).

that include them present a straight adjustment; however, it is also feasible to make a logarithmic adjustment between the emission and the concentration of the type $E = a^{*}\ln[\mathrm{Na}] + b$, by a simple logarithmic transformation of the concentrations prior to the calculation of the regression line, and the subsequent retrotransformation when applying the linear equation to calculate concentrations. This type of adjustment is usually extremely useful when the sample values are high but not very different. As a result of this restriction, determination of the detection or quantification limit cannot be performed reliably on the standards used, although the high concentrations used guarantee that the readings can never be confused with the fluctuation of the baseline of the device.

The accuracy and precision of sodium analysis by flame emission spectroscopy are shown in Table 2. In recent years, some manufacturers have named AES instruments as 'optical emission spectrometers' (OES) because they measure the emitted light when excited atoms return to the ground state. Since this latter term is more widely used, we will use OES rather than AES onward in the article, but both of them are practically interchangeable.

Inductively Coupled Plasma Optical Emission Spectrometry

Another way to produce the excitation of the atoms in food analysis is the use of electrically generated plasmas (highly ionized gases) resulting on inductively coupled plasma optical emission spectroscopy (ICP-OES). It allows to analyze samples with a high degree of variability and minimum interferences that can be prepared either by wet oxidation or by dry ashing. It has been applied to a wide variety of food matrices such as fish, mushroom species, and chocolate-flavored beverages and has been used for sodium analysis in the 234 foods of the US Total Diet Study. AOAC Official Method 984.27 for infant formula uses this technique. A wide range of concentrations can be used without the need for dilution or concentration, and as a multielemental technique, many of the mineral elements can be simultaneously quantified, thus reducing analysis time. These advantages, together with the high speed and excellent instrument stability, make the ICP-OES method highly attractive in view of its analytic applications.

ICP can also be used coupled with a mass spectrometer leading to inductively coupled plasma mass spectrometer (ICP-MS). Mass spectrometers are instruments that separate ions according to their mass to charge ratio (m/z) and then accurately count these ions as they strike a detector. ICP-MS has the potential to yield accurate results for sodium when analyzing a wide range of foods with low sodium concentrations. However, due to the high cost of the equipment, it has been used less frequently when sodium concentrations are higher.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) comprises the spectral region ranging from wavelength 12 800 to 4000 cm^{-1} (or 780–2500 nm). In spite of the early discovery of infrared radiation by William Herschel about 200 years ago, the interaction between NIR radiation and matter has been extensively studied by researchers only over the last few years, essentially due to NIR spectral complexity and weak absorptions when compared, for example, with the absorptions in the mid-infrared region. NIR spectra are the result from overtones and combination bands generated by different functional groups such as C—H, N—H, and O—H. Classical statistical methods, such as univariate analysis, are not considered valid to obtain this information. The establishment of chemometrics, a distinctive discipline in chemistry, comprising many specialized mathematical and statistical tools, has greatly promoted the development of NIRS.

As already mentioned, NIR spectrum of an organic material gives a global signature of composition based on the assessment of the organic chemical structures containing C—H, N—H, and O—H bonds. However, the determination of inorganic compounds as sodium is more challenging compared to organic compounds owing to the lack of a direct relation between the element involved and the spectra obtained. In this case, NIR spectroscopy could be used for determining mineral concentration, due to the association between minerals and organic functional groups in the food matrix and the effect on O—H bonding. The determination of sodium and other mineral elements by NIR is therefore generally dependent on the presence of those elements in mixtures of organic or hydrated compounds and salts (cations and anions).

NIR spectroscopy is being widely adopted for sodium analysis of many food products such as wine and cheeses and human diets, among others. NIR technology is rapid, accurate, low cost (does not require sample processing), nondestructive, and more environmental respectful when compared with other analytic techniques. Table 3 summarizes NIR methods for sodium and sodium chloride in food and biological samples.

Titrimetric Methods

The spectroscopic methods described previously may assume a significant financial barrier for smaller laboratories due to the maintenance of gas supplies and fume extraction equipment. As an analytical chemistry technique, potentiometric titration method for chloride ion (AOAC Official Method 971.27) represents a very quick, sensitive, and cost-effective alternative for the quantification of sodium chloride in foods. The analysis

involves the determination of chloride ion content by a potentiometric precipitation titration using a silver nitrate solution as titrant to subsequently infer the sodium content from the stoichiometry of sodium chloride. The titrations are performed using a Ag Titrode electrode and the equivalence point is determined automatically by the instrument's software. The main disadvantage is the accuracy relies on that sodium chloride is by far the major contributor to the overall sodium and chloride content. However, other many types of sodium sources are used in food industry as preservatives, stabilizers, emulsifiers, humectants, and flavor enhancers such as sodium phosphates, sodium nitrate, sodium ascorbate, and sodium glutamate, among others, and as a result, the sodium content could be underestimated. Likewise, other chloride sources are present in foods such as potassium chloride. A novel trend is to substitute a portion of the sodium chloride additive with potassium chloride in order to maintain a level of saltiness. Finally, the measurement of chloride by silver nitrate titration is known to undergo interference from halogens and other anions, but fluoride, bromide, and iodide contents are normally negligible in foods unless specific technological treatments of the raw materials have been applied.

Titrimetric methods for the determination of sodium ion itself based on the insolubility of sodium zinc uranyl acetate or a complexometric procedure using CyDTA (*trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid) have been developed but not widely accepted.

Sodium-Selective Electrodes

Together with the optical techniques of absorption and atomic emission, this is one of the most common techniques for testing sodium content in foods due to the low cost of the instruments, ease of use, speed, noninvasive nature, and even the at-line analysis in food production lines.

The technique is based on the passage of ions through a glass membrane, being specific for an ion or small group of ions. In the case of sodium, the probe can detect this activity once the membrane has been crossed; this activity is proportional to concentration. Possibilities of interference with other ions exist, that is, specificity is not as high as with spectromorphometric methods, and the formation of complexes with other substances reduces sodium activity and therefore its capacity for determination. However, it is useful for high levels of sodium like in salted products such as ham and cheese, in which controlling salt penetration may be recommended.

Other Techniques

A large number of additional techniques may be used to determine sodium content in foods, from classical gravimetric methods, now virtually obsolete, to techniques that involve the use of instruments that are expensive, sophisticated, and requiring highly skilled personnel, which can limit their effective implementation. The most relevant techniques include the following: nuclear magnetic resonance (NMR) spectroscopy, ion chromatography, x-ray fluorescence, neutron activation analysis, capillary ion electrophoresis analysis, electron-probe microanalysis, helium glow photometry, ion-microprobe analysis, laser probe analysis, ion-scattering spectrometry, Auger electron spectroscopy, impact radiation analysis, enzymatic determination, and α-particle backscattering analysis.

NMR spectroscopy has been used increasingly in recent years for determining sodium content, mainly in living tissue

or biological samples. Therefore, it can be used for foods, particularly for establishing sodium distribution in such samples. NMR detects signals from nuclei in atoms and molecules when they are excited in a strong homogeneous magnetic field. In this technique, Na^+ has a nuclear magnetic moment of 3/2, which allows it to undergo NMR; ^{23}Na is extremely easy to detect in biological samples. However, the results must be analyzed carefully as discrepancies in the quantitative results have been observed, detecting only 60% of sodium.

Solanaceous Fruits Including Tomato, Eggplant, and Peppers

P Padmanabhan, A Cheema, and G Paliyath, University of Guelph, Guelph, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The tomato (*Solanum lycopersicum*) is one of the most commercially important vegetable cultivated worldwide. Tomato is a member of the nightshade family or Solanaceae that includes more than 3000 species. This family also includes other popular species, such as potato, tobacco, peppers, and eggplant (aubergine). Tomato is the only domesticated species of the section *Lycopersicon* of the genus *Solanum*, which consists of 13 species or subspecies. The tomato originated in the western coastal plain of South America. It was first domesticated in Mexico and the fruit was introduced to Europe by the Spanish explorers in the mid-1500s. For many years, tomatoes were considered as poisonous and unsafe to eat as they are members of the nightshade family. Tomatoes were introduced to the United States in 1710 but only became popular as a food item later in that century. Today, tomato is the second most consumed and widely grown nonstarchy vegetable in the world after potato. The average world production of tomato is estimated to be around 159 million tons. In the last few years, tomato consumption has increased considerably as they became an important part of the human diet. Therefore, the area of tomato cultivation has also expanded globally in the last few years. The leading tomato producers are China, India, the United States, Turkey, and Egypt. According to the USDA's estimate, 35% of raw tomatoes are processed into sauces, 18% into tomato paste, 17% into canned tomatoes, 15% into juices, and 15% into catsup.

Pattern of Consumption

Tomatoes form a vital part of a variety of dishes and food products including curries, soups, and pasta. Tomatoes are eaten fresh and commonly consumed as part of salads and sandwiches. They are also served roasted, broiled, and stewed. Ripe tomatoes are processed into various products including tomato paste, ketchup, sauces, sorbets, juice, and puree. Ripe tomatoes are also canned and sold as diced or whole tomatoes. They are also sundried and used in many products. Wines are also made from tomatoes. Unripe green tomatoes are also eaten deep-fried, pickled, or used in salsa. Tomatoes form an essential part of Indian cuisines especially in curries. They are also extensively used in Middle Eastern, Mediterranean, Italian and Spanish cuisines and are used to make pizzas, spaghetti, and pastas.

Botany and Plant Description

The tomato is a perennial plant typically growing to 1–3 m tall, but it is grown as an annual plant. It is a branching herbaceous diploid plant ($2n = 24$), and the growth habit ranges between erect and prostrate. Stem is green and covered with glandular trichomes. Leaves are spirally arranged and the leaflets are ovate to oblong covered with hairs. Inflorescence is a cyme consisting of clusters of 6–12 flowers known as 'truss.' Bright yellow colored flowers are bisexual, pentamerous, and pendulous. Flowers are mostly self-pollinated and also partly cross-pollinated. Bees and bumblebees are the principal pollinators. The fruit is an edible berry and the shape is variable with cultivars. Tomato fruit may be round, oblate, flattened at the top and bottom, or pear-shaped. Immature berries are pale green turning to red when ripe. Botanically, tomato is a berry, but it is nutritionally classified as a vegetable. Berries are fleshy and juicy, which can be bi-or multilocular. Fruit is composed of pericarp, placental tissue, and seeds. Pericarp or the ovary wall can be divided into exocarp, mesocarp, and endocarp. The exocarp consists of a cuticle layer that thickens with fruit maturity and the skin, which includes an epidermal cell layer and three to four layers of collenchymatous tissues. Numerous flattened straw-colored seeds are attached to the placenta, a parenchymatous tissue that becomes gelatinous and softens as the fruit matures.

Tomato Production

Tomato is a frost-sensitive tender warm season crop. It requires a relatively cool, dry climate for optimum growth and high yield with good quality. However, it can survive a wide range of climatic conditions from temperate to hot and humid tropical. An average daily mean temperature of 20–24 °C is considered optimum for growth, yield, and fruit quality. Plants can survive a range of temperatures, but the plant tissues are damaged below 10 °C and above 38 °C. Fruit set and quality are poor at temperatures below 12 °C and 35 °C. Significantly higher or lower temperatures can have negative effects on fruit set and quality. The tomato is a self-pollinating plant and outdoors, can be effectively pollinated by wind currents. Tomato prefers deep, well-drained, sandy loam soils that are rich in organic matter and plant nutrients, with a pH value of 6–7. Soils with very high organic matter content like peat soils, are less suitable due to their high water holding capacity and nutrient deficiencies. Tomatoes are generally transplanted to the field from greenhouse-grown plants. Seeding tomatoes directly into the field is not recommended due to the high cost of hybrid seed and the specific conditions required for adequate germination.

Tomato plants can be distinguished into the determinate or the bush type and the indeterminate or the tall type. Plants are erect and bushy with restricted flowering and fruiting in determinate types and plant growth stops with the commencement of reproductive stage. They have a short and concentrated fruit set that lasts only 2 or 3 weeks, and the fruits ripen much faster than those of indeterminate types. The commonly cultivated commercial varieties are mostly determinate types. The

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00696-6

indeterminate or the tall varieties continue to grow after flowering and are suitable for a long season cropping and harvest period. Most heirloom garden varieties and greenhouse tomatoes are indeterminate, and they produce flowers and fruit throughout the life of the plant. Most cultivated tomatoes require around 75 days from transplanting to first harvest and can be harvested for several weeks before production declines.

Most commercial determinate tomatoes are grown using short-stake culture for trellising. This type of culture produces fruits that are higher in quality and easier to harvest and enhances spray coverage. Staking or trellising tomato plants with bamboo poles, wood stakes, or other sturdy materials provides support and keeps the fruit and foliage off the ground. Staking will increase fruit yield and size, reduce fruit rot, and make spraying and harvesting easier. Determinate tomatoes often require some level of pruning or the removal of suckers (axillary shoots). The need for pruning varies with the variety used but can significantly impact fruit quality and yield. Indeterminate varieties should be staked to facilitate pruning, pinching, harvesting, and other cultivation practices.

Greenhouse Production System

Greenhouse production of tomato has many advantages over the field production such as careful monitoring of the growth conditions and proper maintenance techniques, which allows for off-season year-round production. Greenhouses can produce $\sim$15 times more yield per acre than under field conditions. Also, $>$90% of the yields are marketable fruits in greenhouse compared to 40–60% marketable fruit under field production. Selection of suitable tomato cultivars is a prerequisite for greenhouse tomato production. Generally, most greenhouse tomato cultivars are indeterminate in growth habit. Because of high production costs, the number of fruit per plant is very important, so the chosen cultivar or variety should also set a high number of fruit per plant.

Cluster tomatoes are grown under greenhouse production system. Two systems commonly used for greenhouse tomato production are the soil or the soilless culture. In soil culture, tomatoes are grown under a greenhouse in a plot of soil using similar techniques that are used in the field. In soilless culture (also called hydroponics), the necessary nutrients are delivered to the plant root system in the irrigation water through a network of pipes. The commonly used substrates for plant growth include rock wool, coco fiber (coir pith), perlite, peat, sawdust, and pine bark. Greenhouse tomatoes are started from high-quality transplants to ensure uniform crop establishment.

Fruit Development

After fertilization, tomato fruit development proceeds through several stages. In the first stage, rapid cell division follows immediately after fertilization, leading to a progressive increase in pericarp cell number. The end of this stage is marked by a sharp fall in the rate of cell division, which occurs after 2 weeks of pollination. During the second stage, an increase in fruit weight occurs as a consequence of cell expansion. The fruit turns into the mature green (MG) stage during the third phase. After reaching the MG stage, elaborate metabolic changes occur in the tomato fruit, which marks the beginning of the fruit ripening process. The breaking (BR) and the ripening (RR) stages are the two phases of ripening.

Skin color is the most widely used external index of tomato maturity, and distinct changes in external color can be used to determine harvest maturity. Seed development and locular gel formation are important internal indexes of maturity. MG fruit has fully developed straw-colored seeds, which will not be cut when the fruit is sliced with a sharp knife. The locules of MG fruit are completely filled with jelly at maturity, and the immature green fruits have one or more locules without jelly. Skin color remains green during fruit development on the plant. On reaching maturity, the blossom end of the tomato fruit changes to a light green or whitish color followed by the appearance of one or more distinct white streaks usually at the blossom end. This stage is referred to as 'mature green.'

Ripening

Tomato is considered as a climacteric fruit. Fruit ripening involves a series of biochemical events that convert the green unripe hard acid tasting tomato fruit into a soft fruit with sweet taste and aroma. An increase in respiration, increase in ethylene production, fruit acidity changes, and changes in starch and sugar content are some major biochemical changes that occur during ripening. Tomato fruit develops coloration following a typical sequence with ripening. In most red-colored cultivars, after the MG stage, the tip of the blossom end changes to a pinkish-yellow color, which is referred to as the 'breaker stage.' The breaker stage usually occurs within a day after the MG stage. Later, the entire fruit turns to pink, followed by light red and finally deep red. The ripening stages of mature tomato fruit are classified as green, breaker, turning, and pink. Color change in tomato from green to red during ripening is due to chlorophyll degradation and carotenoid accumulation. Red color is caused by high concentration of lycopene. After red ripe, the last stage is the process of senescence, which involves degradation of cellular tissue eventually leading to the death of the cells.

Tomato flavor involves perception of the tastes and aromas of many chemical compounds and is achieved by a balanced interaction and combination between sugars and organic acids in tomato fruit. The ratio of soluble solids to organic acids is important to sweetness and sourness of tomatoes. Sourness of tomatoes is due to organic acid content, mostly malic and citric acids. Citric acid was found to be the principal organic acid in ripe tomatoes and during maturation its level rises. High acidity and low soluble solid contents will produce a tart tomato, while high soluble solids and low acidity will result in a bland taste. When both soluble solids and organic acids are low, the result is a tasteless, insipid tomato. More than 400 volatile compounds have been identified in tomato, and these volatiles are usually concentrated in the pulp and locular gel of tomatoes, but not in the skin and seeds. Sugars and their influence on taste are gauged in several ways. Total soluble solids (TSS), the titratable acid (TA) ratio, and the total sweetness index (TSI) are three common measures of tomato fruit quality. TSS reflects dry matter content and is inversely proportional to

fruit size. TSS in beefsteak tomatoes ranges from 3% to 5%, in medium-sized fruit from 5% to 7% and in cherry tomato fruit from 9% to 15%. A minimum TSS and TA of 5 and a minimum TA of 0.4, respectively (TSS:TA of 12.5), are considered desirable to produce a good-tasting table tomato.

Postharvest Handling and Storage

Tomatoes picked at the MG stage have a longer postharvest shelf life and can withstand the stresses of handling and transport much better than the fully ripe fruits, which are easily bruised and damaged. Properly handled MG tomatoes can ripen normally and develop flavor to the same extent as vine ripened fruit. However, if immature green stage fruit is inadvertently picked, eating quality is reduced. Immature green tomatoes will not ripen properly and be of low quality. Tomato fruits are very delicate with a very short postharvest shelf life and are easily susceptible to damage and bruises. Appropriate postharvest handling and storage techniques are essential for maintaining acceptable quality and extending the postharvest shelf life of tomatoes. After harvesting, tomatoes are cooled to reduce field heat, washed, and sorted by size, color, and variety. Fresh tomatoes can be stored after they have been harvested and sorted or they can first be packaged before storing. Cooling before and during storage is important. Tomatoes will deteriorate if they are kept at temperatures below 10 °C for longer than 2 weeks or if kept at 5 °C for longer than 6–8 days. Tomatoes are sensitive to chilling. Tomatoes that suffer chilling injury fail to ripen, their color development is irregular, and they are likely to suffer premature softening, browning of seeds, and increased decay.

Chemical Composition of Fresh Tomato

The chemical composition of tomatoes is greatly dependent on factors such as cultivars, maturity, light, temperature, weather, and cultural practices. The chemical composition of tomato fruit is important in the development of various fruit quality attributes: color, texture, appearance, nutrient value, taste, flavor, and aroma. Generally, sugar content of tomato is a function of stage of maturity. Sugars contribute to the soluble solids portion of the fruit that in turn contribute to the tomato flavor. Free sugars constitute about 60% of the tomatoes and are mainly D-glucose and D-fructose with traces of sucrose and raffinose. Starch content declines with fruit maturity. It varies from 1–1.22% in immature fruit to 0.1–0.15% in red ripe fruit. The texture of fruit is greatly controlled by the pectin content. Organic acid content and acidity influence the taste and flavor of tomato fruit. Citric acid and malic acid are the principal organic acids in tomato fruit. As the fruit matures, acidity increases to a maximum and then declines. Acidity is maximum at breaker and pink stages.

Tomatoes represent a low-energy nutrient-dense food with unique composition of several phytochemicals that may positively affect health. Tomato and tomato-derived products are excellent sources of folate and vitamins A, C, and E in the form of α-tocopherol (Table 1). Alpha-tocopherol can improve endothelial functions by preventing platelet aggregation and adhesion. Among the regularly consumed vegetables, only carrots are a better dietary source of vitamin A than the tomato-based foods. Tomatoes and tomato products also contain appreciable amounts of fiber. The tomato paste contains about 11.8 g fiber per cup. Vitamins C and E have very potent antioxidant properties. Tomato fruits are also an excellent source of ascorbic acid and are the major source of vitamin C next to citrus. The major phytochemicals in tomato are the carotenoids comprising 60–64% lycopene, 10–12% phytoene, 7–9% neurosporene, and 10–15% carotenes. Tomato contains significant amounts of α-, β-, γ-, δ-carotene ranging in concentrations from 0.6 to 2.0 mg kg^{-1}, significantly contributing to the provitamin A and vitamin A content. Tomatoes are excellent dietary sources of potassium. Dietary potassium helps lower blood pressure, reduces the adverse effect of excess sodium intake on blood pressure, reduces the risk of kidney stones, and possibly reduces age-related bone loss. Tomatoes can supply at least twice the potassium per 100 kcal compared with other common sources. Increasing potassium intake

through increased tomato consumption is a healthful choice to increase the content of potassium in human diet.

Tomato Bioactives

Flavonoids constitute the largest group of phenolics in tomatoes and influence aroma, fragrance, and color characteristics of fruit. Flavonols (such as quercetin and kaempferol), flavanols (such as catechins), flavanones (such as naringenin), and stilbenes (such as resveratrol) constitute the main classes of tomato flavonoids. Up to 98% of flavonoids are usually concentrated in the tomato skin, and relatively, small quantities occur in the other parts of the fruit. According to the USDA flavonoid database, red tomatoes contain on an average 15 mg flavonoids as aglycones per kg FW. Naringenin (45%) is reported as the principal flavonoid followed by quercetin (39%), myricetin (10%), and kaempferol (5%). Besides flavonoids, chlorogenic acids and the related compounds form the main phenolic components in tomato. Other studies also detected rutin as another major flavonoid in tomato. Occurrence of ferulic, caffeic, chlorogenic, and p-coumaric acid was also identified in tomato fruit and skin. Many of these phytochemicals have potent antioxidant properties and in combination with lycopene may contribute to the numerous health benefits of tomatoes. The content of phenolic compounds of processed products was lower than that of fresh tomatoes. Tomato fruit usually does not contain anthocyanins, and the red color in tomato is from the carotenoid pigment, lycopene. Recently, purple-fruited tomatoes were developed through breeding programs in Oregon and Canada and also through genetic engineering. Purple tomatoes have the added health benefits from the presence of anthocyanins besides the other health benefiting components in them.

Lycopene

Lycopene content of fresh tomatoes often varies with cultivars and cultivation practices. On a fresh weight (FW) basis, tomato (on average) contains about 35 mg kg^{-1} of lycopene, with red cultivars containing an average 90 mg kg^{-1} of lycopene and yellow ones only 5 mg kg^{-1}. Processed tomatoes (sauce, paste, juice, and ketchup) contain two- to 40-fold higher lycopene content than fresh tomatoes. Nearly 85% of the average daily intake of lycopene in the human diet (about 25 mg day^{-1}) is obtained from fresh and processed tomato products. According to some studies, field-grown tomatoes appear to contain higher levels of lycopene ranging from 5.2 to 23.6 mg per 100 g FW than greenhouse-grown tomatoes (0.1 and 10.8 mg per 100 g FW).

Lycopene is the most abundant carotenoid in tomatoes and tomato-based foods, which is responsible for the characteristic red color of ripe tomato fruits. Unlike some carotenoids, lycopene lacks the provitamin A activity. Lycopene is about 2 times greater than β-carotene and 10 times greater than vitamin E in its potency to quench singlet oxygen and is one of the most potent antioxidants in food. Lycopene occurs in all-*trans*-configuration (95%) in fresh tomatoes, while processing and cooking can convert trans-form into the more bioavailable cis-form. Lycopene is the principal phytochemical in tomatoes accounting for its strong antioxidative activity associated with its ability to act as free radical scavenger. Generally, tomato and tomato-based food products can supply at least 85% of lycopene in human diet. Lycopene is a key intermediate in the biosynthesis of many important carotenoids, such as beta-carotene, and xanthophylls.

β-Carotene

β-Carotene is a strong antioxidant and also a scavenger of singlet oxygen. It is also a provitamin A as it can be converted into retinol. In commercial cherry tomato varieties, β-carotene content reached 1.2 mg per 100 g FW. Bioaccessibility of β-carotene from raw tomatoes was reported to be about 0.1%. Studies demonstrated the photoprotective effects of β-carotene on photooxidative damage and sunburn in humans. A significant reduction in erythema formation was also noticed when β-carotene was applied on human skin or with a dietary intervention alone or in combination with α-tocopherol for 12 weeks. Low concentrations of serum β-carotene have also been associated with an increased risk of congestive heart failure and cardiac death in men. However, some studies do not favor the absolute supplementation of high doses of β-carotene because the initial antioxidant activity of β-carotene is followed by a prooxidant action at high oxygen tension, which may be related to its adverse effects. Furthermore, intervention studies have shown that β-carotene supplementation had no protective effect on total mortality of diabetic male smokers and also in subjects with lethal prostate cancer with the use of β-carotene during radiation therapy compared with that of placebo.

Lutein

Average lutein content of raw tomato was reported as 32 μg per 100 g FW, while cherry tomatoes were reported to contain up to 800 μg per 100 g FW. These carotenoids have also attracted attention for their role in preserving eye health and vision in association with zeaxanthin. It has also been reported to be used in atrophic age-related macular degeneration. The association between the consumption of lutein and the maintenance of visual function and eye health has not been clearly demonstrated so far.

Health Benefits

Antioxidant Activity

Several studies have investigated on the antioxidant effects of lycopene and tomato supplementation in human diet. Data from studies that examined the antioxidant effects of lycopene and tomatoes consistently show improved antioxidant status with tomato/tomato product consumption and after lycopene supplementation. However, two clinical trials of lycopene supplementation reported neutral effects on oxidative stress markers. One study conducted in relatively healthy individuals ($n=60$) and two studies ($n=40$ and $n=57$) in individuals with type 2 diabetes showed decreased lipid peroxidation rates and decreased susceptibility of low-density lipoproteins

(LDLs) to oxidation after daily consumption of tomatoes or tomato juice. Others have reported less susceptibility to oxidation of DNA and LDL after tomato product consumption. Studies also reported that the plasma antioxidant capacity decreases when tomatoes and tomato products are removed from the diet and increased when they are added back.

Cardiovascular Diseases (CVD)

Oxidative modification of LDL is a key step in the development of atherosclerotic lesions. Consuming antioxidant-rich plant foods such as tomatoes may be one way to reduce the risk of cardiovascular atherosclerotic disease through inhibition of the oxidative process of LDL. High levels of tomato-based product intake were associated with a reduced risk of cardiovascular disease (CVD) and myocardial infarction in women. Furthermore, some clinical trials have also supported a relationship between CVD and lycopene intake. Studies have also shown that lycopene may reduce cholesterol synthesis and increase LDL degradation. Decreased triglyceride levels and LDL cholesterol and increased high-density lipoprotein cholesterol levels were noticed in subjects who consumed fresh tomato and tomato juice. Consumption of tomato products daily for 2–4 weeks has been shown to reduce plasma lipid peroxides and susceptibility of LDL to oxidation and also to increase antioxidant enzymes. An inverse association between greater consumption of tomato-derived product intakes (>7 servings per week) and CVD risk was observed in women, and such an association was not observed with lycopene intake alone. Epidemiological data and results from *in vitro* and animal experiments partly showed promising role of lycopene and tomato products in preventing CVD. However, there is still a lack of more well-organized human clinical trials and dietary intervention studies using well-defined subjects to provide clear evidence for the protective mechanism of lycopene in the prevention of CVDs.

Cancer

Consumption of tomatoes and tomato-based products had been found to be associated with a decreased risk of chronic diseases, such as cancer. Epidemiological studies and various *in vitro* and *in vivo* studies also support the protective effects of high intake of tomato and tomato products containing lycopene on some types of cancer including prostate cancer. The Health Professionals Follow-Up Study, a prospective epidemiological study of about 47 000 men, is of particular importance since it provided the strongest epidemiological evidence to support an association between tomato product consumption and a reduced incidence of prostate cancer. This study showed that consumption of 2–4 servings of raw tomatoes per week was associated with a significant 26% reduced risk of prostate cancer when compared with no servings per week.

Some clinical trials also observed a reduction in prostate-specific antigen (PSA) levels as a surrogate marker for prostate cancer status, while other studies showed a weak effect or no effect of tomato consumption or lycopene supplementation on prostate cancer risk. Preliminary cell culture studies conducted using human prostate and mouse hepatic cancer cell lines indicated that tomato aglycone polyphenols, including quercetin, kaempferol, and naringenin, inhibited cancer cell proliferation in both types of cell lines in a dose-dependent manner, without having cytotoxic effects. Lycopene administration (10 mg) for 3 months decreased PSA level, tumor grade, bone pain, and urinary tract symptoms in patients with metastatic prostate cancer. However, lycopene is not potent enough to be used clinically as a drug for prostate cancer because high concentrations are needed to achieve significant response in humans.

In addition, lycopene can inhibit other cancer types (breast, colorectal, endometrial, lung, oral, and pancreatic). Mixed results have been noticed in the epidemiological studies examining the association between lycopene and colorectal cancer risk. Some clinical trials have also reported beneficial effects of lycopene-containing supplements on colorectal and breast cancer biomarkers. Several possible mechanisms of the action of tomato phytochemicals responsible for the anticancer effects have been suggested including antioxidant activities, alteration of xenobiotic metabolism, modulation of the IGF-1, inhibition of cell-cycle progression, and increase in the formation of gap junctions.

Metabolic Diseases, Obesity, and Other Conditions

Evidence to support the benefits of tomatoes in terms of protection against diseases associated with metabolic syndrome and obesity is available. In particular, lycopene reduces transcript levels of proinflammatory cytokines with the downregulation of interleukin-6 expression. The effect of tomato-derived lycopene consumption on markers of inflammation and oxidative stress was monitored in a group of patients with extreme obesity. Abnormally higher markers of inflammation and oxidation products and lower plasma carotenoids were noticed in obese patients compared to control subjects. Studies also showed that anti-inflammatory effects derived through consumption of tomato products were superior to that of lycopene ingested as a single compound. Supplementation of a low-tomato diet with tomato products resulted in changes in inflammatory markers such as C-reactive protein (CRP), IL-6 and tumor necrosis factor-α (TNF-α). A decline in CRP and cholesterol level was noticed after a 2-week dietary tomato juice supplementation (containing ~21 mg lycopene and 45.5 mg and 435 mg each vitamin C), and this effect was stronger with higher dose of vitamin C addition. It has been demonstrated that lycopene can stimulate the production of anti-inflammatory cytokines such as IL-10 to control inflammation and can inhibit the activation of the transcription nuclear factor kappa B (NFkB) and the generation of the proinflammatory cytokines including TNF-α, IL-6, and IL-8 in macrophages and adipocytes.

Two studies reported reduced blood pressure after dietary lycopene supplementation. Studies also demonstrated an inverse association between serum lycopene and markers of oxidative stress and bone resorption in postmenopausal women aged 50–60 years. Also, significant increase (20.6%) in the bone resorption marker NTx was noticed after 30 days of dietary lycopene restriction, which could lead to a long-term increased risk of fracture. Health beneficial effects of the dietary intake of α- and β-carotene and of lycopene on glucose metabolism in men have been noticed. Studies also reported a linear decrease in β-carotene and lycopene content in persons with impaired glucose tolerance and in persons with newly

diagnosed diabetes compared to persons with normal glucose concentrations.

UV Protection

The protective effect of tomato products and lycopene against UV-induced sunburn has been reported. In these studies, subjects who consumed synthetic lycopene alone, a softgel encapsulated tomato extract, or a tomato drink showed a decrease in solar simulator-induced sunburn indicating the skin-protective effects of tomato and tomato products.

Bioavailability

Lycopene bioavailability is influenced by a number of factors including food processing and dietary composition. In plant foods, lycopene can occur in a number of forms such as carotenoid–protein complexes in chloroplasts or in crystalline form inside the chromoplasts. Lycopene bioavailability can be greatly enhanced by various processing methods that break down the cell walls, making lycopene more accessible, and also through enhanced *cis*-isomerization. Bioavailability of lycopene is higher in processed tomato products than in unprocessed fresh tomatoes. Furthermore, lycopene bioavailability is also affected by processing methods and storage. Improper processing methods, handling, and storage (i.e., exposure to light and oxygen) can degrade lycopene or alter the ratio of lycopene isomers.

In fact, thermal processing greatly improves lycopene bioavailability by disrupting cellular membranes releasing lycopene from the tissue matrix. Multiple studies have demonstrated that lycopene from thermally processed tomato products is more bioavailable than lycopene from fresh tomatoes. Lycopene bioavailability is greatly affected by dietary composition and food matrix. Consuming lycopene-containing food with fat increases its bioavailability as lycopene is a lipid-soluble compound. For instance, a study found that the consumption of tomato salsa with avocado (as lipid source) led to a 4.4-fold increase in lycopene absorption as compared with salsa without avocado.

On ingestion, lycopene is released from the food matrix, and once inside the enterocyte, lycopene is packaged with other dietary lipids into chylomicrons. Then, it is incorporated into mixed micelles. Micelles contain bile salts, cholesterol, and fatty acids from the meal, and the amphiphilic nature of the micelle structure helps to keep the lipophilic nutrients soluble in the aqueous phase. Heat processing of tomatoes converts the all-*trans* lycopene to various *cis*-isomers. Cis-lycopene isomers are regarded as more bioavailable because they are more soluble and better absorbed from the intestinal lumen than the all-*trans* isomer. Isomerization may also take place *in vivo* and the gastrointestinal lumen, liver, and enterocytes were identified as potential sites of lycopene isomerization *in vivo*. Lycopene passively diffuses across the apical membrane of the intestinal cells. Studies have shown that lycopene absorption can also be facilitated by a cholesterol membrane transporter known as scavenger receptor class B type I (SR-BI). It has been suggested that lycopene absorption may be facilitated by other transporters, but this has not yet been confirmed. Chylomicrons are then transported across the basolateral membrane and make their way into the lymphatic system, which eventually releases chylomicrons into the blood. Competition by other carotenoids or cholesterol may also influence lycopene absorption.

Solanum melongena L. (Eggplant)

Solanum melongena L. or eggplant is also known as aubergine in England or brinjal in India. Eggplant is believed to have originated in India. *Solanum melongena* belongs to the tribe Solaneae and is a member of the subgenus *Leptostemonum*, the largest subgenus of the genus *Solanum* which includes almost one-third of the species within the genus *Solanum*. Eggplant is a diploid species ($2n = 24$) with a basic chromosome number of 12. Eggplant is a perennial plant but cultivated as an annual for its edible fruit. The plant has an erect woody branching stem with or without spines. Purple flowers have 5 calyx lobes and occur singly or in clusters of 2 or more flowers. Fruit are borne singly or in clusters. Eggplant fruit is a pendant berry and shows high variability in their shape (round, ovoid, cylindrical, or elongated), size, and fruit color (green, white, violet, purple, black, or orange with or without patches or stripes). The presence or absence of chlorophylls and anthocyanins as well as their distribution pattern determines the fruit color diversity in eggplants. Two other *Solanum* species *S. aethiopicum* and *S. macrocarpon* L. are also commonly known as 'eggplants' and cultivated for their edible fruits. *Solanum aethiopicum* also known as the scarlet eggplant is a native of Africa. It differs from *S. melongena* in its small white corollas and usually bright scarlet fruit that often resemble *Capsicum* peppers. This species is widely grown in Africa and South America for its edible fruits. *Solanum macrocarpon* L., the gboma eggplant, is also a native to central Africa and is grown for its edible fruits and leaves. The presence of deeply lobed leaves and very large calyxes usually distinguishes this plant from *S. melongena*.

Economic Importance, Production, and Uses

Today, eggplant is cultivated globally for its edible fruits. In 2011, total eggplant production accounted to about 46.8 million tons. China and India lead the world production of eggplant followed by Turkey, Egypt, Japan, and Italy. Eggplant is grown in many countries throughout the tropics, subtropics, and Mediterranean area, since it requires a relatively long season of warm weather to give good yields. It grows best between 20 and 35 °C, while temperatures below 20 °C and above 40 °C retard growth. Growth is halted at temperatures below 10–12 °C and the crop is frost-sensitive. It thrives well in fertile well-drained soils with a pH of 5.5–6.8. A growing season of about 120 days is required for its successful production. Eggplant is transplanted rather than directly seeded in the field to establish uniform plants. Eggplant is commonly grown in open field, but it is also commercially grown in greenhouses. Grafting is mostly used in conditions of intensive production. Eggplant is grafted mostly onto tomato or tomato interspecific hybrids (*L. esculentum* × *L. hirsutum*), which are resistant to several soil pathogens and also tolerant to low soil temperatures. Eggplant cultivar diversity differs from country to country. Most European and American commercial cultivars are

characterized by fruits that are globose, intermediate, or long, with an almost black and shiny epidermis and weighing 200–400 g. Asian countries such as Thailand, China, and India are also characterized by astonishing diversity in eggplant fruit sizes, shapes, and colors. Eggplants are used in a variety of ways such as grilled, stewed, and fried. It is also added to various curry dishes in India and Thailand.

Nutritional Composition

Eggplant is low in calories and fats and contains mostly water (Table 1). It also has some protein, fiber, and carbohydrate. Eggplant fruit is a good source of various vitamins like B_1, B_2, B_6, C, K, thiamine, niacin, and pantothenic acid and minerals like magnesium, potassium, manganese, and copper. In general, the purple varieties showed more protein content than the white and green varieties. Purple eggplant also contained significant amounts of essential amino acids, such as leucine, valine, lysine, and isoleucine. Additionally, eggplant fruit contains various antioxidant bioactive compounds including phenolic compounds, such as caffeic, p-coumaric and chlorogenic acid, and flavonoids, such as nasunin and delphinidin in the peel of colored varieties. Nasunin is an anthocyanin purple pigment (delphinidin-3-coumaroylrutinoside-5-glucoside), which is the predominant phytochemical in eggplant. Nasunin is mainly confined to the peel of eggplant and it represents between 70% and 90% of the total anthocyanins in the peel. Nasunin is a potent antioxidant that effectively scavenges reactive oxygen species, such as hydrogen peroxide, hydroxyl, and superoxides. Chlorogenic acid is another predominant phenolic compound found in eggplant, which is also a powerful free radical scavenger found in plant tissues. Some of the health benefits associated with chlorogenic acid include antimutagenic (anticancer), lipid-lowering, antimicrobial, and antiviral activities. Besides chlorogenic acid, 13 other phenolic acids have been identified at varying levels in different commercial eggplant cultivars, although chlorogenic acid was the predominant phenolic compound in all of them. The phenolic acids are responsible for eggplants' bitter taste and the browning that result when the flesh is cut. Eggplant is ranked as a vegetable with high antioxidant activity that is attributed to the anthocyanins and phenolic compounds contained in eggplants. Phenolic composition of skin and pulp of eggplant fruit differs. Generally, eggplant peels contain more phenolic compounds than the pulp. Eggplant fruits also contain other antioxidants including the carotenoids lycopene, lutein, and α-carotene, as well as the flavonoids myricetin and kaempferol.

The presence of two kinds of steroidal saponosides imparts bitter taste to eggplant. They are glycoalkaloids and melongosides. The principal glycoalkaloid specific to eggplant is solasonine and is the eggplant analogous of the potato solanine (aglycone solanidine) and the tomato tomatine (aglycone tomatidine). The glycoalkaloids solamargine and solasonine and their common aglycone solasodine were also found in eggplant. High concentration of solasonine and melongosides in the fruit can cause bitterness, making the fruit unpalatable. Most cultivated species of eggplant normally do not contain high levels of alkaloids. Eggplant fruit bitterness is influenced by cultivars, fruit maturity, cultivation and harvest methods. These steroidal saponosides are characterized by their antimicrobial, insecticidal, fungicidal, hypocholesterolemic, anticancer, and hypotensive activities. Eggplants also have nicotine than any other edible vegetable ($100\ ng\ g^{-1}$). The nicotine content in eggplant or any other food is negligible compared to passive smoking. Eggplant also contains measurable amounts of oxalates, which at high concentration can crystallize and cause health problems such as kidney calcium oxalate stones.

Health Benefits

Numerous health benefits are associated with the consumption of eggplants. Besides having potent antioxidant potential, eggplant has been used to lower blood cholesterol. A human trial showed only a modest and transitory effect of the consumption of eggplant powder on total cholesterol and its fractions, triglycerides, and apolipoproteins in blood. Some *in vivo* studies also have demonstrated that eggplant fruit phenolic compounds had a significant hypolipidemic property. Another study found no effects at all on serum cholesterol levels and does not recommend eggplant as a replacement to statins. Among the eight commonly consumed vegetables, eggplant showed the lowest bile acid binding capability, severalfold less than okra and beets. Circulation of bile acids in the body is prevented by binding bile acids resulting in reduced fat absorption and the utilization of cholesterol from the bloodstream to synthesize more bile acids, thereby lowering cholesterol levels. Also, eggplant extracts have been found to inhibit protein-activated receptor-2 inflammation associated with atherosclerosis. Eggplant phenolics are touted as having anticancer properties. Nasunin, the major anthocyanin in eggplant skins has antioxidant activity, and it has been shown to suppress the development of blood vessels required for tumor growth and metastasis in an *ex vivo* animal study and an *in vitro* human cell assay. Nasunin is bestowed with numerous health beneficial biological properties such as protecting blood cholesterol from peroxidation, preventing cellular damage, and lessening free radical damage in joints, which is a primary factor in rheumatoid arthritis. The eggplant glycoalkaloids solamargine and solasonine and their common aglycone solasodine showed antiproliferative activities against human colon (HT29) and liver (HepG2) cancer cells.

Capsicum sp. (Peppers)

Peppers are members of the genus *Capsicum*, which is composed of more than 200 varieties and is native to the tropics of Central and South America. The genus name *Capsicum* is believed to be originated from the Greek word *capsicon* via the Latin *kaptein*, which mean 'to bite.' The five principal domesticated species of *Capsicum* are *Capsicum annuum*, *Capsicum baccatum*, *Capsicum chinense*, *Capsicum frutescens*, *and Capsicum pubescens*. *Capsicum annuum* is, perhaps, the most economically important widely cultivated species today and includes sweet, bell, hot, and jalapeño peppers. The species *C. baccatum* include aji amarillo, a chili that is an integral part of Peruvian cuisine, Bishop's crown, peppadew, and aji limon. Habanero, bhut jolokia, and Scotch bonnet peppers are some *C. chinense* varieties known for their heat and pungency.

Capsicum chinense is the most commonly cultivated and distributed species of northern South America and West Indies. *Capsicum frutescens* known indigenously as the 'bird pepper' are usually very small, pungent and include the famous tabasco pepper. *Capsicum pubescens* is primarily found in Central and South America and is characterized by hairiness of leaves and black seeds, and some varieties like the rocoto and manzano can thrive in higher elevations.

Capsicum fruits show great variations in their pod color, shape, size, pungency, and flavor. Bell pepper is a cultivar group of *Capsicum annum*. All five species yield pungent fruits commonly called red pepper or simply capsicum. Varieties of *C. annuum* produce mild fruits commonly known as paprika, bell pepper, sweet pepper, or green pepper. Bell peppers are grown for their edible bell-shaped colored fruits with three or four lobes. The color of bell peppers can be red, yellow, orange, green, purple, brown, white, and black. Green peppers are unripe, less sweet and slightly bitter than the colored varieties. Purple varieties also tend to be less sweet and bitter than the orange, red, or yellow varieties. Plants are branched, mostly erect, annual or perennial herbaceous shrub that grows to 30–80 cm tall. Small, off-white, pendent flowers are borne singly or in clusters of one to two flowers. Corolla is five-lobed with five stamens and with bluish/purplish anthers. Fruit is a berry with a fleshy, firm, and hollow pericarp. Usually, fruits of the purple and white varieties do not have a green stage.

Method of Consumption

Capsicum annuum and *C. frutescens* are the most consumed spices in the world. Peppers form a significant part of the human diet in many parts of the world. Fruits are consumed in fresh, cooked, or processed forms. Fresh peppers are often used in salads. Chilies are also sold as frozen, canned, dried (whole or crushed pieces), and pickled fruit. Fruit is also processed into various fermented products, powders, sauces, curry pastes, and salsas. Dried chilies are often ground into powders and added into various culinary preparations and other dishes. Fresh or dried chilies are also used to make hot sauce. Chili in the form of powder or paste is a vital ingredient of Indian curries. Fresh market types, such as bell, Cuban, and squash, are usually nonpungent and eaten raw or stir-fried. Leaves of *Capsicum* are edible and are eaten or added to soup and stews in many parts of Southeast Asia. Carotenoid extracts (oleoresins) are used as a coloring agent by the food, cosmetics, and pharmaceutical industries.

Nutritional Value

Peppers are good sources of vitamins C and A. Significant cultivar differences exist in the content of vitamin C. On a FW basis, vitamin C content has been shown to increase with fruit maturity. A serving (100 g) of raw green sweet pepper can provide more than the recommended dietary allowance (60 mg) of this vitamin. Peppers also contain vitamins B_2 (riboflavin), B_3 (niacin), E, K, and B_6 (Table 1). Vitamin A occurs in pepper as β-carotene and provitamin A. Vitamin A content and its accumulation increase with fruit maturity. Carotenoids serve as powerful antioxidants and have provitamin A activities. More than 30 different carotenoid pigments have been identified in pepper fruit. These include β-carotene and a number of xanthophylls including lutein, zeaxanthin, violaxanthin, cucurbitaxanthin A, and β-cryptoxanthin. Among them, only β-carotene and β-cryptoxanthin possess provitamin A activity and the oxidative cleavage of these compounds yields retinal. Beta-carotene contents vary within varieties of peppers. Some cultivars of hot pepper have as much as 12 mg kg^{-1} total carotenoids, while in others, its level is undetectable. The main carotenoids responsible for the red color of pepper fruits are the three xanthophylls unique to *Capsicum*, that is, capsanthin, capsorubin, and capsanthin 5,6-epoxide. Though these carotenoids lack provitamin A activity, they are effective antioxidants and a source of red pigments.

Carotenoid content is often an indicator of nutritional value and quality in pepper. The predominant carotenoids in unripe fruit are lutein, β-carotene, and violaxanthin. During maturation, lutein levels decline and levels of β-carotene, β-cryptoxanthin, and zeaxanthin increase. At the breaking stage of fruit development, the red carotenoids, capsanthin and capsorubin, are produced. Capsanthin levels continue to increase as fruit ripen composing between 37% and 80% of total carotenoid content. Carotenoids accumulate as the fruit ripens and the red color of some peppers results from the carotenoid accumulation. Antioxidant phytochemicals, carotenoids, and anthocyanins are responsible for the pigmentation of peppers. The principal red pigments are capsanthin and capsorubin, while lutein, beta-carotene, zeaxanthin, violaxanthin, and antheraxanthin are the yellow and orange pigments. Red peppers also contain lycopene, which has many health beneficial attributes. Besides being rich in phytochemicals, peppers provide dietary fiber.

Though the pericarp, flesh, and seed of pepper contain flavonoids, pepper is not considered to be a rich source of flavonoids. Flavones and flavonol aglycones constitute the most prevalent flavonoid groups in pepper. Quercetin and luteolin are the prevalent flavonoids in peppers. Luteolin and its derivatives form the primary flavones, while quercetin and its derivatives are the primary flavonol aglycones. Quercetin is the major flavonoid in chili pepper. Quercetin derivatives also dominate in green pepper. Other flavones identified in pepper include apigenin, O-glycosyl flavones, and C-glycosyl flavone. Several studies also reported that total flavonoid content and the levels of individual flavonoids decline with fruit maturity. Studies also found that colored peppers generally had higher quercetin and luteolin contents (red peppers had higher contents than yellow and orange peppers).

The major phytochemicals in hot peppers are capsaicinoids. They are a group of phenolic alkaloids specific to the genus *Capsicum*. More than 20 capsaicinoids have been identified in pepper. Capsaicin is the predominant component of the pungent flavor in hot pepper, followed by its analog dihydrocapsaicin and these two compounds together contribute more than 80% of the total capsaicinoid content. Capsaicin is the primary component of pepper spray. Capsaicinoids are synthesized in the fruit placenta. A sensation of heat and pain is caused by the binding of the capsaicinoids to receptors in mouth and throat resulting in sensing 'heat' and serves as a natural defense against herbivory. Birds are not affected by these compounds. Domestication and breeding efforts have reduced pungency and capsaicinoid content of some peppers

especially the bell peppers. Capsaicinoid content is a major quality factor in spice peppers (chili, tabasco, and paprika). There is a direct correlation between total capsaicinoid levels and pungency (as measured in Scoville heat units, which is a subjective organoleptic measure, and chili hotness is now determined by high-performance liquid chromatography). Capsaicin and dihydrocapsaicin are undetectable in sweet pepper varieties, but significant amounts of these compounds are present in chili and paprika types. Significant variations in the profile of capsaicinoids are found between and within pepper species.

Health Benefits and Medicinal Uses

Capsicum is used internally to treat diarrhea, cramps, colic, and toothache, and it acts as stomachic, carminative, and stimulant. It can clear the lungs and sinuses, protect the stomach by increasing the flow of digestive juices, trigger the brain to release endorphins, and help protect the body against cancer through antioxidant activity. Peppers have anti-inflammatory activity and shown to have both antihyperglycemia and antihypertension potential. Pepper occupies a top place among various vegetables and ranks high for antioxidant activity. Antioxidant vitamins such as A and C help to prevent inflammation, cell damage, cancer, and age-related ailments and help to boost immunity. Vitamin K helps protect cells from oxidative damage, promotes proper blood clotting, and strengthens bones. Beta-cryptoxanthin, a carotenoid in red peppers, has shown promise for helping to prevent lung cancer related to smoking and passive smoke.

Capsaicin, the pungent compound in chili peppers, is an ingredient of several commercial medicinal formulations for the treatment of muscle pains, toothaches, burning-mouth syndrome, gastric ulceration, painful diabetic neuropathy, and arthritis. Various topical and injectable formulations containing capsaicin have been developed for the treatment of pain. The capsaicin in hot peppers has been shown to decrease blood cholesterol and triglycerides and reduce the risk of stomach ulcers. Although capsaicinoids demonstrated gastroprotective effects in several animal studies, it can also have detrimental effects on the gastrointestinal system at very high doses. Capsaicin also has analgesic, antibacterial, and antidiabetic properties. It is also used to treat bladder hypersensitivity, vasomotor rhinitis, and hyperreflexia of spinal origin. Capsaicin has been reported to have substantial anticarcinogenic effects in several *in vitro* and *in vivo* studies suggesting its use for chemoprevention. Capsaicin showed its antitumorigenic activities in breast cancer and prostate cancer cells. Capsaicin exerted a number anticarcinogenic and tumor-preventive mechanisms such as prevention of cell proliferation and migration and induction of apoptosis. Capsanthin and related carotenoids from fruits of *C. annuum* were found to have *in vitro* antitumor activity in some animal and *in vitro* studies. Epidemiological studies also have revealed that consumption of chili peppers in large quantities was at higher risk of developing gastric cancer than nonconsumers, thus demonstrating the carcinogenic properties of capsaicin. Evidence from animal experiments and clinical studies has suggested that capsaicinoids possess antiobesity properties by enhancing energy expenditure and reducing body fat accumulation.

Sorghum: A Novel and Healthy Food

P Pontieri and L Del Giudice, Istituto di Bioscienze e BioRisorse-UOS Portici- Consiglio Nazionale delle Ricerche, Portici (Napoli), Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Sorghum (*Sorghum bicolor* (L.) Moench) ranks the fifth most important cereal crop in the world in terms of total production and constitutes a major source of proteins, calories, and minerals for millions of people (Figure 1). Total world annual sorghum production is about 60 million tons from cultivated area of 46 million hectares. The most important producers of sorghum are the United States, Sudan, Nigeria, Mexico, India, China, Burkina Faso, Brazil, Australia, and Argentina (Figure 2). More than 35% of sorghum is grown directly for human consumption. The rest is used primarily for animal feed, alcohol production, and industrial products.

With increasing world population and decreasing water supplies, sorghum represents an important crop for future human use. While sorghum is a vital food crop for millions of people in parts of Africa and Asia, it is an underutilized resource in most developed countries, with sorghum being primarily used as animal feed. The use of sorghum not only provides farmers with a market for their products but also saves money, which would otherwise be required to import cereals, which can be very costly. The demand for gluten-free foods for people with celiac disease and other intolerances to wheat is growing particularly in the developed countries. The development of white, tan plant, the so-called food-grade sorghum lines (Figure 3), has enabled white, bland-tasting flour to be produced from sorghum grain. This flour is useful in food products because it does not impart unusual colors or strong flavors and it may be desired over maize flour for these reasons. The most common foods prepared with sorghum are tortillas; thin porridge, for example, 'bouillie'; stiff porridge, for example, tô; couscous; injera; nasha and kisra; traditional beers, for example, dolo, tchapallo, pito, and burukutu; ogi; and baked products, for example, cakes, cookies, muffins, bread, and pizza. The purpose of this article is to summarize the characteristics of sorghum as a plant species and as human food and to discuss the relevance of experimental results obtained with food-grade sorghum cultivars grown in field trials in San Bartolomeo in Galdo, southern Italy, since 2006. These results demonstrate that sorghum cultivars grow well in Mediterranean environment and that it is possible to obtain white flour for the production of gluten-free cookies of high quality and palatability as food suitable for both celiac patients and healthy population. These studies also provided evidence that DNA sequences encoding toxic proteins for celiac patients are absent in the sorghum genome as also shown by biochemical and immunochemical analyses.

Botanical Nomenclature

Sorghum is a plant belonging to the tribe Andropogoneae and the family Poaceae. Linnaeus described three species of cultivated sorghum in 1753: *Holcus sorghum*, *Holcus saccaratus*, and *Holcus tricolor*. Later, Moench distinguished the genus *Sorghum* from the genus *Holcus*, and Person suggested the name *Sorghum vulgare* for *Holcus sorghum* (L.). In 1961, Clayton proposed the name *Sorghum bicolor* (L.) Moench as the correct name for cultivated sorghum and this is currently the accepted nomenclature. Like most angiosperm (flowering plant) lineages, sorghum is thought to be ~200 Ma old. Sorghum, maize, rice, and wheat diverged from a common ancestor only 50–70 Ma.

Sorghum is a C4 crop particularly adapted to drought-prone areas: hot, semiarid tropical environments with 400–600 mm rainfall – areas that are too dry for other cereals (except for the millets). Sorghum is also found in temperate regions and at altitudes of up to 2300 m in the tropics. It is well suited to heavy soils commonly found in the tropics, where tolerance to water logging is often required.

The main races of cultivated sorghum are bicolor, vulgare, caudatum, kafir, guinea, and durra. Common names of sorghum vary from continent to country levels.

Sorghum is a vigorous grass that varies between 0 and 6 m in height. It has deep and spreading roots with a solid stem. Sorghum leaves are long (0.3–1.4 m) and wide (1–13 cm), with flat or wavy margins. The flower is a panicle, usually erect, but sometimes recurved to form a goose neck. The sorghum kernel is a naked caryopsis and consists of three main anatomical parts – seed coat (testa or pericarp), endosperm (storage tissue), and germ (embryo), which generally account for 6%, 84%, and 10% of the seed mass, respectively (Figure 4). Sorghum is the only cereal grain known to have starch in the mesocarp layer of the pericarp. The endosperm, which is composed of an aleurone layer and peripheral, corneous, and floury areas, is the main storage tissue. The grain or caryopsis is usually partially covered by glumes. Glumes are the maternal plant tissues in the panicle that holds the developing caryopses after pollination. The caryopsis is round and bluntly pointed, from 4 to 8 mm in diameter, and varying in size, shape, and color with variety. Caryopsis color is an important trait that affects grain quality in sorghum.

In some sorghum genotypes, the testa is highly pigmented. The presence of pigment and the color are genetic characters controlled by the R and Y genes. The thickness of the testa layer is not uniform and is governed by the Z gene. In some genotypes, there is a partial testa, while in others, it is not apparent or is absent. Sorghum does not develop significant levels of aflatoxins and fumonisins in the field prior to harvest.

Life Cycle of White Food-Grade Sorghum in Mediterranean Environments

The life cycle of sorghum is very similar to that of corn. The ages of attainment of various stages of development are

Figure 1 *Sorghum bicolor* (L.) Moench.

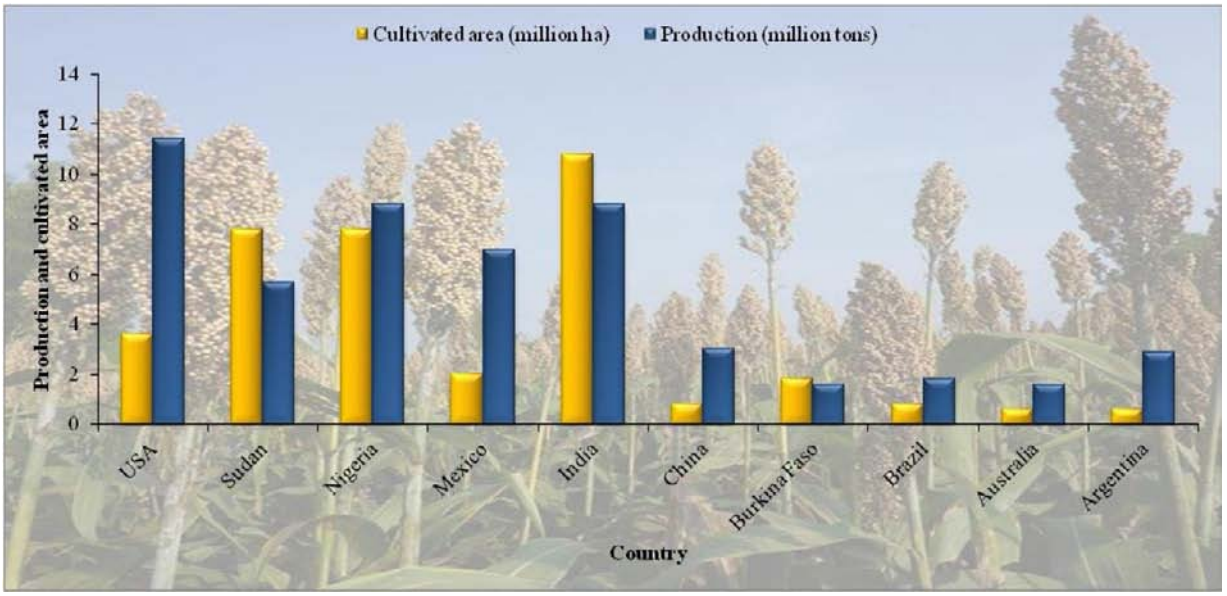

Figure 2 World annual sorghum production and cultivated area. Data are from Food and Agricultural Organization (FAO) (2005). FAOSTAT. http://faostat.fao.org/faostat/.

Figure 3 White food-grade sorghum line.

naturally highly variable depending on the time of sowing, the environment, and the precocity of cultivars. After sowing, seed germination and seedling emergence is completed in 2–3 weeks. The early stages of plant growth are relatively slow: About a month after emergence, the plants have 7–8 leaves and the differentiation in the vegetative reproduction (color change) begins. Immediately after the color change starts, rapid development of the main culm takes place. The plant growth lasts 40–70 days, depending on the variety and the environment, and ends with the formation of the panicle (earring). Immediately after the formation of the panicle, flowering begins and continues along the panicle from top to bottom. After pollination and fertilization, the embryo is formed and the kernels begin to gain weight. Proteins, starches, and lipids accumulate with an increase in the dry weight of the caryopsis and a decrease in water content. The following are the typical stages of maturation of the caryopsis: milk ripeness, dough stage, and physiological maturity. The latter, which marks the end of the accumulation of reserve substances in the seed, is marked by the formation of a layer of suberized cells, called black layer, that closes the phloem and xylem vessels of the stalk of the fruit, effectively cutting them off from the plant. At physiological maturity, the grain has a moisture content of around 35%. After the formation of black layer, the grain begins to dry rapidly, which, in the early varieties grown in Italy, takes place in a comprehensive manner, so that the grain moisture at harvest is almost always

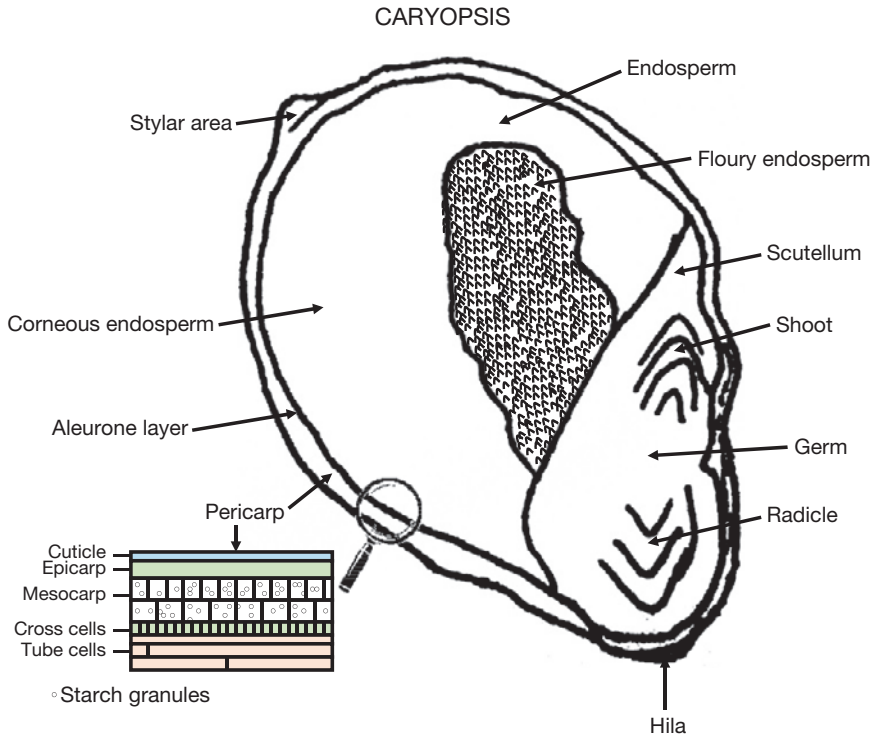

Figure 4 Drawing structure of sorghum grain.

lower than the standard value of 14%. At grain maturation, the sorghum plant remains green, except in cases where extreme environmental conditions (drought and high temperatures) or diseases (such as diseases caused by *Macrophomina* and *Fusarium*) cause premature death of the plant. The complete growth cycle of sorghum in Italy is highly variable in duration ranging between 90 and 150 days. Compared to corn, sorghum has a shortened interval from flowering to physiological maturity: on average, sorghum matures 20–25 days before corn.

Nutritional Components

With the exception of lower oil content, the composition of grain sorghum is quite similar to that of corn. On average, the endosperm makes up 82% of the grain; the germ, 10%; and the pericarp, 8%. The whole grain tends to be relatively low in fiber (2.7%) and contains 7–15% proteins and up to 75% starch. As previously mentioned, the germ is a rich source of oil and protein (28% and 18%, respectively), and the majority of the endosperm is composed of starch and protein. The composition of sorghum grain may fluctuate between different sources due to the genetic and environmental conditions and crop management.

Starch

Sorghum and corn starch have similar properties. The granules have the same shape, but sorghum starch granules are slightly larger. There are minor differences in the rheological characteristics of the starch, including swelling capacity and paste viscosity. The gelatinization temperature of sorghum starch ranges from 71 to 80 °C, which is higher than that of corn, which gelatinizes from 62 to 72 °C. Therefore, sorghum requires a longer cooking time and more thermal energy during processing. It was reported that most sorghum starch contains 20–30% amylose and 70–80% amylopectin; however, waxy varieties (< 5% amylose) have been developed.

Proteins

The majority of sorghum proteins are found within the endosperm of the kernel, distributed within both protein bodies and the endosperm's protein matrix. The major sorghum protein fractions are prolamins and glutelins, with prolamins predominating. The prolamin in sorghum is kafirin, a protein similar to maize zein in molecular weight, structure, solubility, and amino acid composition. Kafirin is found to occur primarily in three forms: α-, β-, and γ-kafirin, with α-kafirin being the major form. These sorghum prolamins are located within the protein bodies in the starchy endosperm. Like many cereals, the limiting amino acid in sorghum is lysine. Sorghum proteins lack the ability to form a gas-holding network in a viscoelastic dough. Therefore, sorghum's use in baked products has been limited thus far.

Fibers

Sorghum contains 6.5–7.9% fiber, of which 86.2% is insoluble. This fiber functions as a structural and protective feature. In cereal grains, dietary fiber (made up of soluble and insoluble fractions) is generally located in the pericarp. As such, the fiber composition in sorghum products, such as flour, depends on the degree of pericarp removal or extraction

level. The insoluble fiber components in sorghum are rich in glucuronoarabinoxylans. In comparison, barley is rich in soluble β-glucans, while wheat has both soluble and insoluble arabinoxylans. These differences in fiber composition may have a significant impact when sorghum is used in value-added products.

Lipids

The majority of lipids found in sorghum are located in the germ. The fatty acid composition of these lipids is quite similar to those found in corn oil. The sorghum oil is primarily made up of the following fatty acids, in order of decreasing concentration: linoleic, oleic, palmitic, stearic, myristic, and hexadecanoic.

Ash

Ash is considered to be the mineral component of the plant and its content could range from 0.99% to 3.40% depending by a number of factors including both the genotype and the environment.

Sorghum for Human Food

Sorghum has traditionally been used for livestock feed in the western hemisphere with a few exceptions, while it has been used as food in both Africa and Asia. Feed sorghums usually are red-seeded with purple or red plant color that causes significant off-color and, often, off-flavors in products used for food. Thus, genetic improvement of this crop with delivery of desirable genes for food processing is a major goal of a number of R&D programs in the United States as well as in other countries.

Previous work has suggested that sorghum possesses characteristics that have both nutritional and functional properties that lend itself to the development of healthy, nutritious foods. Sorghum grain is nutritionally comparable and even superior to major cereals with respect to protein, energy, vitamins, and minerals. It is also a rich source of dietary fiber, phytochemicals, and micronutrients. Traditionally, sorghum has been used in unfermented and fermented breads, porridges, couscous, rice-like products, snacks, and malted alcoholic and nonalcoholic beverages. Recently, interest in sorghum for high-end food products, especially in health food markets, has begun in regions of the world that have traditionally not used this grain in human food systems. Japan has taken the lead in developing snack food products using sorghum, and interest in sorghum's gluten-free properties has developed a demand for high-quality food sorghums within the United States.

Recently, interest has spread in the Mediterranean area for both the cultivation of white sorghum plant species and the production of white sorghum-based foods for healthy gluten-free nourishment, both for celiac populations and for non-celiac populations, as an alternative food to wheat, as part of the program on the development of 'a sorghum chain in the Italian Campania region.' Extensive research information is available on the processing and product development of sorghum. The basic conclusion from that research is that sorghum can be used in a similar fashion, with slight modifications, as other grains, in the production of food products through processing technologies that are currently available. Utilization of sorghum can be increased by various processing treatments including blanching, malting, dry heating, acid treatment, and popping. All these treatments decrease the level of antinutrients and improve digestibility. Sorghum can be utilized for the development of various food products. These include traditional products (porridges, flatbreads, chips, bhakri, suhali, khichri, dalia, shakkerpara, etc.), baked products, extruded products, health products, and weaning and supplementary foods.

Traditional Sorghum Food Products

The main foods prepared with sorghum are tortillas (Latino America); thin porridge, for example, 'bouillie' (Africa and Asia); stiff porridge, for example, tô (West Africa); couscous (Africa); injera (Ethiopia); nasha and kisra (Sudan); traditional beers, for example, dolo, tchapallo, pito, and burukutu (Africa); ogi (Nigeria); and baked products (the United States, Japan, and Africa). Tortillas are a kind of chips prepared from sorghum alone or by mixing sorghum with maize and cassava. Nasha is a traditional weaning food (infant porridge) prepared by fermentation of sorghum flour. Ogi is an example of traditional fermented sorghum food used as weaning food, which has been upgraded to a semi-industrial scale. Injera is a fermented pancake-like bread prepared in Ethiopia from sorghum. Kisra is traditional bread prepared from fermented dough of sorghum. Tô is prepared by cooking a slurry of sorghum flour. Thin porridges (usually used as weaning food) are also prepared in the same manner with less flour to obtain a fluid end product. Porridges prepared with malted sorghums have several order of magnitude lower viscosities than those of nonmalted sorghums. These porridges are particularly useful for the formulation of weaning foods for infants because of their high energy density. Furthermore, the exogenous sources of α-amylase from higher West African plants are useful in reducing the viscosity of cereal porridges, including sorghum ones. Couscous is a steamed and granulated traditional African food originating from North Africa. The traditional method of preparing couscous is a steam-cook process in a special pot called 'couscoussière.' Couscous is prepared by mixing flour with water to obtain agglomerated flour–water mixtures. The agglomerates are then put on top of the 'couscoussière.' The stew cooks in the bottom pot while the granules are steamed on top. White sorghum varieties from tan plants yield the best couscous product. Couscous quality criteria include size uniformity, color, stickiness, and mouthfeel. Dolo is a reddish, cloudy, or opaque local beer prepared essentially from red sorghum malt. The sorghum malting process starts by immersing the grain in water to activate hydrolytic enzymes. Traditional germination involves seedling growth in warm water-saturated air for 3–5 days. The germinated grain is then dried to moisture content of 10–12%. The malt obtained is used to prepare dolo. Briefly, dolo preparation starts by mixing malted sorghum flour with water (1:10, w/v). The mixture is decanted and the supernatant (containing hydrolytic enzymes) is separated from the precipitate (containing

starch). Water is added to the precipitate and the mixture is boiled to gelatinize the starch, but the supernatant is not boiled. It is interesting to note that people, who originally prepare dolo ('dolotières'), empirically know that the supernatant contains 'some things,' for example, enzymes that are thermolabile so they should not be boiled. After cooling, the precipitate is filtered to separate soluble components (starch, sugars, proteins, etc.) and the spent (used as animal feed). The mashing step (incubation of hydrolytic enzymes with their substrates) consists of combining the previous supernatant and the filtrate at 50–60 °C for 12–16 h, to obtain the wort. The wort is cooked and then recooled overnight at room temperature (35–40 °C). The cooled wort is a sweet nonfermented beverage highly appreciated by children. It is traditionally called 'soft dolo.' The fermentation (1–2 days) is initiated by the addition of dried yeasts to the wort. The final product, dolo, is separated from yeasts by filtration. Characteristics of dolo are alcohol content (2–4%, v/v), pH 4–5, stability at room temperature (12–16 h), red color, and opaque appearance.

Sorghum for Baking Products

Sorghum flour does not contain proteins that produce viscoelastic properties similar to that of gluten found in wheat; therefore, acceptable yeast-leavened products from 100% sorghum flour are difficult to obtain. However, sorghum and wheat flour blends have been used to produce many non-gluten-free baked products, including yeast-leavened pan, hearth and flatbreads, cakes, muffins, cookies, biscuits, and flour tortillas. The level of sorghum substituted for wheat flour depends on the strength and quality of gluten in the wheat flour; the baking procedure; the definition of acceptable bread quality; the color, particle size, and aroma of the sorghum flour; and the use of gums, emulsifiers, and other additives.

From 5% to 50% sorghum flour can be substituted for wheat flour. The particle size and shape of sorghum flour often increase the grittiness of the baked products. However, tempering, attrition milling, and other modifications during processing can modify the sandiness of the flour.

White food-grade sorghum has a white kernel with tan plant and glume characteristics (white/tan/tan). The tan plant and light-colored glumes reduce the amount of anthocyanin pigments that cause off-colors in otherwise similar white grains that have purple or red glumes. Tan plants with straw-colored glumes provide grain with excellent properties for processing into whole-grain foods or milling into meal, flour, and grits. White food sorghums do not contain genetically modified organisms, are gluten-free (as are all sorghums), are bland in flavor and light-colored, and have excellent processing properties.

Sorghum Is a Suitable Gluten-Free Food for Celiac Patients

Celiac disease (CD) is a syndrome characterized by damage to the mucosa of the small intestine caused by ingestion of certain wheat proteins and related proteins in rye and barley. CD is a reaction to gluten proteins. Gluten is a complex mixture composed primarily of two classes of the wheat storage proteins, gliadins and glutenins. Gliadins are generally recognized as the primary agent responsible for the development of CD in celiac people. Most of the research into the toxic effects of gliadins has been done with a fraction of α-gliadins, called A-gliadin either intact or digested into small peptides. However, both classes of gliadins and glutenins are reported as toxic. CD is a malabsorptive disorder, present in genetically predisposed individuals, which is the result of ingestion of gluten proteins in wheat or related proteins from barley, rye, and possibly in oats. Symptoms include diarrhea pale stools, enlarged abdomen, physical wasting, anorexia, vomiting, anemia, loss of appetite, fatigue, infertility, anxiety, depression, osteoporosis, and weakness. Modern screening studies show that CD is much more prevalent than previously thought. The average worldwide prevalence has been estimated as high as 1:266. Estimates place the number of persons with CD in the United States at roughly 3 million. The cornerstone treatment for celiac disease is the total lifelong avoidance of gluten ingestion. This means that wheat, rye, and barley have to be avoided, including durum wheat, spelt wheat, kamut, einkorn, and triticale. Sorghum is often recommended as a safe food for celiac patients, because it is only distantly related to the Triticeae tribe cereals wheat, rye, and barley, being a member of the Panicoideae subfamily that also includes maize. Sorghum therefore provides a good basis for gluten-free breads and other baked products like cakes and cookies (biscuits) and in snacks and pasta. In the United States, white food sorghum is currently used in the production of high-quality, gluten-free sorghum flour utilized in a variety of gluten-free foods. Besides, as reported in a later section recently, molecular evidence demonstrating the absence of toxic gliadin-like peptides in sorghum was published, confirming that sorghum can be considered safe for consumption by people with CD.

The mild flavor, light color, pleasing texture, and healthy nutrients in sorghum – a gluten-free grain – make it ideal for gluten-free cooking. As the celiac population reaches three million in the United States and the market for gluten-free foods reaches $700 million, sorghum's versatility makes it appropriate in recipes for gluten-free breads, desserts, pizza, breakfast dishes, and main dishes. Sorghum is an excellent choice for gluten-free foods because it has a similar profile to wheat on the basis of the following characteristics:

1. *Color*: White food-grade sorghum flour is very light in color and will not affect the color of baked goods. This means that it can be used in virtually any type of dish, ranging from white cakes, to sugar cookies, to white bread (Figure 5).
2. *Flavor*: Some people think that sorghum tastes more like wheat than any other gluten-free grain. It is generally described as a pleasant flavor that does not interfere with or dominate the flavor of the food in which it is used. This means that it can be used in any gluten-free food, making it extremely versatile.
3. *Texture*: Unlike rice flour – which is the most commonly used gluten-free flour – sorghum flour has a smooth, non-gritty texture due to processing modifications comprising tempering and attrition milling, as mentioned earlier in the text. A perceived grittiness in rice-based, gluten-free foods is one of the chief objections of newly diagnosed celiac patients.

Figure 5 Sorghum in baking: (a) sandwich breads; (b) pizza; (c) quick breads; (d) cakes. Reprinted with permission from Fenster, C. (2014). *Gluten-free 101: the essential beginner's guide to easy gluten-free cooking*. Houghton Mifflin Harcourt.

4. *Nutrients*: Sorghum flour comes fairly close in nutrient content to unbleached wheat flour, the type used most often in American baking. It is not as nutritious as wheat flour, however.

As mentioned previously, sorghum is gluten-free, and this is particularly important since the incidence of food allergies is growing and it is not unusual for some people to be unable to eat not only wheat but also corn, rice, and soy, which are the most common replacements for wheat. Sorghum provides yet another alternative at least until continued exposure to this grain over time possibly leads to an allergy or intolerance to it.

Sorghum in Nutrition and Health

Sorghum could find a significant niche in the nutritional foods market in developed countries. Unique health foods that have high levels of insoluble dietary fiber, phytates, and phytochemicals could be made from sorghums with high levels of catechins, flavonoids, and phytates and harder to digest proteins. Tannin sorghums contain high levels of antioxidants and may have anticancer properties. Besides, sorghum can contain substantial levels of a wide range of phenolic compounds. The concentration of phenols in some sorghum varieties is comparable to or higher than that of blueberries. Phenolic compounds, especially flavonoids, have been found to inhibit tumor development. The phenolic compounds, flavonoids and tannins, are concentrated in the pericarp, which can be abrasively milled to produce ingredients providing health benefits. Sorghum bran fractions contain high levels of phenols with good antioxidant values and could be exploited as a source of phytonutrients in foods. Their health-promoting properties, in particular their antioxidant activity, and their use as nutraceuticals and functional foods have been reported.

Nutraceuticals are the fastest-growing segment of the food industry. Clearly, with the increasing demand for antioxidant-rich foods and products, new sources are bound to play an important role in this market. Specialty sorghum brans are a promising source of these compounds, given their excellent coloring ability and antioxidant activity. In addition to the potential health benefits of sorghum phenolics, sorghum wax may also have unique health properties. Sorghum wax, which is concentrated on the surface of the pericarp of the grain, is composed of fatty aldehydes (46%), fatty acids (7.5%), fatty alcohols (41%), hydrocarbons (0.7%), wax and sterol esters (1.4%), and triacylglycerols (1%).

The fatty alcohols in sorghum wax can be classified as policosanols, which are primary long-chained alcohols. Since sorghum wax contains only a small amount of wax esters, it was suggested that the term 'long-chained lipids' might be more appropriate than 'wax.' The latter study reported long-chained lipids from different sorghums in the range 37–44% for policosanols, 44 (48)–55% for aldehydes, and 4–5% for acids and that long-chained lipids constituted 0.2–0.3% of sorghum kernels. Therefore, the policosanol content of sorghum kernels was approximately 800 ppm. Sorghum–dried distiller's grains (DDGs), in which nonstarch components are concentrated, contained approximately 2500 ppm policosanols. These amounts are high relative to other sources, for example, brown rice, rice bran, rice germ, and wheat germ. Octacosanol (28:0) and triacontanol (30:0) comprised more than 80% of the policosanols in sorghum kernels and DDG. It has been suggested that mixed C24–C34 alcohols including octacosanol and triacontanol lower the amount of low-density lipoprotein (LDL) cholesterol and raise the amount of high-density lipoprotein (HDL) cholesterol, thus improving the LDL/HDL ratio. It was also indicated that long-chain fatty alcohols, aldehydes, and acids are interconverted in cellular metabolism, so that all three classes might lower cholesterol. It was reported that policosanols are a promising resource for the prevention and therapy of cardiovascular disease. It was found that a crude lipid extract from whole kernel sorghum, which

comprised a wide range of lipid substances including plant sterols and policosanols, lowered cholesterol absorption and plasma non-HDL cholesterol in hamsters.

From the point of view of health, starches in sorghum are considered beneficial to diabetic, since they are released more slowly than those in other cereals. Considering the proteins of sorghum, we must make a separate discussion, since they occupy an important position in bringing benefits in the diet of celiac patients who are intolerant to gluten.

Safety of White 'Food-Grade' Sorghum for Celiac Patients: Clinical, Genomic, Biochemical, and Immunochemical Evidences

In 2007, it was demonstrated by clinical trials that sorghum did not contain toxic peptide sequences with regard to celiac disease and could be considered 'gluten-free' (Figure 6). Until 2011, the white 'food-grade' sorghum was used as food for celiac patients, particularly in the United States. However, experimental evidences at the genomic, biochemical, and immunochemical levels about the lack of gluten in sorghum had not yet been reported. Therefore, research activity was aimed at demonstrating the absence of gliadin in sorghum. In this study, *in silico* genomic approaches and biochemical experiments (Figure 7) were used to characterize protein profiles of storage proteins in different sorghum varieties. These analyses provided molecular evidence for the absence of toxic gliadin-like peptides in sorghum. This finding was supported by immunochemical experiments using the monoclonal antibody R5, which reacts with the gliadin fractions from wheat and corresponding prolamins from rye and barley. It recognizes among others the toxic sequence QQPFP, which occurs repeatedly in the prolamin molecules (Figure 8). Thus, sorghum, similarly to maize and rice, should be considered safe for gluten-intolerant people.

Introduction of White 'Food-Grade' Sorghum in the Mediterranean Area

Since 2006, sorghum grain produced from the white food-grade sorghum cultivars coming from both the United States and Africa was grown in field trials in southern Italy, as shown in Figure 9, and analyzed.

The average values of the results of analyses on white food-grade sorghum grain, grown in a Mediterranean environment, concern the chemical composition reported in Table 1, lipid content reported in Table 2, and the composition of the amino acids reported in Table 3. Those results show that the characteristics of the sorghum cultivars grown in southern Italy are comparable with those of the same sorghum cultivar grown in different environments, namely, the United States and Africa.

In addition, the flour produced from the grain of white food-grade sorghum grown in southern Italy was used to produce, by formulations with other ingredients, pleasing and palatable *gluten-free* cookies shown in Figure 10.

Concluding Remarks

White food-grade sorghum varieties have huge potential for wider use: it can be used in baked, extruded, and other cereal-based products (bread, cookies, expanded snacks, pasta, breakfast cereals, etc.) as partial or complete substitutes for other cereals. The sorghum brans can be used to fortify bread, cookies, and other snacks and to improve the phytonutrient content, as well as dietary fiber and sensory properties. With increasing world population and decreasing water supplies, sorghum represents an important crop for future human use. In fact, while climate change and drought will reduce, especially in the Mediterranean area, the production of cereals, such as wheat, less suitable to those environmental changes, sorghum for human use can be considered a viable alternative to them. Therefore, the aim would be to spread in Italy and in the European countries the use of white sorghum flour mixed with other natural ingredients, such as flour and other gluten-free food components, in order to produce healthy energy-producing foods as an alternative to food based on wheat, where the presence of gluten is the main cause of gastrointestinal intolerance.

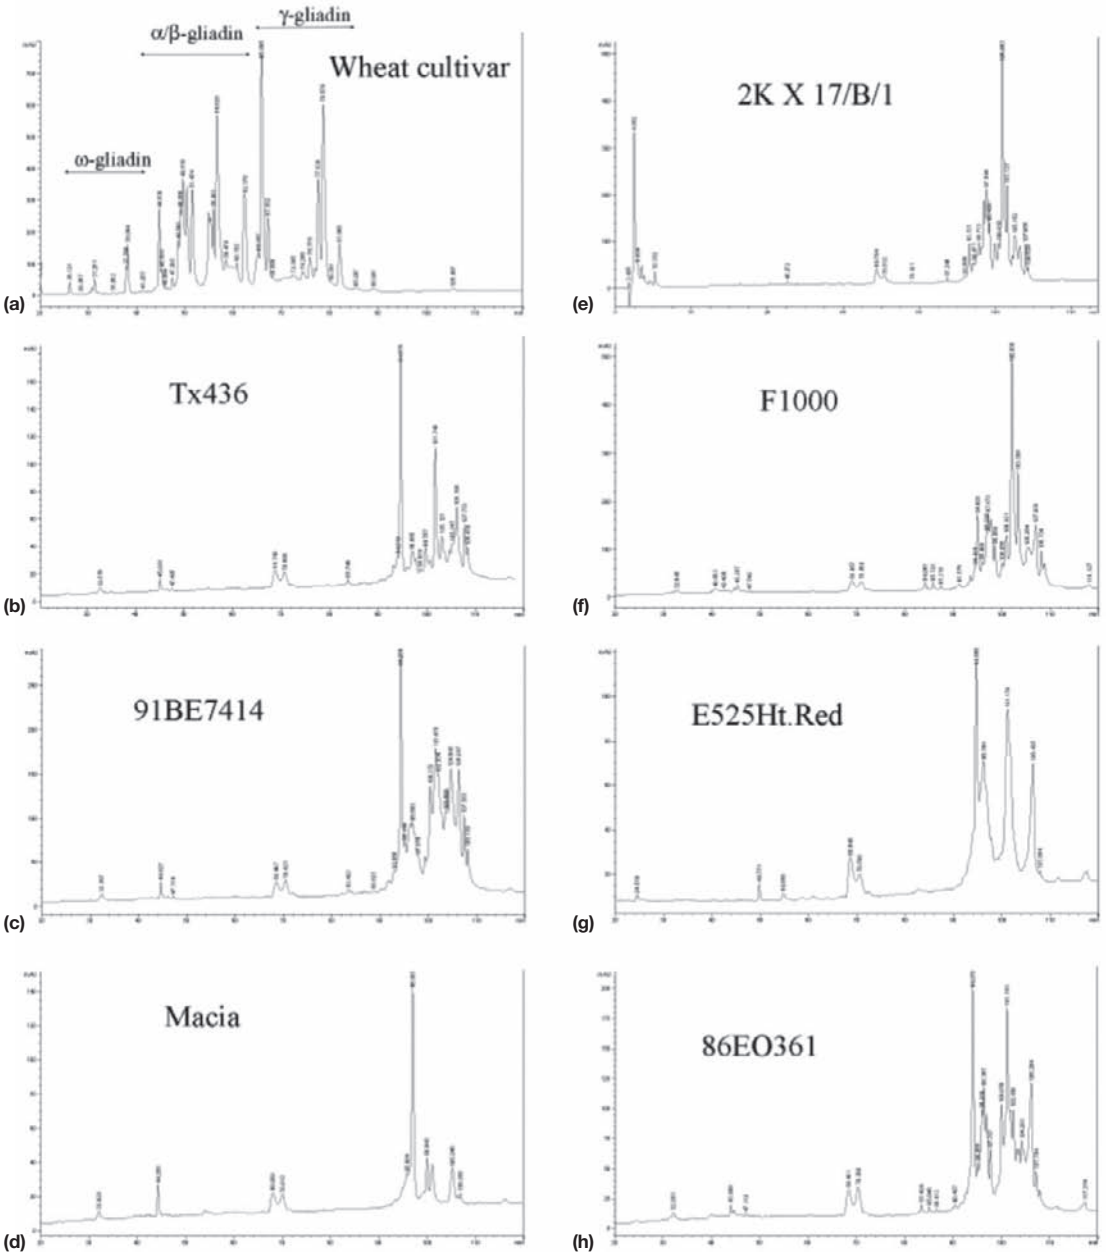

Figure 7 RP-HPLC chromatograms of kafirins extracted from sorghum varieties ((b)–(h)) compared to gliadin extracted from subclasses with improved resolution, on the basis of surface hydrophobicity. The HPLC of gliadin (a) showed a heterogeneous protein profile that could be grouped, on the basis of retention time, in ω-, α/β-, and γ-gliadins, as previously reported. On the contrary, completely different UV chromatograms were observed with kafirins ((b)–(h)). The results provided evidence that proteins with characteristics similar to those of wheat gliadins are absent in all sorghum varieties analyzed. Soy Beans: Dietary Importance

AM Duncan, University of Guelph, Guelph, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Soybeans and their constituent isoflavones have been studied extensively in relation to many aspects of human health. The hypothesis that soy isoflavones could serve as an alternative to hormone replacement therapy has prompted research into menopause-related symptoms and breast cancer and osteoporosis. In addition, cardiovascular disease (CVD) and conditions relevant to men, such as prostate cancer, have also been examined with the common rationale of estrogenic-related etiologies. The dramatic increase in soybean-related peer-reviewed literature over the past 20 years and the history of numerous international symposia on the role of soybeans in health promotion and chronic disease prevention and potential treatments document the magnitude of research activity in these areas. This article will focus on the isoflavones in soybeans and summarize background information on their classification, foods sources, and intake and current literature in specific areas of health including menopausal symptoms, osteoporosis, breast cancer prevention, CVD, and prostate cancer.

Soy Isoflavone Classification, Food Sources, and Dietary Intake

Isoflavones are classified as phytoestrogens, which are defined as a phenolic, nonsteroidal compound structurally similar to estrogen and naturally occurring in plants. The structural similarity of isoflavones to endogenous estrogen allows them to bind to estrogen receptor-α and estrogen receptor-β with a preference for estrogen receptor-β.

Isoflavones have limited distribution in the plant kingdom, its most predominant presence being in soybeans, although they are found in smaller amounts in some nonsoybean foods. Isoflavones are associated with the protein content of the soybean and range from 3 to 5 mg isoflavones per gram soy protein with precise levels dependent on not only processing of the soybean but also geographic location of cultivation, variety, and harvest year. To contribute to a better understanding of isoflavone content of foods and allow for more accurate quantifications of isoflavone intake, the US Department of Agriculture and Iowa State University created a comprehensive and publicly available database of the isoflavone quantity of foods (http://www.ars.usda.gov/Services/docs.htm?docid=24953).

Intake of soy isoflavones is very low in Western populations and much higher in Asian populations. To summarize the current knowledge of adult Asian soy isoflavone intakes, Messina and colleagues in 2006 examined a total of 24 dietary surveys from Japan, China, Hong Kong, and Singapore. The results indicated a typical Japanese intake of 25–50 mg aglycone equivalent isoflavones per day, with lower intakes in Hong Kong and Singapore, and significant regional intake differences in China. Upper intakes were documented at 100 mg day^{-1} in Japan, although only in a minority (5%) of the population.

Soy Isoflavone Metabolism and Pharmacokinetics

Isoflavones are present in soybeans and soy foods in four different chemical forms, namely, aglycone (as is the case in fermented foods) and, more commonly, β-glycoside, malonlyl-β-glycoside, and acetyl-β-glycoside (conjugated to a glycoside unit). Although there is some evidence that bioavailability of the aglycone is greater than the conjugated form, arising from comparisons of maximal circulating concentrations, both forms are absorbed and have comparable half-lives. The major isoflavones (glycoside/aglycone) present in soybeans and soy foods include genistin/genistein, daidzin/daidzein, and glycitin/glycitein at ~50%, 40%, and 10%, respectively.

Following consumption of soy foods, intestinal bacterial enzymes and/or mucosal β-glucosidases cleave the isoflavone glycosidic conjugate to yield the aglycone form. The aglycone isoflavone can be absorbed or may interact further with intestinal bacteria to produce isoflavone metabolites, such as equol (from daidzein), *O*-desmethylangolensin (from daidzein), and p-ethylphenol (from genistein), all of which can also be absorbed. Following absorption, isoflavones undergo extensive first-pass metabolism and then are conjugated to glucuronic acid or sulfate by hepatic phase II enzymes, after which they undergo enterohepatic circulation. The maximum circulating concentrations of isoflavones occur 6–8 h postconsumption, although a biphasic pattern with peaks at 1–2 h and 4–8 h has also been observed. The half-life of isoflavones is ~8 h with most excreted within 24 h. Serum and urinary concentrations of isoflavones have been demonstrated to reflect intake, providing end points for compliance in dietary soy intervention studies.

Isoflavone absorption and metabolism are highly variable among individuals. Isoflavone bioavailability can be influenced by many factors, such as chemical form, dose, source of isoflavone, frequency of consumption, sex, age, microflora, gastrointestinal transit time, food matrix, and background diet. Among the many factors that can influence isoflavone exposure, there is particular interest in the large interindividual variation found in urinary excretion of the isoflavone metabolite equol. Equol is produced by microflora bacteria from daidzein and has unique qualities among the isoflavone and isoflavone metabolites, the most obvious of which is that equol is produced by only 30–40% of the population. Furthermore, equol is one of the most potent isoflavones, with a higher affinity for the estrogen receptor than its precursor daidzein and a longer half-life than both genistein and daidzein, suggesting that the ability to produce equol may increase soy isoflavone exposure. The relevance of equol continues to be an active area of research with the working hypothesis that

equol production status is a major confounding factor in clarifying the health effects of soy isoflavone consumption.

Soy Isoflavones and Health

It has been documented by Messina that, since the early 1990s when the US National Cancer Institute announced their first research program to explore the potential cancer-protective effects of isoflavones, there have been more than 10 000 peer-reviewed articles published. Indeed, as summarized in the following sections, there is an abundance of literature from which to examine the role of soy and its constituent isoflavones in human health.

Menopausal Symptoms

The potential for a dietary alternative to alleviate menopausal symptoms is a major rationale for the study of soy isoflavones, and the intensity of these efforts is evident by the large number of published reviews and meta-analyses. These reviews have focussed primarily on reduction of frequency and/or severity of hot flashes/flushes by soy isoflavones and have concluded either a beneficial role or no apparent benefit over placebo.

In a comprehensive 2003 review, Messina and Hughes concluded that data from 13 soy (34–100 mg isoflavones per day) intervention studies suggested that those with frequent hot flashes should consider soy foods or isoflavone supplements for the alleviation of symptoms. This was confirmed in a subsequent meta-analysis, by Howes in 2006, of 17 isoflavone (48–160 mg day^{-1}) intervention studies that showed overall a significant reduction in hot flashes and the effect was related to the number of baseline hot flashes. The effect of isoflavones on hot flashes was further summarized by Williamson-Hughes et al., but their review of 11 studies identified isoflavone composition as an important consideration: hot flashes were decreased significantly in studies that provided 15 mg genistein per day or more, but not those providing <15 mg genistein per day.

In contrast to the beneficial effects reported in these analyzes, others have concluded that soy or soy isoflavones have no apparent beneficial effects on menopausal symptoms, including a 2004 report by Krebs et al. that summarized 25 studies using a systematic review and subsequent reviews from the Cochrane database in 2007 and 2013. Overall, the repetition of studies and reviews of studies in this area attests to the worthiness of the idea and the fact that some studies conclude that a beneficial effect in the face of methodological challenges provides credence to the role of soy isoflavones in the alleviation of menopausal symptoms.

Osteoporosis

Osteoporosis is a major health risk faced by postmenopausal women due to reduced estrogen production. Soy isoflavones are of relevance for many reasons, including their estrogenic nature, reports of lower incidence of fractures in Asian women (who consume more soy), and associations between isoflavone intake and reduced bone resorption, improved bone mineral density (BMD), and reduced risk of fracture. This evidence has provided a rationale for the completion of multiple intervention studies that have, in turn, progressed to multiple systematic review and meta-analyses aiming to summarize the role of soy isoflavones in the prevention of osteoporosis.

A 2008 review article by Atmaca et al. examined epidemiological and intervention studies on soy isoflavones and bone health in postmenopausal women and suggested beneficial effects on bone turnover markers and BMD. In the same year, Ma and colleagues published two meta-analyses of randomized controlled trials summarizing evidence for effects of soy isoflavone intake on markers of bone turnover and BMD. For their meta-analysis of bone turnover markers, the authors selected nine studies using soy products or isoflavones (37.3–118 mg day^{-1}) for at least 4 weeks, included healthy pre- and postmenopausal women, and included the bone resorption marker urinary deoxypyridinoline and/or the bone formation marker bone alkaline phosphatase. Results suggested significant favorable effects of isoflavone consumption, including decreased urinary deoxypyridinoline and increased bone alkaline phosphatase, with stronger effects observed in participants who were Asian and/or postmenopausal. For their BMD meta-analysis, 10 randomized controlled trials were included that intervened with soy products or isoflavones (4.4–150 mg day^{-1}) for at least 3 months, which included healthy pre- and postmenopausal women, and BMD was an outcome measure. Results suggested a significant favorable increase in spine BMD due to isoflavone consumption. Unlike their bone turnover analysis results, which did not depend on dose or duration, Ma and colleagues found enhanced effects on BMD with isoflavone intake >90 mg day^{-1} for at least 6 months. In contrast to the positive results from the meta-analyses by Ma et al., a meta-analysis by Liu and colleagues in 2009 examining ten randomized controlled trials involving 896 women concluded that the average dose of 87 mg soy isoflavones for at least 1 year did not significantly affect BMD. Further, a meta-analysis of randomized controlled trials by Taku and colleagues in 2010, which included 1240 menopausal women, concluded that soy isoflavone extract supplements (average dose 82 mg isoflavone aglycone equivalents/day for 6–12 months) significantly increased lumbar spine BMD but not femoral neck, hip total, or trochanter BMD. The same investigators published a meta-analysis in the same year that focussed on bone turnover markers and found that an average of 56 mg aglycone equivalent soy isoflavones for 10 weeks to 12 months significantly decreased urinary deoxypyridinoline by 14%, but this was not accompanied by significant improvements in serum bone alkaline phosphatase or osteocalcin. Most recently, however, a systematic review by Wei and colleagues in 2014 concluded that there was a significant effect of soy isoflavones on BMD and urinary deoxypyridinoline, relative to menopausal status, supplement type, isoflavone dose, and intervention duration.

Overall, studies of soy isoflavones in relation to bone health have produced inconsistent results with earlier studies summarizing favorable effects on BMD and bone turnover, while others have found inconsistent or no significant benefit of isoflavones on bone health. These discrepancies will prompt

continued investigation to further clarify the relevance of soy isoflavones in the prevention of osteoporosis.

Breast Cancer Prevention

The link between soy isoflavones and breast cancer prevention was first documented by Lee et al. in 1991 when the diets of 200 Singaporean Chinese women with breast cancer and 420 matched controls were compared; it was found that those with higher intakes of soy protein and total soy products had significantly decreased breast cancer risk. Numerous studies followed and, although inconsistent, meta-analyses suggest a significant protective association. For example, Qin et al. in 2006 pooled 14 case–control and seven cohort studies to conclude an overall inverse association between breast cancer risk and intake of soy foods (RR = 0.75) and soy isoflavones (RR = 0.81). In the same year, Trock et al. reported a meta-analysis of 12 case–control and six cohort studies that also concluded an inverse association between breast cancer risk and intake of soy (RR = 0.86). However, the association was not significant among women living in Asian countries and was stronger in premenopausal women. Wu et al. in 2008 extended the process by selecting only high-quality studies best designed to address the relationship between soy consumption and breast cancer by ensuring that they had a (relatively) complete assessment of dietary soy exposure and appropriate control of potential confounding factors. They also addressed the issue of isoflavone exposure by separating analyses into high-soy-consuming Asians and low-soy-consuming Western individuals. Results from one cohort and seven case–control studies with high-soy-consuming Asians showed a dose-dependent inverse association between breast cancer risk and soy isoflavone intake with a 14% reduction in risk for an isoflavone intake of 10 mg day^{-1} and a 29% reduction for $\geq$20 mg day^{-1}. In contrast, results from four cohort/nested case–control and seven case–control studies with low-soy consumers concluded that there was no significant association between breast cancer risk and soy isoflavone intake in the narrow intake range 0.15–0.8 mg day^{-1}. This is similar to more recent research results from 35 studies meta-analyzed by Chen and colleagues in 2014, which generated a significant inverse association (OR = 0.59) for Asian but not Western women. Overall, although these meta-analyses provide support for a role of soy isoflavones in breast cancer prevention, there is heterogeneity among studies, and there remain inconsistent results with some studies reporting no significant relationship between soy and breast cancer risk regardless of intake.

The relationship between soy and breast cancer prevention has evolved to consider the age of exposure, an idea that suggests that intervention is most effective during the period of most active change, as would be the case for breast development during late childhood/adolescence/puberty. Lamartiniere and colleagues tested and confirmed this hypothesis in several studies using rat models. Furthermore, multiple epidemiological studies have supported the idea by reporting consistently that soy and soy isoflavone exposure during adolescence is related to a significantly reduced adult breast cancer risk. Thus, the concept of timing of exposure is supported and adds a dimension to current understanding of the relationship between soy isoflavones and breast cancer prevention.

Overall, the area of soy and breast cancer prevention continues to be studied, with intervention studies focussing on breast cancer biomarkers, mechanistic studies to explore both estrogen-dependent and estrogen-independent actions, and studies investigating the relevance of individual response, including equol production and nutrigenomics.

There has also been concern regarding safety of soy in relation to breast cancer. These concerns stem from the possibility that a compound with estrogenic properties could cause increased growth of an estrogen-dependent tumor. This is a growing research area, but epidemiological studies that have examined the association of breast cancer recurrence or mortality in relation to soy isoflavone exposure have found either a protective or no significant association.

Cardiovascular Disease

CVD is one of the most frequently studied areas in relation to soy and health with relevance for both women and men. This soy–health relationship also has the greatest public awareness following the 1999 approval of a food health claim by the Food and Drug Association (FDA) in the United States. This health claim allows food manufacturers to label products that meet the criteria of at least 6.25 g soy protein per serving. The claim reads, 'Diets low in saturated fat and cholesterol that include 25 g of soy protein a day may reduce the risk of heart disease. One serving of (this food) provides (this amount) of soy protein.' This health claim was approved based on the totality of evidence at that time and, in particular, a meta-analysis published in 1995 in the *New England Journal of Medicine*, which examined 38 human clinical studies evaluating the effects of soy protein on circulating lipids and reported overall reductions in total cholesterol by 9.3%, LDL cholesterol by 12.9%, and triglycerides by 10.5% following an average soy protein intake of 47 g day^{-1}. This also led the Nutrition Committee of the American Heart Association (AHA) to release a science advisory on soy protein in 2000, which recommended the inclusion of soy protein foods in a diet low in saturated fat and cholesterol.

It is noteworthy that, in the approval of the health claim, the FDA indicated that available evidence did not support a significant role for soy isoflavones in the cholesterol-lowering effects of soy protein. This idea has been corroborated by subsequent meta-analyses of studies intervening with isoflavone extracts, which have not demonstrated significant effects on circulating lipids, compared with soy protein, which has shown significant effects. However, although these soy protein meta-analyses found significant effects, the magnitudes of change in LDL and/or total cholesterol observed were more modest (5%) than the Anderson et al. meta-analysis on which the health claim is based.

The large numbers of studies examining soy and CVD since the approval of the health claim prompted the Nutrition Committee of the AHA to reevaluate the evidence and update their 2000 science advisory. In 2005, they published a revised statement in relation to soy protein, isoflavones, and cardiovascular health that indicated isoflavone supplements are not recommended and earlier research demonstrating clinically favorable effects of soy protein has not been confirmed subsequently.

Although the science advisory noted that soy products could still be beneficial to cardiovascular and overall health, because of their high content of polyunsaturated fat, fiber, vitamins, and minerals and low content of saturated fat, their discouraging statement generated activity among the scientific community, including an announcement in December 2007 from the US FDA that they also intended to reevaluate scientific justification for the soy and coronary heart disease (CHD) food health claim. However, the US health claim remains, and in 2014, Health Canada reached out to stakeholders in their jurisdiction for comments on a proposed health claim relating soy protein and cholesterol-lowering effects. Research activity in the area of soy and CVD continues to clarify the role of soy protein and soy isoflavones by exploring effects of soy on other CVD biomarkers, and better understanding the molecular mechanisms involved using, for example, systems biology.

Prostate Cancer

The hypothesis that soy isoflavones could reduce prostate cancer risk was generated from epidemiological data documenting that prostate cancer rates are low in Asian countries and these rates increase when Asians migrate to the United States. The potential relevance of soy isoflavones to these differences was also supported by higher isoflavone concentrations in the blood, urine, and prostatic fluid of Japanese men relative to their Western counterparts.

Numerous epidemiological studies have focussed on the association between soy intake and prostate cancer risk, which has culminated in meta-analyses. The first, published by Yan and Spitznagel in 2005, included two cohort and six case–control studies and concluded that soy consumption was associated with a 30% reduction in prostate cancer risk. Four years later, the same authors published an updated meta-analysis that included epidemiological studies that related prostate cancer to consumption of soy (15 studies) or isoflavones (9 studies). Results revealed combined significant RR/ORs of 0.74 for soy intake and 0.88 for isoflavone intake. Another meta-analysis by Hwang and colleagues in 2009 combined five cohort and eight case–control studies and reported that both total soy (OR = 0.69) and nonfermented soy (OR = 0.75) foods were significantly associated with reduced prostate cancer risk and, among individual foods assessed (tofu, soybean milk, miso, and natto), tofu was the only food significantly associated with reduced prostate cancer risk (OR = 0.73). The most recent meta-analysis in 2014, by vanDie and colleagues, focussed on men at high risk of prostate cancer and observed a significant inverse association between soy isoflavones and prostate cancer (OR = 0.49), although it only includes two studies.

Given the inaccuracies inherent in dietary assessment, other studies have related prostate cancer risk to circulating and urinary isoflavones. This also allows consideration of the ability to produce equol, the focus of two case–control studies by Akaza and colleagues (2002 and 2004), the first of which showed that those able to produce equol were significantly higher among controls relative to prostate cancer cases. The second case–control study showed not only that equol producers were more frequent among Japanese and Korean men, compared to American men, but also that the proportion of equol producers among Japanese and Korean men was significantly higher in the control group (46% and 59%, respectively) compared with prostate cancer cases (29% and 30%, respectively). The role of soy isoflavones in prostate cancer risk is well studied and includes associations with dietary, circulating, and urinary isoflavones. Nutrigenomics or systems biology more widely continues to advance knowledge and understanding in relation to soy isoflavones and prostate cancer risk.

Summary

The relationship between soy and health has been studied extensively with the focus not only on menopause (menopausal symptoms, osteoporosis, and breast cancer) but also conditions relevant to men (prostate cancer) or both sexes (CVD). Soy has also been studied in respect of other health aspects including cognitive function, diabetes, thyroid health, infant health, and male fertility. Future human soy isoflavone interventions should take into consideration recommendations from the 2009 National Institutes of Health scientific workshop, 'Soy Protein/Isoflavone Research: Challenges in Designing and Evaluating Intervention Studies,' published in the *Journal of Nutrition* (http://jn.nutrition.org/content/140/6/1192S.long).

Soy Beans: Processing

MN Riaz, Texas A&M University, College Station, TX, USA

© 2016 Elsevier Ltd. All rights reserved.

Soybeans and soybean products have been used extensively in the Orient as a source of protein and energy in human diets for at least 4000 years in one form or another. Traditional soy foods such as tofu, soy milk, miso, and tempeh are popular with Asian consumers, whereas modern soy ingredients such as soy flour and other protein ingredient are used by the food industries in the United States and Europe. Awareness of soybeans' properties and the use of soy ingredients in foods have increased dramatically during the last few years. As consumer demands grow for healthy foods, the use of soybean as a key ingredient is expected to expand in the food industry. The author has tried to explain different forms of soy ingredients that are available in the market for a variety of foods; working with all these soy ingredients into food products requires some practical and technical consideration. Food product developers can find a host of different soy ingredients with an array of nutritional benefits with different functionalities associated with each ingredient. There are a variety of specially modified soy concentrates and isolates available for specific application. These soy concentrates and isolates will have different solubility, emulsification, and texturization properties. A number of enzyme-modified concentrates and isolates are also available for food application. These special soy ingredients can boast foaming and aeration properties that allow replacing egg white in some products. Some of these soy ingredients may not be stable in highly acid conditions. Most of the soy protein typically exhibits very good freeze/thaw stability.

Soybean occupies a unique position among legumes. Traditional food legumes are rich in protein but contain limited amount of oil (energy). Soybean contains more protein than the other legumes and also a much higher content of edible oil. However, raw soybeans cannot be used successfully in human foods unless processed properly. There are several antinutritional factors that have been identified in raw soybeans, that is, trypsin and chymotrypsin inhibitors; phytohemagglutinins (lectin); and allergenic factors: glycinin and beta-conglycinin. All of these antinutritional factors can be deactivated, modified, or reduced through proper heat treatment to minimize or eliminate their adverse effects. Since all these inhibitors are proteins, caution should be taken to assure that no destruction of the oilseed protein occurs. This can be accomplished only through optimum processing and good quality control measure.

Processing of Soybeans

Today's modern soybean processing plant will process between 3 and 4 million pounds of soybeans daily or roughly 75 000 bushels or 2500 acres of soybean each day. Furthermore, it is not uncommon to have in excess of one million bushels of bean stored at the processing plant.

Whole soybeans can be processed into several different soy ingredients based on their application. Presently, soybean ingredients that are available in the market for food application are (1) roasted soy nuts; (2) enzyme-active full-fat soy flour and grits; (3) enzyme-inactive full-fat soy flour and grits, also called toasted full-fat soy flour and grits or heat-treated full-fat soy flour; (4) extruder-processed full-fat soy flour and grits (enzyme-inactive): (5) enzyme-inactive low-fat soy flour or grits; (6) enzyme-active defatted flake/soy flour (90 PDI); (7) defatted soy flake/flour with 70 PDI; (8) defatted soy flake/flour with 20 PDI; (9) lecithinated soy flour; (10) textured soy flour; (11) refatted soy flour; (12) soy concentrates; (13) textured soy concentrates; (14) soy isolates; (15) soy germ; (16) soy isoflavones (mechanically extracted); (17) soy isoflavones chemically extracted; (18) fiber from hulls; (19) soy fiber from cotyledon; and (20) organic soy flour and concentrates.

Roasted Soy Nuts

To process soy nuts, soybeans go through cleaning, sizing, and color sorting plant and are then washed prior to being soaked. The beans are evenly distributed into soaking tanks that have monitored water timers. The beans are soaked for a predetermined time based upon the ambient temperature, moisture levels, etc., and then drained. The cleaned, soaked, and drained beans are dumped on a conveyor that carries the beans from the processing room to the roasting line. The beans are placed in a large hopper and then distributed on the stainless steel roasting belt by means of a vibratory feeder. The beans are spread evenly over the roasting belt with a second belt resting on top of them. This keeps the beans completely submerged in the soy oil used for roasting. The beans move through the roaster at a prescribed time based upon the size, temperature, moisture level, etc.

After the beans have been roasted, they enter a second stainless steel conveyor that cools them. They move slowly through the cool down conveyor while large fans pull the heat from them. The beans exit onto a shaker table that eliminates any loosened hulls or pieces. They are then conveyed into a flavoring vessel. Once the flavoring vessel has reached its prescribed volume, the required amount of flavoring is added. The vessel is then sealed and put into the roller/tumbler for mixing. After the flavoring is finished, the vessel is opened and placed in the dumper. The dumper lifts the vessel and dumps the flavored, roasted soy nuts onto a conveyor that transports them to holding hoppers. The selected flavor can then be directly packaged into either bulk or individual bags at the appropriate time. Soy nuts are ideal for healthy eating and dieting. These nuts are low in sodium and fat and at the same time rich in protein and fiber. These nuts can be mixed with other nuts or sold on their own.

Enzyme-Active Full-Fat Soy Flour and Grit Processing

To make enzyme-active full-fat soy flour and grits, the first step is cleaning.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00641-3

Cleaning

Cleaning is important for producing high-quality end products as well as protection of equipment. Cleaning of soybeans is done on sieves under air aspiration so that dust, plant tissue, pebbles, and light contaminating material, as well as bigger impurities (stones, stems, nails, etc.), are separated. The larger impurities are mostly separated step by step in a destoner and a magnetic iron separator. After cleaning the soybeans, the next step is drying the soybeans.

Drying

Soybeans are dried in grain driers to a moisture level of 10%, which is needed prior to dehulling. The temperature of the dryer should be in between 70 and 76 °C to achieve the desired moisture level. Uniform drying of the soybeans is very important for removal of hulls, since we need to remove the hulls from every individual bean and not an average. To do a good job of hull removal, it is essential to subject the beans to some kind of thermal impact. This is necessary because the hulls are attached to the bean with a proteinaceous material, which, when exposed to heat, affects the release of the hulls. After drying the beans, they are stored for tempering approximately for 72 h to stabilize the moisture contents. Dried beans are usually cleaned to remove as many loose hulls, pods, sticks, and other foreign material as possible. This step will increase the efficiency of the cracking rolls and aspirator. After drying, the next step is cracking and dehulling the soybeans.

Cracking and dehulling of soybeans

The primary reason for dehulling is to produce high-protein end products. Hulls amount to around 7–8% by volume of the total of bean processed, and removal of these hulls prior to processing will increase the protein content of the desired end products. Sometimes, fibers are not required in food application where this end product will be used. Clean and dry soybeans are cracked into suitable pieces for dehulling using cracking mill. There should be a minimum of fines and no mashed beans. After cracking, the hulls are separated under air flow and the lighter hulls are withdrawn. It is important at this point to understand exactly how air separation works, since it is presently the basis for all soybean dehulling. With properly dried and cracked soybeans, the cotyledons should separate easily from the hulls. As a practical matter, it is not possible to get an absolute separation of hulls from the cotyledons. After removing the hulls, the next step is milling.

Milling

These dehulled soybeans are ground by hammer or impact pin mill into flours with desired particle sizes. Full-fat products are not easy to pulverize or sieve. Coarse material can be separated from fine by air classification. To make grits, different sizes of screens are used in the hammer mill. These types of flour or grits are used in bread for bleaching wheat flour and conditioning the dough. Usually, enzyme-active soy flour is used in the range of 0.5%.

Enzyme-Inactive Full-Fat Soy Flour and Grit Processing

This type of flour is also called 'toasted full-fat soy flour' or heat-treated full-fat soy flour. In this process, soybeans are cleaned as described earlier. The soybeans are steamed under slight pressure for 20–30 min; cooled, dried, and cracked to remove the hulls; and then milled with sieving as described earlier. These types of flour have very low lipoxygenase activity, so there is less beany flavor. In this process, the undesirable enzymes have been destroyed by heating, and the product will have low PDI (20–30). There are different methods that can be used to heat the soybeans, like infrared radiation. This type of full-fat soy flour is used in bakery products, soy breads, cakes and doughnuts, sweet goods, chocolates and confectionaries, spreads, and wafer filling.

Extruder-Processed Full-Fat Soy Flour and Grits (Enzyme-Inactive)

Extruder-processed full-fat soy flour is processed using wet or dry single-screw extruders. After cleaning, drying, and dehulling, soybeans are coarse ground to be processed in the extruder (as discussed earlier). In this process, a single-screw extruder (wet or dry) is used to cook the soybeans. Extruded soybeans are then ground with a grinding mill to make full-fat flour. This type of flour is used in soup or gravy and some other foods in Brazil and Argentina.

Enzyme-Inactive Low-Fat Soy Flour or Grits

This type of flour is also called 'mechanically processed soybean flour.' In this process, soybeans are cleaned, dried, dehulled, and cracked (as discussed in the preceding text) and then fed to a dry extruder. The extrudate exiting the extruder is in a semifluid and frothy state, while the oil is free within the matrix. The soybean extrudate is fed immediately into a screw press, where the oil is pressed out. The protein-rich meal that comes out of the press in the form of press cake is delumped by using a roller mill and is passed through a meal cooler. After cooling, this material is ground into flour using pulverizer. This type of flour will have 6–8% oil depending upon the processing condition. This flour can be used in bread and bakery and in making textured soy protein.

Enzyme-Active Flake/Defatted Soy Flour or Grits (90 PDI)

This type of soy flake/flour is produced using solvent extraction process. After cleaning, drying, and dehulling (as discussed earlier), the next steps are conditioning and flaking.

Conditioning

Cracked and dehulled soybeans are conditioned in cookers to approximately 70 °C with steam. Small amounts of water can be added to adjust the moisture to approximately 11%, which makes the beans ideal for flaking. A correct heat treatment and adjustment of the moisture will assist in disrupting the cell membranes during flaking so that the oil can be extracted more easily. The main function of the conditioning is to facilitate the flaking step.

Flaking

In order to extract the oil from the beans, it is important to destroy the cell structure of the beans. To achieve this, beans are flaked in the flaking machines, since solvent can flow much more readily through a bed of flakes than through a bed of soy meats or fine particles. The ideal thickness of a flake is in between 0.25 and 0.35 mm. The thickness of these flakes depends upon the size of the cracked beans, conditioning, and the adjustment of the flaking rolls.

Expanding of flakes

Some soy processing facilities started using an expander–extruder after the flaking step and before the extraction. The use of expanders was originally developed in Brazil and was introduced in the United States in early 1980. According to Watkins et al., the use of expander offers several advantages in processing soybeans for extraction:

- The seed is finely homogenized in the expander, freeing the oil for rapid extraction.
- Dense collets are formed (weigh more per cubic foot).
- The collets are porous and do not restrict percolation of solvent through the extractor bed, as it may occur with fragile flakes.
- More oil is recovered by solvent from collets as compared to flakes.
- The solvent drains more completely from the extracted collets, resulting in more complete removal of oil.
- Less energy is required for desolventizing the collets compared to flakes.

Extraction of flakes

Soy flakes are fed into a flash desolventizer or vapor desolventizer. In the flash desolventizer, solvent wet flakes go directly from the extractor into superheated vapor blown at high velocity through a long tube. Solvent is heated under pressure to 115–138 °C. As this vapor is blown through the tube, flakes are conveyed in and picked up by the vapor stream. In short seconds, the superheated solvent will flash off the residual liquid solvent leaving desolventized flakes to be collected in the cyclone. High-PDI soy ingredients are more soluble, but at the same time, they also have highly active enzymes and antinutritional factors. These flakes will have 95 PDI. Defatted flakes can be milled using a hammer mill to produce soy flour. At least 97% of the flour must pass through a US Standard No. 100 sieve. This flour contains 52–54% protein as is. This type of flour is used in bakery application as crumb whitener or dough conditioner. The use of this flour is very limited (0.5%) because of enzymes and beany flavor.

Enzyme-Inactive Defatted Soy Flake/Flour or Grits (70 PDI)

This type of soy flake/flour is produced by using the same method as described in the preceding text (enzyme-active), except that solvent extraction is done at higher temperature. This temperature deactivates the lipoxygenase enzymes and produces defatted soy flake/flour, which is enzyme-inactive and had a PDI of 70. Typical applications of this flake/flour are waffle, pancake mixes, bread, doughnuts, tortilla, and bagels. This flake/flour can be used in bakery products up to 5% of the dry ingredients.

Enzyme-Inactive Defatted Soy Flakes/Flour or Grits (20 PDI)

This type of soy flour is produced by using the same method as described earlier in 70 PDI, except this flake/flour is further toasted after the solvent extraction to reduce the PDI to 20. Typical application for these types of flakes/flours is various bakery applications like biscuit and milk replacer up to 5% of the dry ingredients.

Textured Soy Flour

Defatted soy flour of 70 PDI is processed through a thermoplastic extrusion process to produce textured soy flour. This type of flour is used in processed meats, pizza topping, hamburger patties, tacos, etc. The size of the textured flour will depend upon the application and desired texture. After texturizing the flour, it can be processed through the Comitrol mill to produce different sizes.

Lecithinated Soy Flour

This type of flour is produced by spraying lecithin/vegetable oil onto 70 and 20 PDI soy flour. The most common ratios used in this type of flour are 3%, 6%, and 15% lecithin by weight. This type of flour is a good emulsifier and can be used for partial or total replacement of egg. It improves dispersion of the flour and other admixed ingredients in confection and cold beverage products. It also can increase the water retention in the bakery good and extend the shelf life. Also, this is a good animal protein substitute for use in vegetarian cookies.

Refatted Soy Flour

This flour is produced by adding 1–15% fat back into flour for certain application, mainly to reduce the dustiness and provide fat for a product formula.

Production of Soy Protein Concentrates

Soy protein concentrates are processed selectively by removing the soluble carbohydrates from soy protein flour by either aqueous alcohol or isoelectric leaching. Soy protein concentrates contain at least 65% protein. Defatted flakes or soy flour is used as starting material. Soy protein concentrates contain at least 65% protein. During processing of soy concentrates, objectives are to immobilize the protein while leaching away the soluble, removing the strong flavor components and the flatulence sugars (stachyose and raffinose). In turn, both protein and dietary fiber contents are increased.

There are several different methods to produce soy concentrates:

Extraction of flakes with aqueous 20–80% ethyl alcohol
Acid leaching of flakes or flour
Denaturing the protein with moist heat and extraction with water

Alcohol extraction is considered to produce the blandest products. Mild heat drying conditions are used in an acidic water extraction process to retain high PDIs. Isoflavone content in soy concentrate depends on whether it has been water-washed or alcohol-washed, as isoflavones are soluble in alcohol. Because of its blander flavor, soy concentrate is often preferred over soy flour. Typically, soy concentrates are used in meat patties, pizza topping, bakery products, and meat sauces.

Textured Soy Protein Concentrates

Soy protein concentrates are texturized by using a wet extruder. The size of the textured concentrates depends on its application. After, extrusion-textured soy protein concentrates can be converted into different sizes using size reduction equipment like Comitrol. Typical application of textured soy protein concentrate is in meat products, like patties, sausages, and pizza topping.

Production of Soy Protein Isolates

There are several ways that have been described for manufacturing isolated soy protein. However, the only commercial procedure currently being used is extraction of defatted soy flakes or soy flour with water, followed by centrifugation. In this process, the protein is solubilized at pH 6.8–10 at 27–66 °C by using sodium hydroxide and other alkaline agents approved for food uses. The protein solution is then separated from the flakes or flour by centrifugation. The solids are recovered as a by-product, containing 16–36% protein, 9–13% crude fiber, and 45–75% total dietary fiber when dried to 6–7% moisture content and have been marketed for food use. The solution is then acidified to pH 4.5 by using hydrochloric or phosphoric acid, and the protein is precipitated as a curd. The curd is then washed with water and concentrated by centrifugation and can be neutralized to pH 6.5–7.0 or spray-dried in its acidic form.

Soy isolates, the most concentrated form of soy protein (90% dry bases) available, generally contain about half as many isoflavones as soy flour as a result of losses during processing. Functionally, isolated soy protein has some of the same attributes as soy flour and concentrates but normally is utilized for their higher solubility, whippability, foaming, and binding functionality for a number of food products including meat.

Soy Germ

Soy germs are mechanically separated from the soybeans during the process of dehulling and cracking. Several companies use their patented technology to separate the germ. These germs are then roasted, milled, and converted into different forms, like flour and granules of different sizes. These germs are considered a very rich source of isoflavones and other nutrients. On an average, these germs will have 40% protein, essential fatty acids, omega-3 and omega-6, lecithin, vitamin E, and saponin. Soy germ is by far the most nutrient-dense soy ingredient one can consume to obtain all of the proved health benefits of the soybean.

Isoflavones

Isoflavones currently receive much attention from the scientific world, so consequently, the industry takes up the opportunity to develop unique products that offer consumers an alternative to consuming traditional amounts of soy. Isoflavones are found in high amounts in soybeans. Genistein and daidzein are the major isoflavones found in soybeans. In whole soybeans, the isoflavones are present in a concentration of 0.2–3.0 mg g^{-1}. Soy experts recommend between 30 and 50 mg of isoflavones per day. One would need to consume 20–150 g of soy foods, 200 g or almost 7 ounces of tofu, or 3 cups of soy milk daily to get the recommended amount of isoflavones. Isoflavones are available in several different forms, crunchy granules, flour, and fine powder, can be labeled as 'soy isoflavone concentrate,' which can be incorporated in cereals, snacks, cookies, breads, health bars, drinks, and meat replacements.

Processing of Isoflavones

The concentration of isoflavones in soy foods and soy ingredients depends upon the (1) genetics of soybeans, (2) environment where soybeans are grown, and (3) processing technologies. The level of isoflavones in soybeans, even from the same field, grown all in the same year, may vary in concentration by a factor of five. There are two methods to extract isoflavones from soybeans: (1) chemical extraction and (2) mechanical extraction.

Chemical Extraction of Isoflavones

Material from the solvent extraction process (discussed earlier), when converted into soy concentrates and isolates (discussed earlier), generates a by-product called soy molasses. These molasses are a rich source of isoflavones. In conventional process for the production of a soy protein concentrate in which soy flakes or flours are extracted with an aqueous acid or an aqueous alcohol to remove water-soluble materials from the soy flakes or flour, a large portion of the isoflavones is solubilized in the extract. The extract of water-soluble material including the isoflavones is soy molasses. These isoflavones are chemically extracted by using patented processes by different food companies. The soy molasses is a by-product material in the production of soy protein concentrate that is typically discarded.

Mechanical Extraction of Isoflavones

In this process, soybean germs are mechanically separated from the cotyledons as discussed in the preceding text. These soy germs have five to six times more isoflavones than the rest of the seed. On an average, 400 pounds (181 kg) of soybeans will produce 1 pound (0.45 kg) of germ. Some companies sell these soy germs as a source of mechanically extracted isoflavones to be used in food application, like cereal, bars, supplements, and beverages.

Soy Fiber

Two types of edible fiber are produced from soybean processing operations: hulls and soy cotyledon fiber.

Soy Hull as a Source of Fiber

The soybean hull is also known as the seed coat. On a dry weight basis, hulls constitute about 8% of the total seed, depending on variety and the seed size. In general, the larger the seed, the lower the proportion of hulls. The hull of a dry mature soybean contains about 7–8% moisture. Dry soy hulls contain approximately 85.7% carbohydrates, 9% protein, 4.3% ash, and 1% lipids. Kikuchi et al. studied the chemical and physical properties of soybean cell wall polysaccharides and their changes during cooking. They found that the soy cell wall contains about 30% pectin, 50% hemicellulose, and 20% cellulose. Therefore, most soybean carbohydrates fall into a general category known as dietary fiber. The outer hull is an excellent source of dietary fiber (6 g fiber per 1 cup cooked).

Soy fiber (also called soy bran) is produced from the hull of the soybeans. Until recently, soybean hulls were considered a by-product of soy processing. After separation from seeds during rolling or flaking, they are toasted and ground and then blended back into defatted soy meal to make a meal containing 44% protein. Recently, several new uses of soy hulls have been explored, with an emphasis on use in human food.

During soybean processing operation, the hulls are removed, washed, sterilized, dried, toasted, and ground to different sizes depending upon the applications, such as breads, cereal, and snacks. The natural grittiness of the product typically requires fine grinding. Soy fiber contains approximately 38% crude fiber and 76% total dietary fiber. The fiber components in soybean hulls and in the cotyledon are distinct and should be considered separately.

Soy Cotyledon Fiber

During processing, beans are carefully selected for color and size. These beans are then cleaned and conditioned (to make removal of hulls easier), cracked and dehulled, and rolled into flakes. The flakes are subjected to a solvent bath that removes the oil. The solvent is removed and the flakes are dried, creating the defatted soy flakes that are the basis of all soy protein products.

The production of soy protein isolate involves the removal of soluble material from defatted flakes by aqueous leaching. In the process, part or all of the protein fraction is solubilized, usually at alkaline pH, and the insoluble protein separated by centrifugation. These solids are analogous to the okara product from making soy milk or tofu, but they differ in that they do not contain hulls and have been defatted and treated with mild alkali. The insoluble residue obtained during protein isolation is made up mainly of various hemicellulose materials. After appropriate purification, this material is dried and sold as soy fiber, in competition with other fibers, such as wheat and oat bran. This soy fiber contains 80% total dietary fiber. The dietary fiber content of soy fiber varies greatly, depending on the method used for analysis.

Several of these products are made during processing of soy fiber, after dehulling and oil extraction, and after the soluble sugars and proteins have been removed. By proprietary processing techniques, the water adsorption/binding can be controlled to make products useful in products like beverages, puddings, and retorted soups or in food systems with less water like baked bread, muffins, crackers, cookies, or breakfast bars. Different soy fibers can be produced and are available for commercial application. But most of the published research is on polysaccharides, a mixture of cellulosic and noncellulosic structural components of the cell wall. Generally, it is thought that soluble fiber is associated with cholesterol lowering and improved diabetic control, whereas insoluble fiber is associated with enhanced bowel function. Soy polysaccharides contain mostly insoluble dietary fiber, and clinical studies have shown it to have properties of both insoluble and soluble fibers.

Soy protein concentrates contain both insoluble and soluble fibers. Therefore, foods made with soy protein concentrates can be good sources of dietary fiber. Unlike meat, milk, fish, and egg, soybeans combine their protein bounty with a good source of dietary fiber in products such as soy flour and textured vegetable protein.

Organic Soy Flour and Concentrates

Recently, organic soy flour and concentrates are available for food application. These soy ingredients are made using solvent-free proprietary and patented methods. There is not enough information available for these processes.

Conclusion

Soybeans can be processed into different ingredients based on their application. In general, there are more than 20 different soy-based ingredients, which are available in the market to be used in food and beverages. Each ingredient processing requires a specific procedure and equipment. Processing will affect the functional properties that are important for the food system. The soy processing industry can make one ingredient with different functionalities and characteristics for different food applications. For example, there are more than ten different soy concentrates available in the market. Each of these concentrates is for special application (dairy, meat, beverage, bakery, meat, pet food, nutritional drink, etc.). The same is true for soy isolates. Food industries can buy soy isolates to make baby milk, for meat emulsion, for breakfast cereal, for energy bars, and for nutritional beverages.

Soyfoods Made from Whole Soybeans

Soyfoods (e.g., edamame, natto, and miso) made from whole soybeans (seeds) of the soybean plant (botanical name *Glycine max* (*L.*) Merrill) contain 0.25% calcium, 0.57% phosphorous, 0.01% sodium, 1.50% potassium, 0.02% chlorine, 0.29% magnesium, 0.3% sulfur, 90 ppm iron, 16 ppm boron, 15 ppm copper, 40 ppm zinc, 25 ppm manganese, 1.4 ppm fluorine, 0.5 ppm selenium, 0.05 ppm iodine, 2.5 ppm molybdenum, 6.0 ppm nickel, 6.5 ppm thiamine, 1.0 ppm riboflavin, 18–20% soybean oil, 40–45% soy protein (see in the succeeding text for amino acid profile of the protein), and 35% carbohydrates (see in the succeeding text for sugar profile of the carbohydrate). They also contain ~0.04–0.24% isoflavones (i.e., produced initially to ward off infection challenges by soybean plant diseases during a growing season such as *Phytophthora sojae*). Research indicates significant daily human consumption of soybean isoflavones can increase bone density, thereby lowering risk of osteoporosis; help to lower blood content of low-density lipoproteins; help to prevent prostate enlargement; and reduce the risk of certain types of cancer (e.g., breast cancer, colon cancer, lung cancer, prostate cancer, and uterine cancer). Isoflavones also exhibit antioxidant properties, when consumed.

In 2014, the Food and Drug Administration decided that US consumers' major dietary shortfall of potassium is a public health problem that urgently needs addressing. Because soyfoods are a good source of dietary potassium, an increase in soyfood consumption would help reduce this particular public health concern. An example of the health impact on one US population segment is that only 2.8% of postmenopausal women, ages 50–79, achieve the USDA recommendation that women eat at least 4700 mg of potassium daily. A 2014 American Heart Association study of 90 137 women showed that those who consume >4700 mg of potassium daily are significantly less likely to have strokes and die than women who eat smaller daily amounts.

Other whole-soybean-source soyfoods such as tofu have a variety of additional ingredients added during their manufacture (e.g., to facilitate coagulation of the protein), so they would have even more nutrients/amounts than listed earlier.

Soy Protein (Extracted from the Soybean)

Soy protein is an edible protein (after heat processing) that is produced within soybeans. When removed from soybeans via crushing or extrusion involving adequate heat treatment, soy protein is (historical average) composed of the following amino acids: 2.5% cysteine, 3.4% histidine, 5.2% isoleucine, 8.2% leucine, 6.8% lysine, 1.1% methionine, 5.6% phenylalanine, 4.2% threonine, 1.3% tryptophan, 4.2% tyrosine, 5.4% valine, 4% alanine, 7.7% arginine, 6.9% aspartic acid, 19% glutamic acid, 3.7% glycine, 0.1% 4-hydroxyproline, 5.3% proline, and 5.4% serine.

In its initial form (i.e., following crushing/extrusion from soybeans as described earlier), soy protein is known as soybean meal and contains a bit less than half protein by weight. The carbohydrate portions are 2.5–8.2% sucrose, 0.1–0.9% raffinose, 1.4–4.1% stachyose, 0.6% rhamnose, 0.1% fucose, 0.1% ribose, 2.4% arabinose, 1.0% xylose, 0.9% pinitol, 0.9% mannose, 7.6% galactose, and 8.1% glucose.

Following a sifting process, it is known as soy flour. The most common use of soy flour is for the addition to baked goods to increase their protein content and extend their shelf life. Other uses are in nutrition bars and textured vegetable protein meat extender.

If the soy protein is washed with water (following crushing/extrusion) to remove soluble polysaccharides (e.g., the carbohydrates known as stachyose and raffinose), the resultant soy protein is known as soy protein concentrate and contains at least 65% protein by weight. It is commonly utilized for making textured soy protein concentrate meat substitute added to sausage and comminuted meat products and for making functional soy protein concentrate emulsification-aid ingredient used to stabilize high-fat soups and sauces.

If the soy is washed with water-and-alkali solution, followed by isoelectric precipitation of the soluble protein, the result is 'isolated soy protein.' It is often also called soy protein isolate or soy isolate and contains a minimum of 90% protein by weight. It is most commonly used in the production of high-protein beverages, infant formula, ground meat, meatballs, frankfurters, and bolognas to improve texture and in brines for injected-meat products.

Applicable to Human Nutrition

Soy protein concentrate and soy protein isolate each are a complete (i.e., 'ideal') protein (i.e., one that provides all essential amino acids in diet) for humans. They are also a good dietary source of calcium, with an absorption rate approximately equal to milk.

In 1999, the US FDA approved a (label) health claim that associates the consumption of a minimum of 25 g soy protein per day with reduced blood cholesterol content and with reduced coronary heart disease (CHD) in humans.

Applicable to Animal Nutrition

For animals, the ideal protein concept refers to the amino acid profile of the feed ration (total food) eaten by livestock, poultry, and/or farmed fish. Feed rations that contain ideal protein are those in which the protein – when digested – yields all of the essential amino acids, in proper proportions, for the

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00642-5

growth and/or bodily tissue maintenance needs of that animal. That can be achieved by mixing soy protein with corn (*Zea mays* L.) in specific varying proportions to match the nutritional needs of the animal by species, age, etc.

Ideal protein varies for different species (e.g., pigs require different protein amino acid profile than chickens do). Ideal protein varies for different stages in the life of a given animal (e.g., poultry require more sulfur-containing amino acids such as methionine during life stages when feather growth is at a comparatively high rate, and dairy cattle require additional methionine during peak milk production period). During those brief time periods, the (extraordinary) amino acid needs of the animals can be met via the addition of small amounts of applicable synthetic amino acids to the daily feed ration.

Research indicates significant daily consumption of soybean isoflavones will increase the lean muscle growth rate of swine.

Animal Feeding Environmental Impact

Feed rations formulated to contain 'ideal protein' have been shown to reduce the amount of nitrogen (nitrates) excreted by livestock and poultry, by as much as 50%. That is because nonideal protein rations result in the removal of amino groups from molecules (e.g., in ration) via the energy-consuming metabolism of 'excess' amino acids eaten by that animal. For example, when livestock are fed with more lysine (amino acid) than their body needs in a given day (i.e., the animal's body can only utilize the essential amino acids in precise amounts/ratios of their daily diet), that excess lysine is metabolized to nitrogen-laden urea and then excreted in the animal's urine.

Conventional Soybean Oil

Soybean oil is an edible oil that is produced within its beans (seeds) by the soybean plant (botanical name *Glycine max* (*L.*) Merrill). When removed from soybeans via crushing and refining processes, soybean oil is (historical average) composed of 60.8% polyunsaturated fatty acids, 24.5% monounsaturated fatty acids, and 15.1% saturated fatty acids. However, soybean varieties have recently been created that possess as little as 7% saturated fatty acids. Soybean oil's individual fatty acid constituents are linoleic (octadecadienoic) acid 53.2%, oleic (octadecenoic) acid 24%, palmitic (hexadecanoic) acid 11.0%, alpha-linolenic (octadecatrienoic) acid 7.8%, stearic (octadecanoic) acid 4.0%, eicosenoic acid 1.0%, behenic (docosanoic) acid 0.5%, arachidic (eicosanoic) acid 0.3%, myristic (tetradecanoic) acid 0.1%, palmitoleic ((hexadecenoic)) acid 0.1%, and margaric (heptadecanoic) acid 0.1%.

In 2014, the US FDA allowed a (label) health claim that associates the consumption of a product serving containing a minimum of 160 mg ALA (alpha-linolenic acid) with being a 'good' source of linolenic acid per the ALA RACC (reference amount customarily consumed) ($\geq$10% of RACC 1.6 g day^{-1}).

Soybean oil also contains 9–12 mg g^{-1} of alpha-tocopherol, 74–102 mg g^{-1} of tau-tocopherol, and 24–30 mg g^{-1} of delta-tocopherol.

Value-Added Soybean Oils

Commercially grown in 2014 were new soybean varieties whose oil contains more than 70% oleic acid, instead of the typical 24% oleic acid content of soybean oil produced from traditional varieties of soybeans. That elevated oleic acid content and the resultant reduced saturated fat content provide an oil that is more heart-healthy to consume and possesses greater heat resistance for longer effective oil product life during frying.

Coming after 2014 were new soybean varieties whose oil contains more than 18% stearidonic acid, instead of the typical 0% stearidonic acid content of conventional soybean oil. Stearidonic acid is a fatty acid naturally produced in the seeds of some plants (e.g., *Nasa carunculata*, *Nasa hornii*, *Nasa* cf. *magnifica*, and *Borago officinalis L.*). When consumed by people, stearidonic acid is partially converted within the human body into the long chain $n-3$ (i.e., 'fish oil-type' omega-3) fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).

When fed to applicable farmed fish (grown in aquaculture production), stearidonic acid is partially utilized by the animal for energy and partially converted into EPA and DHA, which are subsequently deposited in the fish meat. In 2004, the US Food and Drug Administration granted a label 'qualified health claim' status to EPA and DHA, for the product label to state 'supportive but not conclusive research shows that consumption of EPA and DHA fatty acids may reduce the risk of CHD.' Research also indicates that human consumption of adequate amounts of EPA and DHA helps to prevent postpartum depression.

The coming stearidonic acid-containing soybean oil will thus be a source of beneficial omega-3 fatty acids without the risk of mercury contamination commonly present in fish meal made from wild-caught ocean fish. This land-source omega-3 dietary alternative will also ease pressure to overfish the wild species of omega-3-containing fish.

Soy Beans: The Crop

K Nill, US Soybean Export Council, Saint Louis, MO, USA

Soybean Plant

Soybean (*Glycine max* (L.) Merrill.), a green, bushy legume, is the world's single largest provider of protein for mankind's use. That protein can be consumed directly in the form of soy foods such as tofu, edamame, nattō, miso, and soy flour-fortified baked goods or indirectly in the form of meat, milk, and eggs resulting from the feeding of soy protein to livestock, poultry, or farmed fish. Soybeans are also a major source of edible soybean oil.

This summer annual plant varies in height from less than a foot (0.3 m) to more than 3 ft (1 m) tall. The seeds (soybeans) are borne in pods and, historically, contain 13–26% oil and 38–45% protein (on a moisture-free basis). Its leaves contain some carotenoids (i.e., isoprenic plant pigments utilized by higher animals in the formation of vitamin A), which may be consumed by livestock in the form of soybean hay.

A massive increase in the production and international trade of soybeans during the past 60 years has been a major cause of the world's average human life span increasing from 46.6 to 69.3 years during that time period. Inclusion of adequate dietary protein has had an especially beneficial impact on the average life span in developing countries, because their diets had been universally too low in protein.

Although 45 countries commercially grow at least some soybeans, for a world total of 284 million metric tons (MMT) in 2013, only seven countries produce enough soybeans to consistently have a significant annual exportable soybean surplus. They are Brazil (55 MMT), the United States (48.7 MMT), Argentina (40.7 MMT), Paraguay (7.3 MMT), Uruguay (4.4 MMT), India (4 MMT), and Canada (4 MMT). Those seven countries export soybeans and soybean meal to more than 100 countries.

Soybean Physiology and Production

The soybean plant has approximately 80 000 genes. It is a self-pollinating plant (i.e., the male and female reproductive structures are located within each flower, so monoecious pollination occurs prior to the flower opening). Research indicates that post-opening pollination by bees can help increase yield by reducing the number of aborted flowers, that is, those that bloom but subsequently fail to become soybean pods.

Soybeans are planted in the spring after topsoil warms up to consistently greater than 50 °F, or they can be planted in midsummer after a wheat/barley or vegetable crop has been harvested from the field (in the southern half of the United States or northern half of South America). Shortly after planting, the soybean germinates and its roots produce isoflavone compounds to signal and attract *Rhizobium japonicum* bacteria to live symbiotically within the nodules on the soybean plant's roots where the *Rhizobium* 'fix' nitrogen from the air, thereby providing natural nitrogen-source fertilizer needed by the crop. In return, the soybean plant manufactures sugars needed by the *Rhizobium* bacteria and provides those sugars to the nodules in its roots. Soybean plants produce flowers 6–8 weeks after planting and can continue adding flowers (each capable of becoming a soybean pod) for up to an additional 6 weeks.

Conventional breeding of soybean varieties had slowly increased the genetic yield potential of the US soybean crop during 1945–95. As a result of US farmers' post-1995 adoption of new soybean production technologies such as biotechnology-derived varieties (now >94% of US-planted area), precision agriculture (also known as site-specific crop management), 'no tillage,' and other conservation tillage practices (in which herbicides are utilized for weed control instead of mechanical tillage/disturbance of soil), the US national soybean crop average yield reached a record-high 47 bushels per acre (3 MT ha^{-1}) in 2014. Other nations that have adopted fewer of these new technologies have proportionally lower yields on comparable soil/climate fields.

The biotech herbicide-tolerant varieties enable greater weed control compared to conventional soybean production. These new soybeans enable crop rows to be planted closer – as close as 7 in. instead of the conventional 30 in. – because the farmer no longer needs room between rows for the mechanical tools of weed control. That closer crop row spacing also conserves field soil moisture and provides additional natural weed suppression, by shading the ground between plants.

In precision agriculture, the required application amounts of inputs such as seed, fertilizer, and pesticides are minimized via satellite-guided steering and automatic nozzle shutoff avoiding double planting/spraying of field headlands where the equipment is turned around in order to head back down the field each pass. According to the 2008 research, the average input-reduction savings achieved by adopters of precision agriculture at that time were $19 per acre for corn, $18.50 per acre for soybeans, and $39 per acre for cotton. In addition, for soybeans, avoiding the double planting of field headlands results in an *increase in yield per acre* (versus double-planted field areas). The 2009 research by Ohio State University compared a nonprecision self-propelled sprayer using foam markers to a satellite RTK-guided sprayer possessing satellite shutoff individually controlled sprayer nozzles. On fields with no obstructions such as waterways, it found the former to waste two or three field passes versus the latter. That equated to eight wasted (i.e., overlapped) acres on a 100 acre field. The wastage, and thus the concomitant savings achieved via precision agriculture, was even greater on fields with waterways or other natural obstacles.

Farmers using the no-till method of production plant soybean seeds directly into the soil, through the previous crop's dead plant residue. This reduces the need for fuel-consuming deep plowing and multiple cultivation tillage operations with

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00640-1

heavy equipment, which reduces field greenhouse gas emissions by approximately 88%. The reduction in plowing/cultivation greatly diminishes field soil erosion and soil moisture loss during the growing season. Because the plant residue from the previous crop is left on the field surface, it also captures drifting snow during the winter months in northern latitudes and holds it so that snowmelt soaks into the field's soil when it melts in the spring. The plant residue is eventually consumed by the field's subterranean earthworms and microbes, so it eventually passes into the soil in the form of organic (humus) soil material. Another result of the soil moisture conservation and snow-capture impacts of no-till soybean production has been a slight expansion of the soybean-planted areas into adjacent regions that were previously considered too arid for soybeans. Soybeans now reliably produce an economically viable yield of one metric ton (37 bushels) per acre in dry US regions where total annual precipitation (rainfall plus snowmelt) is only 18 in. These developments have, in their aggregate, resulted in US soybean production now being sustainable (i.e., able to produce at this level essentially forever without any degradation of fields).

Coming in the future will be new drought-tolerant soybean varieties that hold the potential to significantly expand the world's geographic areas on which soybeans are produced. Some of the strategies being pursued to create these new soybean varieties are

- insertion into soybean plant of the HAHB4 gene from the sunflower (*Helianthus annuus* L.) plant, resulting in the soybean plant tolerating drought stress longer before yield loss occurs;
- insertion into soybean plant of the flavodoxin gene, resulting in the soybean plant tolerating drought stress longer;
- insertion into soybean plant of a promoter to increase expression of the gene for aldehyde dehydrogenase, an enzyme that detoxifies (metabolites incurred via drought stress);
- breeding for enhanced leaf survival so that the crop can survive intermittent severe drought stress and still produce a harvestable yield (this has involved selecting for those with extreme low epidermal (leaf) water conductance, moderate osmotic adjustment, and low critical relative water content);
- breeding for the *slow-wilting* trait (in which higher ascorbic acid content of leaf stomata cells results in them closing faster in times of water stress to minimize leaf water loss);
- breeding for increased pinitol (a cyclic-molecule carbohydrate) content in leaves, which enables photosynthetic activity to continue longer during times of drought stress.

The likely regions for significant overseas expansion of soybean-planted area, following commercialization of the coming drought-tolerant soybean varieties, will include northern Australia, Ethiopia, Kazakhstan, Mozambique, northwest Russia, Sudan, and Tanzania.

Following harvest, soybeans are sold by grade. In the United States, soybean grade criteria are overseen by the US Department of Agriculture (USDA). After cleaning, US grade No. 1 soybeans are processed directly into soy foods such as tofu, miso, nattō, and edamame. They cannot contain more than 1% foreign material (e.g., weed seeds and dust), more than 2% damaged kernels, or greater than 10% split kernels. That is because those could potentially result in the production of undesirable flavors in the resultant soy foods.

US grade No. 2 soybeans cannot contain more than 2% foreign material, more than 3% damaged kernels, or greater than 20% split kernels. US grade No. 3 soybeans cannot contain more than 3% foreign material, more than 5% damaged kernels, or greater than 30% split kernels.

US grade Nos. 2–4 soybeans are typically crushed under high pressure at an elevated temperature to separately yield soybean oil and soybean meal/flour. The heat inactivates antinutritional factors (e.g., trypsin inhibitors) that are present within raw soybeans. Heating of soybeans to a temperature of 212 °F (100 °C) for 15 min causes these trypsin inhibitors to be rendered inactive in the resultant soybean meal/flour, so digestion by human/animal is unimpeded.

Soybean Oil

AJ Dijkstra

© 2016 Elsevier Ltd. All rights reserved.

Historical

The soybean (*Glycine max*) was domesticated in China and has spread from there, first to neighboring countries and later all over the world. The bean was used to produce soya sauce, tempeh, and soymilk, which is also used to make tofu. Soybean oil production did not start until solvent extractors became available. In a patent disclosing the production of lecithin (German Patent 382912) that was granted to Hermann Bollmann in 1923, the inventor describes how he extracts soybeans with a mixture of 75 parts of benzene and 25 parts of alcohol. The extraction is continued for about an hour and he then removes the solvent from the miscella. He warms the evaporation residue to 103 °C and introduces steam for a quarter of an hour. This causes lecithin to precipitate.

The interesting thing about this patent is that Bollmann used 1000 kg of soybeans. They were apparently available when he applied for the patent in Germany in 1921. In the United States, Francis Turner also applied for a patent (US Patent 1,448,581) for a water-degumming process of crude vegetable oils "such, for instance, as cottonseed, cocoanut, sesame and peanut oils." Turner did not mention soybean oil, but in 1923, the first soybean extraction plant was opened in the United States by the Monticello Cooperative Soybean Products Co. in Illinois. It used benzene and was the first solvent extraction plant in the United States.

In 1935, the main soybean producer was Manchuria; it produced five times the amount grown in the United States and exported it to Europe. In Belgium, the oil mill Vandemoortele that originally crushed flaxseed started to use soybeans from Manchuria when moving into the realm of edible oils in the 1930s but had to stop production during WWII due to the lack of raw materials. Soybean extraction was resumed after the war but another oil mill, De Smet, was less lucky. Its extractor did not survive the war so the owner designed and built a new one himself, which was the start of the current engineering company Desmet Ballestra.

After WWII, the United States became the major producer of soybeans, and soybean oil became the most important oil, not only in the United States but also worldwide. In the 1970s, soybeans started to be grown in Brazil, Paraguay, and later Argentina so that at the time of writing, South America produces more soybeans than the United States – 157 million tons versus 108 million tons for the United States of a global production of just over 300 million tons. In 2006, soybean oil production was overtaken by the production of palm oil.

Because the soybean is such an important crop in the United States, it has been and continues to be the subject of intensive research and development. This R&D covers plant breeding, genetic modification, oil extraction, refining and modification processes, oil meal utilization, oil properties and use in food products, and so forth.

Oil Production

Soybeans contain about 18–21% oil and 38–44% protein on a moisture-free basis. This explains why soybeans are primarily grown for the meal rather than for the oil. In this respect, soybeans differ from all other oilseeds. Sunflower seed and rapeseed are grown to provide oil. They also provide a meal, but the value of the oil produced from these latter seeds is much higher than the value of the coproduct meal. For soybeans, the meal represents 60–70% of the total returns.

It is therefore the demand for meal that determines how many soybeans are planted. This determines in its turn how much soybean oil will be available. This amount of oil is less than global demand for edible oil, so other crops will have to meet this demand and this is the role played by palm oil since this oil does not have meal as a coproduct. Of course, there are other oils beside soybean oil and palm oil, and the production of most of these oils also entails the production of meal, but several of these oils are local like cottonseed oil, sesame seed oil, and groundnut oil.

Producing palm oil costs a certain amount of money, and except when there is a shortage of oil, this cost price sets the price for other vegetable oils including soybean oil. Producing soybeans also costs a certain amount of money, and given the price of soybean oil, the value of meal can be calculated as a difference. In other words, world demand for meal determines the amount of soy, and together with the world demand for oil, it also determines the amount of palm oil produced. The cost price of palm oil determines the cost of the (soybean) meal.

The situation is more complex since the oil palm goes on producing once it has started growing fruit bunches, and palm oil also has a meal coproduct in the form of palm kernel meal. There are also other oilseeds and vegetable oils. One of these oils is olive oil, an oil that leads a life of its own. It contributes to the global availability of vegetable oils, but it is expensive to produce. So, the amount produced reflects what some people are willing to pay for a specialty or gourmet oil. Another oilseed is cottonseed. This is a by-product of growing cotton. Given the prices of oil and meal, it is profitable to mill this by-product and sell the resulting oil and meal, but that only affects the amounts of soybean and palm oil produced but not their interdependence. It is this interdependence that causes more palm oil to be needed when a European government decides to subsidize the use of rapeseed oil for the production of biodiesel.

Because its use in poultry farming requires a high (>48%) protein content and a low (<3.5%) fiber content, soybeans are often dehulled before being extracted. In the classical dehulling process, the beans are dried and tempered in intermediate storage. This makes the beans shrink away from the hulls so that after cracking, the hulls can be separated from the cracked cotyledons by winnowing. In the so-called 'hot dehulling' process, the beans are conditioned to a temperature of

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00638-3

65–70 °C in a tower in which tubes that are heated with low-pressure steam heat the beans quite quickly. This and the subsequent superficial heating in a fluid bed dryer cause the hull to shrink away from the cotyledon. Cracking leads to a mixture of separate hull fragments and cracked cotyledons that are separated in cascade aspirators.

For the cracking process, two or three sets of superimposed fluted rolls are used wherein opposing rolls run at different speeds to grip the beans. Cracking should aim at breaking the bean into four to six smaller pieces and avoiding fines and mashed beans. Subsequently, the cracked cotyledons are flattened into flakes of some 0.25–0.30 mm thickness between polished flaking rolls.

Processing the flakes in an expander is optional. The expander is a kind of extruder in which the flakes are compressed until on leaving the die, the compacted mass expands, causing further cell rupture. The resulting collets have the advantage that they have a higher bulk density than the flakes, so expanders are often used to increase the capacity of an existing oil mill. Collets also have the advantage of a reduced liquid holdup, which saves energy in the desolventizer.

The extraction solvent used is invariably hexane. Industrial hexane is a mixture of alkanes with a boiling range of 66–69 °C comprising *n*-hexane (~62%), methylpentanes (~23%), and methylcyclopentane. It is highly inflammable, and its explosive range in air is 1–8% by volume. Consequently, extractors are operated at a slightly subatmospheric pressure to prevent the hexane from escaping.

Solvent extractors operate countercurrently to minimize the oil content of the solvent-wet extraction residue, or marc, leaving the extractor, and maximize the oil content of the miscella, the solution of oil in hexane. Two types of extractor are in industrial use: percolation and immersion. In the immersion type, the screen under the material being extracted has so little open area that it constitutes the greatest flow restriction. Immersion extractors provide more contact time between solvent and seed material but require more draining time than percolation extractors. Both types ensure a miscella strength of around 30% oil and a residual oil content in the meal of <1 wt%.

The marc leaving the extractor is then treated to remove the solvent, first by indirect heating and then by heating with live steam. This raises the temperature of the meal to 105–100 °C in the toasting section where antinutritional enzymes like urease and trypsin inhibitor are denatured. Since the live steam causes the moisture content of the meal to increase, the meal has to be dried. Air is used to dry the meal to a residual water content of 13–14 wt% and cool it down at the same time.

The hexane-laden vapors leaving the desolventizer are at atmospheric pressure. Using their latent heat to evaporate the hexane from the miscella requires the latter to be under a reduced pressure; in industrial practice, this pressure is about 500 hPa absolute. The latent heat content of the vapors leaving the desolventizer upon evaporation is <90% of the hexane present in the miscella so that the composition of the liquid leaving the first evaporator is around 80 wt% oil. It is further concentrated using steam and finally treated in a steam stripper operated at 200–400 hPa absolute to remove the last traces of hexane.

If the oil has to be shipped, it must be degummed with water to prevent a deposit being formed during transport and storage. In this water-degumming process, an amount of water that is about the same as the gum content of the oil is mixed with the hot oil, allowed to hydrate the mucilaginous matter, and then separated by a centrifuge. Drying these gums yields lecithin.

However, this lecithin may originate from soybeans that have resulted from genetic modification, and some food manufacturers have cashed in on the irrational and emotional fear among some consumers in Europe of anything to do with GMOs. They substituted soy lecithin by sunflower seed oil lecithin and charge more for their products, which they can now promote as GMO-free. This has affected the demand for soy lecithin.

Oil Refining

Crude soybean oil, the evaporation residue of the miscella, has a phosphatide content of 2–4 wt%. Water degumming can reduce this content to 0.5% or less but the lecithin market is too small to absorb all the dried gums. This means that they have to be disposed of in another way. One way is to mix the gums with the meal and sell them at meal value, but a more profitable way may be the enzymatic hydrolysis of the gums. Figure 1 shows the molecular structure of the phosphatides and which bonds are susceptible to which phospholipase.

If phospholipase C is used to catalyze this hydrolysis, the reaction products are diglycerides and phosphate esters of choline, ethanolamine, and inositol. The first phospholipase C that was commercially available was specific for phosphatidylcholine (PC) and phosphatidylethanolamine (PE), but since then, a phospholipase C has been developed that catalyzes the hydrolysis of phosphatidylinositol (PI) into a diglyceride and inositol phosphate. These hydrolysis products do not retain any oil, and the diglycerides contribute to the neutral oil yield. If the enzyme is a phospholipase A_1 or A_2, the reaction products are lysophosphatides or ultimately glycerol phosphates and free fatty acids. These enzymes catalyze the hydrolysis of all vegetable phosphatides and also reduce oil retention by the gums.

If crude oil is used as the substrate for this enzymatic hydrolysis, the resulting oil will have a residual phosphorus content that is close to the phosphorus content that would have resulted from water degumming. This means that the oil has to be neutralized by alkali refining. If the enzymatic hydrolysis is preceded by an acid treatment to decompose the nonhydratable phosphatides, the residual phosphorus content could be sufficiently low to permit physical refining. However, the yield advantage of physical refining over alkali refining is small for soybean oil because of its low free fatty acid content.

The alkali refining process that is used in the United States is the so-called long-mix process. In this process, dilute lye (14–18 °Bé or 130–180 g NaOH per l of water) is added and mixed into cold oil. Then, the oil is heated until a clear separation between oil and soapstock is obtained. The soapstock is removed by centrifugal separator, and to lower the residual soap content, the oil is either washed with water or treated with silica hydrogel. The soapstock can be acidulated by

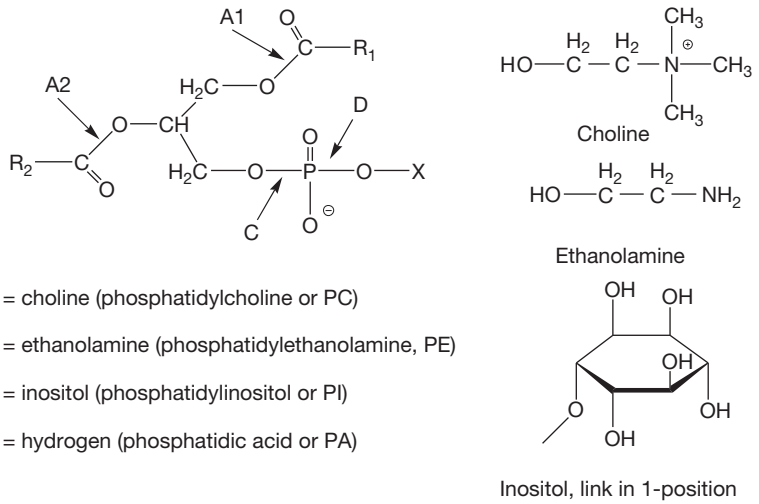

Figure 1 Molecular structures of phosphatides and their substituents.

adding sulfuric acid and collecting the supernatant layer of acid oils or sold as a feed ingredient. The acid oils can be sold as a feed ingredient or as raw material to the oleochemical industry or biodiesel industry.

After having been neutralized or degummed to <10 ppm phosphorus, the oil has to be bleached. The bleaching process achieves more than just reducing the oil color. It catalyzes the decomposition of peroxides, removes residual soaps and residual phosphatides by adsorption, and also adsorbs colored compounds like chlorophyll. The bleaching process is simple. If the oil temperature is below 100 °C, the oil is heated to this temperature; an amount of, for instance, 0.5 wt% of bleaching earth is added and dispersed in the oil that is kept under a mild vacuum. After some 30 min, the spent earth is removed by filtration, and to reduce oil loss via the spent bleaching earth, the filter cake is blown with steam.

In vertically integrated oil mills that also comprise a refinery, the spent earth can be sent to the extractor. This has the advantage that the hexane-extractable oil is recuperated from the spent earth. Another advantage is that the extracted spent earth can then be sold at meal value. To facilitate transport of the spent earth to the extractor, it can be mixed with some crude oil. Blowing the filter cake with steam can be omitted.

Next, the bleached oil is stripped under vacuum with steam. This process is called either deodorization when the oil is almost neutral by having been alkali-refined or physical refining when the oil has only been degummed. In both processes, malodorous compounds present in the crude oil are removed by volatilization together with other volatile compounds. Examples of these other volatile compounds are free fatty acids and tocopherols.

Although some batch deodorizers are still in use for specialty oils, soybean oil is invariably deodorized in large continuous deodorizers comprising a number of superimposed trays. The oil to be deodorized is first of all deaerated to prevent dissolved oxygen reacting with the oil; then, it is heated by an extensive system of heat recuperation comprising plate heat exchangers where heat is exchanged between outgoing and incoming oil and one or two thermosiphon systems. In the trays, the oil is agitated to ensure heat transfer and removal of volatiles by injecting stripping steam. The amount of steam in weight is small (around 1 wt%), but the volume of this steam is very large because of the low molecular weight of water, the low pressure, and the high temperature. 1 wt% water at vacuum stripping conditions of some 220–250 °C and 2–4 mbar absolute pressure occupies 5000 times the volume of oil.

A very efficient system of volatile removal is the use of a packed column through which the oil trickles downward, while stripping steam moves upward. This counter-current system makes more efficient use of the stripping steam than the cross--current trays. So, less steam is needed, a smaller vacuum pump suffices, and less energy is required to maintain the vacuum.

The vapors leaving the deodorizer pass through a scrubber where they are washed with cooled condensate or they are condensed onto one of two ice condensers operating in tandem. In the case of soybean oil, it may be advantageous to condense the deodorizer vapors in two stages. The least volatile components of this vapor will be condensed in the first, high-temperature stage and provide a condensate that is relatively rich in tocopherols that have a high market value (vitamin E and antioxidants). The second low-temperature scrubber or condenser will take care of the remaining condensables. After the oil has been cooled, it has to be stored and protected from oxidation. A low temperature and nitrogen blanketing help in this respect.

Oil Modification and Food Uses

Three modification processes are commonly used to alter the physical properties of an oil or oil blend: hydrogenation, interesterification, and fractionation. In the case of soybean oil, the hydrogenation process is the most important, but because this process produces *trans* isomers and their content has to be mentioned on the labels of consumer packages, this process has become less prevalent. Formerly, soybean oil (IV = 131) would be hydrogenated to an IV of 110, and the resulting product would be fractionated (winterized) to remove high-melting triglycerides so that the resulting olein

fraction would have a good cold stability at refrigerator temperature and improved oxidative stability making it an ideal salad oil. Now, non-modified oil is used instead.

Formerly, the oil used for margarine production would be hydrogenated in a rather nonselective manner to a melting point close to 40 °C and used for margarine as such. Now, it is more common to blend a hardstock with liquid oil whereby attempts are made to reduce the *trans* isomer content of this hardstock. If the soybean oil to be used in this hardstock has to be *trans*-free, this can only be achieved by full hydrogenation (IV = 0) followed by interesterification of the fully hydrogenated fat with liquid oil. However, the solid fat content profile of the interesterification product differs from what can be achieved by partial hydrogenation. Its crystallization behavior differs and final product properties are different.

Better products are obtained by using hardstocks based on fats that are more saturated like palm oil and lauric oils like coconut oil and palm kernel oil and, especially, their interesterification products. Soybean oil can then be used as the liquid oil in the margarine fat blend.

Composition of Soybean Oil

Crude soybean oil as obtained by miscella evaporation contains many different components. The main component is triglyceride oil or triacylglycerol (TAG). The composition of this oil is determined by its fatty acid composition or, to be more precise, by the fatty acid compositions of the *sn*-1-, 2-, and 3-positions.

Table 1 shows that saturated fatty acids have a strong preference for the outer 1,3-positions and that linoleic acid (18:2) has a certain preference for the middle 2-position. This is a common phenomenon for vegetable oils. In animal fats like lard, the saturated palmitic acid has a preference for the 2-position, and there is a difference between the 1- and 3-positions.

According to Table 1, soybean oil contains 7% linolenic acid. At one stage, this acid was blamed for the flavor reversion and short shelf life of soybean oil. This led to research aiming at selective hydrogenation of linolenic acid and also to plant breeding efforts to reduce the linolenic acid level. Now, we have the impression that yes, linolenic acid is more prone to degradation but not so much more than linoleic acid, which also contains bis-allylic hydrogen atoms in the methylene group in between two double bonds. So, the 54% of linoleic acid contributes much more to the lack of stability of soybean oil than its 7% linolenic acid.

Another reason to change the fatty acid composition of soybean oil by plant breeding and genetic modification is the current *trans* isomer scare. Soybean oil is the main oil in the United States, and it is used in margarines and shortenings after partial hydrogenation. This process leads to the formation of *trans* isomers, especially elaidic acid and its isomers. They provide the oil with the solid fat content profile that is required for these consumer products. In order to produce fats with a similar solid fat profile that contain less or no *trans* isomers, more saturated fatty acids are required; this has been another target in soybean oil modification. Table 2 gives some examples of what has been achieved in this respect.

Another genetically modified soybean could be quite interesting from a nutritional point of view. Its oil contains 28% of stearidonic acid and 8% of gamma-linolenic acid (GLA). Stearidonic acid (18:3 or (6*Z*,9*Z*,12*Z*,15*Z*)-octadeca-6,9,12,15-tetraenoic acid) is the Δ6-desaturase product of linolenic acid, a metabolic step that is difficult in humans and a step in the direction of EPA (eicosapentaenoic acid). The other nutritionally significant acid, GLA (18:3 or (6*Z*,9*Z*,12*Z*)-octadeca-6,9,12-trienoic acid), also bypasses a difficult desaturase step on the way to arachidonic acid, 20:4$\omega-6$.

In addition to TAG molecules, soybean oil also contains some diacylglycerol (DAG) molecules. These have been formed by partial hydrolysis of the TAG. This hydrolysis also generates a free fatty acid. Since the FFA content of crude soybean oil is low in comparison with most other major vegetable oils, the DAG content of soybean oil is also lower.

The next group of compounds present in crude soybean oil consists of the phosphatides. The three main phosphatides are PC, PE, and PI. Their concentrations depend on climatic conditions during seed fill. In addition, lecithin contains some phosphatidic acid (PA) or rather its potassium salt and some acetylated PE. Water-degummed soybean oil contains variable amounts of calcium and magnesium salts of PA and some PE (Table 3).

Table 1 Fatty acid composition of soybean oil by position

	16:0	*18:0*	*18:1*	*18:2*	*18:3*
sn-1 position	16.7	5.4	24.3	46.4	6.4

Table 3 Ranges (in percentage of total) of concentrations and fatty acid composition of soybean phosphatides

	PC	*PE*	*PI*
Concentration	35–46	25–27	13–18
16:0 Content	14.9–20.5	15.8–31.6	25.6–47.7
18:0 Content	3.2–6.3	3.2–4.4	8.2–11.7
18:1 Content	7.5–13.7	8.4–8.7	4.9–9.1
18:2 Content	58.8–64.8	53.2–64.7	36.2–44.4
18:3 Content	2.0–6.0	3.2–63	2.7–6.4

The observation that the fatty acids in PI tend to be more saturated than in the other phosphatides is also shown in the stereospecific fatty acid compositions of the triglycerides and phospholipids listed in Table 4.

Because the literature values in the tables in the preceding text refer to different samples, there are some differences between these values. However, they clearly show that the phosphatides are more saturated than the triglycerides and that PI is the most saturated phosphatide.

Like other vegetable oils, soybean oil also contains phytosterols that can be free or esterified with a fatty acid. Table 5 lists their concentrations in the oil.

The data in Table 5 originate from three different sources. The range is from one source, the next column from another, and the last four columns from the third source. They do not contradict each other, and together, they provide a clear picture of the phytosterol content of crude soybean oil. When the oil is refined, the sterol content decreases. It does not decrease during degumming operations, but decreases somewhat when the oil is alkali-refined. Bleaching hardly affects the sterol content, but the vacuum steam stripping process can lead to substantial loss of sterols.

Source: Table 7.5 in Johnson, L. A., White, P. J. and Galloway, R. (2008) (eds.) *Soybeans, chemistry, production, processing, and utilization*. Urbana IL: AOCS Press; Table 2.47 in Gunstone, F. D., Harwood, J. L. and Dijkstra, A. J. (2007) (eds.) *The lipid handbook* (3rd ed.). Boca Raton: CRC Press; Table 7.5 in Verleijen, T. (2002) *Stability of minor components during vegetable oil refining*, PhD Thesis, Ghent University.

Soybean oil also contains tocopherols but no tocotrienols, which are only found in palm oil and coconut oil. The tocopherol content of soybean oil is given in Table 6.

Again, the table has been compiled using data from different sources. The columns headed Range and Mean refer to the first source and the two columns headed Single refer to two other sources. The tables are internally reasonably consistent and therefore provide a reliable picture of the tocopherol content and composition in soybean oil.

Like most vegetable oils, soybean oil also contains some β-carotene and lutein (xanthophyll), but their concentrations are quite low at only a few ppm. This is very much lower than the carotenoid content of palm oil, which is in the range of 500–700 ppm. Chlorophyll content of soybean oil is also quite low at <500 ppb. This is very much lower than the chlorophyll content of rapeseed oil, which ranges from 5 to 25 ppm, or olive oil, where the range is 10–30 ppm.

Squalene (6*E*,10*E*,14*E*,18*E*)-2,6,10,15,19,23-hexamethyltetracosa-2,6,10,14,18,22-hexaene, a symmetric triterpene, is a precursor for phytosterols. Soybean oil contains about 7–17 ppm, and because of its volatility, the squalene content of deodorizer distillate may reach a few percent, which may be sufficiently high to warrant its isolation. In comparison with some other oils, the squalene content of soybean oil is on the low side as illustrated by Table 7.

Sphingolipids are a group of nonglyceride lipid components that have stimulated interest in soy foods from a human health perspective because sphingolipid consumption has been associated with decreased colon cancer and skin cancer in rats. Sphingolipids have three characteristic components, one of which is a sphingosine (2-amino-4-octadecene-1,3-diol). The amino group of the sphingosine forms an amide linkage with an α-hydroxy fatty acid such as α-hydroxypalmitic

Table 6 Tocopherol contents of soybean oil (ppm)

acid, and the primary hydroxyl group of the sphingosine forms an ether linkage with glucose. So, the resulting glucosylceramide has a strongly polar group, which is why it remains in the defatted soy flakes after extraction.

Spectroscopy: Types

AK Malik, R Kumar, and Heena, Punjabi University, Patiala, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

'The Light of Knowledge' is used often as a phrase, but it is appropriate with reference to spectroscopy. All of us know the structure of atoms and molecules comes from studying their interaction with light. Spectroscopy deals with the study of interaction between matter and radiated energy as a function of wavelength. It deals with the use of visible light dispersed according to wavelength historically, but later on, the concept was expanded to the measurement of the quantity as a function of either wavelength or frequency. It is one of the most important tools in a scientist's toolkit. Astronomers use spectroscopy to study light from different objects in the universe.

Latin: 'spectrum' – ghost or spirit

Greek: 'σκοπειν' – to look carefully

This article gives a brief introduction about spectroscopy and its types. It mainly focuses on the various types of spectroscopic techniques that are commonly used in analytic purposes in diverse fields, especially in food and health sciences. These spectroscopic techniques have been successfully applied in food and health sciences since decades to ensure safety, quality, and traceability of food and provide healthy lifestyle to mankind. The objective of this article is to provide healthy information about the types of spectroscopic techniques to the readers.

Electromagnetic Radiations

Electromagnetic radiation is a type of energy that is commonly known as light. Generally, light travels in waves, and all electromagnetic radiation travels at the same speed, which is about 3.0×10^8 ms^{-1} through a vacuum. Electromagnetic waves are produced by motion of electrically charged particles. The energy propagates as a wave such that the crest and troughs of wave move in a vacuum at a speed of 299 792 458 ms^{-1}. The many forms of these radiations appear different to the observer; light is visible to the human eye, but x-rays or radio waves are not. Some important characteristics of electromagnetic radiations are as follows:

1. These are produced by the oscillation of electric charge and magnetic field. The electric and magnetic components are mutually perpendicular to each other and are coplanar.
2. These are characterized by their frequencies or wavelengths or wave number.
3. All types of these radiations travel with the same velocity and require no medium for their propagation.
4. The energy of electromagnetic radiation is directly proportional to its frequency. The phenomenon of it was given by Planck known as Planck's law, $E = h\nu$.
5. When visible light (a region of electromagnetic radiations) is passed through a prism, it split up into seven colors. This phenomenon is known as dispersion (Figure 1).

Terms related to electromagnetic radiations:

1. *Wavelength* (λ): The distance between two adjacent crests or troughs in a particular wave. It can be expressed in angstrom unit or nanometer ($1\ \text{Å} = 10^{-10}$ m and $1\ \text{nm} = 10^{-9}$ m).
2. *Wave number* ($\bar{\upsilon}$): It is the reciprocal of wavelength and is expressed in per centimeter. It is defined as the total number of waves that can pass through a space in 1 cm.
3. *Frequency* (ν): It is defined as the number of waves that can pass through a point in 1 s. It is expressed in cycles per second or in hertz ($1\ \text{Hz} = 1\ \text{cycle s}^{-1}$).
4. *Energy* (E): Energy of the particular radiation can be calculated by applying the relation $E = h\nu = hc/\lambda$, where h = Planck's constant = 6.626×10^{-34} Js.

Table 1 shows the relationship among various parameters associated with electromagnetic radiations.

Electromagnetic Spectrum

Different regions of electromagnetic spectrum (Figure 2) provide different kinds of information as a result of such interactions. Electromagnetic spectrum comprises all the possible range of electromagnetic radiations. Radiations can be considered as a form of radiant energy that is propagated as a transverse wave. It vibrates perpendicular to the direction of propagation and imparts a wave motion and described in terms of wavelength or frequency. The reciprocal of the

wavelength is termed as wave number and is the number of waves in unit length.

Spectroscopic Types

1. UV–vis spectroscopy
2. Vibrational spectroscopy
   2.1 Infrared spectroscopy
   2.1 Raman spectroscopy
3. Nuclear magnetic resonance (NMR)
4. Electron spin resonance (ESR)
5. Mass spectrometry

Spectroscopic techniques have been applied in all the technical fields of science and technology. Techniques of spectroscopy are so much sensitive that the single atom or different isotopes of atoms can easily be identified among 1020 atoms or among different species. Trace amounts of pollutants are often detected by these spectroscopic techniques.

UV–Vis Spectroscopy

It involves the promotion of electrons from the ground state to higher energy state, so the alternate name for this is electronic spectroscopy:

- It is useful to measure the aromatic conjugation and the number of conjugated double bonds.
- It also distinguishes between homoannular and heteroannular conjugated dienes.
- Electronic transition occurs in the range of 200–800 nm.

This rests heavily on empiricism, particularly in the study of aromatic and heteroaromatic systems, but it can provide information completely unobtainable from spectrophotometer of any other spectroscopic technique.

Theory of electronic transitions

After absorbing the UV light of a particular energy, electron is promoted to higher energy and the other electrons are unaffected. The excited state is produced in a very short time, and consequently during electronic excitation, the atoms of molecule do not move. Not all the transitions from filled to unfilled orbitals are allowed; some are forbidden. For the forbidden transitions, the probability of the transition to occur is low and the intensity of associated absorption band is also low.

Types of electronic transitions

- $\sigma-\sigma^*$: UV photon, high energy required, and methane absorbing at 125 nm
- $\pi-\pi^*$: Organic compounds, wavelengths 200–700 nm, and requiring unsaturated groups
- $n-\sigma^*$: Saturated compounds with heteroatom containing unshared pair of electrons
- $n-\pi^*$: Unsaturated groups, low epsilon (10–100), and having shorter wavelengths

The $\sigma-\sigma^*$ transition requires an absorption of a photon with a wavelength that does not fall in the UV–vis range. Thus, only $\pi-\pi^*$ and $n-\pi^*$ transitions occur in the UV–vis region (Figure 3).

The absorption law (the Lambert–Beer law)

When a beam of monochromatic radiation passes through a homogeneous absorbing medium, the rate of decrease of intensity of radiation with thickness of absorbing medium is proportional to the intensity of incident radiation as well as the concentration of the solution.

Mathematically,

$$-\frac{dI}{dx} = k'Ic$$

where I = intensity of radiation after passing through thickness 'x', dI = small decrease in intensity of radiation, k = proportionality constant or absorption coefficient, and c = concentration of the solution in moles per liter.

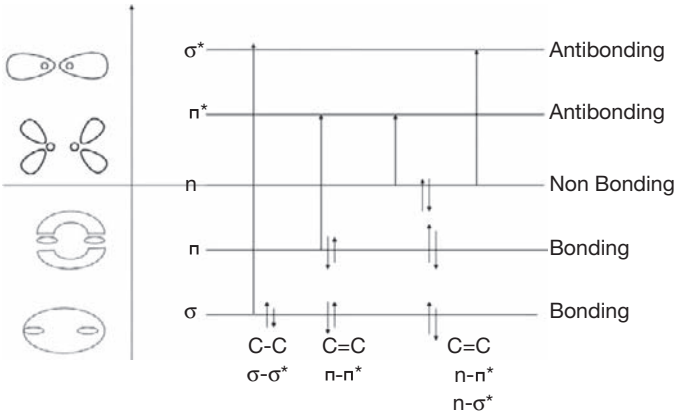

Figure 3 Types of electronic transitions.

The absorbance of radiation can be calculated as

$$A = \varepsilon cl$$

Components of spectrophotometer

A spectrophotometer measures the amount of light that a sample absorbs. The instrument operates by passing a beam of light through a sample and measuring the intensity of light reaching a detector:

- *Source of UV radiation*: It is important that the power of the radiation source does not change abruptly over its wavelength range. The electrical excitation of deuterium or hydrogen at low pressure produces a continuous UV spectrum. The mechanism for this involves the formation of an excited molecular species, which breaks up to give two atomic species and an ultraviolet photon. This can be shown as

$$D_2 + \text{electrical energy} \rightarrow D_2^* \rightarrow D' + D'' + h\nu$$

- *Sources of visible radiation*: The tungsten filament lamp is commonly employed as a source of visible light. This type of lamp is used in the wavelength range of 350–2500 nm. The energy emitted by a tungsten filament lamp is proportional to the fourth power of the operating voltage. Tungsten lamps contain a small amount of iodine in a quartz 'envelope' that also contains the tungsten filament. The iodine reacts with gaseous tungsten, formed by sublimation, producing the volatile compound WI_2.
- *Cuvettes*: The containers for the sample and reference solution must be transparent to the radiation, which will pass through them. Quartz or fused silica cuvettes are required for spectroscopy in the UV region. These cells are also transparent in the visible region. Silicate glasses can be used for the manufacture of cuvettes for use between 350 and 2000 nm.
- *Detectors*: The photomultiplier tube is a commonly used detector in UV–vis spectroscopy. It consists of a photoemissive cathode (a cathode that emits electrons when struck by photons of radiation), several dynodes (which emit several electrons for each electron striking them), and an anode. Photomultipliers are very sensitive to UV and visible radiation. They have fast response times. Intense light damages photomultipliers; they are limited to measuring low-power radiation.

When the sample absorbs light, its intensity is lowered. The photoelectric cells (P1 and P2 in Figure 4) will receive an intense beam from the reference cell and weak beam from the sample cell. It generates alternating current that flows from the photoelectric cell to the electronic amplifier. The amplifier is coupled to small motor that in turn is coupled to pen recorder. Thus, it records the absorption bands automatically. The amplifier coupled with motor drives an optical wedge into the reference beam until photoelectric cell receives light of equal intensities from the sample as well as the reference beam.

UV spectroscopy and food and health

Food is a complex system comprising water, proteins, carbohydrates, and fats, together with many other minor components. Appearance, color, flavor, and texture are important aspects of sensory quality of food. The demand for good quality of food and safety in food production requires appropriate analytic tools to investigate food. UV–visible spectroscopy has been useful in the analysis of food additives, food preservatives, flavors, fat content, enzymes, glucose, flavoring minerals, vitamins, etc. Food additives and preservatives help to keep the product's life span longer and make the product healthier for consumer. The UV–visible spectroscopy has been mainly used to examine the quality of edible oils. It has been used in the determination of anisidine value, peroxide value, and color of the edible oils. In most of the analytic methods, UV–visible spectrophotometer is used as a detector coupled with either GC or HPLC systems.

Vibrational Spectroscopy

Infrared spectroscopy

The 'infrared' covers the range of the electromagnetic spectrum between 0.78 and 1000 mm. Unlike ultraviolet spectrum that consists of relatively few peaks, the IR spectrum contains a large number of absorption bands. These bands provide a wealth of information about the structure of an organic compound. IR radiation causes the excitation of the vibrations of covalent bonds within the molecule. These vibrations include

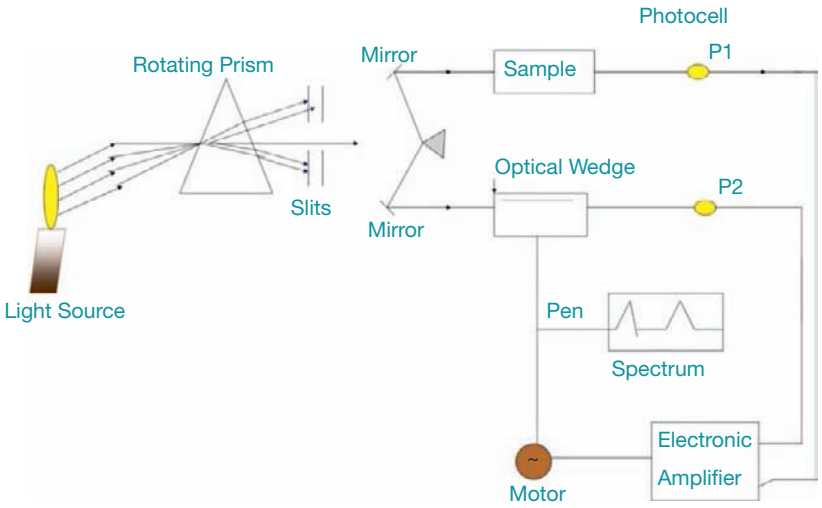

Figure 4 Block diagram of ultraviolet spectrophotometer.

the stretching and bending modes. An infrared spectrum is commonly obtained by passing infrared radiation through a sample and determining what fraction of the incident radiation is absorbed at a particular energy. IR absorption positions are generally presented as either wave numbers ($\bar{\upsilon}$) or wavelengths (λ). For a molecule to show IR absorptions, it must possess a specific feature, that is, an electric dipole moment of the molecule must change during the vibration. This is the selection rule for infrared spectroscopy.

Region	*Wavelength range (mm)*	*Wave number range (cm^{-1})*
Near	0.78–2.5	12 800–4000
Middle	2.5–50	4000–200
Far	50–1000	200–10

Principle

The molecules have to fulfill certain requirements to absorb IR radiations:

- The natural frequency of vibrations of some part of a molecule should be the same as the frequency of incident radiation.
- Its absorption should cause a change in the molecule electric dipole (dipole moment).

Molecular vibrations

Each atom has three degrees of freedom, corresponding to motions along any of the three Cartesian coordinate axes (x, y, and z). Linear molecules possess $3N–5$ fundamental vibrational modes, while nonlinear molecules have $3N–6$ vibrational modes. Among the $3N–6$ or $3N–5$ fundamental vibrations (normal modes of vibration), those that produce a net change in the dipole moment may result in an IR activity, and those that give polarizability changes may give rise to Raman activity.

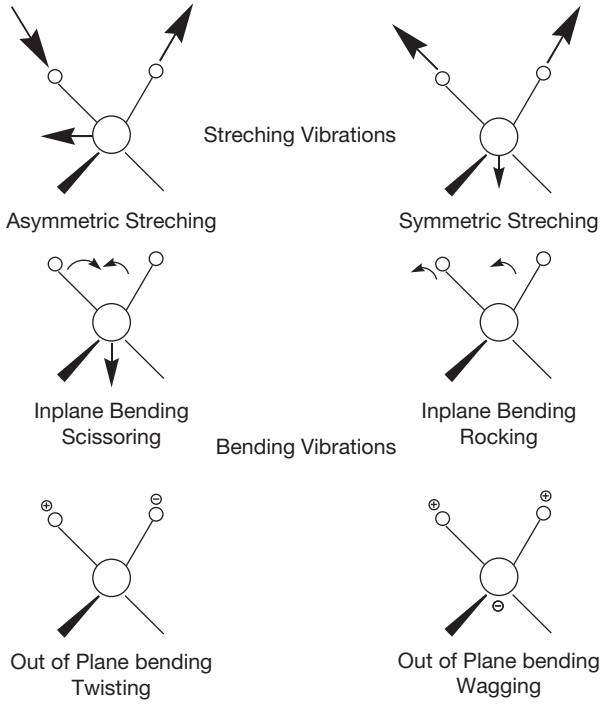

Figure 5 Different types of vibrational modes for a nonlinear CH_2 group.

Naturally, some vibrations can be both IR-active and Raman-active. The major types of molecular vibrations are stretching and bending. The various types of vibrations are illustrated in Figure 5.

Infrared radiation is absorbed, and the associated energy is converted into these types of motions. The absorption involves discrete, quantized energy levels. However, the individual vibrational motion is usually accompanied by other rotational motions. These combinations lead to the absorption bands, not the discrete lines, commonly observed in the mid-IR region. Each of the vibration modes may give rise to a different

absorption band, so that CH_2 group gives rise to two C–H stretching bands at ν_{sym} and ν_{anti}. Some of them have the same frequency and they may overlap. It is also necessary that a particular vibration should produce a fluctuating dipole; otherwise, it cannot interact with electric field of the infrared light.

Vibrational frequency

The stretching vibrational frequency of a bond is calculated accurately by applying 'Hooke's law,' which is represented as follows:

$$\overline{\upsilon} = 1/2\pi c(k/\mu)^{1/2}$$

where 'μ' is the reduced mass, m_1 and m_2 are masses of the atoms concerned in grams, k is the force constant of the bond and relates to the strength of the bond, and c is the velocity of radiation.

IR spectroscopy and food and health

IR spectroscopy is mainly used to distinguish the organic compounds on the basis of carbonyl group stretching frequency. As far as food science is concerned, the use of near IR (NIR) region is of significant importance. NIR uses the range from 780 to 2500 nm. The record of NIR region involves the response of molecular bonds O–H, C–H, C–O, and N–H. There is an extensive use of NIR technique in the field of milk and dairy products. IR spectroscopy is useful in the identification of a variety of adulteration problems using experimental and statistical methods. NIR is another rapid, reliable, and nondestructive technique widely used for quality and processing control for the characterization of various food products without using reagents or solvents. Spectroscopic methods act as state of art to test various food supplements.

Raman spectroscopy

The phenomenon of Raman scattering was discovered in 1928 by Indian physicist C. V. Raman, who received the Nobel Prize in Physics in 1930 for his work. Raman spectroscopy provides information about the molecular vibrations that can be used for sample identification and quantification. Raman spectroscopy can be used to study the solid, liquid, and gaseous samples. This technique involves shining a monochromatic region source on a sample and detection of the scattered light. Typically, in Raman spectroscopy, high-intensity laser radiation with wavelengths in either the visible or NIR regions of the spectrum is passed through a sample. The major portion of the scattered light has the same frequency as the excitation source; this is known as Rayleigh or elastic scattering. A very small portion of the scattered light has different energy from the laser frequency due to the interaction of light with the vibrational energy levels of the molecule in the sample. The shift in energy (wavelength) depends upon the chemical structure of the molecules. Plotting of intensity of this shifted light versus frequency results in a Raman spectrum of the sample. Generally, Raman spectra are plotted with respect to the laser frequency such that the Rayleigh band lies 0 cm^{-1} on the scale. On the scale, the band positions will lie at frequencies that correspond to the energy levels of different functional group vibrations. Thus, the Raman spectrum can be interpreted similar to the IR absorption spectrum.

Basic principle and its origin

The Raman spectrum is based upon molecular deformations in the electric field, E, determined by molecular polarizability, α. The high-intensity laser beam can be considered as an oscillating electromagnetic wave with electric field. Upon the interaction of electric field, E, with the sample, it induces electric dipole moment, $P = \alpha E$, which deforms the molecule. Because of periodical deformations, molecule starts vibrating with characteristic frequency. Therefore, monochromatic light with particular frequency excites molecules and transforms them into oscillating dipoles. Such oscillating dipoles emit light of three different frequencies (energies). A simplified diagram (Figure 6) illustrates these concepts. Thus, three types of phenomena can occur: (1) when the light is incident on the molecule, it interacts with the molecule, but the net energy change is zero. So, the frequency of the scattered light is the same as that of the incident light. This process is known as Rayleigh scattering (2) When the light is incident and the material absorbs energy and the emitted light photon has a lower energy than the absorbed photon, this outcome is labeled as Stokes Raman scattering (3) When the light is incident on the molecule and the molecule loses energy and the emitted photon has a higher energy than the absorbed photon, this process is known as anti-Stokes Raman scattering.

Raman shift

Raman shifts are typically reported in wave numbers, as this value is directly related to energy. The following formula is used:

$$\Delta\omega = \left(\frac{1}{\lambda_0(\text{nm})} - \frac{1}{\lambda_1(\text{nm})}\right)$$

where '$\Delta\omega$' is the Raman shift expressed in wave number, λ_0 is the excitation wavelength, and λ_1 is the Raman spectrum wavelength. Most commonly, the unit used for expressing wave number in Raman spectra is cm^{-1}. Since wavelength is often expressed in units of nanometers (nm), the aforementioned formula can be expressed as

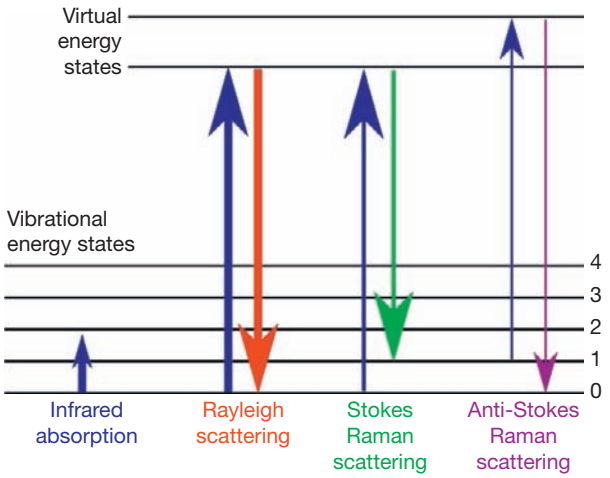

Figure 6 Mechanism of Raman scattering.

$$\Delta\omega\,(\mathrm{cm}^{-1}) = \left(\frac{1}{\lambda_0(\mathrm{nm})} - \frac{1}{\lambda_1(\mathrm{nm})}\right) \times \frac{10^7\,\mathrm{nm}}{\mathrm{cm}}$$

Instrumentation

A Raman spectrometer consists of an excitation source, a monochromator, a sample holder, and a detector. Two major types of techniques are used to collect the Raman spectra: dispersive Raman spectroscopy and Fourier transform Raman spectroscopy. These differ from one another in terms of the laser source used and the way by which the Raman scattering is detected and analyzed. Several types of lasers can be used as excitation sources, like argon ion (488.0 and 514.5 nm), krypton ion (530.9 and 647.1 nm), He:Ne (632.8 nm), and diode laser (630 and 780 nm). Nowadays, more and more often researchers use multichannel detectors like photodiode detector or more commonly charged coupled devices to detect the Raman scattering light.

It was found that Raman signals are quite weak and people are constantly trying to improve Raman spectroscopy techniques. Surface-enhanced Raman spectroscopy (SERS), confocal Raman spectroscopy, coherent anti-Stokes Raman scattering, resonance Raman spectroscopy, and Raman sensing are new advancements in the field of Raman spectroscopy, which increase the sensitivity of this technique.

Raman spectroscopy and food and health

The study of biomolecules with Raman spectroscopy helps in the evaluation of quality of natural food products as it provides information about the change in the structure of proteins, lipids, and water of muscle food, which occurs during deterioration. SERS with gold-coated substrates was used to analyze phosmet, a pesticide in apples. SERS can be used to target specific DNA and RNA sequences using a combination of gold and silver nanoparticles and Raman-active dyes. The gold nanoparticles facilitate the formation of a silver coating on the dye-labeled regions of DNA or RNA, thus allowing SERS to be performed. Raman gas analyzers have many practical applications. For instance, they are used in medicine for real-time monitoring of anesthetic and respiratory gas mixtures during surgery. Raman spectra were used to differentiate between the normal and diseased tissues and different chemical stages of cells and tissues. Raman techniques can be used as an alternative tool for the detection of cancer as they have been used for the determination of the nature of tumor.

Electron Paramagnetic Resonance Spectroscopy

Electron paramagnetic resonance (EPR) spectroscopy or ESR is a nondestructive analytic technique with a variety of applications that include oxidation and reduction processes, biradicals and triplet-state molecules, and reaction kinetics, as well as numerous additional applications in medicine, biology, and physics. Its basic principle is similar to NMR, but it is electron spins that are excited instead of spins of atomic nuclei. ESR technique is less widely used as compared to NMR as all stable molecules have all their spins paired.

Principle

The basis of EPR lies in the spin of electron and its associated magnetic moment. Every electron has magnetic moment and spin quantum number, $s=1/2$, with magnetic components, $ms=+1/2$ and $ms=-1/2$. When the electron is placed in applied magnetic field, B_0, the two possible spin states of the electron have different energies. The lower energy state occurs when the magnetic moment of the electron, μ, is aligned with the magnetic field and a higher energy state occurs when μ is aligned against the magnetic field. The two energy states are labeled by the projection of electron spin, ms, on the direction of magnetic field, where $ms=-1/2$ is the parallel state and $ms=+1/2$ is the antiparallel state (Figure 7). So for a molecular species with one unpaired electron, the energy state of the electron can be defined as $E=g\mu B_0 ms=\pm 1/2 g\mu B_0$:

$$\Delta E = g\mu B0$$

where 'g' is electron's so-called g-factor, $g=2.0023$ for the free electron, and 'μ' is the Bohr magneton.

An unpaired electron can move between the two energy levels by either absorbing or emitting a photon of energy $h\nu$ such that the resonance condition, $h\nu=\Delta E$, is obeyed. This leads to the fundamental equation of EPR spectroscopy, $\Delta E=g\mu B_0$.

The EPR measurements are made with microwaves in the 9000–10 000 MHz (9–10 GHz) region. Furthermore, EPR spectra can be generated by either varying the photon frequency incident on a sample while keeping the magnetic field constant or doing the reverse. In practice, it is usually the frequency that is kept fixed. A collection of paramagnetic centers, such as free radicals, is exposed to microwaves at a fixed frequency. When the strength of external magnetic field is increased, the gap between $ms=+1/2$ and $ms=-1/2$ energy states is widened until it matches the energy (frequency) of the microwaves. At this point, the unpaired electrons can move between their two spin states. Since there typically are more electrons in the lower state, due to the Maxwell–Boltzmann distribution, there is a net absorption of energy, and thus, the absorption observed is converted into a spectrum.

Hyperfine coupling

Since an EPR spectrum is produced as a result of a change in an electron's spin state, it might be thought that all EPR spectra for a single electron spin would consist of a single line. However, in the actual practice, an unpaired electron, by way of its

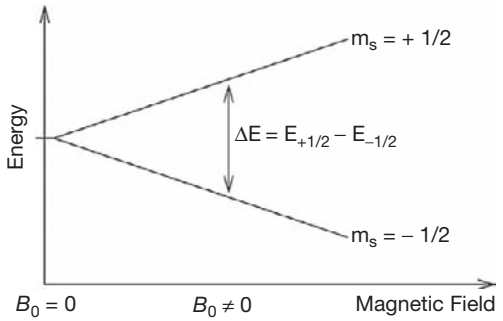

Figure 7 Splitting pattern of energy states of electron as a function of magnetic field.

magnetic moment, interacts with nearby nuclear spins. The resulting interaction between the electron and nuclei is called hyperfine splitting. As a result of hyperfine splitting, a multilined spectrum is obtained. Hyperfine interactions provide a great deal of information about the sample including providing information about the number and identity of nuclei in a complex as well as their distance from the unpaired electron. Thus, the previous equation gets modified to $E = g\mu B_0 ms + amsmi$.

where 'a' is the hyperfine coupling constant and mi is the nuclear spin quantum number for the neighboring nucleus. The coupling patterns that are observed in EPR spectra are determined by the same rules that apply to NMR. So the number of lines that result from the coupling can be determined by the formula $2nI+1$, where n is the number of equivalent nuclei and 'I' is the spin. This formula gives only the number of lines and not their relative intensities. Coupling to n equivalent nuclei, each with spin ½, gives '$n+1$' lines. But since there are multiple nuclei interacting, the relative intensities of the lines follow the binomial distribution as shown in the succeeding text.

Number of equivalent nuclei	*Relative intensities*
1	1:1
2	1:2:1
3	1:3:3:1
4	1:4:6:4:1
5	1:5:10:10:5:1
6	1:6:15:20:15:6:1

For example, the EPR spectrum of the radical anion of benzene $(C_6H_6)^-$ gives seven lines with relative intensity, 1:6:15:20:15:6:1, as the electron is delocalized over six equivalent hydrogen atoms.

If an electron couples with several sets of nuclei, then the overall pattern is determined by first applying the coupling to the nearest nuclei and then further splitting of each line by the coupling to the next nearest nuclei and so on, for example, radical anion of pyrazine, where coupling to two nearest equivalent N^{14} ($I=1$) nuclei gives a quintet with relative intensities: 1:2:3:2:1.

ESR spectroscopy and food and health

1. Food irradiation is used to destroy microorganisms, parasites, molds, yeasts, and insects, which are responsible for deterioration and spoilage reduction of the quality of food. In this process, the radiations inhibit the division of microorganisms and create radiolytic products and free radicals. Free radicals in wet samples decay in a fraction of seconds with the formation of neutral species. These radicals are quite stable in a dry environment. Their concentration in rigid matrices is quite low but high enough to be detected by EPR spectroscopy. The direct detection of persistent radicals by ESR is usually possible in dry foods. In the ESR spectrum of dry foods, generally, a single line with a g-value ranging between 2.003 and 2.006 and a peak-to-peak line width between 4 and 12 G are observed. However, in many cases, a sextet of lines due to the presence of Mn^{2+} is obtained, which is frequently observed in the ESR spectra of biological systems.
2. ESR spectroscopy can be used to study the oxidative processes in food and beverages. Oxidative reactions in the food cause the spoilage of food and affect the shelf life and quality of food. The oxidation of lipids causes rancidity, the oxidation of proteins results in off-flavors, the oxidation of vitamins and polyunsaturated fatty acids reduces the nutritional value, while the oxidation of food pigments leads to discoloration. Radicals are intermediates in many of these reactions. Therefore, ESR can be used to study the early stages of these reactions and for designing protective measures against oxidation of food.

NMR Spectroscopy

Over the last 50 years, NMR has become the prominent technique for the determination of organic molecules. NMR was first described and measured in molecular beams by Isidor Rabi in 1938. In 1944, Rabi was awarded the Nobel Prize in Physics for this work. In 1946, Felix Bloch and Edward Mills Purcell expanded the technique for use on liquids and solids, for which they shared Nobel Prize in Physics in 1952. It is an analytical chemistry technique that is used in quality control and research for determining the content and purity of sample as well as its molecular structure. It has become one of the most powerful techniques for the determination of molecular structure, now extending to species as large as proteins. It is also routinely used in advanced medical imaging techniques, such as in magnetic resonance imaging (MRI).

Basic theory and principle

NMR is based on the absorption of electromagnetic radiation in the radiofrequency region of the spectrum resulting in changes in the orientation of spinning nuclei in a magnetic field. This technique is exclusively applicable for nuclei with spin, $I \neq 0$. In the presence of magnetic field, these nuclei become nondegenerate due to differences in the spin. The application of electromagnetic radiation can excite the nuclei into higher energy level. The frequency that causes the excitation is determined by the difference in energy between energy levels.

Commonly used solvents in NMR are carbon tetrachloride (CCl_4), deuterochloroform ($CDCl_3$), deuterodimethyl sulfoxide (DMSO-d6), deutero water (D_20), deuterobenzene (C_6D_6), and trifluoroacetic acid, and trimethylsilane (TMS) is used as internal standard in NMR.

Chemical shift

It expresses the difference in the resonance frequency of a given proton compared with that of the methyl protons of TMS. Chemical shift is usually expressed in parts per million:

$$\text{Chemical shift}\,(\delta) = \frac{\text{Diiference between a resonance frequency and that of reference substance}}{\text{Operating frequency of the spectrometer}}\,(\text{ppm})$$

Chemical shift is affected by the shielding and deshielding of the concerned nucleus.

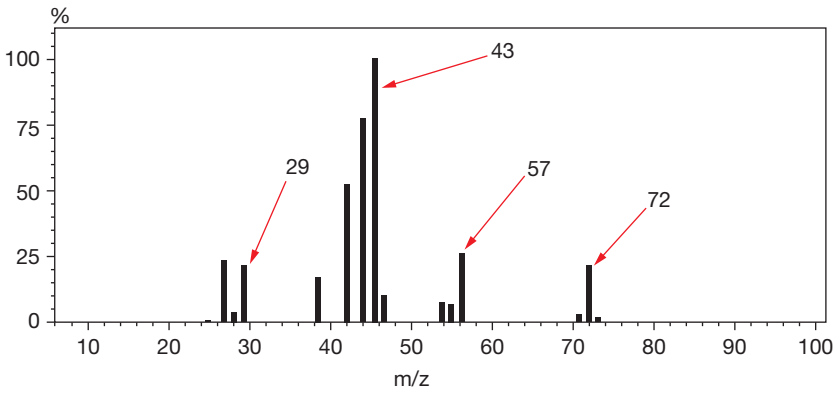

Figure 8 Mass spectrum of pentane.

NMR and food and health

The major application of NMR is MRI, which is an important tool in the diagnosis and evaluation of diseases. It is a test that uses the strong magnetic field and pulses of radio wave to make detailed images of organs and structures inside the body. MRI scan can be used to examine almost any part of the body including the brain and spinal cord, bones and joints, breasts, heart and blood vessels, and liver, uterus, and prostate gland. The results of an MRI scan are used to help diagnose conditions, plan treatments, and assess how effective previous treatment has been. MRI scan is the best way to see inside the human body without cutting it out:

1. Due to the fact that many foods are proton-rich due to the presence of water, carbohydrate, and proteins, proton NMR becomes the most common type of NMR to determine these abundant food components. These components influence the intrinsic properties of food during processing, storage, and transportation. NMR is used in fat analysis and fatty acid composition.

Mass Spectrometry

Mass spectrometry is a powerful analytic laboratory technique used to quantify the known material, to identify unknown compounds present in a sample, and to elucidate the chemical structure of different molecules. The complete process involves the conversion of sample into gaseous ions, with or without fragmentation, followed by the characterization by their mass-to-charge ratio (m/z) and relative abundances. It is based upon slightly different principles to other spectroscopic principles.

Basic principle

The mass spectrometer generates multiple ions from the sample under investigation; it then sorts and separates according to their specific mass-to-charge ratio and then records the relative abundance of each ion type. The first step in the mass spectrometric analysis is vaporization and ionization basically by electron ionization. These molecular ions undergo fragmentation. The ions are then accelerated through a potential difference and focused into a beam. The charged particles passing through a magnetic field are deflected along a circular path on a radius that is proportional to the mass-to-charge ratio, m/z. The ions are separated according to their mass-to-charge ratio and are detected in proportion to their abundance. Thus, the mass spectrum of a molecule is produced. It displays the result in the form of a plot of ion abundance versus mass-to-charge ratio.

The ionization process may be represented as

$$\underset{\text{Molecule}}{\text{M}} : +e^- \rightarrow \underset{\text{Molecule ions}}{2e^- + \text{M}^+} \rightarrow \underset{\text{Fragment ions}}{m_1^+ + m_2}$$

Components of instruments

The instrument consists of three major components:

1. *Ion source*: For producing gaseous ions from the sample being studied
2. *Mass analyzer*: For resolving the ions into their characteristic mass components according to m/z.
3. *Detector*: For detecting the ions and recording the relative abundance of each of the resolved ionic species

The mass spectrum

A mass spectrum is usually presented as a vertical bar graph, in which each bar represents an ion having a particular m/z ratio and the length of bar represents the relative abundance of that ion in the sample. The most intense ion is assigned an abundance of 100, and it is referred as the base peak. Most of the ions formed have a single charge so the m/z value is equal to the mass itself. A few compounds have mass spectra that do not contain molecular ion peak, because all the molecular ions break into fragments. A typical mass spectrum of pentane (C_5H_{12}) is shown in Figure 8 in which $m/z = 43$ is the base peak.

Mass spectroscopy in food and health

As far as health science is concerned, the sample used for MS study may include body fluid such as urine, blood, serum, and saliva or tissue samples such as blood cells. MS is based on the breakdown of sample into charged ions. MS has widespread applications and is used in the identification of proteins, peptides, and oligonucleotides.

Spices and Flavoring Crops: Fruits and Seeds

L Wilson, University of Iowa, Ames, IA, USA

© 2016 Elsevier Ltd. All rights reserved.

This article is a revision of the article Spices and Flavoring Crops | Fruits and Seeds by G D Bagchi and G N Srivastava from the Encyclopedia of Food Sciences and Nutrition, volume 9, pp. 5465–5477, © 2003, Elsevier Science Ltd.

Introduction

There are about 30 types of fruits and seeds that are commonly used as spices and for flavoring purposes throughout the world. Their frequency of use varies in different parts of the world. In this article, some of the most commonly used spices and flavoring crops are discussed in detail, and the remaining equally important ones are summarized in Table 1: each section deals with an individual spice in terms of its common name, botanical name, family, and parts used, along with diagnostic, morphological, and anatomical characters; details of handling, drying, and storage have also been given wherever available. Additionally, information about antioxidant content and antifungal or bacterial properties has been given where applicable.

Allspice or Pimento

Allspice consists of the dried fruits of *Pimenta officinalis* Lindl. (Myrtaceae). Dried berries are globular, 4–7 mm in diameter, hard, and dark reddish brown; the surface of the berry is rough with protuberances, and the apex bears the remains of the calyx and the style; there is a short stalk, or its scar at the base. The berries are bilocular each with hard, dark brown, reniform seeds (Figure 1(a) and 1(b)).

The epidermis of the exocarp bears stomata and nonglandular hairs up to 150 μm in length. The mesocarp, toward the outside, consists of numerous oval or rounded oil cavities up to 210 μm in diameter; numerous scattered, variable, pitted stone cells occur singly or in groups; beneath, there is a zone of fibrovascular bundles; ground tissue is parenchymatous and contains 'rosette' calcium oxalate crystals. A group of stone cells, 30–60 μm in diameter, are present toward the inner side. The endocarp consists of a few layers of compressed parenchyma (Figure 1(c)).

Allspice is aromatic and pungent and possesses the flavor and aroma of clove, nutmeg, cinnamon, and black pepper, hence the name 'allspice.' Mature berries are removed from the twig when still green by hand or flail, sorted, and dried in the sun for 6–8 days; when dull reddish brown, the berries are packed in jute bags. At present, sun-drying of berries is done on a concrete barbeque. Because of frequent shifting of the berries in and out of the sheds during rainy days, many berries break. Hence, mechanical drying is preferable, and it is also more economical than sun-drying.

Anise

Anise is the dried fruit of *Pimpinella anisum* L. (Apiaceae). The schizocarps are 2–5 mm, ovoid–conical, grayish brown, and pubescent, with a pedicel attached; they are crowned with a short, bifurcate stylopod. The mericarps, attached to the carpophore, are broadly ovoid; they are flat or concave on the commissural side and convex and pubescent on the dorsal side (Figure 1(d) and 1(c)).

The exocarp has an outer striated cuticle with stomata and rectangular epidermal cells bearing surface hairs up to 150 μm in length. The mesocarp consists of five fibrovascular bundles underlying ridges, 2–4 vittae on the commissural side and 20–40 vittae on the dorsal side. The endosperm of the seed is composed of thick-walled parenchymatous cells containing oil and aleurone grains and one or two small 'rosette' calcium oxalate crystals (Figure 1(f) and 1(g)).

Anise has a characteristic and agreeable aromatic odor and a pleasant taste. Fruits are harvested when their color changes from green to gray; shattering is minimized by avoiding overripening and harvesting during the morning with scythes or reaping machines. The crop is piled into small stacks and allowed to wither for 2–3 days; it is then threshed and dried in partial shade. After winnowing, sieving, and cleaning, the crop is dried naturally to 18% moisture followed by artificial drying at 80–90 °C; it is then packed and stored in a cool, dry room. For keeping spices belonging to family Apiaceae, the maximum tolerance limit of moisture is 10%. Reducing the moisture below 8% can generally have a bad effect on the quality due to loss of volatile oils. Crushed or ground spice is stored in airtight containers.

Anise extract functions as an antimicrobial agent for *Proteus mirabilis*, *Citrobacter koseri*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Enterobacter aerogenes*, *Micrococcus luteus*, *Staphylococcus epidermidis*, and *Candida albicans*. Additionally, anise was shown to contain antioxidants powerful enough to pass the same tests as common synthetic antioxidants such as BHA and BHT.

Black Pepper

Black pepper consists of the dried, unripe fruit of *Piper nigrum* L. (Piperaceae). It is the oldest and most important spice and commonly known as the 'king of spices.' There are about a hundred cultivars of black pepper under cultivation. There is considerable variability among the accessions with regard to various morphological as well as floral characters like leaf shape, size, spike length, density, composition of male, female, and bisexual flowers in the spike, fruit set, shape, weight and volume of the fruit, and time taken for maturity. The fruit, though known as a berry, is a sessile globose drupe with a pulpy pericarp. The berry is globular, 6 mm or less in diameter, brownish black, with a coarsely reticulate surface, and single-seeded. The seed is almost white hollow and adheres to the pericarp (Figure 1(h) and 1(i)).

Table 1 Some other commonly used spices from fruits and seeds

Botanical name	*Common name*	*Family*	*Part used*	*Characters*
Aframomum korarima (Pereira) Engler	Korarima cardamom	Zingiberaceae	Fruit and seed	Fruits ovate, about 4 cm by 2 cm pointed seeds reddish brown, striated
Aframomum melegueta (Rosc.) K. Schum.	Grains of paradise	Zingiberaceae	Fruit and seed	Fruits ovoid 10 cm long, pointed. Seeds inverted subpyramidal, somewhat four-sided, 2–3 mm by 2.5 mm, testa rich reddish brown, papillose
Amomum subulatum Roxb.	Greater or Nepal cardamom	Zingiberaceae	Fruit and seed	Fruit is dark red-brown, globose capsule, 2.5 cm long; several cardamom seeds, similar to true cardamom, embedded in a vicid pulp
Bunium persicum (Boiss.) Fedts	Black caraway	Apiaceae	Fruit	Mericarp oblong (3–4 mm by 0.7–1.0 mm), yellowish dark brown with ridges
Dipteryx odorata Willd.	Tonka beans	Fabaceae	Fruit	Fruit egg-shaped with hard shell and pulpy flesh surrounding a single seed with a black wrinkled surface
Garcinia indica Choisy	Kokam	Clusiaceae	Fruit	Fruit globose or spherical 2.0–3.75 cm in diameter, dark purple when ripe
Juniperus communis L.	Juniper	Pinaceae	Fruit	Fruit subglobose, 5–9 mm in diameter externally smooth, shining, purplish black to dusky red purple internally yellowish brown to dusky yellow flesh, containing many large, schizogenous cavities; ripe fruits are collected, and dried flavor diminishes after storing fruits for more than a year
Mangifera indica L.	Amchoor	Anacardiaceae	Fruit	Fruit a drupe, variable in form and size, leathery, dotted with glands; mesocarp of unripe fruit hard, acidic; ripe fruits juicy; endocarp stony; skin of unripe fruit removed, mesocarp sliced and dried in sun; the dried product is packed in wooden casks and may also be seasoned before drying
Nigella sativa L.	Black cumin	Ranunculaceae	Seed	Seeds trigonous, black, rugulose, and tuberculate; seeds are collected mostly from wild plants
Piper cubeba Linn. f.	Cubeb	Piperaceae	Fruit	Fruit globular, 3–6 mm in diameter with a stem-like portion about 7 mm long, apex with four remains of stigma; dusky red, brown or, rarely, grayish; coarsely reticulate; nearly full grown fruits are collected and dried in sun
Piper longum L.	Long pepper	Piperaceae	Fruit	Catkin is subcylindrical, up to 40 mm by 5–7 mm; grayish black and composed of numerous small immature drupes and bracts embedded spirally in the axis; immature catkins are harvested and immediately dried in the sun or oven to prevent formation of mold
Pistacia vera L.	Pistachio	Anacardiaceae	Fruit	Drupe oblong, linear to globose, laterally compressed, 10–20 mm by 6–12 mm; outer husk variously colored, readily separating from the dehiscent or indehiscent grayish white, bony keeled nutshell (endocarp) enclosing yellow to green kernel
Punica granatum L.	Anardana (pomegranate)	Punicaceae	Seed	Seeds hard, angular, covered with a juicy red, pink or yellowish white pulp; seeds of ripe fruits are taken out and sun-dried or dehydrated
Sisymbrium irio L.	London rocket (khub-kalan)	Brassicaceae	Seed	Seeds ovoid (1.3 mm long), reddish or yellowish brown, mucilaginous
Trachyspermum ammi (L.) Sprague	Bishop's weed (Ajwain)	Apiaceae	Fruit	Cremocarp ovoid (2–3 mm long), muricate, grayish brown; mericarps compressed with distinct ridges and tuberculate surface harvested when fruits turn brown; plants are pulled out and dried completely on threshing floor; fruits are separated by rubbing
Tamarindus indica L.	Tamarind	Fabaceae	Fruit	Fruits 5–20 cm by 2 cm in size; epicarp surface rough, brownish hard and brittle; mesocarp pulpy light brown changing with age to dark brown or black; containing some branched fibers and numerous seeds
Vanilla pompona Schneider	Pompon or West Indian vanilla	Orchidaceae	Fruit	Pods are 10–17.5 cm long and 2.5–3.3 cm in diameter
Vanilla tahitensis J.W. Moore	Tahitian vanilla	Orchidaceae	Fruit	Pods 12–14 cm long and about 9–10 mm wide with tapering ends; pods are harvested when tips of the pods turn brown
Xylopia aethiopica (Dunal) A. Richard	Xylopia, Netawu	Annonaceae	Fruit	Mature carpels cylindrical, incurved, about 5 cm long, embedded in the center of the receptacle; seeds glabrous, ellipsoid (about 0.5 mm by 0.25 mm), brown

Reproduced from Macrae, R., Robinson, R. K. and Sadler. M. J. (eds.) (1993). Spices and flavoring (flavoring) crops: fruits and seeds. *Encyclopedia of food science, food technology and nutrition*. London: Academic Press.

The exocarp is cutinized and darkly pigmented, with rectangular cells beneath containing calcium oxalate crystals. The hypodermis consists of stone cells interspersed with parenchyma. The mesocarp is comparatively broad: The outer seven to eight layers are parenchymatous with scattered oleoresin cells, and beneath, there is a zone of fibrovascular bundles, a region of compressed cells, a layer of large oil cells, and two layers of small parenchyma cells. The endocarp consists of a layer of 'beaker cells,' the radial and inner walls of which are strongly lignified. The seed coat is differentiated into the distinct layers; whereas the outer perisperm cells contain aleurone grains, the inner cells contain starch grains (Figure 1(k)).

The fruits are aromatic and pungent. The quality of black pepper depends upon piperine and essential oil present in the oleoresin. Piperine contributes to the pungency, and essential oil is responsible for the characteristic flavor. The harvested green berried spikes are heaped for a day and spread on a mat or floor. The berries are separated from spikes by rubbing. After separation, the berries are cleaned and put out for drying. The fresh harvested berries will have a moisture content of 80%, and this has to be dried to 8% moisture content for safe storage. A blanching treatment by dipping the berries for 1 min in boiling water gives a glossy appearance to the dried berries and reduces the microbial load on the product. Due to enzymic oxidation of color compounds present in the skin, the color of pepper turns black during drying, which effectively masks the green color that is left in the berries after drying. The berries are dried under the sun for 4–7 days until the outer skin of the berries becomes black in color with a wrinkled appearance. Small and light berries are removed from the dried produce. Berries can be dried in a solar cabinet dryer in 4 days with a spreading density of 18 kg m^{-2} and resulting in a black dried produce. By contrast, sun-dried berries take 5 days to dry with a spreading density of 5 kg m^{-2} and resulting in a dull black color. Dark black berries obtained from solar cabinet drying are preferred in trade over the dull black berries obtained from open sun-drying. Sixty kilograms of fresh pepper can be dried in the indirect heating type of dryers in about 30 h. After drying, the pepper has to be garbled. Ungarbled pepper contains fractions, dust, stalk, pinheads, and immature, overmature, and large berries. The grading is done by a combination of size sieving and weight classification by air blast. The major grade is the average-sized black pepper known as 'Malabar Garbled,' which constitutes 95% of India's export. The recovery of black pepper from fresh berries is 35–36%. For black pepper powdering, a normal pin type of hammer mill is used so that there is no temperature rise during grinding. The ground pepper is only used as a raw material for oleoresin and in the oil industry. White pepper (Figure 1(j)) is usually prepared from overripe berries. In this state, the skin comes off easily, and the resultant product is dried. White pepper fetches double the price of black pepper. The piperine content also is found to be apparently higher in white pepper due to its concentration in the endosperm of the berries. In India, the berries are dipped in water and the skin removed by rubbing with hand. The skinless berries are dried in open sun for 7 days to obtain white pepper. The skin is also removed in a pulping machine after steam cooking. At the National Research Centre for Spices in Calicut, a process of steaming and boiling the despiked pepper for 13 min and rolling it in a container in running water to remove outer skin has been developed. In some less developed countries, the berries are soaked in river water prior to skin removal and drying.

After sun-drying, the berries are cleaned and polished with a piece of cloth. The recovery of white pepper is about 28% of the fresh ripe berries. In European countries, the green or fresh flavor of pepper is desired in certain food preparations. Green pepper is made in canned and bottled forms. In the canned form, it is prepared by heat-sterilizing green berries and packing them in 2% brine solution for protection. However, the rupturing of berries and making the covering liquid turbid are problems associated with this method. These problems have been overcome with proper canning methods (commercial sterilization or 'bot cook') and the introduction of a trace of pepper oil into the can before sealing. In bottled green pepper, heat processing is avoided, but a higher salt strength of 15–20% of the covering liquid is essential for good preservation. At CFRI, undermature berries are dried by arresting the enzyme action responsible for oxidative blackening and drying by mechanical means at low temperatures. The product has an excellent green flavor.

Extract from the black pepper has been found to be an effective antimicrobial agent for *Bacillus subtilis*, *Bacillus sphaericus*, *Staphylococcus aureus*, *Klebsiella aerogenes*, and *Chromobacterium violaceum*. During the drying process of the black peppers, the antioxidants are lost, but they are available predrying and are comparable to those of anise.

Capsicum

Capsicum is composed of dried fruits of the genus *Capsicum* L. (Solanaceae). Cayenne pepper and red pepper are two of the various synonyms of *C. frutescens* L., whereas paprika is *C. annuum* L. The fruits of *C. frutescens* are 6–150 mm long, laterally compressed, musky brownish to deep red, smooth or wrinkled, and bi- to tetralocular with central placentae united at the base-apical placentae with longitudinal ridges; the seeds are numerous, discoid, flat, hard, smooth, yellow, and about 2–5 mm long (Figure 1(l) and 1(m)).

The exocarp consists of five to seven rows of subrectangular cells, 25–60 μm by 15–20 μm; the outer epidermis is cuticularized and the mesocarp is parenchymatous, 30–85 μm by 15–20 μm. Many cells contain oil droplets and chromatophores, or sandy crystals. The innermost layer consists of larger cells, 0.8–1.7 mm by 0.2–0.4 mm. The endocarp is single-layered, consisting of parenchymatous and sclerenchymatous cells, the latter directly beneath a layer of giant cells possessing thick, lignified, porous walls. The dissepiment consists of a zone of tangentially elongated, collapsed cells (some containing microcrystals) and epidermal cells on either side, radially elongated, containing capsaicin (Figure 1(n)).

The odor of the spice is characteristic, sternutatory but agreeable, and mildly to intensely pungent. The stem of the entire plant is cut, hung, and exposed to the sun to remove 80% moisture; it is then dried further in a dryer to a critical moisture level; pricking the skin longitudinally reduces the drying time. Completely dried fruits are removed by a dressing machine and packed in polythene bags. The dried peppers can then be

ground and packaged, or they can be extracted to obtain the essential oil for food and nonfood applications.

Several variations of *Capsicum* have been shown to contain antimicrobial properties in respect to *B. cereus*, *B. subtilis*, *C. albicans*, *C. sporogenes*, *C. tetani*, *E. aerogenes*, *E. Cloacae*, *E. coli*, *K. pneumonia*, *P. vulgaris*, *P. aeruginosa*, *S. typhimurium*, *S. marcescens*, *S. aureus*, *S. epidermidis*, and *S. pyogenes*. *Capsicum annuum* has been shown to contain a large amount of antioxidants.

Caraway

Caraway is the dried fruit of *Carum carvi* L. (Apiaceae). The mericarps are separated, crescent-shaped, 3–7 mm by 1–2.3 mm, and brown, with five lighter-colored, filiform primary ribs, between which, on the dorsal surface, there is a secondary rib (Figure 1(o) and 1(p)).

In the transverse section, the epicarp consists of slightly tangentially elongated epidermal cells, and its outer surface is cuticularized; the mesocarp consists of a zone of several rows of collapsed, tangentially elongated parenchymatous cells, with fibrovascular bundles located in the rib portion; large vittae, two and four in number, are present on the commissural and dorsal side, respectively; the endocarp contains inner epidermal 'cross cells' that are closely adherent to the seed coat (Figure 1(q) and 1(r)).

The odor and taste of caraway are characteristically aromatic. The endosperm structure of the seeds and handling, drying, and storage of the spice are the same as for anise.

Caraway has been proved to be an effective antibacterial agent for *Escherichia coli*, *Pseudomonas syringae* pv. *phaseolicola*, *P. syringae* pv. *Pisi*, *P. syringae* pv. *aptata*, *P. syringae* pv. *apii*, *P. syringae* pv. *atrofaciens*, *P. syringae* pv. *lachrymans*, *P. syringae* pv. *maculicola*, *P. syringae* pv. *tomato*, *P. syringae* pv. *glycinea*, *P. cichorii*, *P. viridiflava*, *P. corrugata*, *P. tolaasii*, *P. reactans*, *P. agarici*, *Erwinia carotovora* subsp. *carotovora*, *E. carotovora* subsp. *atroseptica*, *E. herbicola*, *Agrobacterium tumefaciens*, *Burkholderia gladioli* pv. *agaricicola*, *Ralstonia* solanacearum, *Xanthomonas campestris* pv. *phaseoli*, *X. campestris* pv. *phaseoli* var. *fuscans*, *X. campestris* pv. *vesicatoria*, *X. campestris* pv. *campestris*, *Bacillus megaterium*, *Clavibacter michiganensis* subsp. *michiganensis*, *C. flaccumfaciens* pv. *betae*, *and Rhodococcus fascians*. Caraway has also been shown to contain a moderate amount of antioxidants.

Cardamom

Cardamom is the dried fruit of *Elettaria cardamomum* Maton (Zingiberaceae). It is popularly known as the 'queen of spices.' There are many varieties, which are classified on the basis of their capsule size and color. Some of the important varieties are Alleppey, Mysore, Malabar, and Mangalore cardamoms. The capsules are trilocular, containing seeds on an axile placenta; they are 1–2 cm long, oblong–ovoid, three-sided, and greenish to pale buff or yellowish in color; each locule contains five to eight seeds, 3 mm by 2–3 mm, and dark reddish brown, adhering together with a membranous aril to form a single mass (Figure 1(s) and 1(t)). The pericarp in the transverse section shows an outer exocarp with cells up to 30 μm long. Parenchymatous cells of the mesocarp are up to 180 μm long, containing one or more calcium oxalate crystals. The inner mesocarp contains fibrovascular bundles and resin cells. Endocarp cells are compressed and invaginate into locular partitions (Figure 1(u)). Seeds, in the transverse section, show a three cell-layered aril containing a pale-colored substance and calcium oxalate crystals. It has an outer epidermis followed by a layer of pigmented, large, clear cells containing volatile oil, a one- to two-layered parenchyma, and a layer of sclerenchymatous, thick-walled, dark brown 'beaker cells,' each with a nodule of silica; the perisperm consists of starch-containing polygonal cells, the endosperm cells containing proteinaceous substance having a waxy or horny nature, and the embryo cells containing aleurone grains and fixed oil (Figure 1(u) and 1(v)).

The seeds are much more aromatic than the pericarp and possess a characteristically warm and slightly pungent taste. Fruits on the same raceme ripen at different times, and ripe fruits are collected before splitting. A green curing method is common in commerce. Fully mature green capsules, not having excessive shrinkage and splitting, which are not fully ripe yet, retain a good color after drying. The temperature and relative humidity of drying air inside the drying chamber are the two important factors to be controlled in the cardamom drying system. The recommended temperature for cardamom is 45–55 °C. Cardamoms are dried by different systems by kiln, driers, electric driers, or infrared driers. Cardamom drying has two phases; in the first phase, the surface moisture and moisture in fleshy parts of the mesocarp have to be removed, and in the second phase, the moisture in the seeds inside has to be removed. Controlled temperature, quick removal of the moisture, and quick flushing out of moisture-laden air from inside the drying chamber to prevent condensation are basic criteria in the retention of a green color. The dried cardamom capsules are placed into a wire mesh cylinder. The wire mesh cylinder is swung to separate the flower stalks, and the capsules are cleaned by winnowing. The cleaned capsules are packed in gunny bags lined with black polythene sheet for better retention of green color during storage. Grading of green cardamom is done according to the standard specifications at the exporter level. Extra Bold and Bold are the superior qualities.

Cardamom extract has been proved to be an effective growth inhibitor for *Staphylococcus aureus*. Additionally, cardamom has been shown to contain moderate levels of antioxidants.

Bleached Cardamom or White Cardamom

Bleached or white cardamom refers to varieties that do not retain the green color during drying or lose the color during storage. This product fetches lower prices. Freshly harvested ripe capsules are pretreated by soaking in a 1% solution of bleaching powder for 30–60 min followed by dipping the lot in dilute HCl solution (0.2–0.5%) for 2–3 min. The treated capsules are washed and sun-dried to 8% moisture level. But the sulfur dioxide content was found more in the capsule treated by the previous method; a simple treatment with hydrogen peroxide (solution of 0.5% strength) has been standardized to overcome this problem. Complete drying using a solar cabinet dryer is obtained in 3 days in comparison with 5

days under open sun-drying, and the color of the capsules is white, the required bleaching obtained without sulfur bleaching. The volatile oil in cardamom is responsible for cardamom's aroma and therapeutic properties. Green cardamom yields more oil than bleached cardamom.

Celery

Dried celery seeds are the dried fruit of *Apium graveolens* L. (Apiaceae). The schizocarps are ovoid and laterally compressed and occasionally possess a pedicel. The mericarps, usually separated, are ovoid, slightly curved, 1–2 mm by 0.5–1 mm, and light to olive brown; the commissural surface is flat and the dorsal surface convex and smooth, with five longitudinal ridges (Figure 1(w) and 1(x)).

In the transverse section, the mericarps are equilaterally pentagonal; the exocarp has a striated cuticle, and the epidermis has stomata – some of the cells are papillose; the mericarp is parenchymatous and has 4–15 vittae, of which two are on the commissural side, and fibrovascular bundles occur in each primary rib; the endocarp consists of a layer of tangentially elongated cells with yellowish orange to greenish yellow walls, and the spermoderm consists of collapsed cells. The structure of the endosperm is similar to that of anise (Figure 1(y) and 1(z)).

The fruit bears a characteristic celery aroma and taste. Celery yields 2–3% of pale yellow volatile oil, which is valued both as a fixative and as an ingredient of perfumes. Handling, drying, and storage of the spice are also similar to those of anise. The quality of celery depends upon its volatile oil content, and hence, the higher the oil content, the better the quality. The seed yield shows a significant and positive correlation between plant height, total umbels per plant, number of umbellets per umbel, weight of the main umbel, and number of seeds per umbel. All these characters have a positive effect on celery seed yield.

Coriander

Coriander spice is derived from the dried, ripe fruits of *Coriandrum sativum* L. (Apiaceae). It was one of the earliest spices used by mankind. The schizocarp is globular, yellowish brown, and 2–5 mm in diameter, with five calyx teeth and a short, conical stylopodium at the apex. Each mericarp has five prominent, straight, longitudinal primary ribs and four undulate, secondary ribs, which are easily separated, being deeply concave on the commissural side and convex on the dorsal side (Figure 2(a) and 2(b)). In the transverse section, the exocarp consists of a layer of small, thick-walled epidermal cells, and the mesocarp consists of several rows of thin-walled, somewhat collapsed parenchymatous cells, separated from a broad continuous zone of thick-walled, strongly lignified sclerenchyma fibers. The commissural side has two large elliptical vittae. The endocarp is a layer of tabular cells, and the cells of the seed coat are tangentially elongated and brownish. The structure of the endosperm is similar to that of anise (Figure 2(c) and 2(c)).

The spice has a characteristically pleasant and fragrant odor and an aromatic taste. Significant variations for oil content in coriander have been observed, ranging from 0.17% to 0.26%. The preferred cultivars of the plant for essential oil production are the small fruit varieties with a variable oil content of 4% or more. For spice use, however, it is the larger fruits from Morocco and India that are more commonly preferred. It has been reported that large thick-skinned fruits are less aromatic and have a lower oil content than the smaller thin-skinned fruits. There is no correlation between the number of fruits in the main umbel and yield. The flowers on the branches in the middle of the stalk are the most productive. It has been found that the number of umbels per plant is the chief contributing character and that the plant height determines the yield. Handling, drying, and storage are similar to those for anise.

Coriander has been proved to be an effective antibacterial agent for *B. subtilis* and *E. coli*. Additionally, there have been moderate levels of antioxidants discovered to be present in coriander.

Cumin

Cumin consists of the dried, ripe fruit of *Cuminum cyminum* L. (Apiaceae). The schizocarps are about 6 mm long, attached to short pedicels, and separated into mericarps. The fruit resembles caraway but can be distinguished by its straighter mericarps and bristly hairs along the ribs (Figure 2(e)–2(h)).

In the transverse section, the exocarp has an outer epidermis bearing stomata and a thin and striated cuticle; the hairs on the secondary ridges are larger than those on the primary ridges, being up to 2 mm long, and multicellular with broad bases and rounded apices; the mesocarp is parenchymatous, consisting of five fibrovascular bundles beneath the primary ridges, two vittae on the commissural side, and four vittae on the dorsal side. The parenchymatous cells of the endocarp have pale yellowish walls, and the seed coat consists of a layer of epidermal cells, each containing a prismatic crystal of calcium oxalate. The endosperm is similar to that of anise fruits (Figure 2(h) and 2(i)).

The spice has a peculiar, strong odor, and the flavor is warm and slightly bitter. The volatile oil content varies from 3% to 6%. The crop is piled into small stacks and allowed to wither for 2–3 days; it is then threshed and dried in partial shade. After winnowing, sieving, and cleaning, the crop is dried naturally to 18% moisture followed by artificial drying at 80–90 °C; it is then packed and stored in a cool, dry room. For keeping spices belonging to family Apiaceae, the maximum tolerance limit of moisture is 10%. Reducing the moisture below 8% can generally have a bad effect on the quality due to loss of volatile oils. Crushed or ground spice is stored in airtight containers.

Cumin has also been proved to be an effective antibacterial agent for *Escherichia coli*, *Pseudomonas syringae* pv. *phaseolicola*, *P. syringae* pv. *pisi*, *P. syringae* pv. *aptata*, *P. syringae* pv. *apii*, *P. syringae* pv. *atrofaciens*, *P. syringae* pv. *lachrymans*, *P. syringae* pv. *maculicola*, *P. syringae* pv. *tomato*, *P. syringae* pv. *glycinea*, *P. cichorii*, *P. viridiflava*, *P. corrugata*, *P. tolaasii*, *P. reactans*, *P. agarici*, *Erwinia carotovora* subsp. *carotovora*, *E. carotovora* subsp.

Additionally, cumin has been show to contain moderate levels of antioxidants.

Dill

Dill consists of the dried and ripe fruits of *Anethum graveolens* L. (Apiaceae), usually composed of separated mericarps, which are brown, glabrous, broadly oval, and compressed (about 4 by 2.5 mm) with five ribs – three short dorsal and two lateral, yellowish, and winglike (Figure 2(j)–2(m)).

The exocarp has a striated cuticle and an epidermal layer of rectangular cells bearing stomata. The parenchymatous mesocarp has three fibrovascular bundles below the dorsal ridges and two in lateral ridges. The inner side of the vascular bundles consists of several tangentially elliptical, sclerenchymatous cells having reticulate thickenings. The mesocarp has two vittae on the commissural side and four vittae on the dorsal side. The seed coat consists of a layer of epidermal cells, and the endosperm is similar to that of the anise fruits (Figure 2(m) and 2(n)).

The aromatic odor and taste of dill are similar to those of caraway. Handling, drying, and storage are as described for anise.

Dill has been proved to be an effective antimicrobial agent for *P. aeruginosa and S. flexneri*.

Fennel

The spice is the dried fruit of *Foeniculum vulgare* Miller (Apiaceae). The schizocarp is oblong–oval or elliptical, usually with long pedicels (4–5 mm by 1–3.5 mm); at the end is a short, conical stylopodium. The mericarps are attached to a divided carpophore and separate easily. Each is broadly elliptical, more or less curved (dorsal surface is convex), and light brown to light olive in color, with five prominent, longitudinal, primary ribs (Figure 2(o)–2(q)). Based on the appearance of the plant and seed and the compositional data of the volatiles from the fruit, fennel is classified into two subspecies and further classified into numerous varieties. The important varieties are the following:

- *F. vulgare* ssp. *piperitum* wild fennel
- *F. vulgare* ssp. *capillaceum* with three varieties
  (1) *F. vulgare* var. *vulgare* – bitter fennel
  (2) *F. vulgare* var. *dulce* – sweet fennels
  (3) *F. vulgare* var. *azoricum* – culinary Florence fennel

In the transverse section, the epidermis of the exocarp shows polygonal tabular cells, having occasional stomata and a smooth cuticle; the mesocarp is parenchymatous with two to four vittae on the commissural side and four vittae on the dorsal side, whereas the endocarp consists of narrow, elongated cells in a parquetry arrangement in a transverse section as long, narrow, rectangular cells with groups of short cells. The endosperm has a structure similar to that of anise (Figure 2(r) and 2(s)).

Fennel has a pleasant, aromatic odor and a taste resembling that of anise. The volatile oil content in fennel ranges from 0.7% to 6.0%. The main constituent of oil is anethole. Handling, drying, and storage of this spice are also similar to those of anise.

Fennel has been proved to be an effective antimicrobial agent for *P. aeruginosa and S. flexneri*.

Star Anise

Star anise is the ripe dried fruit of *Illicium verum* Hook. Filius (Magnoliaceae). The fruit whorl (2.5–4.5 cm in diameter) is formed of six to eight (rarely seven to nine), one-seeded, boat-shaped, woody, wrinkled, ridged, reddish brown follicles that are internally smooth, lustrous, and light brown, about 9–19 mm in length, and surmounted on a curved peduncle. The seed is light brown, compressed-ovoid, shiny, and smooth with a conspicuous hilum and raphe (Figure 2(t) and 2(u)).

In the transverse section, the exocarp consists of a striated cuticle and epidermal cells bearing stomata. The mesocarp consists of parenchymatous cells with brown contents. The cells toward the central zone are larger (up to 220 μm in length), and the inner mesocarp cells have thicker walls, the thickness increasing toward the dehiscent side of the carpel. Resin and stone cells occur scattered throughout the mesocarp, and vascular bundles occur in between the central and inner regions. The endocarp consists of thin-walled, sclerenchymatous palisade cells up to 440 μm in length. The seed coat consists of an outer, thick-walled epidermis of sclerenchymatous, pitted palisade cells up to 200 μm in length, followed by five layers of sclerenchyma and two or more layers of parenchyma containing numerous calcium oxalate crystals (Figure 2(v)). The odor and taste of star anise are anise-like. The plant starts fruiting at the age of 6 years and continues until it is over 100 years old. Fruits are collected before full maturity and dried in the sun.

Vanilla

Vanilla is the cured, fully grown, unripe fruit of *Vanilla planifolia* Andr. (Orchidaceae). The fruits are linear and flattened (120–350 mm by 5–9 mm), and both ends taper; the fruit occasionally splits into three parts in the tip; fruits are externally dusky to moderate brown, longitudinally wrinkled, and covered with minute crystals of vanillin; many minute seeds are embedded in a brownish black, balsamic fluid (Figure 2(w) and 2(x)).

In the transverse section, the outer epidermis of the epicarp shows red to brown bodies, some with calcium oxalate and vanillin crystals. The hypodermis is composed of collenchymatous cells with dark-colored contents, and the sarcocarp consists of loosely arranged, large deeply undulate parenchyma, becoming smaller on the inner side; most cells contain brownish contents and oily globules, and some have raphides of calcium oxalate up to 400 μm long. There is an interrupted circle of leptocentric fibrovascular bundles surrounded by a few spiral or pitted tracheae. The cells of the inner epidermis of the endocarp are elongated into numerous, thin-walled, nearly

straight, glandular hairs containing a gummy, resinous secretion (Figure 2(x) and 2(y)).

At the time of harvest, in the vanilla fruit or pods, the normal aromatic components forming the characteristic vanilla flavor do not exist in their final form, but appear only following a curing (fermentation) process involving enzymatic actions on glucosides, the most important of which is glucovanillin, which produces vanillin (the main aromatic component of vanilla) and sugar as a result of the action of glucosidase. Similarly, aldehydes, protocatechuic acid, benzoic acid, vanillic acids, anisic alcohol, etc. are also formed. These different compounds impart subtlety to the fragrance of natural vanillin.

The different stages of the curing methods are as follows:

(1) Cessation of the vegetative life of the bean to allow the onset of enzymatic reactions
(2) Raising of the temperature to promote this action and to stimulate at first rapid drying, thereby preventing the appearance of harmful fermentation
(3) Slower drying followed by the production of different fragrance components
(4) Conditioning of the product, during which the procedures for commercial presentation and to obtain a good preservation are carried out

The improved method involves sorting or grading, scalding or blanching, autoclaving, loading, and mechanically drying in a tunnel dryer, followed by drying in the shade. After scalding and autoclaving, the vanilla is chopped into 20 or 30 cm pieces. This leads to an acceleration of the oxidative and enzymatic reactions. The cuts are put through the dryer at a temperature of 65 °C each day. As soon as they come out, they are put into an isothermal chest for the next 24 h, with the temperature being maintained at around 50 °C. These operations are repeated for 12 days, after which a product containing 20–25% moisture is obtained, with a yield of about 4.5–1.0. The transfer to the isothermal chests after the tunnel drying is vital, in addition to equilibrate their moisture content. The process requires a series of sheds or buildings for 'sunnings' and 'sweatings' and 'mahogany sweating boxes' or 'aging boxes.' The total process takes about 5–6 months, including aging. Finally, the beans are graded, bundled, and packed in special tins lined with waxed paper.

The best-grade beans are very dark, chocolate brown in color and oily in appearance with a strong vanilla odor. Vanilla should be stored in a cool, dry place in an airtight container to stop the beans becoming brittle.

Fenugreek

Fenugreek is the dried seed of *Trigonella foenum-graecum* L. (Fabaceae). The seeds are yellowish brown, oblong–rhomboidal (2.5–5 mm by 2–3.5 mm) with an oblique furrow on one side, smooth, hard, and mucilaginous. The hilum is in a notch, the raphe short, the endosperm translucent, and the embryo waxy and yellow (Figure 3(a)–3(d)).

In the cross section, the spermoderm consists of an outer cuticle followed by a layer of palisade cells (measuring 65–70 μm by 8–20 μm) with flat bases and pointed apices, a layer of hourglass cells, and four to five layers of parenchyma. The endosperm consists of an outer layer of cells containing aleurone grains, followed by several layers of thin-walled mucilaginous cells; the embryo cells contain aleurone grains and fixed oil (Figure 3(d)).

Fenugreek possesses a strong, pleasant, sweetish odor and tastes mucilaginous, farinaceous, and slightly bitter. The pods split easily and are threshed on the floor with sticks to free the seeds. The seeds are then winnowed, cleaned, and further dried in the sun. Dried fenugreek seeds can be stored for about 2 years.

Mustard

Mustard is composed of the dried, mature seeds of the following *Brassica* L. species (Brassicaceae): *B. nigra* (L.) Koch (black mustard), *B. alba* Boiss. (white or yellow mustard), and *B. juncea* (L.) Czern & Coss. (Rye or Indian mustard).

Black mustard seeds are globular, 1–1.6 mm in diameter, dark brown to nearly black, minutely reticulate, and mucilaginous. The kernel is greenish yellow and oily (Figure 3(e) and 3(f)). White mustard seeds are spherical, about 2 mm in diameter, minutely pitted, and mucilaginous (Figure 3(h)). Indian mustard seeds resemble black mustard but are larger and brown in color.

The testa of black mustard in transverse section consists of an outer epidermis of polygonal tubular cells, 40–50 μm long, containing mucilage; hypodermis consists of empty, polygonal cells, 10–105 μm by 60–90 μm; the inner epidermis of testa consists of slightly lignified, palisade cells (unequal in height), followed by cells of tegmen containing tannin. The endosperm has an outer aleurone layer of thick-walled cells containing fixed oil and aleurone grains and an underlying layer of collapsed cells. Embryo cells are polyhedral and thin-walled, containing fixed oil and aleurone grains (Figure 3(g)). White mustard in the transverse section resembles black mustard but differs in that it has two layers of somewhat collenchymatous cells beneath the epidermis of the testa; the palisade cells have no tannin (Figure 3(i)).

Black mustard is slightly odorous and tastes acrid and pungent when crushed and moistened. White mustard seed is not pungent. The fruits are harvested when they begin to turn yellow. Then, they are threshed by beating with wooden mallets. The threshed seeds are separated from the husks by winnowing and then dried in the sun for a couple of days. Seeds are stored in seed bins or gunny bags. Storage of the whole seed for 12 months reduces the volatile oil content by 54%, but for ground seeds, the loss is 84%.

Nutmeg and Mace

Nutmeg is the dried kernel, and mace is the dried aril of the seed of *Myristica fragrans* Houtt. (Myristicaceae). The kernel constitutes 16–17% and mace constitutes 2.0–2.5% by weight of the fruit. Nutmegs are ovoid (2–3.5 cm by 1.5–3 cm) and the kernels are grayish brown externally and reticulately marked with small furrows. Numerous minute, dark reddish brown points and lines, constituting a thin layer of perisperm,

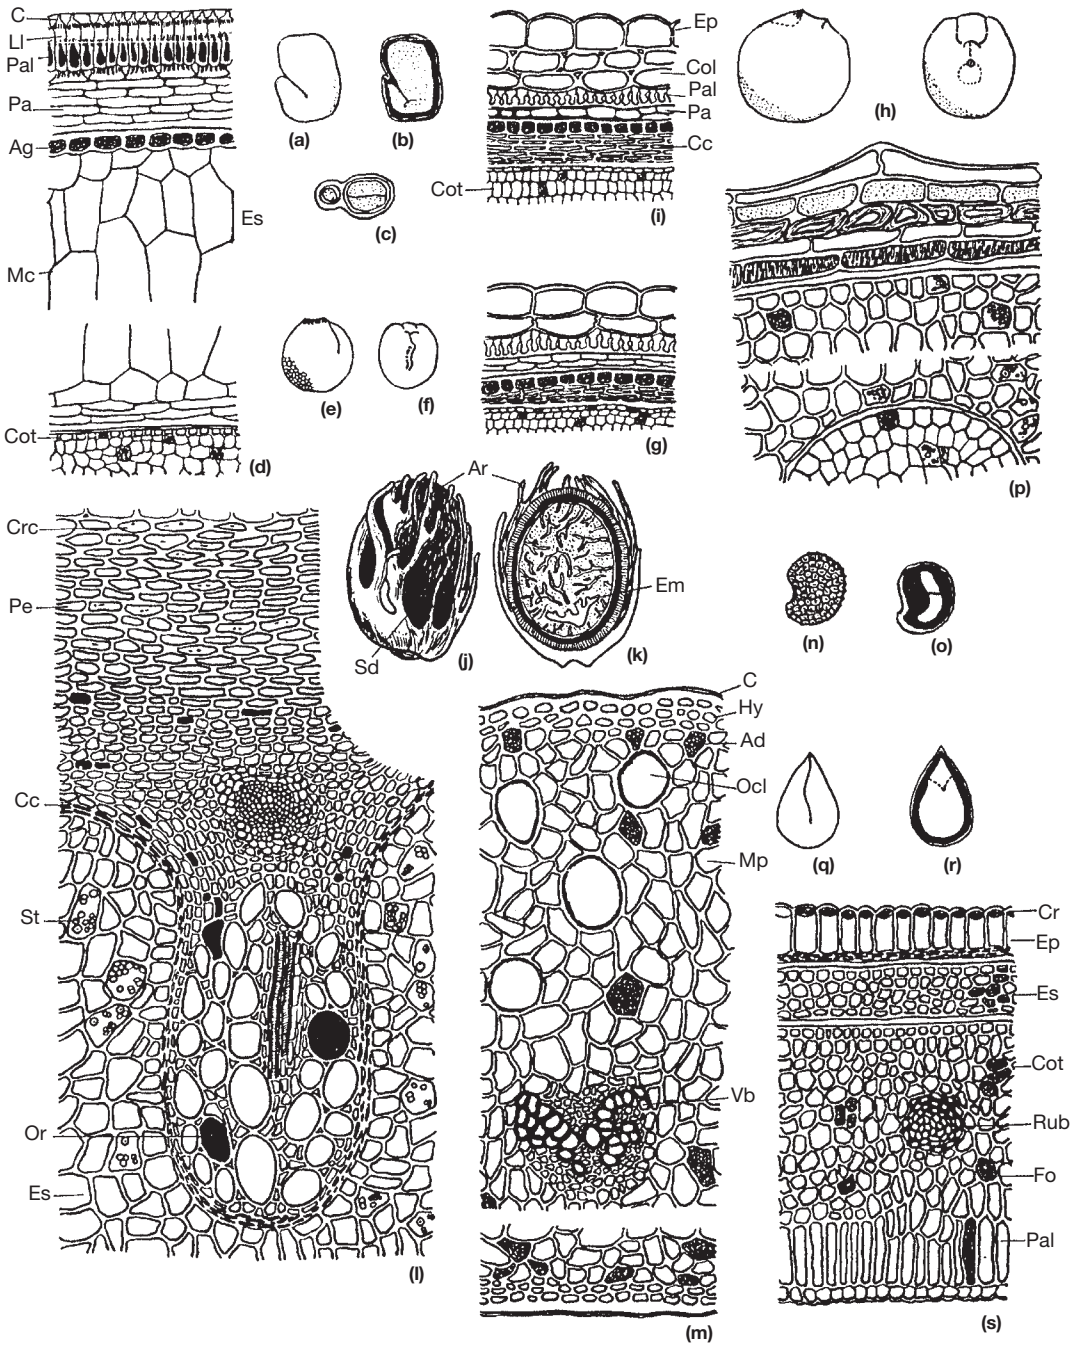

Figure 3 Spices from seeds. Fenugreek: (a) seed; (b) longitudinal section of seed; (c) transverse section of seed; (d) cross section through seed coat, endosperm and part of cotyledon. Mustard black: (e, f) seed; (g) cross section through seed coat, endosperm and part of cotyledon; (h) Mustard, white or yellow; (i) cross section through seed coat, endosperm and part of cotyledon. Nutmeg and mace: (j) nutmeg surrounded by mace; (k) same as (j), cut longitudinally; (l) cross section through perisperm and endosperm of nutmeg; (m) cross section through mace. Poppy: (n, o) seed; (p) cross section through seed coat, endosperm and part of cotyledon. Sesame: (a, r) seed; (s) cross section of seed. Abbreviations: Ad, amylodextrin granules; Ag, aleurone grains; Ar, aril; Bc, beaded cells; Bel, beaker cells; C, cuticle; Cc, compressed cells; Ch, chloroplast, Col, collenchyma; Cot, cotyledon; Cp, carpophore; Cr, crystal; Crc, crystal cells; Cro, cross cells; Dl, dehiscence line; Em, embryo; End, endocarp; Ep, epidermis; Es, endosperm; Exo, exocarp; Fl, fiber layer; Fo, fixed oil; Gc, giant cell; H, hair; Hc, hourglass cells; Hp, horny protein; Hy, hypodermis; Li, light line; Mc, mucilage cells; Mes, mesocarp; Mp, mesophyll; O, oil; Oc, oil cavity; Ocl, oil cells; Or, oleoresin; P, pedicel; Pa, parenchyma; Pal, palisade; Pe, perisperm; Pl, placenta; R, raphe; Rc, reticulated cells; Re, resin; Rub, rudimentary vascular bundle; Sc, seed coat; Scl, sclerenchyma; Sd, seed; Se, secretory cells; St, starch; Stc, stone cells; V, vittae; Vb, vascular bundle. Reproduced from Macrae, R., Robinson, R. K. and Sadler. M. J. (eds.) (1993). Spices and flavoring (flavoring) crops: fruits and seeds. *Encyclopedia of food science, food technology and nutrition*. London: Academic Press.

grow inward into the endosperm at the furrows; the hilum lies in a small, circular depression at one end (Figure 3(j) and 3(k)). Mace consists of flattened lobed pieces about 25 mm or more in length, somewhat less in breadth, 1 mm thick, buff or light brown, translucent, smooth, horny, and brittle (Figure 3(j) and 3(k)).

In the longitudinal section, nutmeg has a perisperm of about 0.12 mm thick. The cells of the peripheral perisperm are flattened and polyhedral; some contain prisms of an unidentified crystalline substance. The cells of the inner perisperm are parenchymatous and grow into endosperm, blunt-ended ruminations, each containing a vascular strand and numerous volatile oil-containing cells. The endosperm contains abundant bunches of needle-shaped, fat crystals; small, irregular aleurone grains with large crystalloid; and rounded (up to 22 μm in diameter) simple or compound starch grains and scattered tannoid cells (Figure 3(l)).

In the transverse section, mace contains the following: an outer epidermis of irregularly shaped, thick-walled cells covered by cuticle; a hypodermis consisting of a layer of thick-walled cells and one or more additional layers of comparatively thin-walled cells; and a parenchymatous mesophyll consisting of densely packed amylodextrin granules, numerous large oleoresin cells, and vascular tissues (Figure 3(m)).

Nutmeg and mace have a characteristic nutlike aroma and taste. The volatile oil content of nutmeg and mace is 15% and 20%, respectively. The fruits are harvested when split on the tree or, more usually, gathered after they have fallen to the ground. Mace is separated from the pericarp by hand or between boards, without breakage (which reduces its quality), and dried in the sun or artificially. Drying of mace and its storage is a delicate process. Mace has to be dried to a 5% moisture level, for which it takes about 16 h under open sun, 24–28 h in the shade, and 5–6 h in mechanical drying. A mild blanching followed by sulfiting helps in the retention of color and quality of mace. Nutmegs are dried in their shells on large wooden trays and turned daily for uniform drying and to avoid fermentation. Artificial drying between 35 and 40 °C prevents cracking of the shells and any melting of fat in the kernels. Various traditional methods are practiced to crack the nuts, which are stored and graded according to size and quality. This involves immersing the nutmegs in water and separating unhealthy or floating ones; the sound ones are drained, air-dried, and stored in bins before packing. Introducing a little carbon disulfide prevents insect attack.

Extract from nutmeg and mace has been found to be an effective antimicrobial agent for *Bacillus subtilis*, *Bacillus sphaericus*, *Staphylococcus aureus*, *Klebsiella aerogenes*, and *Chromobacterium violaceum*.

Poppy Seeds

Poppy seeds are obtained from *Papaver somniferum* L. (Papaveraceae) capsules. The seeds are white, yellow, brown, bluish, or nearly black and subreniform (1–1.25 mm long), with a reticulate surface; the hilum and micropyle are situated in a depression near one end (Figure 3(n) and 3(o)).

In the cross section, the seed consists of an outer epidermis of tangentially elongated, thin-walled cells, a layer of parenchymatous cells containing numerous very small prismatic crystals of calcium oxalate, a layer of thick-walled cells, a layer of parenchymatous cells, and a layer of thick-walled reticulate cells. The cells of the endosperm and embryo are polygonal and contain aleurone grains and globules of fixed oil (Figure 3(p)).

The odor and taste of the seeds are pleasant and nutlike. For the collection of the seeds, the capsules are dried on the plant for about 15 days. After plucking by hand, these are threshed, and the seeds are separated and stored.

Sesame

Sesame is the seed of *Sesamum indicum* L. (Pedaliaceae). The seeds are yellowish white, brown, or gray to black, flat pyriform (2.5–3.5 mm by 1.2–2 mm by 1 mm), and finely punctate, with four delicate, longitudinal ridges at the edges of the flat faces. The raphe extends from the hilum at the pointed end as a line along the center of one flat face to a broader end, and the scanty endosperm surrounds a large embryo. The hulled seeds are cream or pearly white in color (Figure 3(q) and 3(r)).

In the cross section, the seed coat consists of an epidermis of radially elongated cells (30–60 μm on sides and 45–130 μm at ridges), with thin, cutinized outer walls; each cell contains a 'rosette' calcium oxalate crystal; the rest of the testa consists of collapsed cells containing numerous, prismatic calcium oxalate crystals, and the endosperm and cotyledons consist of polygonal parenchymatous cells containing fixed oil and small aleurone grains measuring 2–10 μm (Figure 3(s)).

The seeds have a faint nutty odor and taste and are ripe at the end of about 5 months. The whole plants are then cut down and made into stooks to dry, and the seeds are shaken out from the capsules and stored.

Sesame seeds have been proved to have moderate amounts of antioxidants.

Spices and Flavoring Crops: Leaf and Floral Structures

L Wilson, University of Iowa, Ames, IA, USA

© 2016 Elsevier Ltd. All rights reserved.

This article is a revision of Spices and Flavoring Crops | Leaf and Floral Structures by G. D. Bagchi and G. N. Srivastava from the *Encyclopedia of food sciences and nutrition*, vol. 9, pp. 5477–5486, © 2003, Elsevier Science Ltd.

Introduction

The aromatic leaves and floral structures of more than 30 plants are commonly used as spices and flavorings. The leaves and floral structures have delicate flavors, and these spices require proper care, particularly during the drying process. Leaf spices are also used fresh. The diagnostic morphological and anatomical characters of the most commonly used spices are dealt with in detail, along with their common names, botanical names, family, and parts used. Handling, drying, and storage details are given wherever available. Additionally, data about antioxidant content and antifungal or bacterial properties have been given where applicable. Other spices that have specific, but equally important, uses are summarized in Table 1.

Chervil

Chervil consists of the dried leaves of *Anthriscus cerefolium* Hoffm. (Apiaceae). The leaves are decompound and oval, and the leaflets are 2–5 × 2–4 cm, alternate, thin pale green, and pinnate; a few hairs occur on the midvein and the margins of leaflets (Figure 1(a)).

In surface view, the lower epidermal cells have more wavy walls than those on the upper epidermis; stomata are numerous on the lower epidermis, but absent on the upper; hairs, usually unicellular and pointed, are on both surfaces of the main vein and the margins, but more arise on the lower surface; the mesophyll consists of a row of palisade cells, 18–75 × 16–35 μm in size, followed by spongy parenchyma containing vascular bundles; an oil duct is found below the midvein (Figure 1(b) and 1(c)).

The odor of chervil somewhat resembles that of caraway and anise. The leaves, after collection, are then dehydrated by circulating hot air (50 °C) and fragmented mechanically and packed in plastic-lined bags.

Laurel or Sweet Bay

The leaves are derived from *Laurus nobilis* L. (Lauraceae). They are lanceolate–acuminate, 10 cm or more long, coriaceous, pellucid-punctate, and with revolute, entire margins; the upper surface is glabrous and shiny and olive green to brown; the lower surface is dull olive to brown with a prominent midrib and veins (Figure 1(d)).

In a cross section, the leaf has a thick cuticle, and the epidermal cells, in surface view, have sinuous, pitted, and thick walls; the lower epidermal walls are more curvilinear and distinctly beaded; the lower epidermis alone bears stomata arranged singly or in pairs; the mesophyll has two layers of palisade parenchyma and a region of spongy parenchyma containing scattered spheroidal oil reservoirs and fibrovascular and collenchyma tissues; the latter occur above and below the vascular bundle of the midrib, but not in the veins (Figure 1(e)–1(h)).

The leaves are characteristically fragrant when crushed but taste bitter.

Laurel has been shown to be an effective antimicrobial agent for *Escherichia coli*, *Listeria monocytogenes*, *Salmonella typhimurium*, and *Staphylococcus aureus*. Laurel has also been shown to have a moderate antioxidant content when cultivated but a higher content when found in the wild.

Marjoram (Sweet)

Marjoram consists of dried leaves, with or without flowering tops, of *Majorana hortensis* (L.) Moench (Lamiaceae). The pinnate leaves are obovate to broadly elliptical, 21 × 11 mm in size with entire margins and short petioles; both surfaces are grayish green, glandular-punctate, and pubescent. The floral parts have light grayish yellow, obovate, thin, and up to 5.5 × 3.5 mm bracts; gamosepalous calyxes, about 3 mm long with five prominent teeth; and gamopetalous, white to pink or pale lilac corolla, about 3.5 mm long (Figure 1(i)).

In a transverse section and/or surface view, it is possible to see an epidermis with a thin cuticle, one to two palisade layers, and upper and lower epidermal cells with slightly wavy, knotty, and vertical walls. Glandular and nonglandular hairs occur on both surfaces, and the latter are uniseriate, with two to five cells in length and more or less bent inward at the apex; some are papillose. Glandular hairs are of two types, one with a one- to two-celled stalk and a one- to two-celled glandular head and the other with no stalk and a large, eight-celled head; the latter is sunk in a depression in the epidermis; stomata occur on the lower epidermis with two 'neighboring' cells (Figure 1(j) and 1(k)).

The odor and taste of sweet marjoram are aromatic, characteristic, and slightly pungent; the plants are harvested as soon as they flower. The plants are cut and tied in bunches and dried in open air or spread on wire trays in ventilated rooms and dried by circulating warm air.

Marjoram was shown to contain a considerable amount of antioxidants that could be most effectively extracted using supercritical fluid extraction.

Mint

Mint consists of the dried leaves and flowering tops of *Mentha piperita* L. (peppermint) and *Mentha spicata* L. (spearmint) belonging to the family Lamiaceae. *Mentha piperita* is a hybrid

Table 1 Some other commonly used spices from leaves, flowers, and flower parts

Botanical name	*Common name*	*Family*	*Part used*	*Characters*
Allium ascalonicum L.	Shallot	Liliaceae	Bulb	Bulbs about the size of a nut, white, leaves basal; bulbs may be taken up and dried or allowed to remain in the ground and dug up when needed; after lifting, they are skinned, washed, and tied in bunches for marketing
Allium cepa L.	Onion	Liliaceae	Bulb	Bulbs have variable sizes: small bulbs are silvery and large bulbs are red or yellow in color; bulbs are harvested when mature, which is indicated by the tops drooping just above the bulb while the leaves are still green; onions are stored in crates, and before storage, they are thoroughly cured
Allium fistulosum L.	Leek	Liliaceae	Leaf	Leaves terete and hollow, usually clustered
Allium sativum L.	Garlic	Liliaceae	Bulb	Compound bulb, subglobose, has 8–15 bulblets, bulblets ovoid, three- to four-sided, covered with whitish scale leaf that encloses whitish flesh, one or two translucent scales, in the center, two or three yellowish to yellowish green leaves present; harvested when tops turn yellow, exposed to sun for 4–5 days and winnowed; after a fortnight of curing, they are packed in bags and stored
Allium schoenoprasum L.	Chive	Liliaceae	Leaf	Leaves 10–25 cm, terete or grooved above, scape 15–35 cm; the cut leaves are gathered into bunches of about 2.5 cm diameter and secured and packed in layers in trays
Angelica archangelica L.	Angelica	Apiaceae	Leaf and young stem	Leaves ovate, 30–90 cm, two- to three-pinnate, ultimate pinnae toothed; leaves cut for drying and frozen in early summer; the stems should be harvested before the plant flowers
Cinnamomum tamala Nees & Eberm	Tejpat (Indian cassia lignea leaf)	Lauraceae	Leaf	Leaves subcoriaceous, opposite, triple-nerved rarely alternate, elliptic–oblong, acute base, acuminate, glabrous, shining; leaves are collected and dried in sun for 3–4 days and packed in a cylindrical bamboo nets for marketing
Gaultheria fragrantissima Wall.	Wintergreen	Ericaceae	Leaf	Leaves alternate, oblong–lanceolate to elliptic rhomboid, 7–13 × 2–6 cm, serrate, stiffly coriaceous, glands dotted
Hyssopus officinalis L.	Hyssop	Lamiaceae	Leaf	Leaves sessile, 13 × 2–8 mm; opposite, linear, or lanceolate; entirely hairy on both surfaces; harvested just as flowers begin to bloom
Levisticum officinale Koch	Lovage	Apiaceae	Leaf and flowering top	Lower leaves large with long petioles, up to three-pinnate, about 70 cm long; uppermost leaves entire and lanceolate; flowers yellow in stiff umbels; fresh leaves are generally used; drying of thick leaves takes 4–5 days
Marrubium vulgare L.	Farasiyum	Lamiaceae	Leaf	Leaves opposite, petiolate, downy, oval, up to 5 cm long, surface wrinkled, and has protuberances, margin dentate; harvested before full flowering and dried in the shade below 35 °C
Melissa officinalis L.	Balm	Lamiaceae	Leaf	Leaves opposite, ovate, or triangular; up to 3.5 cm long, hairy, margin broadly dentate; usually, fresh leaves are used; for drying, stems are cut and tied in small bunches and hung in airy space
Mentha pulegium L.	Pennyroyal	Lamiaceae	Leaf	Leaves shortly petioled, up to 1.25 cm long, round to oval, entire or slightly crenate and pubescent; leaves are used fresh or in dried form
Murraya koenigii L. Spreng.	Curry leaf	Rutaceae	Leaf	Leaves imparipinnate, leaflets 9–25, ovate–lanceolate, dentate, acuminate, base oblique, glabrous above, pubescent beneath, gland-dotted; fresh or shade-dried leaves are used
Nepeta cataria L.	Catnip	Lamiaceae	Leaf	Leaves ovate, coarsely crenate; harvested when in full bloom
Pimenta racemosa (P. Miller) J. W. Moore	West Indian bay	Myrtaceae	Leaf	Leaves obovate or elliptic, leathery, shining above; during harvesting, either leaves are stripped from the trees or both shoots and leaves are removed and tied in bundles for drying
Ruta graveolens L.	Rue	Rutaceae	Leaf	Leaves alternate, 15 cm long, two to three, pinnate, oblong to spathulate, with many small oil glands; leaves are usually used fresh
Salvia sclarea L.	Clary, clary sage	Lamiaceae	Leaf	Leaves petiolate, opposite, ovate, apex obtuse, base cordate, crenate margin, thinly hairy above
Tanacetum vulgare L.	Tansy	Asteraceae	Leaf and flowering top	Leaves downy, one to two pinnate, margin dentate, capitula in flat umbels, golden yellow, about 1 cm in diameter; collected when in flower and dried in the shade at below 35 °C

between *Mentha spicata* and *Mentha aquatica* since *Mentha spicata* itself is a hybrid. Therefore, *Mentha piperita* is a triple hybrid. It is an allohexaploid, $2n = 6x = 72$. However, this species has a variable chromosome number, which ranges from $2n = 36$ to $2n = 134$ with polyploid and aneuploids. *Mentha spicata* ($2n = 48$) has originated by hybridization between *Mentha longifolia* and *Mentha suaveolens* and doubling of chromosomes. The resultant polyploid behaves as allotetraploid. Peppermint leaves are dark green, about 4.5 × 2.3 cm, petiolate, ovate, and with serrate margins. The apex is acute and the

Origanum: (o) a portion of flowering twig: (p) cross section through midrib of leaf; (q) lower epidermis in surface view. Abbreviations: C, calyx; Col, collenchyma; Cor, corolla; Cp, compressed parenchyma; E, endocarp; F, fiber; Gh, glandular hair; H, hair; Hb, hair base; Hy, hypodermis; Mes, mesophyll; O, ovary; Oc, oil cavity; Ocl, oil cell; Od, oil duct; P, pericarp; Pal, palisade; Pap, papilla; Pg, pollen grain; Ph, phloem; Pp, pigmented parenchyma; R, receptacle; Rc, reticulate cells; S, stigma; Sc, stone cells; St, stomata; Sta, stamen; Sty, style; Vb, vascular bundle; Xy, xylem. Reproduced from Spices and flavoring (flavouring) crops: leaf and floral structures. In: Macrae, R., Robinson, R. K. and Sadler, M. J. (eds.) *Encyclopaedia of food science, food technology and nutrition*. London: Academic Press, 1993.

midrib is prominent, and dot-like oil glands are visible with a hand lens. Nonglandular hairs are present on the lower epidermis over the midrib and veins at the margins, and a few arise on the midrib of the upper epidermis. Verticillaster inflorescences are usually arranged in compact, oblong, or oval terminal spikes: calyxes are gamosepalous, purplish, about 3 mm long, glandular-punctate, and five-toothed; corolla is short, tubular, light purple, and four-cleft; there are four stamens; and style is with bilobed stigma (Figure 1(l)). Spearmint differs from peppermint in having a sharply pointed, long, narrow spike; an absence of nonglandular hairs in the upper epidermis; fewer and shorter hairs on the lower surface over the midrib, with few, if any, over the veins; and the absence of crystals in the glandular hairs.

In a cross section, peppermint leaves show a cuticle covering at both the upper epidermis and lower epidermis, with the upper epidermal cells having moderately thicker outer walls than the lower epidermal cells; glandular hairs containing groups of crystals; a mesophyll consisting of a layer of palisade cells and spongy tissue; and a conspicuous group of collenchyma cells between the upper epidermis and the vascular tissue of the midrib and veins. In the surface view, the cuticle is striated over the midrib, veins, and margins, and the upper epidermal cells are irregular with wavy walls, except in the latter regions; numerous small crystals are present in the cells of the upper epidermis and lower epidermis (Figure 1(m) and 1(n)).

Peppermint has a characteristic aromatic odor and taste, with a cooling sensation on the breath, whereas the odor and taste of spearmint are characteristic and aromatic but not followed by a cooling sensation. Mints are harvested, when in bloom, in bright sunny weather, by cutting with a sickle 2–3 cm above the ground. The harvested herb is allowed to dry partially in the open. Drying is completed by circulating warm air, which avoids overheating and obviates drying for too long. After attaining the desired brittleness, the leaves are stripped from the stem and completely dried. Afterward, they are fragmented mechanically or through wire sieves.

Origanum or Oregano

This consists of the dried leaves and flowering tops of *Origanum vulgare* L. (Lamiaceae). The leaves are light green to greenish brown, with crenate to crenate–serrate margins, and are about 3 cm long, and are glandular-punctate. The flowers are in spikelike clusters: bracts are broadly ovate, $2.5–3 \times 2$ mm with prominent hairs on the outer surface; calyxes are gamosepalous, four-toothed, and deeply clefted on two sides; corolla is 5 mm long and gamopetalous; four stamens are epipetalous; and style is plumose (Figure 1(o)).

In surface view and/or transverse section, the epidermal cells of both surfaces of the leaf are irregular in shape with uneven and thickened walls; both surfaces have numerous curved, pointed, unicellular, nonglandular hairs up to 900 μm long; the surfaces of some hairs are smooth, whereas many have papillose surfaces. Uni- to multicellular glandular hairs are present on both surfaces (Figure 1(p) and 1(q)).

Origanum has a strong camphoraceous odor and a warm, pungent, bitter, camphoraceous taste. The plant is collected when in bloom and dried in the shade at $< 35\ ^\circ C$. Both Turkish oregano and Greek oregano differ from Mexican oregano in aroma and flavor. Oregano has been shown to be an effective antimicrobial agent due to its thymol and carvacrol content.

Parsley

Parsley consists of the dried leaves of *Carum petroselinum* Hoffm. (Apiaceae). The leaves are pinnately compound of three-lobed leaflets; each lobe is divided into smaller, toothlike segments that are usually curly (Figure 2(a)).

The upper and lower epidermal cell walls are, in surface view, sinuate, and stomata are few in the upper and numerous in the lower epidermis. In a cross section, beneath the upper epidermis, the mesophyll consists of a layer of palisade cells about 40–55 μm long followed by a spongy parenchyma; below the vascular bundle of the midrib is an oil duct (Figure 2(b) and 2(c)).

The dried leaves have a characteristic, agreeable, aromatic odor and taste. Fresh leaves are dried rapidly under controlled conditions of heat and air flow to avoid loss of essential oils and to preserve a good, green color.

Rosemary

Rosemary consists of the dried leaves of *Rosmarinus officinalis* L. (Lamiaceae). The leaves are about 3.5 cm long and 2–4 mm wide, numerous, opposite sessile, linear, leathery, entire, and slightly glossy with revolute margins. The upper surface is dark green, while numerous branched trichomes on the lower surface make it gray and wooly and glandular-punctate with a prominent midrib (Figure 2(d)).

In surface view, the cells of the upper epidermis are polygonal with unevenly thickened and beaded walls, while the lower epidermal cells are larger and thin-walled. In a cross section, the collenchyma tissue present below the upper epidermis forms a thick-walled hypodermal layer; collenchymatous cells also surround the vascular bundle of the midrib. One to three layers of palisade cells are up to about 80 μm in length and are followed by a zone of spongy parenchyma. A dense, tangled mass of branched, multicellular, smooth hairs cover the lower epidermis, and the tips of the hairs are pointed and curved; glandular hairs are uni- to multicellular. In the midrib vascular bundle, the vessels are arranged in radial rows (Figure 2(e) and 2(f)).

The odor of rosemary is characteristically aromatic, having a slight camphoraceous note; the taste is pungent, aromatic, bitter, and camphoraceous. Rosemary is harvested when flowering has started. At that time, 30–50 cm of the top along with leaves and flowers is harvested with a sickle or by forage harvester. Care should be taken not to cut the woody portions of the stem. The first harvest is obtained $\sim$6 months after planting, and subsequent harvests can be obtained every 4 months. Harvested leaves are dried in the shade.

Rosemary proves to be an effective antimicrobial agent for *Staphylococcus aureus*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, *Klebsiella pneumonia*, *Enterococcus faecalis*, *Escherichia coli*, *Staphylococcus epidermidis*, *Bacillus subtilis*, and *Candida albicans*. Additionally, rosemary antioxidants have allowed it to be used in meat formulations.

Figure 2 Spices from leaves and flower tops. Parsley: (a) a portion of flowering twig; (b) cross section of leaflet through main vein; (c) surface view of lower epidermis. Rosemary: (d) a portion of flowering twig; (e) cross section through midrib of leaf; (f) lower epidermis in surface view. (eds.) *Encyclopaedia of food science, food technology and nutrition*. London: Academic Press, 1993.

Sage

Sage consists of the dried leaves of *Salvia officinalis* L. (Lamiaceae). The leaves are grayish green, oblong–lanceolate, about 8.5×2.5 cm, petiolate, and with an acute apex, finely crenate margins, densely pubescent and glandular-punctate having glands obscured by hairs (Figure 2(g)).

The upper epidermal cells, in surface view, have few stomata and straight, beaded walls, whereas the lower epidermis bears numerous stomata, and the cells have wavy, beaded walls; numerous nonglandular and glandular hairs occur on both surfaces. The nonglandular hairs are uni- or multicellular, and the multicellular hairs are more numerous, very long, narrow-pointed, and mostly smooth, but some have a papillose surface; glandular hairs are also uni- or multicellular. The midrib vascular bundle is surrounded by parenchymatous and collenchymatous cells, and the mesophyll consists of one to three layers of palisade cells followed by spongy tissues (Figure 2(h)–2(j)).

Sage is aromatic in odor and somewhat bitter in taste. The leaves are gathered for use while the plants are in bloom and are dried in the shade or indoors by circulating warm air.

Sage proves to be an effective antimicrobial agent for *B. cereus*, *B. megaterium*, *B. subtilis*, *Aeromonas hydrophila*, *Aeromonas sobria*, and *Klebsiella oxytoca*. Sage was extremely effective in small quantities against *Staphylococcus aureus* and *Aeromonas hydrophila*. There is evidence of a moderate antioxidant content in sage that can easily be extracted.

Savory

Savory consists of dried leaves and flowering tops of *Satureja hortensis* L. (Lamiaceae). The leaves are green to grayish green, nearly sessile, entire, linear oblong to spatulate when unfolded, glandular-punctate, acute to rounded at the apex, tapering at the base, $12–35 \times 1–2$ mm, and pubescent. The flowers are tubular–bilabiate, purple, and up to 5 mm long in leaf axils; calyxes are campanulate, hispid on the nerves, and with five subulate teeth; corolla is about 4–5 mm long; stamens are didynamous; style is with bilobed stigma (Figure 2(k)).

In the surface view, epidermal cell walls of the upper and lower surfaces are sinuate and beaded; the stomata are elliptical. The nonglandular hairs are uniserial and numerous, with up to six cells and a pointed, distal cell; the glandular hairs are numerous and have an up to 12-celled head and one-celled stalk (Figure 2(l)–2(n)).

The odor of savory is characteristically aromatic, and the taste is aromatic and warm. The leaves are collected when the plants are in bloom and are dried in the shade or indoors by circulating warm air, before packaging.

Savory has been shown to be an effective antimicrobial agent for *B. amyloliquefaciens*, *B. atrophaeus*, *B. macerans*, *B. megaterium*, *B. pumilus*, *B. sphaericus*, *B. subtilis*, *Escherichia coli*, *Kocuria varians*, *Micrococcus luteus*, and *Pantoea agglomerans*.

Basil (Sweet)

Sweet basil consists of the dried leaves of the *Ocimum basilicum* L. (Lamiaceae). The leaves are ovate, tip acute, petiolate, green, up to 5 cm long, and finely serrate. Hairs arise on the veins, especially on the underside of the leaf, which is also glandular-punctate (Figure 2(o)).

In surface view, the upper epidermis and lower epidermis have wavy cell walls, and the nonglandular hairs are one- or multicelled, uniseriate, and with pointed apices; the surfaces of the hairs are finely warty. Glandular hairs have a two- to four-celled head and occur on both surfaces, but more on the upper surface. In transverse section, a single palisade layer lies beneath the upper epidermis, followed by a zone of spongy parenchyma; the vascular tissue of the midrib and large veins is separated from the upper epidermis and lower epidermis by parenchymatous and collenchymatous tissues (Figure 2(p)–2(r)).

The odor of basil is fragrantly aromatic, and the taste is warmly aromatic and pungent. Fresh leaves can be dried in open air but more efficiently indoors by controlled artificial heat and circulating air. Dried leaves can be ground and graded to produce fine, medium, or coarse particle sizes before packaging.

Basil proves to be an effective antimicrobial agent for *Staphylococcus aureus*, *Escherichia coli*, *B. subtilis*, *Pasteurella multocida*, and some pathogenic fungi. Additionally, basil contains moderate levels of antioxidants.

Tarragon

Tarragon consists of the dried leaves of *Artemisia dracunculus* L. (Asteraceae). The leaves are lanceolate, entire, sessile, glabrous, and bright green. The edges of dried leaves curve toward the lower surface and are finely revolute, 4×3.5 mm in size (Figure 3(a)).

The cuticle on both surfaces is striated over the midrib and veins. The epidermal cell walls of both surfaces are undulate; occasionally, small, inconspicuous glandular hairs of 35–40 μm diameter are present on the epidermis. The mesophyll consists of two rows of palisade cells toward the upper surface and a single row toward the lower. Below the midrib vascular bundle are a few collenchymatous cells, and on the upper side, two secretory ducts are present (Figure 3(b) and 3(c)).

The odor and taste of tarragon are agreeable, aromatic, and like that of anise. The leaves are dried indoors by artificial heat and circulating air to ensure retention of aroma and color. After being crushed by machine into particles of a suitable size, the product is packed in bags or kraft paper or retail packaging (glass, plastic, and metal).

Tarragon proves to be an effective antimicrobial agent for *Alternaria alternata*, *Alternaria solani*, *Aspergillus niger*, *Botrytis* sp., *Dreshlera* sp., *Fusarium acuminatum*, *F. chlamydosporum*, *F. culmorum*, *F. equiseti*, *F. graminearum*, *F. nivale*, *F. oxysporum*, *F. proliferatum*, *F. sambucinum*, *F. scirpi*, *F. semitectum*, *F. verticillioides*, *Monilia* sp., *Penicillium jensenii*, *Phoma* sp., *Pythium ultimum*, *Phytophthora capsici*, *Rhizoctonia solani*, *Sclerotinia* sp., *Trichothecium* sp., *Verticillium dahliae*, and *V. tenerum*.

Thyme

Thyme consists of the dried leaves and flowering tops of *Thymus vulgaris* L. (Lamiaceae). The leaves are linear/

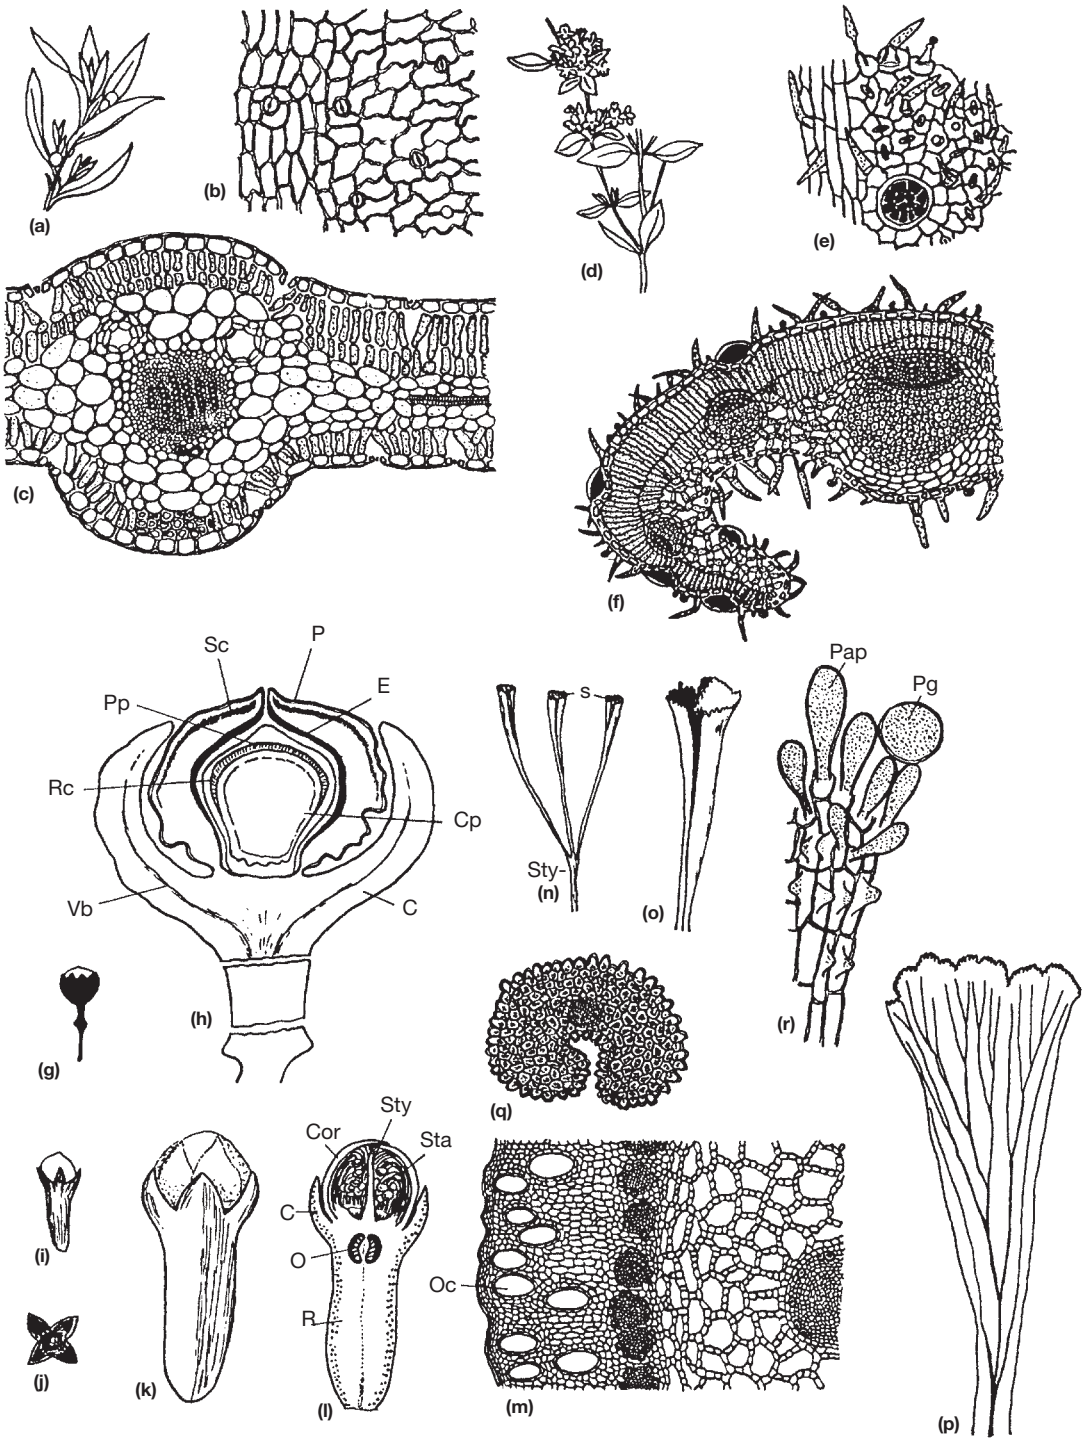

Figure 3 Spices from leaves, flower tops, and flowering parts. Tarragon: (a) a portion of flowering top; (b) surface view of upper epidermis; (c) cross section of leaf through midrib. Thyme: (d) a portion of flowering twig; (e) surface view of lower epidermis; (f) cross section of leaf blade. Cassia bud: (g) bud; (h) longitudinal section through bud. Clove: (i,k) whole clove; (j) same viewed from above; (l) longitudinal section of the same; (m) transverse section through the receptacle. Saffron: (n) style with three stigmas; (o) a stigma; (p) the same showing vascular supply; (q) transverse section through lower portion of stigma; (r) upper end of stigma showing papillae and pollen grain. Abbreviations: C, calyx; Col, collenchyma; Cor, corolla; Cp, compressed parenchyma; E, endocarp; F, fiber; Gh, glandular hair; H, hair; Hb, hair base; Hy, hypodermis; Mes, mesophyll; O, ovary; Oc, oil cavity; Ocl, oil cell; Od, oil duct; P, pericarp; Pal, palisade; Pap, papilla; Pg, pollen grain; Ph, phloem; Pp, pigmented parenchyma; R, receptacle; Rc, reticulate cells; S, stigma; Sc, stone cells; St, stomata; Sta, stamen; Sty, style; Vb, vascular bundle; Xy, xylem. Reproduced from Spices and flavoring (flavouring) crops: leaf and floral structures. In: Macrae, R., Robinson, R. K. and Sadler, M. J. (eds.) *Encyclopaedia of food science, food technology and nutrition*. London: Academic Press, 1993.

linear–lanceolate, ovate or oblong, up to 6 × 0.5–2 mm, and with an acute apex, obtuse base tapering into a petiole, and revolute margins. The upper surface is light gray or light brownish gray to weak olive green with numerous hairs; the lower surface is grayish, pubescent, and glandular-punctuate. About 12 flowers arise in axillary whorls: the calyxes are tubular, bilabiate, about 4 mm in length, pubescent, and 9–12-nerved with the upper lip being three-toothed; the lower lip has two hairy, ascending, attenuate divisions and the throat is hairy; the corolla is about twice as long as the calyx, purplish, and bilabiate; the stamens are didynamous; and style is with bilobed stigma (Figure 3(d)).

The epidermis of both leaf surfaces in the surface view shows wavy walls and numerous nonglandular and glandular hairs; the nonglandular hairs are uni- or multicellular with papillose walls and are stiff and pointed. The glandular hairs are of two types: one with a short stalk and unicellular head and the other with an 8–12-celled head, which measures up to 18 μm in diameter, and with no stalk. In a cross section, the mesophyll consists of one or two layers of palisade cells and is variable in size, followed by spongy tissues; the vascular bundle of the midrib has numerous fibers; the lamina contains two to three small vascular bundles on both sides of the midrib (Figure 3(e) and 3(f)).

Thyme has a fragrant and aromatic odor when crushed, and the taste is aromatic, warm, and pungent. About 15 cm from the tops of the plants is harvested, when in bloom, and the clipped stems are dried in the sun or in a well-ventilated shed or room.

Thyme proves to be an effective antimicrobial agent for *Salmonella enteritidis*, *Salmonella typhimurium*, *Escherichia coli*, *Listeria monocytogenes*, *Y. enterocolitica*, *Shigella flexneri*, *Shigella sonnei*, and *Staphylococcus aureus*.

Cassia Buds

Cassia buds consist of the dried flowers of *Cinnamomum cassia* Blume (Lauraceae) gathered shortly after opening. They are dark brown, are club, have urn- or top-shaped bodies, and are enclosed within a grayish brown, cup-shaped calyx with a dome-like visible top of the pericarp. The calyx tube is rough and hard and frequently has the pedicel attached; the exposed pericarp is smooth and lustrous with the small protuberant base of the style visible (Figure 3(g) and 3(h)).

In longitudinal section, the cortex of the calyx contains parenchymal cells up to 75 μm long, secretion cells up to 66 μm long, and stone cells up to 80 μm long. The pericarp consists of a sclerenchymatous epicarp about 45–58 μm in radial thickness; the parenchymatous mesocarp contains prismatic calcium oxalate crystals, stone cells, secretion cells, and vascular tissues. The endocarp sclerenchymatous cells of the ovary canal are thick-walled and without a lumen, while the cells of the remaining region are rectangular and moderately thick-walled and contain large prismatic crystals of calcium oxalate (Figure 3(h)).

Cassia buds have a cinnamon-like odor and a sweet, warm pungent taste akin to that of cassia bark.

Cassia bud extract has been proved to be an effective antimicrobial agent for *Aeromonas hydrophila*, *Alcaligenes* sp., *Citrobacter* sp., *Enterobacter aerogenes*, *Escherichia coli*, *Flavobacterium* sp., *Klebsiella ozaenae*, *Klebsiella pneumonia*, *Micrococcus roseus*, *Plesiomonas shigelloides*, *Pseudomonas aeruginosa*, *Salmonella typhi*, *Salmonella paratyphi A*, *Salmonella paratyphi B*, *Staphylococcus aureus*, *Streptococcus anginosus*, *Streptococcus intermedius*, *Streptococcus mitis*, *Streptococcus morbillorum*, *Streptococcus mutans*, *Streptococcus oralis*, *Streptococcus salivarius*, *Streptococcus sanguis*, *and Streptococcus uberis*. Antioxidants have been shown to be present in moderate concentrations from the extracts of the cassia buds.

Cloves

Cloves are dried flower buds of *Syzygium aromaticum* (L.) Merrill & Perry (Myrtaceae). Cloves are like small, round-headed nails, about 10–17.5 mm long, and blackish brown in color. The stalk consists of a cylindrical hypanthium, above which is a bilocular ovary containing numerous ovules on axile placentas; the 'head' consists of four, slightly projecting, calyx teeth, four membranous petals, and numerous incurved stamens surrounding a large style (Figure 3(i)–3(l)).

In transverse section, the hypanthium (receptacle), cut below the ovary, shows an epidermis with a thick cuticle and numerous, scattered, ranunculaceous stomata on the surface. The outer cortex contains two to three rows of large, ovoid to elliptical oil reservoirs (up to 200 μm in length) lined by a secretory epithelium and embedded in the parenchyma; beneath is a zone consisting of an interrupted circle of bicollateral, fibrovascular bundles accompanied by a few sclerenchyma fibers and crystal fibers containing rosette calcium oxalate crystals. The bundles are embedded in parenchymatous cells with sinuate walls, and beneath these is a zone of parenchyma, in which some cells possess thickened angles and wavy walls, whereas others form chains around intercellular air spaces. Next is a zone of small-celled parenchyma followed by a second or inner zone of fibrovascular bundles, along with a few thick-walled, pericyclic fibers (Figure 3(m)).

The sepals have an epidermis similar to the hypanthium, with numerous stomata on the outer surface; a mesophyll with a few slender, vascular strands and numerous, ovoid oil glands; and rosette crystals of calcium oxalate. The petals have straight-walled epidermal cells, an undifferentiated mesophyll containing oil glands, rosette calcium oxalate crystals, and small vascular strands. The filament of the stamen bears oil glands beneath the epidermis, and the connectives bear a large oil gland at the apex.

Cloves have a strong, pungent, and spicy odor and a pungent, aromatic taste. Cloves are propagated by seeds. Hulled washed seeds produce better seedlings than unhulled fruits. The seeds are planted in shaded nurseries, and seedlings are raised. Shade and wind breaks are necessary in the early stages of growth. Trees begin to flower at about 4–5 years and continue to produce until 70 years of age. The crimson buds are picked before the corolla expands and are evenly spread under the sun on a concrete floor or on mats and gently stirred to bring about uniform drying. In good weather, drying is completed in 4–7 days. Quick drying produces the best-quality spice. Some cloves are dried on zinc sheets or in kilns. Cloves are apt to absorb moisture if, while drying, they are left in the open overnight. The average annual yield of dried cloves per

tree is about 3 kg but yields of 18 kg or more per tree are also not uncommon. Finally, they are packed in sacks known as 'mats' made of coconut leaves and stored in a dry room. Prolonged storage may cause a loss of volatile oils.

Cloves have been shown to contain a moderate amount of antioxidants in its extracts.

Saffron

Saffron is made from the dried stigmas of *Crocus sativus* L. (Iridaceae). The three stigmas are attached to the top of the style and are 25 mm long, cornucopia-shaped, dark red, and with fimbriate margins. The styles are about 10 mm long, cylindrical, solid, and yellowish brown to pale yellowish orange (**Figure 3(n)–3(p)**).

The stigma consists of thin-walled parenchyma containing coloring matter and covered by a thin-walled epidermis. The distal end of the stigma shows numerous bladderlike, cylindrical papillae up to 150 μm in length, among which occur a few smooth, spherical, pollen grains from 40 to 120 μm in diameter (**Figure 3(q)–3(r)**).

The odor of saffron is strong and characteristically aromatic, and the taste is bitter/aromatic. The flowers are collected every morning, as they open, and the stigmas are then collected, by either pulling them out or cutting them using fingernails, after which the flowers are discarded. The value of saffron depends heavily on the methods by which the stigmas are processed. The stigmas are placed in sieves in layers 2–3 cm thick. These sieves are placed 15 cm above an almost spent fire for drying. By stacking them and by changing their order or position, the product is carefully dried. Stigmas are protected against dampness and light, because light bleaches saffron to a dull yellow color. Saffron should be preserved in amber-colored bottles or tin boxes.

This article is a revision of the article Spices and Flavoring Crops | Leaf and Floral Structures by K. K. Sinha from the *Encyclopedia of Food Sciences and Nutrition*, volume 9, pp. 5486–5491, © 2003, Elsevier Science Ltd.

Background

The use and cultivation of spice plants date back to the beginning of our history. Most of the spices that we value today were known to the ancient civilizations of China, Egypt, Greece, Rome, the East Indies, and the rest of the Old World. Spices have also been responsible for the rise and fall of empires and the great sea voyages to explore the distant corners of the globe. The search for spices by early European explorers also led to the discovery of new continents and waterways.

Spices are derived from different plant parts, including roots, stem, leaves, flowers, fruits, and seeds. This article, however, deals only with those spices and flavoring crops that are obtained from tubers and roots. These are categorized into two groups, major and minor crops, depending upon their distribution and usage in different parts of the world.

Major Crops

Ginger

Ginger is the most important of all the spices obtained from underground plant parts. It has been in use in India and China since very ancient times. However, it is difficult to trace with certainty the exact place of its origin. Ginger was mentioned by the Chinese philosopher Confucius (551–479 BC) in his *Analects*. Ginger was also one of the first oriental spices to be known to the Europeans. The Greeks and Romans first obtained ginger from the Arab traders. It was known in Germany and France in the ninth century and in England during the tenth century.

Ginger is derived from the rhizomes of *Zingiber officinale* Rosc., a plant belonging to family Zingiberaceae. It is a slender perennial herb, mostly grown as an annual, and is 30–100 cm tall with a robust rhizome borne horizontally just below the soil surface. The fleshy sympodial rhizome is hard and thick, somewhat laterally compressed, often palmately branched, and varying in shape and size in different cultivated types. It is covered with small, distichous scales with an encircling insertion and with fine fibrous roots in the top layers of the soil. It is pale yellow in color externally and greenish yellow within.

The crop is always propagated vegetatively using small fragments of the rhizome known as 'seeds' or 'setts.' It is also grown both as a pure crop and as an intercrop. It may be grown in rotation with paddy rice, samai (*Panicum miliare*). If irrigation facilities are available, ginger may be rotated with vegetables, chili, groundnut, ragi (*Eleusine coracana*), and maize. Ginger is sometimes grown mixed with turmeric, which grows rapidly early on and provides partial shade to the developing ginger. It is harvested at different stages depending upon the requirements of the user. Green ginger is harvested between 5 and 7 months after sowing, and the rhizomes are used for preservation as preserved ginger. Final harvesting is carried out after 8–10 months from planting for the production of dried ginger. Shriveling, yellowing, and withering of the leaves, accompanied by drying and lodging of the aerial shoots, indicate maturity of the rhizomes.

The maturity of the rhizome has a significant influence on both its quality characteristics and its suitability for processing into preserved or dried ginger. The optimum time for harvesting ginger in India is 245–260 days from planting, after which the rhizomes become more fibrous. Harvesting of the mature ginger is mostly done by hand using a spade, hoe, or digging fork. In advanced countries, the late crop is also harvested by mechanical diggers. Extra care is required for the harvesting of healthy rhizomes. The soil, roots, and shoots are subsequently removed, and the rhizomes are carefully washed and dried for storage (see Figures 1 and 2).

Several commercial types of ginger are recognized in cultivation, which are generally named after the localities where they are grown. The types with less fiber, which varies from 1.7% to 9.0%, have a higher demand. Some of the prized types of ginger in international trade include Jamaican ginger, Indian ginger, African ginger, and Chinese ginger, and these vary in taste and aroma.

Since the rhizome is perishable, it is susceptible to attack by the soilborne fungi, insects, and white ants. Rhizome rot or soft rot is the most serious disease found all over the ginger-growing areas of the world. Healthy and disease-free rhizomes are thus selected for storage. The use of specific fungicides for the treatment of rhizomes before storage is recommended on a regional basis. The treated rhizomes are air-dried under shade to remove excess moisture. The optimum conditions for the

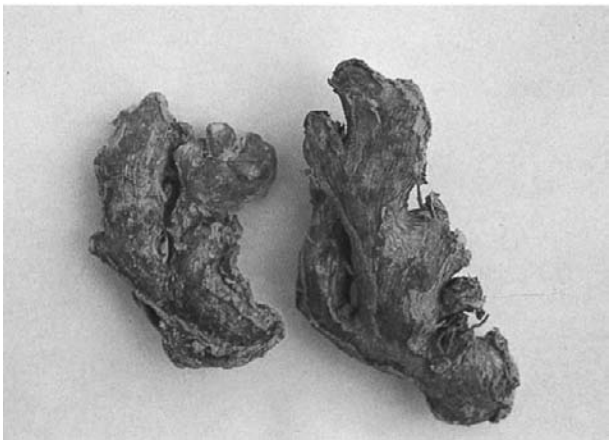

Figure 2 Spices and flavoring crops: rhizome of dried ginger (*Zingiber officinale*).

Figure 3 Spices and flavoring crops: rhizome of turmeric (*Curcuma domestica*).

storage of fresh ginger have been investigated in detail in Hawaii. Harvested rhizomes should be washed immediately and then air-dried in the shade for 1–2 days. The rhizomes can be stored safely for up to 6 months by maintaining the temperature at 12 °C and the relative humidity at 65%.

In India, the ginger is loosely stored in pits, which may be up to 1 m deep. These pits are cool and provide protection against sunlight. A layer of sand or sawdust is spread at the bottom of the pit before storing the rhizomes. The pit is left uncovered or covered with a wooden plank, which in turn is plastered with mud, with a hole in the center for aeration.

As mentioned earlier, there are three primary products of ginger rhizomes: fresh or green ginger, preserved ginger in syrup or brine, and dried ginger. Green ginger is consumed mostly in the areas of production and nearby places. Preserved and dried products are the major forms in which ginger is traded internationally. Dried ginger is used as a spice and also for the preparation of its extracts.

Commercial preparation of preserved ginger is mostly practiced in China, Hong Kong, Australia, and India. Young juicy rhizomes are dried, cleaned, and boiled in water until they become tender. They are then peeled, scraped, and boiled several times in a sugar solution. Sometimes, preserved ginger is also prepared in the dry state by dusting the drying rhizomes with crystalline sugar.

The preparation of dried ginger involves processing the cleaned rhizomes by peeling, splitting them into pieces, immersing them into boiling water for about 10 min, and, finally, drying. The appearance of processed ginger (black or white), the contents of volatile oil and fiber, the pungency level, and an assessment of the aroma and flavor are important in the quality evaluation of dried ginger.

The characteristic pleasant and aromatic odor of ginger is due to essential oil, which can be separated from the dried rhizome by steam distillation. The essential oil, known in the trade as 'oil of ginger,' is greenish to yellow in color; mobile (viscous on aging), with the characteristic warm and aromatic odor; but not the pungent flavor of the spice. The pungent principles of ginger are nonvolatile oleoresin, commonly known in the trade as 'gingerin.' This can be extracted from dried ginger by percolation with a suitable solvent. It is a viscous and dark brown oil and retains the full pungency of the spice. Besides the pungent principles, the oleoresin also contains gingerol, shogaol, and zingerone.

In medicine, ginger is used as a carminative and digestive stimulant. It also dilates the blood vessels in the skin, causing a feeling of warmth. Its preparations are also useful in the treatment of coughs and colds. Ginger is extensively used in culinary preparations such as soups, puddings, pickles, gingerbread, and cookies and is an ingredient of all curries, except those used with fish. Ginger is also popular for flavoring beverages such as ginger ale and ginger beer.

Ginger has been shown to contain high levels of antioxidants, which are easily extracted.

Turmeric

Turmeric, another important spice, is also obtained from the underground plant part, that is, the stem. The plant, a native of Southeast Asia, is widely cultivated in India, Sri Lanka, Indonesia, China, Taiwan, Peru, Haiti, and Jamaica, of which India is by far the largest exporter.

Turmeric is obtained from the rhizomes of *Curcuma domestica* Val. (syn. *C. longa* L.), also a member of the family Zingiberaceae. The plant is a robust perennial herb with a short stem and tufted leaves. The rhizomes, brownish yellow in color, consist of a central bulbous portion bearing a number of fingerlike lateral offshoots. Although the characteristic yellow matter is distributed throughout the plant, it is highly concentrated in the rhizome. There are several varieties of turmeric distinguished by the names of the localities in which they are grown. Turmeric cultivated in the hills is said to be of a better quality than that raised in the plains. Even the same variety that is grown in plains and on the hills shows distinct differences in quality and yield (see **Figure 3**).

Cultivation of turmeric requires a hot and moist climate, a liberal water supply, and a well-drained soil. It can be grown successfully in rice fields on raised beds beyond the reach of stagnant water. It is usually rotated with ragi (a cereal grass cultivated in Africa and Asia), paddy, and sugarcane. It is rarely cultivated as a pure crop and is usually grown mixed with castor bean,

maize, ragi, onions, brinjal, and tomato. The plants thrive well in partially shaded areas, but shade adversely affects the yield.

Turmeric is a good host for many pathogenic microorganisms and insect pests. Rhizome rot and leaf spot caused mainly by *Taphrina maculans* Butler are the important diseases of turmeric. The use of Bordeaux mixture or any other nonmetallic fungicide has been suggested as a remedy.

The crop is ready for harvesting in about 9–10 months, when the lower leaves turn yellow. The rhizomes are carefully dug up with handpicks. The leafy tops are then cutoff, and the roots are removed. The adhering soil particles are removed by brisk shaking or by rubbing, and the rhizomes are then thoroughly washed with water, placed in small heaps, covered with turmeric leaves, and left to dehydrate. The fingers and bulbs (or mother rhizomes) are then separated and cured separately.

The curing of turmeric involves boiling or steaming the fresh rhizomes in water, followed by drying and polishing. The rhizomes are boiled for 45–60 min over a slow fire until they become soft. The rhizomes are then cooled and spread out to dry in the sun. Boiling of the rhizomes in very dilute solutions (0.05–0.1%) of mild alkali modifies the color of the core of the rhizome to the desired yellow orange. The duration of boiling markedly affects the color and aroma of the final product. After boiling, the rhizomes are dried in sunlight for 10–15 days. Sun-drying gives rise to a surface-bleaching effect. After drying, the rhizomes become quite hard and brittle and break with a metallic sound. Drying is followed by polishing, which includes cleaning off the outer skin, rootlets, and adhering particles of soil and making the rhizomes smooth. Polishing is performed either manually or in power-operated drums. The dried turmeric is coated with a slurry of turmeric powder in the course of polishing to impart a better color to the rhizomes.

The cured rhizomes are stored in pits dug at a raised site. The bottom and sides of these pits are lined with *Saccharum spontaneum* (commonly known as Rellu grass) and palmyrah mats. The pits, after being filled with cured turmeric, are covered with mats and grass and, finally, with earth. The produce may be stored for a year. The turmeric is also stored in 'godowns' or warehouses in gunny bags.

The coloring matter of turmeric is yellowish crystalline curcumin, which can be extracted from the powder either by direct solvent extraction or by extraction with alkali and subsequent precipitation with acid.

Turmeric is mainly used for domestic culinary preparations and is an important constituent of curry powder. Turmeric is also used as coloring agent in the textile, food, and pharmaceutical industries. In the Indian system of medicine, turmeric is used to some extent as a stomachic (i.e., promoting the appetite or assisting digestion), tonic, and blood purifier. The juice of the fresh rhizome is used as an antiparasitic for many skin diseases. Oil of turmeric, distilled from the dried rhizome, shows antiseptic properties.

Minor Crops

Spices Obtained from Roots

Angelica

Angelica has been in use as a spice since AD 1500. It is obtained from the roots of *Angelica archangelica* L., a member of the family Apiaceae. It is native to Syria but is known to occur in many parts of Europe and western Asia. In India, it is grown in the Kashmir Valley.

The plant is a stout perennial herb with large, pinnately compound leaves and small, greenish-white flowers. The dry rootstocks yield 0.35–1% of essential oil, the main constituent of which is β-phellandrene. The roots contain several furocoumarins such as angelicin, bergapten, and xanthotoxin in addition to umbelliprenin and several phenols. The dried roots are frequently used for flavoring cakes, candy, and beverages. Angelica root is the main flavoring ingredient of gin. It is also used in perfumery and medicine. In medicine, the roots have been shown to possess stimulant, expectorant, and diaphoretic (i.e., inducing perspiration) properties.

Horseradish

The horseradish (*Armoracia lapathifolia* Gilib.) is a member of the family Brassicaceae and has been in use as a condiment since ancient times. The plant is a native of southeastern Europe and is widely grown in Europe, America, and the hilly regions of India.

The plant is a tall, hardy herb with glossy green, toothed leaves. The roots are fleshy, yellowish white, and cylindrical. Initially, the root is about 2.5 cm in diameter, but it may reach a length of 1 m. The English refer to the plant as 'red cole,' perhaps due to the hot sensation experienced when ingesting even small pieces of root. The roots are dug up and are scraped or grated before use. Both fresh and dried roots are used as a condiment, which aids digestion and prevents scurvy. It is similar to mustard in most of its properties. The smell and flavor of horseradish come from the glycoside sinigrin, which decomposes in the presence of water by enzyme action to form mustard oil.

Asafoetida

Asafoetida is the dried latex obtained mainly from living rootstocks or tap roots of several species of Ferula, namely, *F. foetida* Regel., *F. alliacea* Boiss., *F. rubricaulis* Boiss., *F. asafoetida* Linn., and *F. narthex* Boiss, of the family Apiaceae. The plants are perennial herbs that are mainly distributed from the Mediterranean region to Central Asia. The main regions of asafoetida production are eastern Iran and western Afghanistan. Some species are also found in the Punjab and Kashmir regions of India.

The plants bear large, carrot-shaped roots, 10–15 cm in diameter at the crown after 4–5 years of growth. At the time of flowering, the upper part of the root is laid bare, and the stem is cut off close to the crown. The exposed surface is covered by a dome-shaped structure made up of twigs and mud. The exudate (milky juice) oozing out from the cut surfaces is scraped off after a few days. The collection of the resin and the slicing of the root are repeated until exudation ceases.

Asafoetida occurs in three forms in commercial trade: tears, mass, and paste. The tears make the purest form of resin; it is bitter and acrid in taste and emits a strong and peculiar odor.

Asafoetida contains mainly resin (40–64%), gum (25%), and volatile oil (10–17% on a dry-weight basis). The resin portion consists mainly of asaresinotannol, free or combined with ferulic acid. Umbelliferone seems to be present in combined state. Oil of asafoetida is obtained by steam distillation of the gum resin.

Asafoetida is generally used for flavoring curries, sauces, and pickles. Medicinally, it stimulates the intestinal and respiratory tracts and the nervous system. It is useful in asthma, whooping cough, and chronic bronchitis.

Sarsaparilla

Sarsaparilla is obtained from the dried roots of several tropical species of Smilax, a member of the family Liliaceae. Some of the important spice-yielding species include *S. aristolochiaefolia* Mill. (Mexico), *S. officinalis* H.B. & K. (Honduras), and *S. regelii* Killip & Morton (Jamaica). The plant thrives best in hot and humid climates and on light, well-drained sandy loam rich in humus.

The plants are climbing or trailing vines with prickly stems. The rhizomes are short and thick, with very long, thin roots. The plants are harvested after attaining 2–3 years of age. They are carefully dug up and cut off near the stock, which is then covered up again with surface soil. The harvested roots are then washed well, dried in the sun, and tied up in bundles. The roots contain a bitter principle that is used as a flavoring agent. It is chiefly used as a beverage condiment for the preparation of soft drinks. Sarsaparilla is mostly used in combination with winter green and other aromatic plants.

Medicinally, sarsaparilla has been used to treat syphilis and other skin diseases.

Sarsaparilla contains a moderate amount of antioxidants that can be extracted and helps reduce oxidative damage in the intestinal tract.

Spices Obtained from Rhizomes or Tubers

Zedoary

Zedoary (*Curcuma zedoaria* Rosc. syn. *C. zerumbet* Roxb.) closely resembles turmeric (*C. longa*) in appearance. It is a native of northeast India and is widely cultivated in many parts of China, Sri Lanka, and India.

The plant bears green leaves with brownish-purple veins and grows up to a height of 50 cm. The rhizomes, which are large and fleshy, are cut into small pieces and dried. Dried slices have a bitter and strong, camphoraceous taste and are used for commercial purposes.

Steam distillation of the rhizome yields a light yellow oil. The odoriferous constituent is said to be a sesquiterpene alcohol belonging to the tricyclic group.

Zedoary was an important spice in the past, but these days, it is usually used only for flavoring liqueurs and curries. The rhizomes have aromatic, stimulant, and carminative properties. Besides its use as spices, the rhizomes are also used for the preparation of shoti starch (flour), a substitute for arrowroot and barley. It is highly valued as a dietary item, especially for infants and convalescents. A red powder, 'abir,' is also prepared from powdered rhizomes by treatment with a decoction of sappan wood.

Mango ginger

Mango ginger (*Curcuma amada* Roxb.) is a member of the family Zingiberaceae. The plant is native to India and occurs in the wild state in parts of Bengal, Konkan, and Madras (see Figure 4).

The plants are herbaceous, and the rhizomes have the characteristic odor of green mangoes. At the time of harvesting, entire plants are lifted up with a crowbar, and the rhizomes are collected, cleaned, and dried in the shade. On distillation, the rhizome yields essential oil, which consists mainly of pinene, ocimene, and linalool. The rhizome is mostly used in pickles and is considered stomachic and carminative. It is also applied over contusions and sprains.

Figure 4 Spices and flavoring crops: rhizome of mango ginger (*Curcuma amada*).

Mango ginger has proved as an effective antimicrobial agent for *M. luteus*, *B. cereus*, and *B. subtilis*. Additionally, antioxidants were found to be present in mango ginger and were found to be easily extractable.

Galangal

Galangal is of three types: lesser galangal, greater galangal, and light galangal. The reddish-brown rhizomes are used as condiment and have an aromatic spicy odor and a pungent taste.

The lesser galangal (*Alpinia officinarum* Hance.), a member of the family Zingiberaceae, is a native of southern China. The plant is a perennial herb with a raceme of showy flowers and attractive foliage. The rhizome is smaller and has a stronger odor and taste. The lesser galangal is used as a spice in cooking and also in medicine and for flavoring liqueurs. It is also used to impart a pungent flavor to vinegar.

The greater galangal (*Alpinia galanga* (L.) Willd.) is also a perennial herb with showy flowers and beautiful foliage. It is commonly found in Indonesia and Malaysia and is also cultivated in Bengal and southern parts of India. The green rhizomes contain essential oil consisting mainly of methyl cinnamate and cineol. It gives a pungent taste like a mixture of pepper and ginger. Medicinally, it is useful in respiratory troubles, especially in children. The rhizomes are also carminative and stomachic.

The light galangal (*Alpinia speciosa* (Wendl.) K. Schum) is a native of the Eastern Archipelago, off the Coromandel Coast of southeast India. Its rhizome is much larger and is generally used as substitute for greater galanga, and even as a substitute for ginger in many preparations.

Galangal has proved to be an effective antimicrobial agent for *Staphylococcus aureus*, but not for *Escherichia coli*. In addition, antioxidants have been found in a moderate concentration that can function as a lipoxygenase inhibitor.

Spices and Flavoring Crops: Uses and Health Effects

K Srinivasan, CSIR – Central Food Technological Research Institute, Mysore, India

Herbs and Spices

Herbs such as basil, mint, and rosemary are grown and harvested fresh for cut leaves and used for cooking, garnish, or medicinal purposes. Spices are parts of herbal plants such as aromatic seed, berries, bark, root parts, and even the stigma of a flower. Herbs and spices have a long history of both culinary and medicinal uses. Spices are traditionally consumed as food adjuncts to enhance sensory quality of foods, the quantity and variety consumed in tropical countries being particularly extensive. Besides contributing to flavor, color, and aroma to our everyday diet, spices have also been long recognized to possess physiological effects supposed to be beneficial to human health. They act as stimulus to the digestive system and relieve digestive disorders, and some spices are of antiseptic value. Their attributes, such as tonic, carminative, stomachic, diuretic, and antispasmodic – largely empirical nevertheless efficacious, have found pharmacological applications in the indigenous systems of medicine. In India, the indigenous Ayurvedic system of medicine uses herbs and spices for health including tumeric for jaundice, basil to protect the heart, mace for stomach infections, cinnamon to stimulate circulation, and ginger as the universal medicine, in particular for relieving nausea and indigestion. Traditionally, the Chinese have integrated food and health including herbs and spices in specially prepared soups, dishes, or beverages for both sustenance and purported health benefits. Ginseng and ginkgo biloba are used to improve stamina and cognitive performance, respectively. Other medicinal uses include galangal for abdominal pain, nutmeg for the management of diarrhea, and cinnamon for colds and flu (Figures 1 and 2).

With the long history of the use of spices dating back to 5000 years BC, and spices significantly contributing to human health by providing bioactives, these may be considered as the first ever recorded functional foods. Spices make foods palatable without salt and hence assist in the desirable reduced daily intake of sodium. Similarly, they make foods palatable without fat, thus enabling to meet healthy fat intake. The use of spices also encourages variety in food intake, thus supporting nutrient diversity by encouraging number of food choices.

Spices do not contribute anything significant to human nutrition. Due to low levels of consumption of spices, their impact on nutrient makeup may not be as dramatic as other food ingredients. In the last four decades, several health beneficial effects of spices have been experimentally documented that suggest that the use of these food adjuncts extends beyond taste and flavor. The emerging research literature suggests that specific spices may confer unique health benefits. Although human studies are limited, considerable attention to this has been drawn because of the positive results from *in vitro* and *in vivo* animal studies.

Proven Health Effects of Herbs and Spices

Digestive Stimulant Action of Spices

Digestive stimulant action of spices is the most common experience of many. Spices such as ginger (*Zingiber officinale*), mint (*Mentha spicata*), ajowan (*Trachyspermum ammi*), cumin (*Cuminum cyminum*), fennel (*Foeniculum vulgare*), coriander (*Coriandrum sativum*), and garlic (*Allium sativum*) are common remedies used in traditional medicines or ingredients of preparations to cure digestive disorders. The mechanism of digestive stimulant action of spices has been understood by extensive animal studies. Many commonly consumed spices – turmeric (*Curcuma longa*), red pepper (*Capsicum annuum*), ginger, fenugreek (*Trigonella foenum-graecum*), mustard (*Brassica nigra*), cumin, coriander, ajowan, tamarind (*Tamarindus indica*), and onion (*Allium cepa*) – stimulate bile acid production by the liver and its secretion into bile. Bile acids play a major role in fat digestion and absorption. Several spices are also evidenced to stimulate the activity of digestive enzymes of pancreas, particularly lipase and terminal digestive enzymes of small intestinal mucosa (Figure 3).

Antidiabetic Potential of Spices

Among spices that have been evaluated for antidiabetic attribute, fenugreek seeds, garlic and onion, and turmeric have been found to be effective in improving the glycemic status and glucose tolerance in diabetic animals/type 2 diabetic patients. Animal studies and clinical trials on antidiabetic properties of fenugreek and onion have been particularly extensive, while human studies are limited in the case of garlic and turmeric. Studies have unequivocally demonstrated the antidiabetic potential of fenugreek in both type 1 diabetes and type 2 diabetes. The addition of fenugreek seeds to the diets of diabetic patients or animals results in a fall in blood glucose and improvement in glucose tolerance. The hypoglycemic effect is attributed to the fiber and gum, which constitute as much as 52% of fenugreek seeds. The fiber-rich fenugreek is believed to delay gastric emptying by direct interference with glucose absorption.

Garlic and onion are two other spices, which have been widely tested for their antidiabetic potential. Both these spices have shown hypoglycemic potential in different diabetic animal models and in limited human trials. The hypoglycemic potency of garlic and onion is attributed to the disulfide compounds present in them, di(2-propenyl) disulfide and 2-propenylpropyl disulfide, respectively, which cause direct or indirect stimulation of insulin secretion by the pancreas. In addition, they may also have insulin-sparing action by protecting from sulfhydryl inactivation by reacting with endogenous thiol-containing molecules such as cysteine, glutathione, and serum albumins (Figure 4).

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00645-0

Figure 1 Spices used for enhancing taste and flavor of foods.

Turmeric is also claimed to possess beneficial hypoglycemic effect and to improve glucose tolerance in a limited number of studies. Nephropathy is a common complication in chronic diabetes. High blood cholesterol is an added risk factor that determines the rate of decline of kidney function in diabetic situation. Dietary curcumin (of turmeric) and onion have been found to have a promising ameliorating influence on the severity of renal lesions in streptozotocin-diabetic rats. Hypocholesterolemic effect of these spices as well as the ability to lower lipid peroxidation under diabetic condition is implicated in the amelioration of renal lesions. Capsaicin of red pepper has been shown to be useful in diabetic neuropathy. Topical application of 0.075% capsaicin cream was effective in pain management. These antidiabetic spices may be used in conjunction with antidiabetic drugs to minimize drug dosage.

Cardioprotective Effect of Spices

(a) *Hypolipidemic influence*: Several common spices have been evaluated for cholesterol-lowering effect in a variety of experimental situations in both animals and humans. Garlic, onion, fenugreek, turmeric, and red pepper are found to be effective as hypocholesterolemic agents under various conditions of experimentally induced hypercholesterolemia/hyperlipidemia. Garlic, fenugreek, and onion are effective in humans with hyperlipidemic condition. Consumption of garlic has been associated with a reduction in total cholesterol, low-density lipoprotein cholesterol, and triglyceride levels. Many clinical studies have indicated that consuming one clove of garlic (or equivalent) daily will have at least 10% cholesterol-lowering effect. With the availability of dehydrated garlic powder containing a standardized level of the parent sulfur compound – alliin – effective clinical work could be undertaken with a relatively low and acceptable daily dosage of 300–900 mg (equivalent to one clove of garlic). Fenugreek seeds were hypocholesterolemic in rats with hyperlipidemia induced by either a high-fat or high-cholesterol diet. Defatted fenugreek seed was effective in diabetic hypercholesterolemia in dogs and in humans. The hypolipidemic effectiveness of turmeric/curcumin, of red pepper/capsaicin, and of onion and garlic has been periodically reviewed. Spice compounds curcumin and capsaicin have been associated with a decrease in LDL cholesterol and an increase in HDL cholesterol levels in animal studies.

(b) *Antithrombotic property*: Besides the beneficial effect on serum lipid profile (lowering of LDL cholesterol and triglyceride levels), the antiplatelet aggregation and the antiplatelet adhesion properties of several spices also contribute to cardiovascular protection. The spices/spice compounds documented to have inhibitory effect on platelet aggregation are garlic, onion, curcumin, cuminaldehyde, eugenol, and zingerone. Garlic in particular exhibits antithrombotic and hypotensive properties, both of which also contribute to cardiovascular protection besides the hypolipidemic properties.

(c) *Suppression of LDL oxidation*: Antioxidant properties of spices are of particular interest in view of the impact of oxidative modification of LDL cholesterol in the development of atherosclerosis. Recent evidences have indicated that free radicals contribute to cardiovascular disease. Oxidative modification of LDL is hypothesized to play a key role during the development of atherosclerosis. Since spices have high antioxidant concentrations that have the potential to inhibit the oxidation of LDL, the use of antioxidant spices is a promising proposition.

(d) *Thermogenic influence*: Obesity-related insulin resistance has emerged as a potent risk factor for cardiovascular disease. Dietary factors that affect satiety and thermogenesis could play an important role in determining the prevalence and severity of this problem. Among spices that may have a role to play in this regard, red pepper (or its pungent principle capsaicin) and garlic are promising and more data are required to substantiate this benefit. The use of spices to displace fats and salt in the diet may reduce cardiovascular risk.

Gallstone Preventive Effect

Persistent high-cholesterol diet leads to cholesterol saturation in bile resulting in the formation of cholesterol crystals – gallstones in gall bladder. Studies on experimental induction of cholesterol gallstones in mice and hamsters by feeding a lithogenic diet have revealed that the incidence of gallstones is 40–50% lower when the animals are maintained on 0.5% curcumin or 0.015% capsaicin-containing diets. Animal studies have also revealed significant regression of preformed cholesterol gallstones by these spice principles in a 10-week feeding trial. The gallstone preventive potential of other known hypocholesterolemic spices – garlic, onion, and fenugreek seeds – has also been recently evidenced in animal

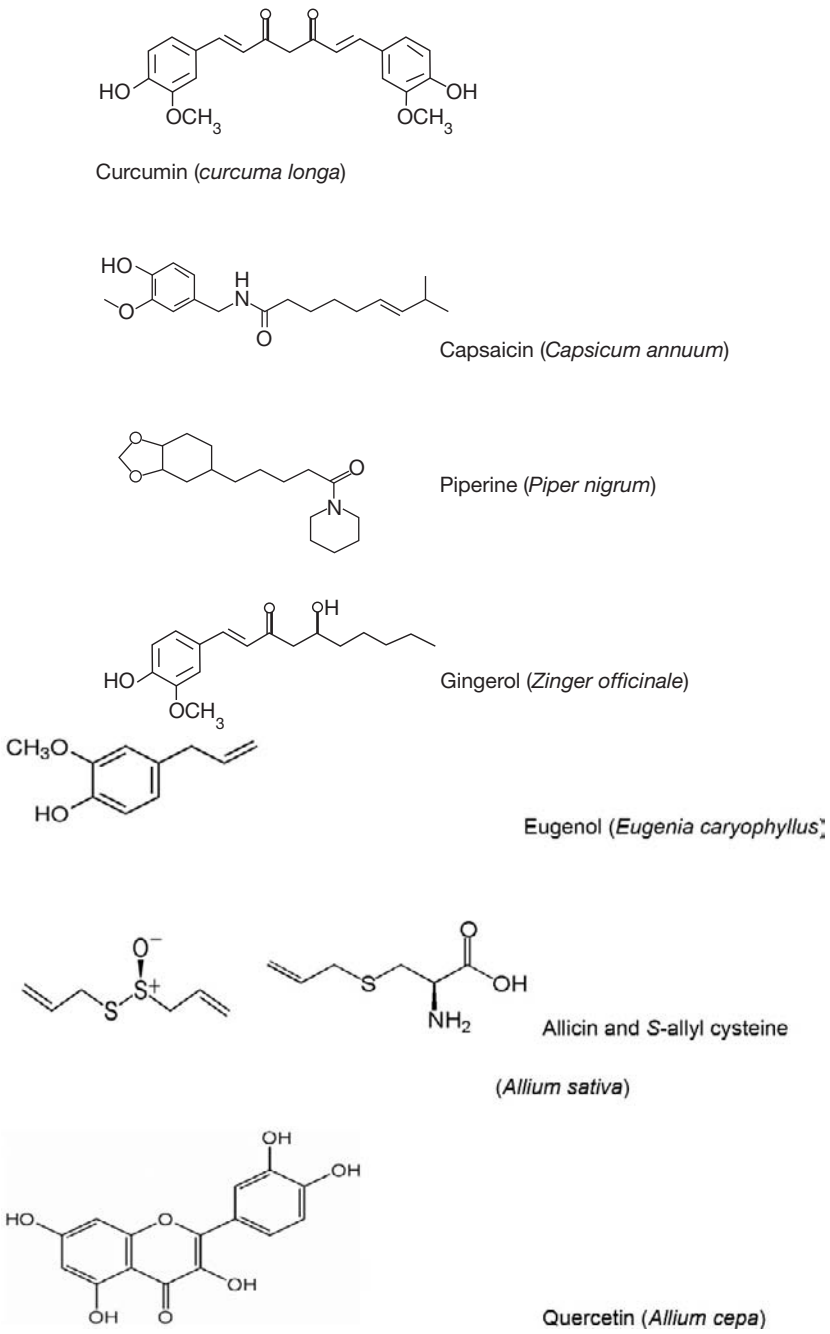

Figure 2 Formulas of compounds present in spices with health effects attributable to their bioactive compounds.

studies. The antilithogenicity of these spices is attributable to the lowering of cholesterol concentration and enhancing the bile acid concentration, both of which contribute to the lowering of cholesterol saturation index and hence its crystallization. In addition to their ability to lower cholesterol saturation index, the antilithogenicity of these spices may also be due to their influence on biliary proteins.

Anti-Inflammatory Property

Lipid peroxides play a crucial role in arthritis and other inflammatory diseases. Turmeric happens to be the earliest anti-inflammatory drug known in the indigenous system of medicine in India. Turmeric extract, curcuminoids, and volatile oil of turmeric have been found to be effective as anti-inflammatory in several animal studies. Both *in vitro* and *in vivo* animal studies have documented the anti-inflammatory potential of spice principles curcumin (of turmeric), capsaicin (of red pepper), and eugenol (of clove). Anti-inflammatory effect of curcumin in patients who have undergone surgery for hernia was found comparable to that of phenylbutazone. In rheumatoid arthritis patients, administration of curcumin produced significant improvement. Capsaicin has received considerable attention as a pain reliever. In patients with

osteoarthritis and rheumatoid arthritis, topical application of creams containing 0.025% or 0.075% capsaicin was an effective and safe alternative to analgesics employed in systemic medications. Capsaicin has also been suggested for the initial management of neuralgia consequent to herpes infection. There is also evidence for the benefit of ginger in ameliorating arthritic knee pain. Ginger doses of 0.5–1.0 g per day were efficacious in osteoarthritis and rheumatoid arthritis.

Antimutagenicity and Anticancer Effect

Phenolic substances present in spices have been reported to possess substantial anticarcinogenic activities. The majority of these naturally occurring phenolics possess antioxidative and anti-inflammatory properties, which appear to contribute to their chemopreventive or chemoprotective activity. Certain phytochemicals from spices have been shown to inhibit one or more of the stages of the cancer process (initiation, promotion, growth, and metastasis). Inhibition of phase I metabolic enzymes (involved in procarcinogen activation) and induction of phase II metabolic enzymes (involved in carcinogen deactivation) may account for the chemopreventive effects of spices. Spices may also protect against oxidative stress and inflammation, both of which are a risk factor for cancer initiation and promotion (as well as other pathological conditions).

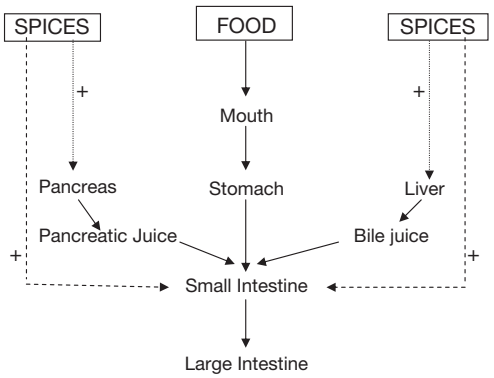

Figure 3 Digestive stimulant action of spices.

Spices that have antioxidant property can function as antimutagens. Since mutagenesis has a direct bearing on cancer initiation, antimutagenic spices can probably be anticarcinogenic too. Turmeric/curcumin and garlic have been shown to be antimutagenic in several experimental systems. *In vivo* studies in experimental animals suggest that turmeric and curcumin inhibit the formation of mutagens. Spices with known anticarcinogenic effects in animal models of cancer include turmeric, garlic, and ginger. Turmeric has been found to have chemopreventive effects against cancers of the skin, forestomach, liver, colon, and mouth in mice. Animal studies involving experimental induction of tumor of specific tissues with potent chemical carcinogens have revealed significant reduction of the incidence of tumor in curcumin treatment. Several studies indicate that curcumin can suppress both tumor initiation and tumor promotion. Curcumin is a powerful inhibitor of the proliferation of several tumor cells. With many evidences suggesting that curcumin can suppress tumor initiation, promotion, and metastasis, and with proven safety of its consumption (up to 10 g per day), curcumin offers enormous potential in the prevention and therapy of cancer.

Cancer-preventive ability of garlic has been indicated by etiological studies wherein higher intake of Allium products is associated with reduced risk of several types of cancers, especially stomach and colorectal. Garlic is effective in the detoxification of carcinogens through its effects on phase I and phase II enzymes. Several mechanisms have been proposed to explain the cancer-preventive effects of garlic and its organosulfur compounds. These include inhibition of mutagenesis, modulation of enzyme activities thus suppressing bioactivation of carcinogen molecules, inhibition of carcinogen-DNA adduct formation, free radical scavenging, inhibitory effects on cell proliferation and tumor growth, and induction of apoptosis. Pungent vanilloids especially [6]-gingerol present in ginger (*Z. officinale*) have been found to possess potential chemopreventive activities.

Antioxidant Activity

Oxidative damage has been implicated in the etiology of disease processes such as cardiovascular disease, inflammatory

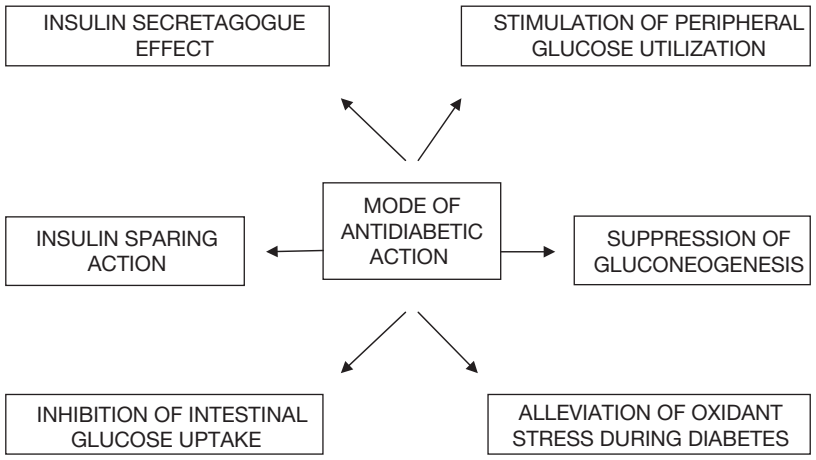

Figure 4 Possible mechanisms of antidiabetic action of spices.

diseases, cancer, neurodegenerative diseases, and other degenerative diseases. Excessive free radical generation overbalancing the rate of their removal leads to oxidative stress. Antioxidants are compounds that hinder the oxidative processes and thereby delay or suppress oxidative stress. The bioactive compounds present in spices that possess potent antiatherogenic, anti-inflammatory, antimutagenic, and cancer-preventive activities are in fact antioxidants that are experimentally evidenced to control cellular oxidative stress and thereby exert a beneficial role in preventing oxidative stress-mediated diseases.

Most of the health effects of spices on cancer, cardiovascular disease, inflammatory diseases, and neurodegenerative diseases may be mediated through their potent antioxidant effects. Suppression of oxidative stress and inflammation by spices is important in their cancer-preventive role, since both oxidative stress and inflammation are a risk factor for cancer initiation and promotion. The antioxidative effects of spice compounds – curcumin, eugenol, capsaicin, piperine, gingerol, and spices such as garlic, onion, and fenugreek – have been experimentally evidenced. The studies to this effect are exhaustive and experimental evidences are plenty in the case of curcumin of turmeric and eugenol of clove. Studies with several *in vitro* systems as well as *in vivo* animal studies have revealed that spice principles curcumin, eugenol, and capsaicin have beneficial antioxidant property by quenching oxygen free radicals, by inhibiting the production of reactive oxygen radicals, and by enhancing the antioxidant enzyme activities.

The antioxidant activity of the spice compounds in mammalian system involves one or more of the following: (1) free radical scavenging, (2) suppressing of lipid peroxidation, (3) enhancing the antioxidant molecules in tissues, (4) stimulating the activities of endogenous antioxidant enzymes, (5) inhibiting the activity of inducible nitric oxide synthase, (6) inhibiting LDL oxidation, and (7) inhibiting enzymes of arachidonate metabolism. By virtue of antioxidant activity, curcumin has been documented to be anti-inflammatory, antimutagenic and cancer-preventive, antiatherogenic and cardioprotective, hepatoprotective, neuroprotective, anti-cataractogenic, effective wound healant, etc. (Figure 5).

Beneficial Influences of Pungent Spices on Gastrointestinal System

Influence on small intestinal ultrastructure and absorptive function

Piperine of black pepper also causes an increase in intestinal brush border membrane fluidity and stimulated the activities of membrane bound enzymes due to the alteration in enzyme kinetics. Ultrastructural studies with piperine showed an increase in microvilli length. Thus, piperine may induce alterations in membrane dynamics and permeation characteristics,

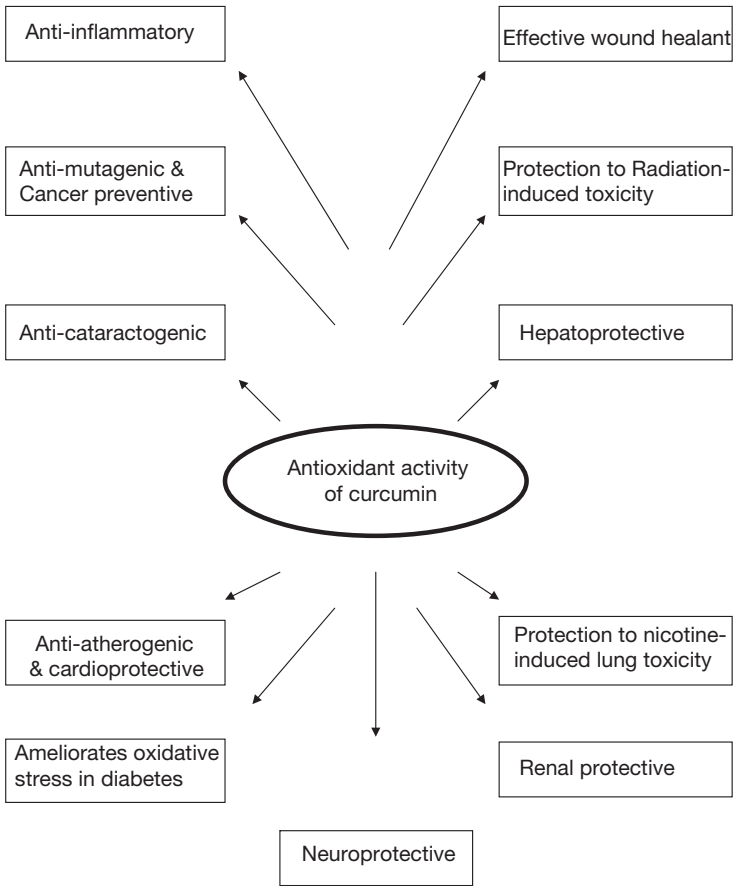

Figure 5 Health implications of antioxidant property of spices.

along with induction of the synthesis of proteins associated with cytoskeletal function, resulting in an increase in the absorptive surface, thus assisting efficient permeation through the epithelial barrier. Dietary pungent spices – black pepper/piperine, red pepper/capsaicin, and ginger – were evidenced to induce alteration in brush border membrane fluidity and passive permeability property, associated with the induction in the increased microvilli length, resulting in increased absorptive surface of the small intestine.

In view of dietary black pepper/piperine, red pepper/capsaicin, and ginger specifically altering the ultrastructure and permeability characteristics of small intestines, these spices have been examined for their possible influence on intestinal absorption of minerals. Higher absorption of iron, zinc, calcium, and β-carotene from duodenum, jejunum, and ileum portions of small intestines isolated from rats prefed these spices has been observed. These pungent spices alter permeation characteristics presumably by increasing absorptive surface and thereby enhance intestinal absorption of micronutrients.

Effect on gastric mucosa

Pungent spices have long been implicated to cause gastric mucosal injury. On the other hand, protective action of piperine against experimental gastric ulcer has been evidenced in rats and mice. Piperine protected animals from gastric ulceration in a dose-dependent manner as indicated by inhibition of the volume of gastric juice, gastric acidity, and pepsin activity. Protective effect of dietary black pepper/piperine, red pepper/capsaicin, and ginger with respect to activities of antioxidant enzymes in gastric and intestinal mucosa has been evidenced with significantly enhanced activities of antioxidant enzymes in both gastric and intestinal mucosae, suggesting a gastrointestinal protective role. These pungent spices were also found to alleviate the diminished activities of antioxidant enzymes in gastric and intestinal mucosa under conditions of ethanol-induced oxidative stress. The gastroprotective effect was also reflected in their positive effect on mucosal glycoproteins, thereby lowering mucosal injury. The amelioration of the ethanol-induced decrease in the activities of antioxidant enzymes in gastric and intestinal mucosa by dietary pungent spices suggests their beneficial gastrointestinal protective role.

Enhancing Effect of Piperine of Black Pepper on Bioavailability of Drugs/Phytochemicals

Piperine of black pepper is now established as a bioavailability enhancer of various structurally and therapeutically diverse drugs and other substances. Potential of piperine to increase the bioavailability of drugs in humans is of great clinical significance. Most of the clinical trials have shown that piperine increases levels of medications. This effect is due to the inhibitory interaction of piperine with cytochrome P_{450} enzymes of the liver and small intestine that are involved in drug metabolism.

Antimicrobial Activity

Antimicrobial activity has been demonstrated *in vitro* for several herb and spice extracts and essential oils from thyme, oregano, parsley, cilantro, and cinnamon. Growth of several bacteria strains has been shown to be inhibited by various concentrations of these culinary herb and spice extracts in the culture medium. Antimicrobial phytochemicals fall into several categories: phenolics/polyphenols, terpenoids and essential oils, alkaloids, and lectins and polypeptides. Phenolic and polyphenols possess multiple antimicrobial mechanisms of action when compared to other phytochemical categories. They are capable of forming an irreversible complex with nucleophilic amino acids in protein, leading to their inactivation and therefore loss of function in bacteria. Phenolic and polyphenols have been reported to disrupt microbial membranes, inactivate microbial enzymes, and activate immune response by stimulating macrophages.

Other Flavoring Crops

Vanilla (*Vanilla planifolia*)

Vanilla is a flavor derived from pods of the genus Vanilla (*Vanilla planifolia*). Among many compounds present in the extracts of vanilla, the compound vanillin (4-hydroxy-3-methoxybenzaldehyde) is primarily responsible for the characteristic flavor and smell of vanilla. A major use of vanilla is in flavoring ice cream. Vanilla contains high levels of antioxidants. It has sedative property and hence alleviates anxiety. Vanilla is also used as an aromatherapy remedy being considered a popular scent for conferring aphrodisiac effects (Figure 6).

Cocoa (*Theobroma cacao*)

Cocoa bean is the dried and fully fermented fatty bean of *Theobroma cacao*, from which cocoa solids and cocoa butter are extracted. They are the basis of chocolate. A cocoa pod has a rough and leathery rind about 3 cm thick, which is filled with sweet, mucilaginous pulp. In general, chocolate and cocoa are considered to be a rich source of antioxidants such as procyanidins and flavonoids, which may impart antiaging properties. Chocolate and cocoa also contain good amount of flavonoids, specifically epicatechin, which may have beneficial cardiovascular effects on health. The stimulant activity of cocoa is attributable to the compound theobromine. Prolonged intake of flavanol-rich cocoa has been linked to cardiovascular health benefits. It is believed that the improved blood flow after consumption of flavanol-rich cocoa may help to achieve health benefits in the heart and brain in terms of learning and memory. Foods rich in cocoa are understood to reduce blood pressure.

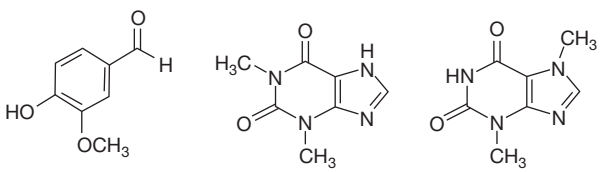

Figure 6 Formulas of bioactive compounds present in other flavor crops.

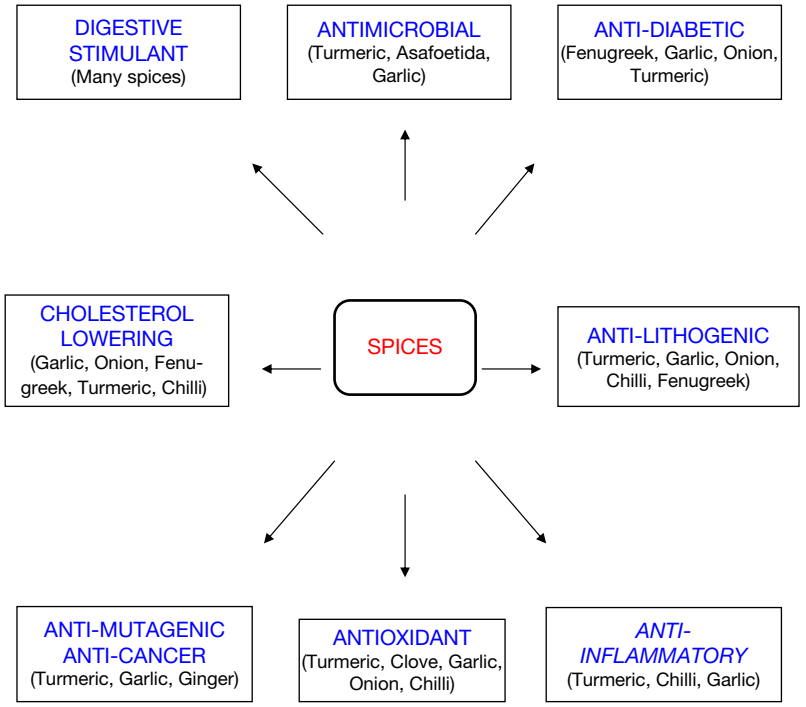

Figure 7 Summary of multiple health effects of spices.

Tea Leaves (*Camellia sinensis*)

Tea is the most widely consumed aromatic beverage in the world. Tea contains a large number of bioactive chemicals, including flavonoids, vitamins, caffeine, and several polysaccharides. It has been suggested that green and black tea may protect against cancer; catechins found in green tea are thought to be more effective in preventing liver cancer and colorectal cancer, while both green and black teas may protect against cardiovascular disease. Epidemiological studies have investigated the effects of green tea consumption on the incidence of human cancers and suggest significant protective effects of green tea against oral, pharyngeal, esophageal, prostate, digestive, urinary tract, pancreatic, bladder, skin, lung, colon, breast, and liver cancers and lower risk for cancer metastasis and recurrence.

Conclusions

By making the food attractive and palatable through flavor, aroma, and color, spices can reduce the need to use less healthy ingredients such as salt, fat, or sugar. Many health beneficial attributes of these common food adjuncts have been experimentally evidenced in the past few decades that include digestive stimulant action, antiatherogenic and cardioprotective potential, antilithogenic property, antidiabetic influence, anti-inflammatory property, and cancer-preventive potential. The antioxidant and hypolipidemic properties of spices have far-reaching nutraceutical value. The antioxidant properties of bioactive compounds present in spices are of particular interest in view of the impact of suppression of oxidative stress in the development of degenerative diseases such as cardiovascular disease, neurodegenerative disease, inflammatory disease, and cancer. Spices thus deserve to be considered as nutraceuticals beyond their role in imparting taste and flavor to our food (Figure 7).

Spoilage: Bacterial Spoilage

X Dousset, E Jaffrès, and M Zagorec, INRA, UMR 1014 Secalim, France; LUNAM Universite, Nantes, France

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Although food spoilage cannot be considered a health issue, it deals with food safety and has important economic and ecological consequences. In fact, about one-third of all the food that is produced for human consumption worldwide (i.e., dairy, fish and meat products, fruits and vegetables, cereals, and roots) is lost or wasted. A significant proportion of the loss is due to spoilage by microorganisms, resulting in final products with an inadequate shape or appearance. Consequently, spoiled food is lost because it does not fit the quality criteria, and will thus be removed from the market before commercialization, or it is wasted at the end of the food supply chain, because it will be rejected by the consumer. Various bacteria can spoil food, and whether or not they are harmful for consumer health, they cause a change in color or texture, an undesirable taste, or an unpleasant odor. The list of bacterial species involved in food spoilage is long and encompasses both Gram-positive and Gram-negative species. Some can develop in a wide range of products and are responsible for the spoilage of different foodstuffs, whereas others are specific to a product or a process. Moreover, worldwide, for a given type of food, the bacterial spoilage may be different, depending on the various processes or storage conditions that may be in use in different countries. As an example, low temperature during the storage and transportation of meat or milk, used mostly in industrialized countries, selects psychrotrophic bacteria. This is not the case in some developing countries, which in addition may have a warm and humid climate.

A variety of methods have been used to ensure microbial food safety, like fermentation, smoking, drying, and addition of various curing agents and subsequent storage at low temperatures or under different oxygen concentrations. Fermentation is quite an efficient process, so that spoilage of fermented products is relatively rare. Salts like nitrite/nitrate and NaCl also contribute to diminishing bacterial growth, although some bacterial species can resist salt addition. The use of cold storage considerably reduces spoilage as it limits bacterial development. However, as mentioned earlier, it may select psychrotrophic or psychrophilic bacteria, and some of these may cause spoilage. The use of atmospheres poor in oxygen or of vacuum packaging limits spoilage by aerobic bacteria but may result in the development of other types of spoilage like blown pack spoilage of vacuum-packed meat caused by the bacterial production of gas.

Clearly, the bacterial spoilage of food is diverse, results from many different mechanisms, and can be caused by many different bacteria. We will present the main bacterial spoilage for dairy, meat, and seafood products and products of vegetable origin. We will also briefly discuss new information that is being gained through high-throughput DNA sequencing methods about the bacterial species that may be responsible for the spoilage of food products and through metabolomics studies that can reveal the bacterial metabolic activities responsible for spoilage.

Dairy Products

Milk production exceeds 700 million tons annually, but about 10–20% of the initial milk and dairy production is lost worldwide. Europe is the main producer of dairy products. A large proportion of them found on the market are fermented, like cheese (20 million tons) or yogurt. Starter cultures, often used in the industrial production of fermented products, usually overgrow indigenous microbiota, lead to a pH drop, and thus limit the possibility of spoilage bacteria having a negative effect on the quality of the products. The addition of salt in cheese making also contributes to reducing spoilage. Nevertheless, dairy product spoilage is still reported, and some examples are listed in the succeeding text.

In fresh cheese, like cottage cheese, the relatively high pH may not be sufficient to inhibit the development of psychrotrophic species of *Pseudomonas* and coliforms. The spectacular 'blue mozzarella cheese' spoilage has been reported in Italy and Germany. It is caused by *Pseudomonas fluorescens* strains producing a blue pigment (i.e., pyocyanin) after mozzarella cheese packs are opened, changing the milky white balls typical of this product into inky blue balls. *Pseudomonas fluorescens* and other *Pseudomonas* species, such as *Pseudomonas putida* and *Pseudomonas fragi*, may also be responsible for the rancid flavors and odors caused by their lipid and fatty acid metabolism. In addition, several *Pseudomonas* and *Bacillus* species can produce proteases that may degrade caseins causing the bitterness of cheese and influencing milk coagulation. Extracellular lipase and protease activities produced by *Pseudomonas* can be heat-stable and therefore affect milk quality even after heat treatment, such as pasteurization or ultra-high-temperature treatment. Slime production by some lactic acid bacteria has also been reported. This property is considered beneficial for fermented yogurts since it contributes to their texture but undesirable in many other products. Slime production by *Alcaligenes viscolactis* in cottage cheese and by *Pseudomonas putida* or *Pseudomonas fragi* on cheese surfaces has been reported as spoilage. Moreover, the butter smell due to the diacetyl molecule participates in the quality of some dairy products but is undesirable in others. Diacetyl is produced by various bacteria, in particular lactic acid bacteria, but degraded by other species. Therefore, some lactic acid bacteria may be considered spoilers through diacetyl production in some products, whereas diacetyl degradation by some species may result in spoilage in other products requiring a buttery flavor. *Propionibacterium freudenreichii* contributes to the Swiss-type cheese taste and to the 'eyes' or holes typical of these cheeses by producing gas. This phenomenon is well controlled by cheese makers, but occasionally, lactic acid bacteria or Clostridia may produce a gassy defect in an uncontrolled

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00649-8

manner, leading to holes of unwanted size. *Clostridium tyrobutyricum* may cause this spoilage and, by producing butyric acid, may also provoke a rancid taste. Early blowing in fresh cheese in the early ripening stage and late blowing occurring well into the ripening stage of hard and semihard cheeses are also important causes of spoilage. It results in considerable losses as large-volume productions can be spoiled. Gas (CO_2) and butyric acid production by bacterial metabolism lead to balloon-like expansion of cheeses and to rancidity, respectively. Several gas-producing bacterial species belonging to Enterobacteriaceae can be responsible for early blowing, while *Clostridia* spp. are the main causes of late blowing. Clostridial spores, initially present in raw milk, can germinate and then grow during the cheese making process. *Clostridium tyrobutyricum* is the main species causing late blowing, but *Clostridium butyricum* and *Clostridium sporogenes* have also been reported as involved in this defect.

These examples show that bacterial spoilage of dairy products may affect the color, texture, odor, or appearance of the product and can be caused by various Gram-positive and Gram-negative species.

Seafood Products

Seafood consumption is constantly increasing worldwide, with industrial Asia being the main producer. Seafood products constitute notably the main source of protein, lipid, vitamins, and mineral nutrients in many countries. This significant role in consumer food choices is strongly linked to the healthy diet image and the nutritional properties associated with seafood product consumption. At the same time, losses and waste of seafood products can reach a high level, due to their high sensitivity to spoilage. For example, 30–50% of the initial catch is discarded, lost, or wasted, with more than half at the production, distribution, and consumer stages, thus largely because of spoilage. In the first steps after catching fish or seafood, spoilage is the result of either autolytic activities by free enzymes, naturally present in the flesh (lipases, proteases, decarboxylases, etc.), or lipid autooxidation, leading to secondary metabolites (esters, alcohols, aldehydes, ketones, etc.) associated with strong off-odors. In the subsequent processing steps, most spoilage is due to the development of specific spoilage bacteria. These microorganisms can grow easily on seafood products due to their ideal physiological conditions, such as a neutral pH, a high water activity, and a high content of low-molecular-weight compounds like free amino acids and nucleotides.

The microbiota present in seafood and fish products arise from an initial contamination by the environment (i.e., seawater) and fish microbiota (skin and gastrointestinal tract), and subsequently by contact with different surfaces during the processing steps, or through the addition of various ingredients. By growing on seafood, spoilage bacteria can implement metabolic pathways resulting in the production of a variety of molecules. In fact, bacterial spoilers can produce volatile compounds, organic acids, biogenic amines, or exopolysaccharides responsible for slime production. However, the main agents in this microbial spoilage are not always clearly identified, as there is no correlation between a total number of bacteria and spoilage, and only a fraction of the total flora is involved. Nevertheless, many studies have been conducted to elucidate this spoiling fraction in seafood products, and, among them, several have shown that the nature of the spoilage microbiota is partly selected by the production process (thermal treatment, preservation process, atmosphere used for packaging, storage temperature, etc.). For example, spoilage of temperate and tropical raw fresh fish, such as halibut, sea bass, mullet, swordfish, salmon, haddock, and sea bream, stored on ice under aerobic storage, is mainly provoked not only by Gram-negative bacteria belonging to the *Shewanella* genus, especially the group '*Shewanella putrefaciens*-like' including *Shewanella putrefaciens* and *Shewanella baltica*, but also by different *Pseudomonas* species, such as *Pseudomonas fragi*, *Pseudomonas fluorescens*, *Pseudomonas putida*, and *Pseudomonas lundensis*. Species from the '*Shewanella putrefaciens*-like' group are notably able to produce sulfur compounds like hydrogen sulfide (H_2S) from the sulfur-containing amino acid L-cysteine. H_2S is responsible for the strong, putrid, and sulfur off-odor of spoiled seafood. These bacteria can also produce hypoxanthine from inosine (Ino) or inosine monophosphate (IMP). Ino and IMP may themselves arise from the autolytic processing of adenosine triphosphate, present in large amounts in fish muscles, which is degraded into adenosine diphosphate and adenosine monophosphate. Hypoxanthine is responsible for the bitterness and acrid taste of spoiled fresh fish. Some *Pseudomonas* species are also able to produce spoilage metabolites like esters, ketones, and aldehydes resulting from amino acid (notably glycine, serine, and leucine) catabolism and sulfur compounds such as methyl mercaptan (CH_3SH) and dimethyl sulfide [$(CH_3)_2S$], both formed from methionine breakdown. Another example of a raw seafood product in which the spoilage microbiota is dominated by Gram-negative bacteria is farmed freshwater prawn (*Macrobrachium rosenbergii*). After long-term storage on ice, its spoilage microbiota is dominated by more than 80% of Gram-negative bacteria such as *Pseudomonas*, *Aeromonas hydrophila*, *Aeromonas veronii*, and *Shewanella putrefaciens*. Another significant case is the king scallop (*Pecten maximus*) stored at cold temperature under aerobic conditions, which can be spoiled not only by a microbial flora dominated by *Pseudomonas* and *Shewanella* but also by the psychrotrophic Gram-positive species *Brochothrix thermosphacta*.

One way to reduce the impact of these spoilage bacteria is to change the atmosphere surrounding the seafood products by using either vacuum or CO_2-enriched modified atmosphere packaging (MAP), the latter being particularly suitable for inhibiting the growth of *Shewanella* and *Pseudomonas*. Nevertheless, CO_2 does not inhibit all Gram-negative bacteria. For example, *Photobacterium phosphoreum*, a Gram-negative bacterium regularly described as a seafood product spoiler, exhibits a very low sensitivity to CO_2. Consequently, *Photobacterium phosphoreum* is now recognized as the main spoilage bacterial species of several chilled marine fish, like cod, garfish, halibut, and salmon, packaged under modified atmosphere conditions. The main characteristic of *Photobacterium phosphoreum* spoilage is the production of trimethylamine [$N(CH_3)_3$] due to the use of trimethylamine *N*-oxide [$(CH_3)_3NO$] as a terminal electron acceptor during anaerobic respiration. Trimethylamine is responsible for the typical strong fishy, urine, and ammonia-like off-odors of spoiled fish and seafood products.

Another way to increase the protection of fish and seafood products against bacterial spoilage is to apply a thermal treatment during processing, followed by a specific packaging or various processes such as smoking, salting, and/or drying. These treatments are generally sufficient to stabilize or lightly preserve seafood by reducing the load of the majority of spoilage bacteria. However, seafood products can then undergo bacterial recontamination, mainly by Gram-positive bacteria, from the processing equipment, the environment in the production plant, and human handling. Their growth on seafood products can again result in the production of spoilage compounds. This is the case for cold-smoked salmon, where lactic acid bacteria play an important role in the spoilage process. In fact, experimental inoculation of sterile cold-smoked salmon with species from the *Lactobacillus* genus can provoke various spoilage defects. Notably, some *Lactobacillus sakei* strains can produce sulfurous (H_2S), floor cloth, and amine off-odors, *Lactobacillus alimentarius* can produce pungent and sour off-odors, and *Lactobacillus farciminis* can produce sour, acid, milky, and cabbage off-odors. Other lactic acid bacterial species participate in the spoilage of cold-smoked salmon, like *Carnobacterium maltaromaticum*, which produces butter and sour off-odors correlated with the production of large amounts of 2,3-butanedione and 2,3-pentanedione. *Brochothrix thermosphacta* also strongly affects the quality of cold-smoked salmon by producing large amounts of 2-heptanone and 2-hexanone, which are probably responsible for the blue cheese- and butyric acid-like off-odors.

Cooked shrimps constitute an interesting case of microbiological spoilage. Their shelf life depends on several parameters, such as the initial contamination, the efficiency of the heat treatment, the characteristics of the product (Nordic or tropical shrimps, peeled or whole, and brined or not with various brine solutions), and the packaging conditions (atmosphere and temperature of storage), which can all create hurdle effects regarding the growth of spoilage microbiota. The shelf life of Nordic and tropical shrimps packed under modified atmosphere, stored at different temperatures, and brined with various NaCl concentrations has been studied. After storage at 5 °C, shelf life ranged from 3 months when the brine solution was 2.3% NaCl to 6 months with 3.3% NaCl. Lactic acid bacteria were shown to dominate the bacterial population when products reached spoilage, with notably *Carnobacterium divergens* and *Lactobacillus curvatus* when the storage temperature was lower than 8 °C and *Enterococcus faecalis* for a storage temperature higher than 15 °C. The organic acid composition of the brine solution can also influence the spoilage microbiota. For example, a study on brined Nordic shrimps showed that *Enterococcus malodoratus*, *Carnobacterium maltaromaticum*, coagulase-negative *Staphylococcus* spp., *Lactobacillus sakei*, and *Pseudomonas fluorescens* could be detected when the brine solution was composed of benzoic, citric, and sorbic acids. However, when the brine solution contained acetic, citric, and lactic acids, the spoilage microbiota was constituted exclusively by yeast and *Lactobacillus sakei*, which was responsible for the production of sour and butter off-odors. Brine pH has also a significant effect on microorganisms. Indeed, a recent study performed by Danish scientists examined the effect of brine pH on the survival and growth of a spoilage species (*Lactobacillus sakei* isolated from brined and drained MAP shrimp and cold-smoked Greenland halibut) and on several pathogenic bacteria, previously isolated from various seafood products. Enumeration of bacteria after inoculation in brine containing sodium benzoate, citric acid, potassium sorbate, and sodium chloride, at three different pH values (i.e., 4.0, 4.4, and 4.8), showed significant growth reduction at pH 4.0 and 4.4.

Regarding the shelf life of unbrined, cooked, and peeled shrimps (Nordic or tropical), packed under modified atmosphere, the main bacteria involved in their spoilage are *Brochothrix thermosphacta* and *Carnobacterium maltaromaticum*, with the production of strong cheese/feet, sour/fermented, and butter off-odors, related to the release of chemical compounds such as 3-methyl-1-butanal, 2,3-butanedione, 2,3-heptanedione, and acetaldehyde. Interestingly, a study reported that when co-inoculated on cooked and peeled shrimps, *Brochothrix thermosphacta* and *Carnobacterium maltaromaticum* can form a typical wet dog off-flavor, whereas they do not produce this off-flavor when inoculated separately. No new metabolite was detected in *Brochothrix thermosphacta–Carnobacterium maltaromaticum* cocultures by comparison with those produced by both species inoculated alone. The authors suggested that this phenomenon cannot be considered as metabiosis, where one bacterium uses a product from another bacterium as a substrate to synthesize one or several new metabolites, since no new metabolite was produced by the coculture. It can therefore be hypothesized that the wet dog off-flavor is most probably resulting from an interaction between metabolites formed by *Carnobacterium maltaromaticum* and *Brochothrix thermosphacta*.

In conclusion, these examples show that fish and seafood bacterial spoilage mainly affects the odor of the products. More rarely, an undesirable taste (bitterness) or appearance (slime production) results from the spoilage of these food products.

Meat Products

The consumption of meat products is a source of protein for the human diet. According to the Food and Agriculture Organization of the United Nations, there is a need to increase drastically (60%) meat production in order to feed the human population by the year 2050. Worldwide, ~20–25% of meat production is wasted or lost. In industrialized countries like North America, Europe, and industrialized Asia, losses arise mostly at the end of the food supply chain. This might be explained by a large proportion of waste by retailers and consumers, suggesting that spoilage may be the main cause of such waste in this part of the world (which also has the highest meat consumption per capita). Reducing meat spoilage will therefore be an important challenge not only to feed the world but also to ensure the sustainable production of meat products.

Spoilage of meat varies depending on the type of product. As in fish and seafood products, early contamination in the slaughterhouse originates from animal microbiota (gastrointestinal tract, hide, skin, and feather). Consequently, this initial contamination is slightly different when the meat comes from different animals, for instance, birds or ruminants. As for other foodstuffs, subsequent contamination results from contact with equipment and material, during manipulations throughout the processing chain, and from the addition of various ingredients used in meat transformation.

As mentioned earlier for dairy products, fermented or dry-cured meats are usually stable products, and their spoilage by bacteria is not very common. In fact, putative spoiler species belonging to pseudomonads and enterobacteria initially present in the meat decrease during the fermentation and ripening steps. However, proteolytic bacteria like *Serratia*, associated with *Aeromonas hydrophila* and *Burkholderia cepacia*, have been reported to cause spoilage of Iberian dry-cured ham. Cured meat products are also sensitive to lipid oxidation, which can be directly or indirectly linked to bacterial metabolism and provokes undesired odors. The typical color of dry-cured meat products, resulting from bacterial, enzymatic, and chemical reactions, may be affected by the presence of some bacterial species. During fermentation, nitrite reacts with myoglobin, leading to nitrosomyoglobin that contributes to the typical color of cured meat products. Nitrate, added for fermentation, can be reduced to nitrite by bacterial metabolism, and therefore, bacteria can interfere with the desired color of cured meat.

Nonfermented but processed meat products are more sensitive to bacterial spoilage because of the increased number of processing steps and potential contaminations. The bacterial spoilage of various types of nonfermented sausage has been reported, involving some lactic acid bacteria (*Carnobacterium*, *Leuconostoc*, or *Weissella* species), Enterobacteriaceae, *Pseudomonas* species, and *Brochothrix thermosphacta*. Unacceptability due to this spoilage is mainly characterized by off-odors resulting from bacterial metabolism. Various bacterial species may also cause discoloration, especially for red meat products in which a greenish or grayish color is unacceptable.

In northern Europe, marinades are used to preserve and flavor raw meat. They consist of brine with salt, phosphate, sugar, organic acids, spices, and herbs to make up a sauce to flavor meat cuts. This may result in spoilage as sugar addition may contribute to bacterial development, particularly that of lactic acid bacteria.

The use of vacuum packaging has been largely developed for red meats like beef and venison, or lamb, to prolong their shelf life. The absence of oxygen in this type of packaging impairs the development of aerobic bacterial species, like *Pseudomonas* spp. However, the association of vacuum packaging with a cold or chilled storage temperature may result in the development of psychrophilic or psychrotrophic bacteria that produce gas, resulting in blown pack spoilage. The gas provokes swelling of the packs, which are then not acceptable for consumption, and, depending on the gas-producing bacterium, this spoilage may be accompanied by the production of off-odors. Several Clostridia have been reported or suspected to be responsible for blown pack including *Clostridium algidicarnis*, *Clostridium estertheticum*, *Clostridium gasigenes*, and *Clostridium putrefaciens* and psychrotolerant Enterobacteriaceae strains belonging to *Enterobacter*, *Serratia*, *Hafnia*, and *Rahnella* genera. Several lactic acid bacteria (*Lactobacillus sakei*, *Lactococcus piscium*, *Carnobacterium divergens*, and *Carnobacterium maltaromaticum*) have also been isolated from blown packs of beef meat. CO_2 is generally the main gas produced by bacteria responsible for blown pack, but several volatile organic compounds are sometimes associated, too. Consequently, the detection of butanoic acid, 1-butanol, dimethyl disulfide, acetic acid, and 3-methyl-1-butanol associated with CO_2 production has been proposed as a marker to detect the presence of bacterial species responsible for blown pack.

The use of oxygen-enriched atmospheres is also common to ensure red meat storage and enhance the typical bright red coloration of meat due to myoglobin. The high oxygen concentration (up to 70%) may also contribute to inhibiting the growth of strict anaerobic bacteria. However, *Brochothrix thermosphacta* and species of *Leuconostoc*, *Lactobacillus*, *Carnobacterium*, and *Clostridium* genera and of the family Enterobacteriaceae can resist these storage conditions and have been commonly associated with spoilage of modified atmosphere-packed meat products. Although lactococci have long been considered only in dairy products, the species *Lactococcus piscium* has been found in meat products stored under MAP and shown to be responsible for spoilage.

Various meat products, such as pâtés, hams, and sausages, are cooked but remain sensitive to recontamination after cooking. In fact, a single contaminant can develop without any competition on the product because it is not impaired by the presence of an indigenous flora. This is illustrated by a 'special spoilage problem in vacuum-packaged cooked meat products' that was reported in Finland. These products were contaminated by ropy slime-producing *Lactobacillus sakei* strains, which caused a ropy slime defect for a while in a large range of cooked meat products before being eradicated.

From the list of examples cited earlier, it is clear that bacterial spoilage of meat has multiple consequences: the color, odor, texture, and appearance, including that of the packaging, may be affected by a large number of bacterial species. Among them, *Brochothrix thermosphacta* has been the most frequently reported since it is the most versatile species, adapted to the vast diversity of meat products. As a facultative anaerobe, it can resist the various atmospheres used for meat packaging (vacuum, air, and modified atmosphere), although under vacuum packaging, it can be overgrown by other species. It can also cope with high salt concentrations, low pH, and low temperatures. This may explain why it is often incriminated in the spoilage of not only a large variety of meat products but also seafood and fish products, which have some common characteristics with meats from mammals or birds.

Vegetables

The consumption of fruit and vegetable products has increased by 20–30% in Western countries in recent decades. Several sources estimate global losses and waste at around 30% of the initial production intended for human consumption on the basis of literature and FAO food balance sheets. The microbiota present in vegetables partly reflects that of the soil and depends on culture methods (irrigation and fertilization). Compared with the other foodstuffs discussed in this article, one additional reason for bacterial spoilage is due to bacteria that are pathogenic to the plants. Contamination of fruits and vegetables is often related to the sanitary quality during the transformation process, with a bacterial population of the raw vegetable that can reach about 5–7 log CFU g^{-1} and is reduced to 3–4 log after blanching. This flora then increases after the packaging stage to reach 5–7 log CFU g^{-1}. The microbial limit

for consumer consumption of fresh processed vegetables is 8 log CFU g^{-1} of mesophilic aerobic bacteria.

Bacteria can enter through natural openings (stomata and lenticels) or areas injured by different types of plant damage (physical and biological), contaminating and spoiling these vegetables. Vegetables are rich in water (74–94%) but contain low amounts of sugars (8.6%), proteins (2%), and fat (0.3%). They also contain vitamins and minerals. This nutrient-rich environment is favorable for the growth of microorganisms. Unlike fruits, the pH of most vegetables is close to neutral and allows the development of plant spoilage agents (fungi, yeasts, and bacteria). The relatively high redox potential explains the greater presence of aerobic or anaerobic optional bacterial flora. The cell wall of plants is composed of polysaccharides including cellulose, pectin, and hemicellulose. Some spoilage bacteria can produce enzymes, such as xylanases, polygalacturonases, cellulases, proteases, and lipases, which degrade plant cell walls. These phenomena cause cell necrosis and tissue maceration (soft rot). The bacteria most involved in this type of spoilage are *Pseudomonas marginalis* and *Pectobacterium carotovorum*. Recent studies have shown that the aerobic flora of plants increases in the spoiled products but that bacterial diversity is reduced. From a study of 1000 isolates from different vegetables (lettuce, broccoli, onion, spinach, potato, carrot, etc.), 14 different genera and 20 different species were identified as the major ones. Most isolates were Gram-negative, but some Gram-positive ones (two *Bacillus* and one *Clavibacter*) were also present. Seven genera belonged to the family Enterobacteriaceae and several species of *Pseudomonas* were also identified, the majority belonging to the species *Pseudomonas fluorescens* and also *Pseudomonas chlororaphis*, *Pseudomonas corrugata*, and *Pseudomonas putida*. *Pectobacterium carotovorum* and *Dickeya zeae* can lead to maceration of plants through the production of extracellular enzymes such as cellulase and pectate lyase. *Pectobacterium carotovorum* also produces polygalacturonase, which alters the cell wall. *Pseudomonas chlororaphis* produces pectinase, which is the origin of the alteration of plants, and *Burkholderia* strains produce a pectate lyase that can macerate different kinds of plants. This suggests that pectate lyase is the major hydrolytic enzyme involved in the spoilage of vegetables. In processed vegetable products that are packaged under modified atmosphere (at concentrations below 2% O_2 and above 10% CO_2), several Gram-positive bacteria, mostly lactic acid bacteria, have been associated with spoilage of fresh-cut vegetables. It has also been reported that increasing the CO_2 concentration or reducing that of O_2 seems to favor the growth of lactic acid bacteria in fresh processed vegetables. These bacteria can increase from 3 to 6 log CFU g^{-1} after 7 days of storage. *Leuconostoc mesenteroides* has been reported to cause exudation and loss of texture in shredded carrots packed under modified atmosphere and stored at 10 °C for 10 days.

For fruits, bacterial contamination can occur at various stages of agricultural production and processing when the outer surface of the fruit comes into contact with soil, water, the production plant environment, surfaces of conveyor belts, and hands of packing workers. Since spoilage microorganisms may be harbored in the rough outer rind of the fruit, it is difficult to wash and clean fruits effectively. Bacteria are transferred from the external fruit surfaces to the edible portions during cutting, thus contaminating fresh-cut products. Moreover, fresh-cut products may be recontaminated through cross-contamination and improper handling during distribution.

The average water content of fruits is 85% and the carbohydrate content is about 13%. Like vegetables, fruits have a low protein (0.9%) and lipid (0.5%) content and provide a substrate for yeast, fungi, and bacteria growth. However, because of their low pH (3.8–4.6), fruits are not altered by bacteria, but mostly by yeasts and molds. Nevertheless, spoilage bacteria can cause defects in some fruit juices.

In fruit juices, *Alicyclobacillus acidoterrestris* is a thermoacidophilic spore-forming microorganism able to grow at pH values between 2.5 and 6.0. *Alicyclobacillus acidoterrestris* spores can survive conventional juice pasteurization procedures and then germinate, grow, and cause spoilage. The germination of spores and subsequent vegetative cell growth can occur in apple (pH 2.5), tomato (pH 4.0), white grape (pH 2.8), orange (pH 3.6), and pineapple (pH 3.3) juices. Spoilage is characterized by medicinal or phenolic off-flavors or off-odors, whereas the juice may appear normal or have a slight sediment. The compounds responsible for spoilage have been identified as mainly 2-methoxyphenol (guaiacol) and 2,6-dichlorophenol and 2,6-dibromophenol that occur at lower concentrations. The taste thresholds for guaiacol in orange and noncarbonated fruit juices were reported to be around 2 $\mu g\,l^{-1}$ (ppb) and 2.32 ppb in apple juice, while the concentrations of 2,6-dichlorophenol and 2,6-dibromophenol in spoiled mixed fruit drinks were reported to be 16–20 $ng\,l^{-1}$ (ppt) and 2–4 ppt, respectively. A cell concentration of 10^5–10^6 CFU ml^{-1} of *Alicyclobacillus acidoterrestris* is enough to spoil fruit beverages by producing 2 ppb guaiacol.

In low-acid canned food, spoilage resulting from microbial growth is characterized by gas production, abnormal odors/colors, or pH variation. Industrial canning processes are designed to reach sterilization values that ensure 'commercial sterility.' Thermophilic spore-forming bacteria may impair the commercial viability of products stored at ambient temperatures. The species *Moorella thermoacetica/thermoautoautrophica* and *Geobacillus stearothermophilus* have been identified from spoiled green peas and green peas with carrots, with *Moorella* representing more than two-thirds of spoilage bacteria. However, *G. stearothermophilus* accounts for more than 40% of spoilage cases of green beans and more than 80% of those of sweet corn. An *Anoxybacillus* contaminant has been identified exclusively in soups. *Thermoanaerobacterium* (formerly *Clostridium thermosaccharolyticum* spp.) and *Bacillus* sp. have also been identified in 8% and 9% of spoiled canned food samples, respectively. *Bacillus coagulans* is the most common species involved in the spoilage of tomato products. Other genera represent $< 5\%$ of spoilage cases: *Caldanaerobius* sp., *Anoxybacillus* sp., *Paenibacillus* sp., *Thermoanaerobacter* sp., *Clostridium thermopalmarium/thermobutyricum*, *Thermoactinomyces* sp., and several species of *Geobacillus* are the less reported bacteria.

Future Prospects for Studying Bacterial Spoilage with Next-Generation Sequencing Methods

Most of the studies aimed at understanding bacterial spoilage of food are based on the isolation of bacteria from spoiled

products. It is generally considered that the dominant species found in spoiled products is the one responsible for spoilage. Many studies have proved the role of these species in causing spoilage by inoculating food matrices with such isolates to reproduce spoilage. However, the cooperation of species to produce spoilage has also been reported. For instance, the enhancement of the production of cadaverine by *Escherichia coli* when cocultured with *Brochothrix thermosphacta* (which does not produce cadaverine) has been reported. In addition, putrescine production by *Serratia liquefaciens* or *Hafnia alvei* grown alone or with *Carnobacterium divergens* or *Lactobacillus sakei* was enhanced in cocultures. This phenomenon, named metabiosis, reveals that spoilage may result from the combined action of several species.

The recent development of genomics and metagenomics is now used for the description of microbial communities from food, without prior plating on agar media. These technologies detect 'uncultured' bacterial species, sometimes dominant, revealing the limitations of the previous methods used to characterize food bacterial communities. One can thus expect that, in the near future, new species or genera potentially involved in food spoilage will be discovered. Although food microbial communities are generally well known, there is no doubt that, as for many other bacterial ecosystems (soil, gastrointestinal tract, etc.), metagenomics will reveal unexpected bacteria. In addition, the recent deluge of bacterial genome sequences has demonstrated significant intraspecies genomic diversity; within a bacterial species, different strains may have a genome up to 20% longer than other strains. As bacterial genes have an average size of 1 kb, this means that, within a species, several hundreds of additional genes may be present in strains harboring the longest genomes. For example, ~3500 proteins are predicted from the smallest *Escherichia coli* genome, whereas ~5500 are predicted from the largest. These discrepancies reflect varying abilities in the expression of different functions. This also applies to bacterial species responsible for food spoilage; within one species, not all the strains may harbor the same spoilage potential. The genome analysis of bacteria responsible for spoilage will certainly help understand the functions involved in spoilage development, in their regulation, and in the diversity of spoilage.

Metabolomics to Characterize Further the Bacterial Spoilage of Food

The production of malodorous molecules is often involved in the development of food spoilage. In many cases, the presence of bacterial spoilage flora can be correlated to the presence of volatile organic compounds. The detection of aldehydes, acids, alcohols, and/or ketones has often been correlated to spoilage, and there are some examples proving the ability of spoilage bacteria to produce such molecules either in laboratory conditions or in food models. Yet, the difficulty of identifying the bacterial metabolic pathways involved in the production of such molecules persists. This might be because only the end products are analyzed, and information about intermediate metabolites is lacking. Some compounds may also result from spontaneous chemical reactions of precursor molecules and therefore cannot always be attributed to a bacterial enzymatic reaction. Complementary analyses, using various methods, should provide a better description of bacterial metabolism leading to food spoilage. Volatile organic compounds are often analyzed, because methods are available to detect them and because it is simple to link such compounds to undesirable odors. Precursor molecules, such as amino acids, sugars, and fatty acids, should also be measured to decipher metabolic pathways leading to molecules responsible for spoilage. These molecules should then be correlated to bacterial enzymatic functions (and therefore genes) for a better description of the bacterial pathways leading to spoilage.

Spoilage: Yeast Spoilage of Food and Beverages

K Howell, University of Melbourne, Parkville, VIC, Australia

© 2016 Elsevier Ltd. All rights reserved.

Introduction

This article reviews spoilage of foods and beverages by yeasts. Here, yeasts are defined as unicellular eukaryotic microorganisms, and typical species in food substrates include the well-known fermentative yeast *Saccharomyces cerevisiae*, ubiquitous *Candida* and *Hanseniaspora* spp., and problematic species *Zygosaccharomyces* and *Dekkera*. Yeasts are a common microbial partner in foods and beverages (raw, processed, and fermented), and their metabolic activity, if noticeable, generally assists in the creation of a product (e.g., wine, beer, bread, and cheese). Yeasts are used to start the fermentation to create these distinctive foods and beverages, but the same yeasts may also cause spoilage. Contaminant yeasts may grow and adversely affect foods where they are not normally associated, which is of great concern to the food processing and manufacturing industries. In general, spoilage of a food or beverage occurs when the product no longer appeals to the consumer due to a change in texture, color, flavor, shape, or odor and can lead to large economic losses through wastage. Food spoilage will occur when yeasts are in an unbalanced, chemically unstable, or contaminated food or beverage. Control measures for yeast spoilage typically address environmental control points. Here, typical spoilage in economically important foods such as dairy, meat, fruit juices, and wine will be discussed, with a focus on the risk factors associated with foods and beverages and the underlying biochemistry that leads to spoilage characteristics.

Implications of Spoilage and Food Safety

When a food or beverage is spoiled by yeast growth, the consumer will reject the product, leading to wastage, loss of reputation by the food brand or company, and cost of plant and industry cleanup.

Fortunately, despite the range of yeast species associated with food spoilage, yeasts are rarely if ever associated with loss of human life due to food contamination and infections. Often, yeasts pathogenic to humans (e.g., *Candida albicans* and *Cryptococcus neoformans*) are not associated with food and beverage ecosystems. However, there is evidence that the presence of yeasts in food can lead to human allergic and hypersensitive reactions like migraines, respiratory problems, asthma, and gut and bowel syndromes. The literature in this area is growing and may result from human metabolic reactions to intrinsic yeast cellular components, such as cell wall polysaccharides, metabolites, and cellular proteins.

There is an increasing body of evidence that points to an increase in human infections by opportunistic pathogens, such as *Saccharomyces cerevisiae*, *Candida krusei*, *Yarrowia lipolytica*, and *Rhodotorula* spp. Although these outbreaks are not linked to consumption of spoiled foods and beverages, these yeast species are commonly found in food and beverage ecosystems. Under these conditions, healthy individuals are not at risk of illness due to consumption of foods spoiled with yeasts; however, patients with weakened health or immunocompromised status may be susceptible to infection. Trends in this area have raised questions about food safety and yeasts and are relevant in a discussion regarding spoilage of food and beverages by unwanted yeasts.

Factors Affecting Growth and Survival of Yeasts

Yeasts are commonly found in the environment and may be a normal part of the microbiota of a particular food. This can mean that the yeasts may be carried over into the finished food product, for example, in the production of fermented beverages from fruit juice. Control of the growth and proliferation of yeasts is therefore closely associated with the inherent properties of the food or beverage and includes factors such as temperature, water activity, pH and acidity, and the presence of antimicrobials. The stress imposed by each of these factors may limit the survival and growth of yeasts, but the exact limit required to prevent growth is difficult to define as the impact of one factor may affect the impact of another factor. For example, the antimicrobial effect of sulfur dioxide used in fruit and beverage preservation is dependent on the natural acidity and pH, which may influence the growth characteristics of yeasts directly. This also points to the impact of combined factors being synergistic or additive to the overall viability of yeasts. Additionally, the growth state of the yeast cell can influence its susceptibility to an environmental stress, where stationary phase cells are significantly more resistant to changes in temperature, pH, and antimicrobials than cells in the exponential growth phase. Sublethal levels of the factors that affect yeast growth may induce adaptive responses in the yeast population and can lead to inheritable resistance in the spoilage yeast population. Prevention of yeast spoilage requires fundamental understanding of these growth factors and the ability to adjust them to prevent unwanted yeast growth and thus spoilage.

Temperature

The majority of yeasts exhibit optimal growth in the range of 20–40 °C, but there is much variability among yeast species. Although few yeasts grow at temperatures above 40 °C, many yeasts can grow quite rapidly at lower temperatures of 2–10 °C. This is problematic for the stability of refrigerated or low-temperature foods and beverages. Additionally, some yeasts of the species *Candida*, *Cryptococcus*, and *Rhodotorula* can grow at temperatures < 0 °C and can spoil frozen foods, although this is quite uncommon. Yeasts can spoil foods that have been subjected to heat processing, such as soft drinks, syrups, and fruit juices and concentrates. The rate of destruction of yeasts at high temperatures has been calculated in some cases, and it is well

known that *Saccharomyces cerevisiae* is particularly heat-resistant in its ascospore state when compared to the budding cell.

Temperature significantly affects the growth rate of yeasts, and movement outside of the temperature optimum of particular yeasts can reduce generation time and thus proliferation. Another effect of temperature is to influence resistance to antimicrobials (e.g., ethanol), biochemical transformation of sugars and salt, and production of spoilage metabolites.

Water Activity

Water activity (A_W) is an effective way to reduce the growth and viability of bacteria, but less so for yeasts. Many yeast species are tolerant of low A_w and exhibit significant growth. The activity of water is associated with the presence of high solute concentrations, and there is wide variability of yeast ability to grow that often depends on the solute in question. Some yeasts are able to grow in media or substrates with high sugar or salt concentrations, for example, *Debaryomyces hansenii* is very salt-tolerant, and some strains can tolerate up to 24% (w/v) NaCl. *Saccharomyces cerevisiae* also exhibits significant salt tolerance, but this is strain-dependent and is also influenced by pH of the food or beverage in question. *Zygosaccharomyces rouxii* is exceptionally tolerant to high sugar concentrations (up to 70% w/v sucrose).

pH and Acidity

Yeasts exhibit best growth in the range of pH 4.5–7.0. The lower end of the pH scale is preferred by many yeast species, and many species readily grow at pH 2.0–2.5. More rarely, *Hanseniaspora uvarum* may grow at pH 1.5. The pH range of food and beverages encompasses a wide range as well, but it is worth noting that many fruits and vegetables, and juices made from these products, are low in pH, typically pH 2.0–4.0. Fermented dairy products such as cheese and yogurts are stabilized at pH 3.0–4.0, after acidification of the raw milk by bacterial (or other) fermentation. Stronger growth of yeasts at low pH means that they are successful at competing with and dominating other microbial partners, including bacteria. At the other end of the pH scale, some yeasts can grow with reduced vigor at pH 7.0–7.5; however, very few yeast species can grow at pH 9.0. Importantly, as the pH scale is related to acidity in the food product, this factor may work with other factors such as temperature, solute, and water activity to stabilize a product and prevent yeast spoilage.

Antimicrobials

Antimicrobials are a diverse class of chemical compounds, which work to inhibit or minimize growth of microorganisms. Endogenous compounds or exogenous addition of antimicrobials can stabilize foods and beverages to prevent yeast growth.

A commonly used group of antimicrobials used as preservatives in foods and beverages are weak organic acids such as propionic, acetic, benzoic, and sorbic acids. Yeasts have a wide range of resistances to these compounds, but in general, effectiveness depends on the chemical composition of the material. For example, these weak organic acids are only effective at low pH (4.0 and below) as the acids are undissociated and are able to traverse the yeast cell membrane to have their antimicrobial effect. Many yeast species have evolved resistance to these compounds and include *Zygosaccharomyces*, along with some strains of *Candida krusei* and *Pichia membranifaciens*. However, weak organic acids remain a common way to reduce the possibility of yeast spoilage in the food and beverage manufacturing industries.

Ethanol is a potent antimicrobial and is also produced by fermentative yeasts on sugar substrates. For example, the principal wine yeast *Saccharomyces cerevisiae* produces ethanol during the fermentation of grape sugars in wine making. It has been hypothesized that the effect of the ethanol is to inhibit the growth of competing yeast species and allows *Saccharomyces cerevisiae* to numerically and metabolically dominate the ecosystem. However, ethanol does inhibit the growth and metabolism of *Saccharomyces cerevisiae* itself, leading to the undesirable situation of incomplete sugar utilization in grape must and juice with high sugar concentration. There are some yeast species that are tolerant to ethanol at high concentrations, although their metabolism may be affected, and these include *Zygosaccharomyces*, *Dekkera*, *Pichia*, and *Saccharomycodes*. These yeast species are implicated in the spoilage of high ethanol beverages such as wine. The complementary metabolic end product to ethanol, carbon dioxide, may also have an inhibitory growth effect on potential spoilage yeasts. Yeasts that are tolerant to high ethanol are often tolerant of high carbon dioxide and include the species mentioned earlier.

Dimethyl dicarbonate is a preservative compound that has been approved for use in the food industry to control the growth and metabolism of spoilage yeasts. It is effective in the range of 200–250 mg l^{-1}. Natural antimicrobials that work to inhibit growth of spoilage yeasts include essential oils of garlic and onion and vanillin. As these compounds are potent flavoring compounds in food, their use is somewhat limited.

Biochemistry of Spoilage

Food constituents are the substrates for yeast growth, with consequent spoilage, so a good understanding of the biochemical processes of spoilage is important. Transformation of the available compounds gives a wide range of end products that affect the food's sensory, chemical, and physical properties. The range of possible compounds produced is dependent on not only the genetic capability of the yeast in question but also the environmental parameters that can vastly change biochemical pathways, including temperature, pH/ acidity, and antimicrobial concentration.

Carbohydrates

Sugars are the major substrate of spoilage yeasts, and they are widely found in foods and beverages. The availability of sugars such as glucose, fructose, sucrose, and maltose allows central metabolism to occur via glycolysis in some yeasts, for example, *Saccharomyces cerevisiae*, and gives rise to a wide variety of end products such as CO_2 and ethanol that lead to spoilage. Minor compounds like acids, esters, ketones, aldehydes, alcohols, and sulfur compounds are also produced, which can drastically change the aroma and flavor of a spoiled substrate.

Polysaccharides are complex carbohydrates found in fruits and vegetables, which may be extracted and be present in prepared foods and beverages. Polysaccharides such as cellulose and xylan are not commonly affected by yeast growth but can cause problems in a few cases (e.g., growth of *Aureobasidium* and *Galactomyces* on fresh fruit and vegetables). More commonly, spoilage yeasts can degrade pectin, which provides structural stability to a plant cell, and are an integral part to the functionality of foods such as fruits and vegetables. Degradation of starch by yeasts has not been reported in cereal-containing foods, or those that have flour or other cereals as ingredients, although common spoilage yeasts contain amylolytic enzymes.

Nitrogen Compounds

Nitrogen in either free amino acids or inorganic ammonium compounds is required for the growth of spoilage yeasts. Assimilation and metabolism of these compounds affect the production of spoilage-specific sensory compounds, including alcohols, organic acids, and esters. Decarboxylation of free amino acids can lead to the production of flavorsome amines and has been implicated in adverse reactions in sensitive consumers. Although amine production varies with yeast species, in some cases, a carcinogen can be produced, as with the production of urea from arginine and citrulline to produce ethyl carbamate.

Meat products are rarely degraded by proteolysis by spoilage yeasts, as most do not produce extracellular proteases. There are some notable exceptions, for example, *Y. lipolytica*, *Rhodotorula*, and *Cryptococcus* spp. In meat products cured with nitrates, spoilage with *Pichia* and *Cryptococcus* spp. can lead to metabolism of sodium nitrate and sodium nitrite.

Organic Acids

Organic acids are important regulators of acidity and pH in food systems. Changing the acidity and pH can have implications for the flavor and aroma of the product. Organic acids are by-products of central sugar metabolism, with acetic and succinic acids having a large sensory impact. Acetic acid also has a low sensory impact threshold, with several yeasts such as *H. uvarum*, *Candida krusei*, and *Dekkera* spp. being able to produce significant amounts during spoilage of beverages, particularly wine. Yeasts are also able to oxidize organic acids, which can decrease the acidity and increase the pH of the food substrate. As the sensory profile of the food or beverage changes under these conditions, the susceptibility to bacterial contamination may change. Of particular importance is the growth of *Debaryomyces hansenii* and *Y. lipolytica* in fermented dairy products with the removal of lactic acid. The growth of *Schizosaccharomyces pombe* and *Z. bailii* removes malic acid from fruit juices, which increases the pH and dramatically affects the taste and stability of the juice.

Sulfur Compounds

Yeasts commonly produce volatile sulfur compounds as by-products of central metabolism, and this class of compounds is important, as the sensory threshold of these compounds is low. In general, sulfur compounds have negative impacts on the sensory profile of foods, with rotten, smelly, and eggy descriptors given to compounds such as hydrogen sulfide, dimethyl sulfide, mercaptans, and thioesters. *Saccharomyces cerevisiae* differs by strain in the production of sulfur compounds, but yeasts such as *P. membranifaciens*, *Dekkera* spp., and *Wickerhamomyces anomalus* can also produce significant amounts. Volatile sulfur production by *Y. lipolytica* is considered important for distinctive aroma production during the maturation of cheeses; however, this is not considered to be a spoilage process.

Lipids

Lipids are a group of compounds in foods and beverages that confer textural, functional, and sensorially important factors. Lipids can be degraded enzymatically to produce free fatty acids that have rancid and unpleasant off-aromas. Breakdown of lipids is important in meat, dairy, and olive oil systems, where growth of *Candida*, *Cryptococcus*, and *Rhodotorula* can produce lipolytic enzymes that can spoil these foods.

Important Yeasts in Food and Beverage Spoilage

Foods and beverages can support yeast growth, but the spoilage of the product results from secondary metabolism, fermentative, or oxidative processes. The following are examples of yeasts that spoil food using each of these representative mechanisms.

Dekkera/Brettanomyces

Dekkera bruxellensis are spoilage yeasts associated with wine and to a lesser extent other beverages. Its teleomorph is *Brettanomyces*, and these yeasts are commonly known as the 'Brett' yeasts in the wine industry, where they cause an undesirable spoilage of maturing wine. *Dekkera bruxellensis* is slow growing and ethanol- and carbon dioxide-tolerant, which allow it to form significant populations in stable wine that is maturing in cellars. After the primary ethanol fermentation, red wine is stabilized by the addition of sulfur dioxide and stored in oak casks or tanks to mature before blending and bottling for sale. As this maturation time is often for years, *Dekkera* has ample time to grow in the affected wines. *Dekkera* produces distinctive off-taints with secondary metabolism, where phenolic and mousy flavors can spoil the aroma and desirability of the wine. Once a wine is tainted with these aromas, it cannot be recovered and leads to significant economic losses.

Understanding the causes and control of *Dekkera* spoilage in the wine industry has been the focus of vigorous research in recent years, with some interesting findings. Although the yeasts can be isolated from grapes in the vineyard and may persist during alcoholic fermentation, it is thought that contamination may occur via oak barrels and stainless steel wine processing equipment such as pumps, presses, transfer lines, and bottling lines. As sanitation of oak barrels is difficult and often incomplete, quarantine and rigorous record keeping is necessary to stop cross contamination. It is thought that the yeasts may be able to persist in oak barrels by utilizing the wood-derived sugar cellobiose. Additionally, it is thought that

a nonmetabolically active form of the yeast can exist as a viable but nonculturable state, which makes detection and control difficult.

Prevention of *Dekkera* contamination in wines is mostly about good winery sanitation to prevent occurrence in the first place. Intrinsic properties of the wine may affect *Dekkera* growth, as some strains are affected by ethanol >9%, and strains may show adaptation to ethanol concentrations >12%. *Dekkera* is a facultative anaerobe, which suits the wine storage environment where microaeration through the oak barrels can assist with maturation of wine. Small amounts of oxygen stimulate growth and production of off-aromas by secondary metabolism. Although the optimal growth temperature for this yeast has been reported to be between 25 and 28 °C, spoilage has been demonstrated at 15 and 20 °C. Wine cellars are typically kept at low temperatures, which may reduce the risk of growth. The effect of pH has not been investigated to a large degree in *Dekkera*, although some strains can grow at pH 2.0. Application of sulfur dioxide to wine appears to be the best way to reduce growth of *Dekkera*, where 0.2–0.5 mg l^{-1} of molecular SO_2 inhibits growth of most strains. As the presence of the molecular form of sulfur dioxide is dependent on pH, maintaining good control of acidity levels in the wines, especially following secondary (bacterial) malolactic fermentation, is essential. The effect of molecular SO_2 is additive with ethanol concentration, where increasing sensitivity to sulfur dioxide is seen with increasing ethanol.

Contamination by *Dekkera* gives rise to what is commonly called the 'Brett' character in wine. The unique sensory array of aromas is almost diagnostic of *Dekkera* contamination in the winery and can include aromas such as spice, smoky, medicinal, 'band-aid,' horsey, and animal descriptors. The responsible compounds are volatile phenols, with some contribution from acetic and fatty acids. The volatile phenols 4-ethylphenol and 4-ethylguaiacol are sensorially active above 700 mg l^{-1} and are metabolized by secondary metabolism. The starting compound hydroxycinnamic acid is decarboxylated to 4-vinylphenol and 4-vinylguaiacol intermediates before reduction to the aromatic compounds. Other microorganisms in the wine ecosystem are able to produce these compounds, but *Dekkera* is the only yeast able of producing them in high enough quantities to cause a sensory impact on the wine.

Zygosaccharomyces spp.

The *Zygosaccharomyces* genus consists of six species, of which *Z. bailii*, *Z. bisporus*, and *Z. rouxii* are the most relevant to the spoilage of foods and beverages. These yeasts are characterized by fermentative spoilage of products that are high in sugar and include fruit juices, fruit concentrates, syrups, sauces, alcoholic beverages, honey, jams, and confectionary. *Zygosaccharomyces* spp. are found naturally associated with the raw fruit product and can be introduced into processing and manufacturing plants via the fruit surface and be carried through to the final packaged product. Temperature predicts which species is present, as it is more likely *Z. bailii* is present at lower temperatures than *Z. rouxii*.

The fermentative nature of *Zygosaccharomyces* metabolism produces carbon dioxide that is of concern if the food product is in a sealed container, as the increase in gas can cause the container to leak or, in extreme cases, explode. Haze or sediment can occur in beverages as cellular biomass accumulates, and in some cases, surface biofilms can form. Taste modification can occur by the production of secondary metabolites with sensorial impacts on the food or beverage and include acetic acid, esters, and higher alcohols.

In addition to tolerance to osmotic stress caused by high concentrations of sugar solutes, *Z. bailii* is a fructophilic yeast, which is a preference for utilizing fructose during fermentation. Fructose is a fruit-derived sugar, which can be used for energy-yielding metabolism. *Zygosaccharomyces* spp. have a separate high-capacity transport system for fructose and can ferment additional sugars, sugar alcohols, and ethanol. For example, *Z. rouxii* is able to grow in high concentrations of sugar, at 72% glucose and after adaptation 90% glucose. This range of capabilities makes fruit and fruit-derived produces an ideal substrate for growth and fermentation of *Zygosaccharomyces* spp. Antimicrobials found in the processing of fruit products such as wine may not confer any resistance to *Zygosaccharomyces* spoilage as the genus. The genus is resistant to ethanol and thus is a possible spoilage agent of alcoholic beverages. *Z. bailii* can grow in ethanol up to 20%, although this is highly strain-dependent. Fruit substrates are also characterized by low pH, where *Zygosaccharomyces* spp. are adept at growth.

Preventing *Zygosaccharomyces* contamination is the major control point in food industries, so extensive cleaning, sanitation, and quarantine measures for primary processing equipment are paramount. Antimicrobials to be used as biocides have some relevance for this species; however, there is much strain variability in resistance. In particular, *Z. bailii* is particularly resistant to benzoates and sorbates used as preservatives, minimum concentrations to prevent growth often being much higher than the maximum limits allowable by food laws. *Z. rouxii* has a similar resistance profile to *Z. bailii*, but is quite susceptible to benzoic acid, while *Z. bisporus* has intermediate resistance.

Y. lipolytica

Y. lipolytica (previously *Candida lipolytica*) is a dimorphic fungus that is associated with the detrimental spoilage of meat and dairy products and is able to grow in hydrophobic substrate environments. This yeast is characterized by strong extracellular proteolytic and lipolytic properties, which are able to modify the surrounding environment, leading to enhanced growth. These extracellular enzymatic activities can drastically change the aroma, flavor, and texture of the food substrate and result in distinctive spoilage markers.

Y. lipolytica has been associated with the spoilage of cheese, dairy products, meat, and poultry. *Y. lipolytica* is adept at growth at low temperatures, where food products such as these are stored or matured. There are also reports of this yeast growing on and spoiling frozen meats. As this yeast has strong growth in oxidative environments, surface growth is common. Surface discoloration of cheese is common with the growth of *Y. lipolytica*, where catabolism of the amino acid tyrosine gives the pigmented compound melanin. Surface spoilage of uncooked and cooked meats (such as chicken or

turkey) has been observed, where the extracellular proteolytic and lipolytic activities result in spoilage aromas.

Growth of *Y. lipolytica* can be controlled by preservatives, as this yeast shows sensitivity to benzoates and sorbates at reasonable concentrations. Surface application of lactic acid, as well as novel inhibitors such as herb extracts, essential oils, and natamycin, is effective in controlling *Y. lipolytica* growth.

It is worth noting that *Y. lipolytica* is often found in mixed communities of microorganisms in spoiled foods, presumably as the lytic activities release nutrients that can be used by other yeasts or bacteria. In these cases, initial spoilage by *Y. lipolytica* can allow potentially pathogenic organisms to grow and cause disease and other health problems in humans.

On a positive note, the presence of *Y. lipolytica* is necessary and required for the characteristic flavor and aroma of some dried meats and cheeses. For example, the lipolytic and proteolytic activities of this yeast are essential for the maturation and distinctive flavors and aromas of salami, via breakdown of fatty tissues and proteins. Its ability to grow at low A_w and tolerate salt concentrations makes its growth possible. Texture and aroma development in cheese is made possible by growth of *Y. lipolytica*. Lipases, proteases, and esterases release characteristic compounds that contribute to flavor of blue cheese (Roquefort), soft fresh artisanal cheeses, and Pecorino, Cantalet, and Livarot cheeses.

Introduction

The science of sports nutrition is an evolving field offering some exciting new knowledge that can be translated to practical recommendations and may improve performance, but there are also examples of practices and dietary advice that are no longer considered effective or completely safe. Therefore, exercisers and athletes are advised to work with sports nutrition professionals. International Olympic Committee consensus statement on sports nutrition from 2010 states that "athletes will benefit from the guidance of qualified sports nutrition professionals who can advise on their individual energy, nutrient and fluid needs and help develop sport-specific nutritional strategies for training, competition and recovery." The role of sports nutrition professionals is to ensure support for best performance and set foundations for an athlete's long-term health.

Athletes' body weight and height, body composition, training, and daily energy expenditure are immensely diverse across sports disciplines, so individual approach when planning diet is essential, even for team sports because teammates may have quite different nutrition goals. Also, diet should be periodized and adjusted to training. During training, adherence to sports nutrition guidelines is needed on a daily basis. Periods when it is not necessary to achieve sport-specific nutrient goals are opportunity to emphasize nutrient-dense foods. A prudent and balanced diet should be planned for a period of few days, up to 1 week.

Sports nutrition recommendations are primarily for athletes, some recommendations are meaningful only for top-level athletes, but sports nutrition recommendations can be also useful for recreational exercisers. Generally, if weekly volume of exercise is 5 h or less, this can be considered as a desired level of physical activity in a healthy lifestyle, and such individuals can follow guidelines aimed for a general population. If we ought to simplify differences between sports and general nutrition, athletes have higher energy requirements, although some female athletes with low body weight can have very low requirements, and water requirements are higher due to water loss through sweating. Energy balance and water homeostasis are regulated by many long- and short-term mechanisms, but hunger and thirst are principal. Exercise, especially if long in duration and high in intensity, disrupts those regulators, meaning that planning is necessary, but when creating an athlete's diet and hydration plan, dictates of hunger and thirst should be acknowledged. Taste preferences are another important nutritional factor that should not be neglected in individualized sports nutrition, and an athlete's cooking skills can affect compliance and comprehension.

The science of nutrition is complementing reductionist approach with the concept of food synergy. Reductionist approach enabled to detect which nutrients are essential, but we do not consume nutrients but foods, and food synergy considers whole foods and dietary patterns as the most important. Food synergy accredits health effects of, for example, tomato or kiwi fruit to the whole food rather than exclusively to lycopene or vitamin C, respectively. Health effects of whole foods are not explained just by the sum of food components, but additional benefit is provided through synergy, that is, $1+1>2$. In sports nutrition, there are several examples of whole foods that can be considered 'natural sports foods': milk or chocolate milk can be a sports drink or a recovery drink, cherry juice can aid in recovery after exercise and possibly regulate sleep, and highly publicized beetroot juice reduces oxygen cost of exercise and can be regarded as an effective ergogenic aid with small but meaningful effect for endurance exercise. There are studies documenting usefulness of whole foods like bananas or raisins as carbohydrate sources during intense exercise or superior results of meat versus supplements in improving exercise-induced compromised iron status. Studies involving whole foods are valuable contribution to efforts of improving performance, diet, and health of both recreational exercisers and athletes.

Energy Availability

Total daily energy expenditure (TEE) has three components: basal, that is, resting energy expenditure; thermic effect of food (~10% of energy intake on a mixed diet); and physical activity energy expenditure (PAEE). The fourth component is present in a case of a disease or injury. The most variable component of TEE is PAEE and can be as low as 100 kcal for sedentary or higher than resting energy expenditure for very active individuals. PAEE can be divided into nonexercise expenditure and exercise expenditure. Nonexercise activities include occupation, leisure, and all other daily activities. When planning an athlete's diet, PAEE, that is, exercise expenditure, can be estimated using metabolic equivalents (MET). 1 MET = 1 kcal kg^{-1} h^{-1} what is assumed standard resting metabolic rate, and expenditure for a physical activity is expressed as a multiplier. For example, 12 min of vigorous freestyle swimming (MET value of 9.8, code 18230 in 2011 Compendium of Physical Activities) for a person that weighs 75 kg equals 147 kcal (9.8 kcal kg^{-1} h^{-1} × 75 kg × 0.2 h).

For athletes, the concept of energy availability (EA) (energy intake minus exercise expenditure) is preferred over concept of energy balance (energy intake minus TEE). If an athlete achieves energy balance, this does not necessary imply a state that supports optimal health, performance, and desired body weight. Available energy signifies energy that is available for all physiological functions other than exercise. Low EA (<30 kcal kg^{-1} FFM) is the underlying cause of female athlete triad. Adequate level of EA is at least 45 kcal kg^{-1} FFM. Higher levels should be chosen for weight gain and 30–45 kcal kg^{-1} FFM for weight or body fat loss. For the latter, it is important to apply relative reduction of 15–25% rather than absolute

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00224-5

reduction of energy intake and if possible to conduct slow weight loss of 0.7–1% per week for the reason not to compromise body composition.

Application of EA concept requires information of body composition. Athletes can choose among dual-energy x-ray absorptiometry, air displacement plethysmography, skinfolds, or other available methods. Data should be interpreted with great caution, and repeated measurements should be performed in similar condition regarding previous meals, hydration, and exercise and with emptied bowel and bladder. Preferable methods are those that do not rely heavily on prediction equations that are valid for the general population since athletes can be extremely lean, heavy, or tall.

Practical and adequately accurate way to estimate daily energy intake is application of dietary assessment methods. Dietary assessment methods that are used among athletes are no different than those used among other population groups; however, several specificities exist. For estimation of energy intake, several 24 h recalls or 3 to preferably 7 day food records should be substantial. It is important to capture days that are representative with regard to training and to pay attention to items that are often (inadvertently) underreported, like occasional snacks or liquids. Unlike solid foods, liquids are not always perceived as a meal or as energy source, regardless of actual energy content. In an athlete's diet, such underreported liquids can be sports drinks. During keeping of food records, method of choice for estimation of portion size is to weigh food, but for athletes, because of possible very high number of eating occasions and training obligations and if most of meals are eaten away from home, this can be impractical. Acceptable alternative is description using kitchen utensil or food photography atlases.

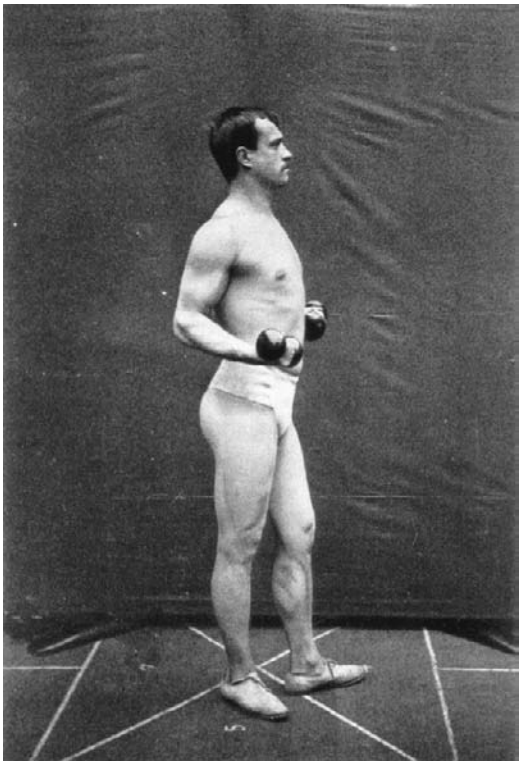

Figure 1 Photography of Charles J. Fritz, US soldier, aged 28 years, taken at the end of his participation in Chittenden's experiment from 1 November 1903 to 8 April 1904. His initial body weight was 76.0 and 72.6 kg at the end of experiment. During experiment, Chittenden varied nitrogen and energy intake and measured nitrogen balance. Reproduced from Carpenter, K. J. (2003). A short history of nutritional science: part 2 (1885–1912). *Journal of Nutrition* **133**, 975–984.

Protein Intake: Quantity, Timing, and Sources

Many exercisers and athletes are focussed only on adequacy of protein intake and thereby neglect food groups that are low in protein like vegetables and fruit. Proteins were once thought the only nutritive food component and have always received special attention. In 2005, Simpson and Raubenheimer proposed protein leverage hypothesis that ad libitum food, energy, and possibly fat and carbohydrate intakes are regulated according to protein intake or diet protein density, meaning that low protein intake leads to overeating and vice versa.

Justus von Liebig (1803–73), German organic chemist, great authority, and considered by some as the father of nutritional science (in Europe), promoted a hypothesis that degradation of muscles is the energy source for contractions. He and other contemporary authorities recommended daily protein intake of 100–135 g for a person of 70 kg and 145–150 g for hard work. Perhaps, these are the roots of protein myth that persists today among some exercisers and athletes having protein intake of 3–4 g kg^{-1}. Early high protein recommendations were challenged by a series of experiments done by Chittenden in 1904 who defined minimal protein requirements as 0.6–0.64 g kg^{-1} (Figure 1).

Recommended dietary allowance (RDA) for adults is 0.8 g kg^{-1} of good-quality protein, and estimated average requirement (EAR) is 0.66 g kg^{-1}. RDA level is sufficient for nearly all (97–98%) and EAR for 50% of healthy individuals. For an individual diet planning, RDA level should be used.

Current RDA and EAR values are based on nitrogen balance studies. This approach has been criticized, and indicator amino acid oxidation method has been proposed for defining protein requirements. The method is based on reasoning that deficiency of an essential (limiting) amino acid increases oxidation of all other amino acids because protein synthesis is impaired. Oxidation of an indicator amino acid is followed, while limiting amino acid intake is increased. When oxidation of indicator amino acid stops decreasing and reaches constant values, this is an indication that limiting amino acid, that is, protein intake level, meets requirements. Proposed RDA and EAR protein requirements based on indicator amino acid oxidation method are estimated to be 1.2 and 0.93 g kg^{-1}, respectively.

Managing an athlete's diet can start with setting protein requirements. It is important to observe protein intake within the context of a whole diet, and adequate protein intake should be accompanied by sufficient energy and carbohydrate intake to prevent protein, both somatic and dietary, being used as an energy source beyond normal levels. Athletes should have protein intake higher than RDA level of 0.8 g kg^{-1} and recommended range for strength and endurance athletes is 1.2–1.7 and 1.2–1.4 g kg^{-1}, respectively. There is an increase in protein

oxidation during endurance exercise and muscle hypertrophy, especially for novices, maintenance of larger muscle mass, and muscle repair during recovery, which explain increased protein needs. There is no evidence to justify protein intake above 2 g kg^{-1} for muscle hypertrophy at adequate EA, but higher protein intake (1.5–2.3 or even 1.8–2.7 g kg^{-1}) is recommended for the reduction of body weight and optimization of body composition. There are some health risks associated with enormous protein intake, but they are not so accented as before, and it is now recognized that both low protein intake and high protein intake have detrimental effect on bone health and protein intake that is optimal for bone health is 1–1.5 g kg^{-1}. Higher protein intake (<2.8 g kg^{-1}) will not impair renal function, but protein intake should be restricted for preexisting or confirmed renal disease.

Blood aminoacidemia before, during, and after exercise and protein intake before sleep improve recovery and muscle protein synthesis, but it is most important to ensure adequate amount of proteins as soon as possible, preferably within <1–5 h after resistance exercise. Adequate amount is usually defined as 20–25 g of high-quality protein, that is, 8–10 g of essential amino acids, depending on the body weight (~0.3 g kg^{-1}). There is some new research showing that the same level of muscle protein synthesis stimulated with recommended dose (20–25 g) can be achieved with formulations that provide suboptimal protein intake but are enriched with leucine, the key amino acid regulator of muscle protein synthesis. When matching the timing of protein intake with desired timing and duration of aminoacidemia, it is useful to account characteristics of fast (whey) and slow (casein) proteins. Whey protein ingestion causes sharper increase in blood amino acids, and return to resting levels occurs within 2–3 h, while casein ingestion results in moderate but prolonged aminoacidemia (~6 h).

There is a shift of protein recommendations for athletes toward meal-based. Daily protein intake should be spread evenly through daily eating occasions, and skewed protein intake, for example, 10% at breakfast and >50% for evening meal, should be avoided. If an athlete's goal is, for example, 80 g day^{-1}, this amount should preferably be ingested as 20 g trough each of 4 daily eating occasions, and it was shown that this pattern is more anabolic than 8×10 g or 2×40 g.

The concept of functional amino acids unifies essential, nonessential, and conditionally essential amino acids. All amino acids are required for tissue protein synthesis, tissue maintenance, gene expression, immunity, energy metabolism, growth, etc. Therefore, both essential and nonessential amino acids are functional as regulators of metabolism, and there is a suggestion that definition of an 'ideal protein' should be extended to include nonessential amino acids. Current definition of high-quality protein is that it provides all essential amino acids in recommended amounts, provides nitrogen for synthesis of nonessential amino acids, and is easily digestible. By this definition, all foods of animal origin (except for gelatin) provide high-quality proteins, while for plant proteins, usually lysine (grains) and methionine (legumes) are limiting amino acids. Lower digestibility and amino acid profile of plant proteins are not major issues in a varied diet with adequate energy and adequate amount of proteins of both plant and animal origins. A variety of protein sources ensure complementation of proteins deficient in one or more essential amino acids and result in completed amino acid pattern. Few plant proteins, including soy, quinoa, and amaranth, are considered high-quality proteins; however, milk proteins (especially whey) are considered superior in enhancing muscle protein synthesis than soy proteins.

When choosing protein source, whole foods should come first, but of course, if this is highly impractical; protein supplements are much better option than not consuming proteins at all. For example, 100 g (raw weight) of meat or fish provides ~20 g of high-quality proteins and additionally ~2 mg of highly bioavailable iron. One egg provides 6.3 g of proteins (3.6 g is in 1 egg white and 2.7 g in 1 yolk) and additionally highly bioavailable lutein and zeaxanthin that accumulate specifically in macular pigment of the retina with potential to improve visual performance of athletes through the reduction of glare discomfort, the reduction of photostress recovery time, enhancement of chromatic contrast, and increase of visual range. Some authors describe lutein and zeaxanthin as 'internal sunglasses.' It was shown that daily consumption of 1 egg through several weeks increases serum lutein and zeaxanthin without compromising serum lipid profile. There has been a paradigm shift regarding dietary cholesterol (and therefore egg consumption) and cardiovascular disease.

Vegetarian Athlete

The latest position of the Academy of Nutrition and Dietetics on vegetarian diets from 2009 states that "well-planned vegetarian diets are appropriate for individuals during all stages of the life cycle, including pregnancy, lactation, infancy, childhood, and adolescence, and for athletes." Adequacy of protein intake in vegetarian diets is not a major issue provided that energy intake is adequate and a variety of plant protein sources are included. Because of quality and digestibility of proteins in plant-based diets, vegetarian athletes should have 10% higher protein intake, that is, 1.3–1.8 g kg^{-1}.

Many characteristics of plant-based diets are beneficial for athletes, like higher intake of carbohydrates or antioxidants, but intake of carninutrients, the term proposed by McCarty in 2004, that are almost exclusively present in foods of animal origin is negligible with vegan diet. Taurine, carnitine, creatine, and carnosine (β-alanyl-L-histidine) are carninutrients with potential effect on performance, and according to current evidence, vegetarian athletes are most likely to benefit from supplementation with creatine and β-alanine.

Carbohydrates

Carbohydrates are ergogenic for all phases of exercise, and failing to achieve adequate intake can adversely affect not only performance but also recovery, mood, or immunity. Strategies that are proved to be effective should be applied appropriately; for example, glycogen supercompensation is not needed for exercise duration <90 min and carbohydrate intake during exercise at low to moderate intensity is counterproductive for recreational exercisers because exogenous carbohydrates provoke insulin secretion and depress fat

oxidation. Strategy that requires additional research is training with low carbohydrate availability to enhance mitochondrial biogenesis. Concomitant protein supplementation or caffeine intake (3 mg kg^{-1}) might counteract disadvantages of 'train low' strategy affecting muscle protein balance and volume and intensity of exercise.

Generally, the recommended range for carbohydrate intake is 6–10 g kg^{-1}, but 5–7 g kg^{-1} is adequate intake for bodybuilders, 3–5 g kg is adequate for lighter training, and 8–12 g kg^{-1} may be needed when duration of daily training is several hours. When using food composition tables in planning diet according to targeted carbohydrate intake, it is important to use data for available or digestible carbohydrates or to subtract dietary fiber from total carbohydrates. Dietary fiber can have energy density of ~0–2 kcal g^{-1} depending on their colonic microbiota fermentability and formation of short-chain fatty acid. When choosing a carbohydrate source, glycemic index (GI) can be orientation, and low GI (<55) is preferable before, moderate to high GI (56–69) during, and high GI (>70) after exercise. The concept of GI has been upgraded with glycemic load (GL) that combines GI and amount of carbohydrates in one serving, and low and high GL is <10 and >20, respectively. The form of carbohydrate source, liquid, gel, or solid food, is not critical for performance or recovery so can be chosen according to individual preferences.

Pre-exercise meal is consumed 1–4 h before exercise and should provide 1–4 g kg^{-1} of carbohydrates. Individuals prone to reactive hypoglycemia should ingest carbohydrates few min or >90 min before exercise.

Exercise should start with adequate muscle and liver glycogen stores. During exercise (>1 h), carbohydrate intake of 30–80 g h^{-1} is ergogenic. For activities that are too short for ingested carbohydrates to pass through the stomach and reach active muscles, novel strategy of rinsing the mouth with carbohydrate solution for a few seconds (swallowing is not necessary) can be useful. Probable explanation for ergogenic effect of this strategy is brain response and perception of fatigue after sensing carbohydrates, both sweet and nonsweet, by receptors in the oral cavity. Perhaps, a factor of anticipated energy flux is included, and perhaps, there are mechanisms connecting central fatigue, energy and glucose homeostasis, and recently discovered sweet taste receptors in extraoral tissues including the gut, brain, and adipose tissues. Mouth rinsing with carbohydrate solution can be useful for individuals experiencing gastrointestinal discomfort due to carbohydrate intake; effect is expected to be greater in a state of depleted carbohydrate reserves, but mouth rinse can also have an additive effect in a state of optimal carbohydrate availability; periodic mouth rinse can be useful during high-intensity exercise when fluid ingestion is not well tolerated or during, for example, soccer match where intermittent high-intensity activity (sprints) slows gastric emptying. There are interesting recent studies showing benefits for sprint performance of mouth rinsing with solutions containing caffeine and quinine.

For exercise duration >2–3 h, recommended carbohydrate intake is 60–90 g h^{-1}. Exogenous carbohydrates oxidation rate can be increased above 1 g min^{-1} if multiple transportable carbohydrates (glucose and fructose) are used. Higher than expected intestinal absorption rate occurs because glucose and fructose utilize different sugar transport proteins, sodium-dependent glucose transporter (SGLT1) and fructose transporter (GLUT5), respectively. A. Jeukendrup introduced the term 'nutritional training' for efforts of adaptation to carbohydrates intake >1 g min^{-1} as a part of training program since very high carbohydrate intake can cause gastrointestinal disturbances. Gastrointestinal disturbances among athletes are primarily consequence of gastrointestinal ischemia, but there are also nutritional factors that include high fructose intake.

Sports drinks that contain 6–8% of carbohydrates are usual carbohydrate source for exercise that lasts <1 h, but for longer exercise, additional carbohydrate sources can be included, and carbohydrate concentration and volume of a sports drink can be manipulated to achieve energy and hydration goals.

Carbohydrates are a limiting factor for prolonged low- to moderate-intensity exercise and a major fuel for high-intensity exercise (>80% VO_2max); therefore, all athletes should restore muscle glycogen during recovery. Optimal amount is 1.2 g kg^{-1} h^{-1} preferably ingested periodically every 15–30 min. The most important factor for adequate glycogen replenishment is to provide 10 g kg^{-1} of carbohydrates during 24 h recovery period. During recovery, endurance athletes are focussed on carbohydrates and strength athletes on proteins, but recovery should address both nutrients. Combination of 0.8 g kg^{-1} h^{-1} of carbohydrates and 0.2–0.4 g kg^{-1} h^{-1} of proteins results in adequate glycogen synthesis, and both carbohydrates and proteins have insulinotropic effect and promote insulin secretion. Elevated insulin has a positive effect on net muscle protein balance (insulin decreases protein breakdown and has no significant effect on protein synthesis).

Fat Intake

General recommendation for fat intake is 20–35% of total daily energy intake. Fat intake under 20% kcal compromises diet palatability, energy intake, essential fatty acids intake, and absorption of fat-soluble vitamins and phytochemicals. Higher than recommended fat intake (>60% kcal) can result in useful 'supercompensation' of intramuscular fat (analogous to glycogen supercompensation), but this is not recommended. To improve often inadequate ω-3 fatty acids intake, especially intake of long-chain eicosapentaenoic and docosahexaenoic acid and ω-3 and ω-6 intake ratio, 2–4 140 g portions of fish per week including at least one portion of fatty fish and also to use olive oil (>70% oleic acid) for cooking instead of other vegetable oils where ω-6 predominate (>50–60%), like sunflower, are recommended. Fish oil supplementation is being studied for its potential to counteract anabolic resistance to diet and exercise among the elderly (~2 g per day through several weeks), but anabolic effect of supplementation with long-chain ω-3 fatty acids was also shown among 25–45-year-old healthy subjects.

Vitamins, Minerals, and Antioxidants

Diet that provides adequate energy and macronutrient intake through a variety of whole foods is the most likely to be also adequate regarding intake of micronutrients and beneficial nonnutritive food components, but it is a challenge to plan

nutrient-dense diet for low energy intake. Micronutrient supplements will have performance-enhancing effect only if deficiency is present. Athletes, especially endurance athletes and females, should periodically check iron status since reversing anemia can take several months and inadequate stores can adversely affect performance before onset of anemia, but routine supplementation without proof of its necessity is strongly discouraged. It might be that magnesium supplements are ergogenic even if deficiency is not present. Indiscriminate use of various vitamin and mineral supplements is no longer considered completely risk-free.

High doses of antioxidant supplements can block beneficial metabolic adaptations to physical activity like increase in insulin sensitivity and mitochondrial biogenesis. Preferable way of ensuring adequate exogenous antioxidants is whole foods that provide additional benefits through synergy of food components. It was shown with a mice model that bioavailability of vitamin C is superior from kiwi than from solution of sodium ascorbate and possible explanation is 'vitamin C_2,' a phytochemical present in kiwi that enhances vitamin C absorption and tissue uptake or perhaps spares vitamin C from oxidation.

Some authors consider endogenous antioxidants more important than exogenous, but there is no doubt that abundance of foods high in antioxidants is important for our health, and it is important to note that food components with antioxidant properties have other roles and, for example, act as enzyme cofactors. Vitamin C is antioxidant and enzyme cofactor for collagen and carnitine biosynthesis, and this is probably why muscles are major body pool of vitamin C. It was shown that ~70 mg of vitamin C saturates muscle tissue and this can easily be achieved by supplementing diet with 0.5–2 kiwi fruits.

Vitamin that is getting significant attention is vitamin D. The roles of vitamin D go far beyond skeletal, and it is now known that muscles contain significant amount of vitamin D vitamers. Vitamin D is needed for skeletal muscle development and improves muscle strength. There are studies showing high prevalence of vitamin D inadequacy among athletes and benefits of supplementation. Deficiency is more likely among athletes who train indoors. Athletes should include reasonable sun exposure in their lifestyle and periodically monitor vitamin D status (serum $25(OH)D_3$ of 75–150 nmol l^{-1} indicates sufficiency) because of potential effects on performance and to reduce risk of chronic diseases. More research is needed on this topic. Also, it will be interesting to see if there is interplay between vitamin D and recently discovered myokine irisin involved in browning of white adipose tissue. Exercise can depress vitamin D levels and induce irisin production, but both affect muscle function and glucose homeostasis.

Hydration

Water balance is affected by both water intake and losses. The most common recommendation for adults is to consume 1 ml of water per 1 kcal of TEE, and it is likely that future recommendations will additionally include reference to urine volume. Water homeostasis among athletes can be heavily disturbed through sweat losses. Sweat evaporation is the most important way of thermoregulation, with the exception of aquatic sports where heat is dissipated through conduction and convection. Loss of hypotonic sweat results in hypertonic hypovolemia, that is, dehydration that affects many physiological functions. Sweat rate for different sports can be <0.5 to $>2\ l\ h^{-1}$.

Many athletes start with exercise in a state of hypohydration, what can easily be avoided unless there is insufficient time between exercise sessions. Water is an adequate choice and can be included in a meal before exercise (~500 ml) or ingested early enough to avoid urge to urinate during exercise. Important advice for recreational athletes is to start the exercise in a state of euhydration since commencing exercise in a state of hypohydration adversely affects the perception of efforts and therefore can reduce the probability of continuation of exercising. Urine color chart validated by Armstrong in 1994 is a practical way to estimate hydration status.

Dehydration defined as loss of $\sim>2\%$ of body weight impairs performance and cognition, and this level of dehydration coincides with occurrence of thirst. It is possible that this level of body weight loss occurs during exercise without hypohydration because of factors affecting both sides of water balance like oxidation of macronutrients or release of water associated with glycogen.

Water intake during exercise should be adjusted to exercise duration, environmental conditions, and carbohydrate intake goals. Ending exercise with increased body weight is a risk factor for hyponatremia. Water intake during exercise should be planned according to previously estimated sweat rate, but dictates of thirst should be highly respected. Sweat losses of vitamins, calcium, copper, iron, magnesium, and zinc do not alter daily requirements, but sweat sodium losses are substantial with great interindividual variability, and sports drinks with 0.5–0.7 $g\ l^{-1}$ of sodium are needed for exercise >2 h. Sodium-containing beverages for shorter events can increase palatability and therefore ingested volume and contribute to water retention. Additional factors that contribute to hedonic ratings of a fluid are flavoring and temperature. Preferred temperature is 10–20 °C, and colder drinks may be appealing but result in earlier satiation of thirst and reduce ingested volume.

Common recommendation for water intake during recovery is to ingest up to 150% of weight loss.

There are many benefits associated with euhydration, including prevention of chronic diseases, and expanded muscle cell volume favors anabolism, but the rule 'more is better' should not be followed.

Ergogenic Aids

To quote R. Maughan: "Most supplements that are effective are against the rules of sport. Most substances that are not banned are not effective. There are, however, some exceptions." These few exceptions include caffeine, blood- and muscle-buffering agents, and creatine. Many athletes strongly believe that use of one or several ergogenic aids is necessity for top-level performance; therefore, because of considerable positive and negative (nocebo) effects of placebo, an athlete should continue with supplementation if it is completely risk-free. Decision about supplementation should be based on best available evidence regarding effective protocol and dose, long-term

safety, and information about quality of the product (actual amount of active component and contamination with toxins and prohibited substances).

Stabilizers: Types and Function

C Rolin, CP Kelco ApS, Lille Skensved, Denmark

© 2016 Elsevier Ltd. All rights reserved.

'Stabilizers' is a generic term for additives that are used for avoiding or retarding physical changes in foods. They typically prevent spatial food parts of different composition from changing in size. Examples of such uses could be the diminishing of whey exudation from a drinkable fermented milk or the maintenance of uniform distribution of suspended vegetable pieces in a salad dressing. The phenomena that are mitigated in these examples involve what chemists may refer to as phase separation and what generally can be named, for example, as flocculation, coalescence, lumping, creaming, demixing, and sedimentation.

There is, on the other hand, no unambiguous rule for when to consider a food material a stabilizer. Additives may also be termed stabilizers when they provide and maintain specific rheological properties; in this role, the same materials could have been called 'thickeners' or 'gelling agents.' When a stabilized food is an emulsion, the stabilizer might be considered an emulsifier, but it is not common to use both designations for the same material. The classification into the one or the other category in practice follows the molecular size, so polymeric materials are considered stabilizers. Arguably, stabilizers are normally thought of in context with prevention of phase separation, but the stability that is provided may also be with respect to other phenomena, for example, the preservation of the brightness of a color.

Chemically, almost all of those stabilizers that can mitigate phase separation are polymers of biological origin, and they can under appropriate circumstances either dissolve or form a gel or a gelatinous suspension with water. They can be classified as gums. The list of stabilizers provided by the Food and Agriculture Organization (FAO) of the United Nations does, on the other hand, include some nonpolymeric materials and some water-insoluble materials.

In a stabilized food system, a polymeric stabilizer normally modifies the contact between an aqueous liquid and some other material. In the absence of stabilizer, the surface of contact between these immiscible parts would 'strive at' shrinking. In the (typical) case that the one material is drops or pieces dispersed in a continuum of the other material, these dispersed bodies would be attracted to each other, and they would 'attempt to' merge, minimizing their combined surface. The various hypothetical working mechanisms for how individual stabilizers can reduce this stickiness involve either adsorption of the stabilizer at the surfaces, or thickening of the food, or a combination of both.

If the stabilizer adsorbs, it can by virtue of its water solubility connect between the aqueous phase and the material to which it adsorbs, and being polymeric, it can do so over a relatively large distance. While still being attached to the surface, it can embrace water and retain it at the surface that thereby becomes less sticky. This mechanism is commonly referred to as steric stabilization (Figure 1).

If the stabilizer thickens the food and we assume the typical case that the aqueous phase is continuous, then the thickening reduces the mobility of pieces of dispersed material and, in turn, their possibility of contacting each other or distributing unevenly – as they would do in the absence of stabilizer due to gravity and buoyancy effects. The reduction of mobility will obviously be particularly effective if the stabilizer turns the system into a gel. On the other hand, for products with which a fluid and drinkable texture is preferred, it may suffice that the stabilizer provides a pseudoplastic viscosity, that is, a viscosity that is high at the low-shear condition of product storage, but low at the higher-shear condition of drinking.

Sources and Production

Some widely used polymeric stabilizers and ingredients that can be used as stabilizers have been collected in Table 1.

Agar, alginate, and carrageenan are isolated from marine plants. Gelatin is isolated from animal parts, typically skin and bones. Xanthan and gellan are produced by bacteria and commercially manufactured by fermentation. Cellulose derivatives (cellulose gum, CMC), guar gum, gum arabic, locust bean gum, pectin, and starch (modified starch) are isolated from terrestrial plants.

The final stabilizers that are sold to food manufacturing companies are ideally and typically powders that have been purified from unwanted parts of the raw material and that (in spite of possible variations in raw material properties) are batch-to-batch uniform. The commercial manufacturing processes typically involve an aqueous extraction that leaches the stabilizer out from the originally solid raw material, followed by operations that separate the ensuing solution from the parts that did not dissolve, in turn followed by operations that separate the stabilizer from the solution, in turn followed by milling of the dried stabilizer so that it becomes a powder. This roomy description fits the aforementioned stabilizers except cellulose derivatives, starch, and traditional qualities of seed gums (guar gum and locust bean gum) and gum arabic.

Extraction is usually done at elevated temperatures, and it may involve the addition of either acid or alkali in order to break linkages that attach the stabilizer to the insoluble raw material parts or linkages that make the precursor of the stabilizer insoluble. The operations that separate the ensuing stabilizer solution from insoluble materials may typically be filtration and centrifugation.

The operations that isolate the stabilizer from the solution include evaporation of water, gel pressing, precipitation, and drying. In some cases, for example, with agar, cooling the hot extract induces gelling. The gel can then be handled so that the held water becomes released while the gel shrinks – a phenomenon known as syneresis. Addition of di- or trivalent salts may

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00652-8

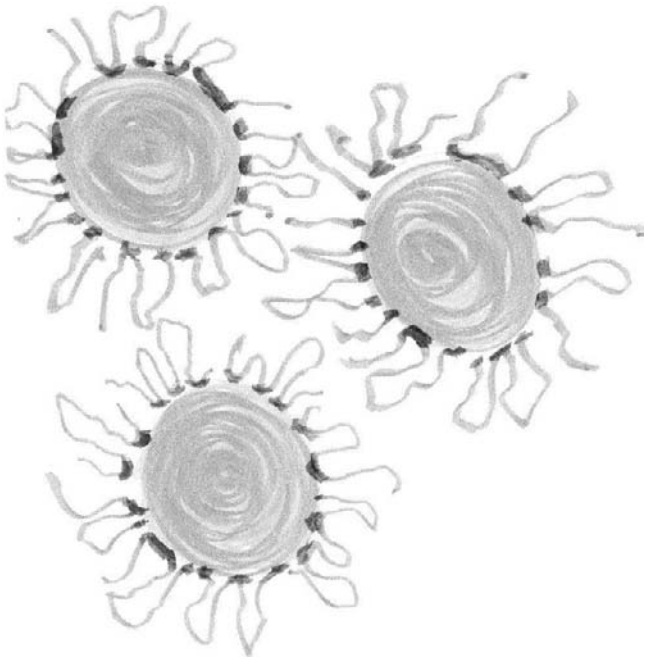

Figure 1 *Steric stabilization*, the pieces of dispersed material (drawn as spheres) are coated by stabilizer molecules (drawn as loops and tails) that on the one hand adsorb to the surfaces of the dispersed pieces (adsorbing stabilizer parts drawn as dark segments) but on the other hand protrude from the surfaces and reach into the surrounding continuous phase.

facilitate the syneresis or precipitate the stabilizer as an insoluble salt. Pressing of gels or subjecting gels to freeze–thaw cycles (traditional Japanese process originally used for agar) may also facilitate syneresis. A different technique is to pour the stabilizer solution into an alcohol whereby the stabilizer precipitates. This is commonly used for manufacturing pectin, xanthan, gellan, clarified versions of LBG and guar, and some types of carrageenan. The disadvantage is that the alcohol needs to be recovered by costly distillation, but the advantage over precipitation with salts is that the alcohol can be removed from the stabilizer by drying, and the stabilizer thereby can regain its water solubility.

The manufacturing of some stabilizers involves modification of functional groups. CMC is produced by reacting cellulose with sodium hydroxide followed by reacting with monochloroacetic acid. The new functional groups contain ionizable carboxyl acid groups that make the product soluble in cold water. Modified starch is a generic term that includes starch that has only been physically modified, but it also includes types modified with adipic anhydride or phosphorous oxychloride for creating starch adipates or starch phosphates, respectively. A certain class of pectin, known as amidated pectin, is made by exposing pectin to ammonia whereupon some of its methyl ester groups are converted into amide groups.

In addition to the stabilizers mentioned in Table 1, a list provided by the FAO of the United Nations also includes the polymeric materials curdlan (CASRN 54724-00-4), dammar gum (9000-16-2), gum ghatti (9000-28-6), karaya gum (9000-36-6), konjac flour (37220-17-0), polydextroses (68424-04-4), propylene glycol alginate (9005-37-2), tara gum (39300-88-4), tragacanth gum (9000-65-1), and a number of cellulose derivatives other than CMC. Further, some nonpolymeric materials are included, for example, sodium, potassium, and calcium salts of acetic, citric, phosphoric, and tartaric acids. In addition to the materials currently listed by the FAO, there are polymeric stabilizers with oriental tradition, for example, soluble soybean polysaccharide and pullulan (9057-02-7). Inulin (9005-80-5) is also often mentioned alongside with stabilizers.

Patterns of Consumption

Commercial stabilizers and their food uses are regulated by national legislation, which in many cases refers to internationally acknowledged standards like the CODEX Alimentarius based on the Joint FAO/WHO Expert Committee on Food Additives (JECFA). Often, the national legislation sets forth the conditions under which permitted food additives may be used in all categories of foods.

JECFA has evaluated that most of the gums that comply with the given specifications/monographs have an acceptable daily intake 'not specified.' This goes for all of the stabilizers listed in Table 1. This means that most stabilizers can be used in many foods in levels that the EU legislation describes as 'quantum satis' (QS) and CODEX JECFA describes as good manufacturing practice (GMP). That is, there is no numerical maximum level, but the use must comply with good manufacturing practice including that the dosage should not exceed what is necessary for achieving the intended effect, and the use should not conceal food of inferior quality or

Table 1 Commonly used stabilizers

Stabilizer	*Raw material*	*Chemical properties*	*Manufacturing*
Agar CASRN 9002-18-0 E 406	*Gelidium* and *Gracilaria* sp. (seaweeds)	Mixture of uncharged agarose and agaropectin, a sulfate-containing, thus anionic, polymer	Pretreatment with either acid or alkali, then hot extraction, filtration, and gel pressing
Alginates CASRN 9005-32-7 (alginic acid) E 400 through E 405	*Laminaria* sp., *Ascophyllum* sp., and other brown seaweed types	Linear polymer of β-D-mannuronic acid and α-L-guluronic acid that can follow in diverse sequences along the molecules; anionic	Alkali treatment of the peel followed by aqueous extraction, then filtrations, and precipitation with calcium salts or acid. Conversion of the precipitate to sodium alginate
Carrageenan CASRN 9000-07-1 E 407 PES E 407a	Rhodophyceae (red seaweeds), wild types and types cultivated in marine fields	Galactose polymer with sulfate ester groups and 3,6 anhydrogalactose varying in amount and location; anionic	Hot extraction at high pH, filtration, gel pressing, or alcohol precipitation. Special types (include PES) that essentially are alkali-treated seaweeds that have not been extracted also exist
CMC, Cellulose gum CASRN 9004-32-4 E 466	Wood or cotton	β-linked glucopyranose (polymer that can be hydrolyzed to glucose) with which some hydroxyl groups are replaced with carboxymethyl groups. Anionic.	Reaction with NaOH followed by $CH_2ClCOOH$
Gelatine CASRN 9000-70-8	Animal skin and bones, typically from pig or cow	Mixture of protein and peptide; amphoteric; hot water-soluble gels upon cooling	Extraction at either low pH (type A gelatin) or high pH (type B gelatin); filtration; drying
Gellan CASRN 71010-52-1 E 418	*Sphingomonas elodea* (microorganism)	Linear polymer with carboxyl, acetyl, and glycerate groups; anionic; soluble in hot water	Fermentation, filtration of broth, and alcohol precipitation. Low-acyl versions by alkali treatment
Guar gum CASRN 9000-30-0 E 412	Endosperm of seeds of *Cyamopsis tetragonolobus* (annual crop)	Galactomannan (polymer of galactose and mannose); mostly uncharged; highly effective thickener	Mechanical processing of seeds for isolating the endosperm; milling; clarified versions have further been water-dissolved, filtered, and precipitated
Gum Arabic CASRN 9000-01-5 E 414	Exudate from the trunks of *Acacia senegal* or *Acacia seyal* trees	Complex branched polymer of neutral saccharides and acidic saccharides; contains glycoproteins; very soluble in water (>30%)	Traditional GA is only mechanically purified (from dust, bark pieces, etc.). Versions that have been purified by dissolution in water, filtration, and drying are commercially available
LBG (locust bean gum and carob gum) CASRN 9000-40-2 E 410	Kernels of St. John's bread – seeds of the carob tree, *Ceratonia siliqua*	Galactomannan (polymer that can be hydrolyzed to galactose and mannose); mostly uncharged; thickener	The hull of the fruit is removed by a combination of charring and mechanical ways. The seed endosperm is then milled. Clarified versions have further been water-dissolved, filtered and precipitated
Pectin CASRN 9000-69-5 E 440	Edible plants. In particular citrus peel, apple solids, sugar beet	Polydisperse, complex structure. Main component mostly linear with carboxyl groups some of which are methyl-esterified; anionic. Special versions contain amide groups	Extraction at low pH, filtration, and alcohol precipitation. Methyl ester content can be varied though acidity of extraction or with enzymes. Amide groups can be introduced by exposure to ammonia (E440 ii)
Starch and modified starch E 1410 through E 1450	Edible plants, for example, corn, tapioca, wheat, and potato	α-Linked glucopyranose (polymer that can be hydrolyzed to glucose). Native types are uncharged	
Xanthan CASRN-11138-66-2 E 415	*Xanthomonas campestris* (microorganism)	Long backbone of cellulose (β-linked glucopyranose), with every second hexose unit having a trisaccharide side chain that contains a carboxyl acid group; anionic	Fermentation, filtration of broth, and alcohol precipitation

adulterated food, and it should not create a nutritional imbalance. The original background for these positive assessments is in some cases that the stabilizers are isolated from materials that have a long record of being eaten as food (e.g., agar, pectin, and seed gums), while in other cases the materials have a long tradition as stabilizers (e.g., gum arabic).

Stabilizers are consumed with the stabilized foods. Stabilized foods are, for example,

- cheese spreads (0.3% carrageenan),
- cocoa milk and milk shake (0.03% carrageenan),
- confectionery jellies (1–2% pectin or carrageenan),
- cultured (acidified) drinkable milk products (0.3% pectin or 0.6% CMC),
- flan and pudding (0.1–0.6% carrageenan),
- hard/chewy candies, for example, liquorice pastilles (30% gum arabic or ≈10% modified starch),
- ice cream (0.1–0.5% alginates, 0.01–0.03% carrageenan, 0.2–0.3% guar, 0.2–0.4% CMC, or 0.2–0.3% LBG – often in combination),
- jam, fruit toppings and ripples, and fruit-containing or fruit-flavored gels (0.3–1% pectin or 0.1–0.3% LBG or combinations),
- marinated or brine-injected meat (≈0.5% carrageenan),
- marshmallow (5–8% gelatin),
- olive fillings (≈1% alginate),
- salad dressing (0.2–0.5% xanthan),
- soft drinks and sodas (gum arabic, LBG),
- tortillas and similar baked products (0.1–0.5% CMC),
- water dessert gels (0.4–0.6% agar or ≈0.4–1.2% carrageenan),
- wine gum (6–10% gelatin or modified starch),
- yogurt (≈1–2% modified starch or 0.3–0.5% gelatin or 0.2% pectin).

Absorption and Mechanism

Owing to their polymeric nature and their resilience to degradation in the upper parts of the human digestive tract, stabilizer additives (those stabilizers that are not legally considered ingredients) pass almost intact through until the large intestine in which they are digested into short-chained fatty acids. This qualifies them for being considered dietary fibers and – since they feed the gut microorganisms – prebiotics. On the other hand, the amounts that would be acquired from normal consumption of stabilized foods are modest in comparison with the dosages that have proved a significant effect in feeding studies.

In particular, pectin has been thoroughly studied because it is a soluble dietary fiber that occurs abundantly in vegetables and fruit and thus in the normal human diet. Administration of pectin in adequate amounts, that is, at least 6 g day^{-1}, has been demonstrated to have the beneficial effect of contributing to the maintenance of normal blood cholesterol level, and the European Food Safety Agency has approved this as a health claim under its Article 13.1 program. The mechanism seems to be rather general and shared with other soluble dietary fibers, like beta-glucan, konjac (glucomannan), hydroxypropyl methylcellulose, and guar gum, all of which have acceptance for similar claims. The dietary fibers influence the uptake of materials from the mid or lower parts of the digestive tract, and they increase the excretion of some materials (among these are bile acids) with the stools. The human body produces bile acids from cholesterol in the liver and secretes them in the duodenum (the first section of the small intestine). After having served their role as a part of the digestive system, the major part of the bile acids is reabsorbed in the ileum (the last section of the small intestine) and returned to the liver, while a minor part leaves with the stools. Pectin and other soluble dietary fibers (and thus most stabilizers) reduce the reabsorption and thus increase the loss of bile acids. This makes the liver synthesize more bile acids for replenishing the stock; and cholesterol is used and removed from the bloodstream in this process.

Health Effects

The stabilizers that are legally considered additives (rather than ingredients) are used in dosages that normally (with exceptions) constitute much less than 1% of the stabilized foods. So, their contribution to the overall diet, its energy content and its nutritional properties, is unimportant. Their safety has been evaluated by expert committees of the major international legislations and should under all circumstances be unproblematic when following the legally stipulated guidelines for use. Some stabilizers have been isolated from edible plants, and their health effects are typical of dietary fibers although the normal human ingestion of them through stabilized foods is so low that their principally beneficial effect must be considered modest.

© 2016 Elsevier Ltd. All rights reserved.

Organism and Sources

The *Staphylococcus* genus includes Gram-positive, nonmotile, and catalase-positive bacteria. Staphylococci are ubiquitous and widely distributed in nature, with some species inhabiting specific ecological niches. Staphylococci live as commensals on the skin and mucous membranes of warm-blooded animals and humans but can also be isolated from environmental sources and from a wide range of foodstuffs such as meat, cheese, and milk and from the surfaces of cookware, utensils, furniture, and clothing, among other items. Foods frequently implicated in staphylococcal food poisoning (SFP) include meat and meat products; poultry and egg products; salads, such as egg, tuna, chicken, potato, and macaroni; bakery products, such as cream-filled pastries, cream pies, and chocolate éclairs; sandwich fillings; and milk and dairy products. Foods that require considerable handling during preparation and that are kept at slightly elevated temperatures ($>7.2\ ^{\circ}C$) after preparation are frequently involved in SFP.

The genus *Staphylococcus* includes more than 70 species and subspecies, which can be divided into two groups according to their capacity to coagulate rabbit plasma: coagulase-positive staphylococci (CPS) and coagulase-negative staphylococci (CNS). The main CPS is *Staphylococcus aureus*. Other CPS include the *Staphylococcus intermedius* group (*Staphylococcus intermedius*, *Staphylococcus pseudintermedius*, and *Staphylococcus delphini*), *Staphylococcus schleiferi* subsp. *coagulans*, *Staphylococcus lutrae*, and some strains of *Staphylococcus hyicus*. In particular, members of SIG are opportunistic pathogens in many animal hosts and occasionally in humans.

Some CNS (particularly *Staphylococcus xylosus*, *Staphylococcus carnosus*, and *Staphylococcus equorum*) have a positive impact on fermentation processes and sensory characteristics of food products; they are frequently used as a component of meat and cheese starter cultures. In other circumstances, some CNS species can present health risks to humans and/or animals. For example, *Staphylococcus saprophyticus*, which may contribute to sausage aroma formation and help to prevent off-flavor during sausage ripening, is a ubiquitous species and is also involved in acute urinary tract infections in young adult women.

S. aureus is the most pathogenic species within the genus and is endowed with a variety of virulence factors, some of which (such as exfoliative toxins A and B; enterotoxins; hemolysins α, β, δ, and γ; leukocidins; and antibiotic resistance determinants) were also detected in genomes of CNS. Both CPS and CNS virulent species or strains can produce a variety of infections in humans and in companion and farm animals. Another relevant phenotypic feature of some *S. aureus* strains is the capacity to form biofilms, a trait that enhances tolerance to antimicrobials and persistence.

S. aureus is the etiologic agent predominantly associated with SFP. In Europe, 346 outbreaks (representing 6.4% of total outbreaks) were caused by staphylococcal toxins in 2012 according to the EFSA EU Summary Report 2012 on zoonoses, zoonotic agents, and foodborne outbreaks. SFP results from ingestion of foods containing preformed staphylococcal toxins that behave as superantigens (SAgs). The International Nomenclature Committee for Staphylococcal Superantigens distinguishes three types of SAg toxins in staphylococci: (i) staphylococcal enterotoxins (SEs) with proved emetic activity in primates, (ii) SAgs whose emetic properties remain unconfirmed (SE-like toxins; SEls), and (iii) toxic shock syndrome toxin-1 (TSST-1). At least 23 different SAgs have been described: the SEs A–E, G–J, and R–T (SEA–SEE, SEG–SEJ, and SER–SET), the SEls K–Q and U–X (SElK–SElQ and SElU–SElX), and TSST-1. Most SAgs have a dose-dependent capacity to cross the intestinal wall and produce a local and systemic action on the immune system. SEs do not seem to be an exclusive trait of *S. aureus*, as they have also been described in CNS from foods and in the genomes of CNS from different sources. SEs are globular single-chain proteins with molecular weights ranging from 22 to 29 kDa, resistant to heat treatments and other environmental conditions (such as freezing, drying, and low pH) that inactivate enterotoxin-producing strains. Unless heat processes are applied, staphylococci are expected to exist in any and all foods that are handled directly by humans or are of animal origin.

One additional concern on staphylococci is their capacity to acquire antimicrobial resistance and particularly the spread of methicillin-resistant strains in health care institutions, the community, and livestock herds. In 2008, the European Centre for Disease Prevention and Control estimated that a total number of 171 200 nosocomial methicillin-resistant *S. aureus* (MRSA) infections are acquired annually in the member states of the European Union (EU), and in Iceland and Norway, resulting in 5400 attributable excess deaths, more than 1 million excess days of hospitalization, and EUR 380 million excess in hospital costs. In 2008, the proportion of MRSA in *S. aureus* blood culture isolates was $<5\%$ in northern Europe, including the Netherlands, and $<10\%$ in Austria, Luxembourg, and Slovenia; between 10% and 24% for isolates in Belgium, the Czech Republic, France, Germany, Hungary, Latvia, Poland, and Switzerland; and $\geq 25\%$ in Bulgaria, Croatia, Cyprus, Greece, Israel, Italy, Malta, Portugal, Ireland, Romania, Spain, Turkey, and the United Kingdom. Bacteremias caused by MRSA are now decreasing (4.8% per year), whereas the number attributable to methicillin-sensitive *S. aureus* increased continuously (3.4% per year). Methicillin resistance results from the acquisition of the *mecA* gene, which codes for an alternative penicillin binding protein (PBP29 or PBP2a) and is associated with the staphylococcal cassette chromosome (SCC) *mec* (SCC*mec*) elements, found in both CPS and CNS. The recently described gene homologue *mecC* is also not restricted to *S. aureus* but found in several staphylococcal species including *Staphylococcus sciuri*, *Staphylococcus stepanovicii*, and *S. xylosus*.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00654-1

Methicillin-resistant *S. aureus* strains have been detected in companion and food animals and in raw meat (pork, poultry, and beef) and milk and may also be present in a variety of other foods. The primary route of zoonotic transmission of MRSA is considered to be the direct or indirect occupational contact of livestock professionals with colonized animals, while the role of food as a source of human colonization or infection is presently considered to be low. If meat and other foods contaminated with MRSA are cooked properly, MRSA cells will be inactivated. However, as with enterotoxigenic methicillin-sensitive *S. aureus* strains, under conditions of temperature abuse, MRSA cells could grow in foods, produce heat-stable enterotoxins, and cause foodborne intoxication. In some individuals, whose normal flora has been depleted by antibiotic treatment, MRSA cells that could potentially be present on contaminated ready-to-eat foods, including processed meats, cheeses, and fresh produce, could cause staphylococcal enterocolitis.

This article focuses on the identification of staphylococci, particularly *S. aureus* (including MRSA), and the detection of SEs in foods.

Detection of Staphylococci in Foods

Given the risk of SFP and the heat stability of SEs, it is required to enumerate CPS at the steps of the production process where the number of staphylococci is expected to be the highest (process hygiene criteria) and to screen samples for the presence of SEs above well-specified M values (food safety criteria) to assess the compliance of the product with the food regulatory requirements (such as EC regulations no. 2073/2005 and 1441/2007).

Although CNS are not routinely screened, they should also be taken into consideration according to the conclusions of several studies:

- The importance of the pathogenic potential of CNS as a source of SEs has been highlighted in human and animal infections as well as in food poisoning.
- Multiple CNS species can serve as reservoirs for *mecA*. In addition to the clonal transmission of methicillin-resistant CNS in meat, horizontal occurrence of SCC*mec* is observed in staphylococcal species.
- The need of monitoring antimicrobial resistance in CNS not only in the meat of slaughtered animals but also in fish products at retail.
- The risk to public health due to consuming raw or undercooked shellfish containing enterotoxigenic plus methicillin-resistant CNS.

Contamination of food processing factories by *Staphylococcus* spp. is screened by culture-based microbiological methods, but characterization of the isolates is usually limited to determination of coagulase positivity. A variety of culture-dependent and culture-independent methods have been developed to detect *S. aureus* in foods. Depending on the suspected level of contamination and the purpose of the analysis, early steps may include nonselective enrichment, selective enrichment, or even direct detection on selective and differential media. In Europe, the analytical reference method for CPS is EN/ISO 6888-1 or ISO 6888-2 (EC regulations no. 2073/2005 and 1441/2007). Several commercial identification systems based on phenotypic tests allow discrimination of CPS and CNS at species levels. RAPIDEC Staph, API Staph, VITEK 2, *MicroScan Pos ID* and Rapid *Pos ID panel* systems, Crystal Rapid Gram-Positive Identification System, Biolog MicroStation System, MIDI Sherlock Microbial Identification System, and RiboPrinter Microbial Characterization System are a few examples. Complementary agglutination tests arranged on different supports (such as latex beads) are often used to confirm the presence of coagulase and staphylococcal protein A. One emerging technology for bacterial detection is based on aptamers. Aptamers are small RNA/DNA molecules that can form secondary and tertiary structures capable of specifically binding proteins or other cellular targets; they are essentially a chemical equivalent of antibodies. Based on the light scattering capacity of gold nanoparticles, aptamer-conjugated gold nanoparticles could be used for rapid single-cell detection of *S. aureus*.

Rapid detection of *S. aureus* can be made using the Accu-Probe culture identification test, which is based on a highly specific DNA probe directed against rRNA. Polymerase chain reaction (PCR) analysis of the 16S–23S rRNA intergenic spacer region (singly or combined with restriction analysis) can discriminate among several *Staphylococcus* species and allows for the identification of pure culture staphylococci within 24–48 h. Furthermore, a variety of identification methods based on amplification (by conventional or multiplex PCR and real-time PCR) of target genes such as *rpoB* (RNA polymerase B subunit), *nuc* (thermostable *S. aureus* nuclease), *coa* (coagulase enzyme), and *sodA* (manganese-dependent superoxide dismutase) among others have been proposed in recent years for identification at species level of both CPS and CNS. Specific detection of *S. pseudintermedius* by PCR reactions targeting the *nuc* gene or PCR-restriction fragment length polymorphism (RFLP) targeting the phosphoacetyltransferase (*pta*) gene has also been described. An oligonucleotide array has also been developed, which targets the *sodA* gene. It is a valuable tool that distinguishes the validated staphylococcal species in one shot and allows rapid, accurate identification of staphylococcal strains from clinical and food origins. DNA microarrays for simultaneous detection of *S. aureus* and other foodborne pathogens have also been developed.

Detection of MRSA

The spread of MRSA outside of clinical settings is a matter of concern. Recent reports of MRSA in livestock, particularly pigs, and in individuals with contact with livestock provided the first evidence of the existence of a livestock-associated (LA-MRSA) reservoir throughout Europe. Since then, LA-MRSA has been identified in many other countries. LA-MRSA strains have important genotypic and phenotypic characteristics: (i) They are nontypeable by pulsed field gel electrophoresis (PFGE) using *Sma*I; (ii) many of them belong to CC398 by multilocus sequence typing (MLST); (iii) SCC*mec* elements are different from those carried by other MRSA genotypes commonly found in the community and health care settings; (iv) they often exhibit coresistance to many non-β-lactam antimicrobials (e.g., antibiotics and metals), including those

commonly used in animal production; (v) the majority of isolates lack toxins such as PVL and other enterotoxins. The EFSA recommends sampling in the environment of pig stables to determine the risks of herds being positive for MRSA.

Conventional methods for the laboratory detection of MRSA include antimicrobial susceptibility testing, detection of PBP2a by latex agglutination tests, and the molecular detection of the *mecA* or *mecC* genes. The EFSA has provided a detailed flowchart for isolation, identification, and typing of MRSA and recommends a harmonized set of antimicrobial substances to be used for testing of susceptibility in *S. aureus*/MRSA. Disk diffusion is recommended for antibiotic sensitivity testing by the National Committee for Clinical Laboratory Standards. Other methods, such as oxacillin agar, have also been demonstrated to have good accuracies. Recently, cefoxitin disks have been reported to be highly accurate for predicting methicillin resistance. Routine diagnostic tests do not, however, provide a mechanism for the identification of *mecA* or *mecC*, which still requires confirmation using PCR assays. However, an oxacillin-sensitive/cefoxitin-resistant profile on antibiotic susceptibility tests is indicative of a *mecC* MRSA genotype. Microelectromechanical systems aiming at determination of antibiotic susceptibility and detection of key genes or proteins are gaining increasing attention for rapid detection of MRSA, especially in the medical field.

When testing antibiotic resistance, care should be taken since MRSA strains can be heterogeneously resistant to methicillin, so only a small proportion of the *S. aureus* colonies that grow from a given sample may show resistance in standard laboratory tests. Consequently, if too few cells appear resistant, an oxacillin-resistant strain may go undetected. Also, in *mec*-negative strains of *S. aureus*, methicillin resistance can be due to hyperproduction of β-lactamase, the production of normal PBP with altered binding capacities and/or other factors that have not been identified to date. These isolates usually have MICs at or just above susceptibility break zones. The isolates are sometimes referred to as borderline-resistant *S. aureus*. And last, the phenotypic expression of resistance may also vary despite genetic homogeneity depending on culture conditions that include temperature and the osmolarity of the medium.

Detection of SEs

European regulations (EC 2073/2005 and 1441/2007) require screening of SEs if CPS counts in milk products during the manufacturing process at the processing step exceed 10^5 CFU g^{-1}. Commercial toxin detection kits (such as Vidas® SET2 kit or Ridascreen® SET Total kit) have been recommended for this purpose by the National and European Union Reference Laboratories for Coagulase Positive Staphylococci. The different types of methods available for detection and investigation of bacterial toxins in food are based on bioassays, immunologic techniques, molecular biology, and mass spectrometry-based methods.

- Bioassays are based on the capacity of an extract of the suspected food to induce symptoms such as vomiting, gastrointestinal symptoms in animals, and/or superantigenic action in cell cultures. Historically, SEs have been detected based on their emetic activity in monkey-feeding and kitten-intraperitoneal tests and, more recently, using animal models such as house musk shrews (*Suncus murinus*). Others (SEls) have not been tested or gave negative results on emetic activity tests.
- Immunologic methods. The most commonly used method for detecting SEs in food is based on the use of anti-enterotoxin polyclonal or monoclonal antibodies. Commercially available kits have been developed according to two different principles: (1) enzyme immunoassay comprising ELISA and enzyme-linked fluorescence assay and (2) reversed passive latex agglutination. Whatever the detection method used and owing to the low amount of SEs present in food, it is crucial to concentrate the extract before performing detection assays. One limitation can be interference from the food matrix, leading to false-positive results. Recent studies have improved these methods in order to make them more sensitive and specific.

Recent advances in nanomaterials, microelectromechanical systems, and microfluidics resulted in the so-called lab-on-a-chip systems for immunodetection of bacteria and their toxins. Some of these innovations can be applied for immunodetection of SEs. For example, antibodies coupled to fluorescent magnetic nanoparticles have been used for a novel sandwich immunoassay on a 3-D fiber solid phase for the detection of SEA and TSST in milk samples. Also, antibodies coupled to fluorescent magnetic microspheres allowed the multiplex toxin detection of SEB and other toxins in a suspension assay. Quantum dots (semiconductor nanocrystals) coated with antibodies were used for the simultaneous detection of SEB and other toxins based on excitation and fluorescence emission. An eight-channel chip and single-walled carbon nanotube-based immunoassay were combined for the detection of SEB, enabling the detection of 0.1 ng ml^{-1} of SEB in a 10-μl sample. Later, this microfluidic platform was improved for the label-free detection of SEB and termed 'biological semiconductor.'

- Molecular biology methods often involve the PCR. These methods usually detect genes encoding enterotoxins in strains of *S. aureus* isolated from contaminated foods. However, these methods have two major limitations: First, staphylococcal strains must be isolated from food, and second, the results inform as to the presence or absence of genes encoding SEs but do not provide any information on the expression of these genes in food. This is important to be considered, since enterotoxin genes may show different patterns of expression in relation to bacterial growth and therefore may be influenced by factors affecting growth and survival such as pH, temperature, water activity, redox potential, and nutritional factors. Very recent efforts have been directed to determining directly which *SE* genes are found in suspected foods. Following the huge SFP event, which occurred in Japan in July 2000 (more than 13 000 people were intoxicated by powdered or liquid milk), a PCR-based methodology was developed whereby *SEA*, *SEG*, *SEH*, and *SEI* genes could be detected in the incriminated powdered skim milk, although cultivable *S. aureus* were not recovered from the sample. Moreover, to evaluate the toxic potential of strains isolated from SFP outbreaks, various authors have recently designed primers to perform PCR and reverse transcription PCR for *SE* genes.

Regarding CNS, failure of SE gene detection in CNS might sometimes be explained by the use of inappropriate methods of DNA preparation, in which cell wall destabilization using lysostaphin was not applied. Another potential cause of false-negative results is that primers for CNS enterotoxin detection were based on known *S. aureus* sequences, whereas CNS sequences, despite close phylogenetic vicinity of organisms, are likely to be divergent. Therefore, polynucleotide DNA microarrays able to detect sequence with similarities down to 70% in contrast to oligonucleotide-based ones seem to be more useful in the detection of CNS enterotoxins.

- Mass spectrometry (MS)-based methods. Owing to the drawbacks with currently available detection methods and the lack of available antibodies against the newly described SEs, other strategies based on physicochemical techniques have been developed recently. Among these, MS has newly emerged as a very promising and suitable technique for analyzing protein and peptide mixtures.

In the case of food analysis, the situation is complex because the matrix can contain many proteins, lipids, and many other molecular species that interfere with the detection of the targeted toxin and may distort quantification. Sample preparation remains the critical step of the analysis. It could be improved by, for example, optimizing digestion parameters or by adding a purification step. The strategy of incorporating an isotopically labeled internal standard into the samples has also been developed.

Thus, an overall approach combining classical microbiology to enumerate CPS strains with immunologic techniques, molecular biology, and MS-based methods offers an interesting alternative for attributing outbreaks to SEs.

Strain Typing

Investigation of the genetic diversity of staphylococcal populations is important in order to distinguish subpopulations or clones with specific features such as enhanced virulence or antibiotic resistance. Subspecies genotypic information on microbial contaminants in food processing factories may be of practical importance, as it may facilitate identification of transient versus persistent strains. While metabolic fingerprinting has limited discriminatory power and is prone to errors due to differences in gene expression, molecular typing methods are widely applied to characterize *S. aureus* subpopulations and hopefully will also be used for typing of other CPS and for CNS. However, the parameters of throughput, speed, simplicity, and cost are very important for routine application in the food industry.

- Random amplification of polymorphic DNA (RAPD-PCR). The simplest and cheapest random PCR-based methods such as RAPD-PCR lack sufficient reproducibility but still can be used for approximation of strain diversity within a given food system or for lab-scale comparison of diversity within a collection of strains.
- Amplified fragment length polymorphism (AFLP) is based on selective amplification of genomic restriction fragments. Interestingly, AFLP has been used for typing of CNS.
- RFLP analysis is based on PCR amplification of variable regions within the bacterial chromosome such as the 16S–23S rRNA gene spacer or the coagulase (*coa*) or protein A (*spa*) genes. The products from PCR amplification are then digested with suitable restriction enzymes and the resulting fragments analyzed by gel electrophoresis. PCR-RFLP can also be used for lab-scale comparison of strain diversity.
- PFGE allows separation of large DNA fragments, such as those generated after chromosome digestion with restriction enzymes. Whole bacterial cell DNA is incubated with (usually one) restriction enzyme(s) (usually *Sma*I for *S. aureus*), resulting in a band pattern that depends on the number of enzyme recognition sites on the bacterial DNA. Changes in the bacterial DNA (such as point mutations, insertions, deletions, gene duplications, and inversion of DNA fragments) may affect the number of restriction sites and the sizes and numbers of the generated DNA fragments. Comparison of band patterns with suitable computer programs allows the calculation of similarity coefficients and the detection of specific clones, such as MRSA clones. One limitation of PFGE is interlaboratory variations.
- Multiple-locus variable-number tandem repeat analysis (MLVA) is based on heterogeneity of loci carrying a variable number of tandem repeats (VNTR). In MLVA, the variability in the number of short tandem repeat sequences is utilized to create DNA profiles. MLVA was initially based on six tandem repeat loci (*spa*, *clfA*, *clfB*, *sdr*, *sspa*, and *coa*). Bioinformatic analysis of *S. aureus* sequenced genomes has allowed the identification of additional VNTR loci. Within these, the variable number of same-sized inserts is reflected by a well-defined variability in length of the loci. The use of single multiplex amplification and flow-through gel electrophoresis by an automated analyzer improved the precision of molecular weight determination and practical applicability of the method in terms of reduction in time and labor requirements.
- MLST was developed as a universal typing method that avoids the biases introduced by experimental conditions. Selected internal fragments of seven housekeeping genes are sequenced after PCR amplification: *arc* (carbamate kinase), *aro* (shikimate dehydrogenase), *glp* (glycerol kinase), *gmk* (guanylate kinase), *pta* (phosphate acetyltransferase), *tpi* (triosephosphate isomerase), *yqi* (acetyl coenzyme A acetyltransferase), and the sequences compared to an MLST database. Mutations in the housekeeping genes yield different allele types, and the combinations of allele types of the different housekeeping genes define each particular sequence type (ST). After analysis with suitable bioinformatic programs (such as eBURST), each strain is assigned to an ST (either existing in the database or new). Cluster analysis of STs allows definition of clonal complexes (CCs), which can be related with pathogenicity or antibiotic resistance. For example, the MRSA ST398 of CC398 is an emerging ST that is massively colonizing livestock and food products and causing human infections.
- Single-locus sequence typing is based on the polymorphic repeat region of the *spa* gene. Spa sequences can be compared to databases (Ridom SpaServer) and used for reliable, accurate, and discriminatory typing of MRSA.
- Typing of the SCC*mec* is widely used for typing of MRSA strains. SCC*mec* mobile elements contain the methicillin

resistance (*mec*) gene complex, the recombinase (*ccr*) gene complex, and the joining region. According to diversity and gene orientation, strains can be assigned to SCC*mec* allotypes.

- DNA microarrays. This technique utilizes multiplex linear DNA amplification where labeled amplicons are hybridized to probes on a slide. Microarrays allow not only strain typing but also multiple detection of other relevant genes such as those coding for virulence determinants or antibiotic resistance.
- Whole genome comparison. The development of technologies for massive DNA sequencing and analysis has introduced the possibility of doing phylogenomic analysis for bacterial strains. The core genome of *S. aureus* contains a set of highly conserved genes present in all strains, while the accessory genome may include mobile genetic elements and encode antimicrobial resistance determinants, toxins, SAgs, or other factors that promote infection. Genome comparisons based on single-nucleotide polymorphisms (SNPs) of the core genome and/or variations in the accessory genome structure and function can provide novel insights into the population structure and biology of this bacterium.

Conclusions

SFP remains one of the most common foodborne diseases in the world following the ingestion of SEs that are produced by enterotoxigenic strains of CPS, mainly *S. aureus*. Prevention of SFP is based on hygiene measures to avoid or reduce contamination of food by *S. aureus*. These procedures must include control of raw materials, proper handling, cleaning, and disinfection of equipment from farm to fork. Thus, an overall approach combining classical microbiology to enumerate CPS strains with immunologic techniques, molecular biology, and MS-based methods offers an interesting alternative for attributing outbreaks to staphylococci. In any case, subspecies genotypic, enterotoxigenic, and resistance information on staphylococci strains, in food processing factories, is of great importance as it may help to properly manage the process hygiene standards, to identify a possible need for improvements in the efficiency of sanitation, or to improve the control of materials entering the food processing facility.

Summarizing remarks: (i) Investigation of both CPS and CNS is important for food safety; (ii) CNS may be growing in relevance as pathogens and carriers of antibiotic resistance (including resistance to methicillin and also to other not less important antimicrobials); (iii) there is a need to clearly establish the enterotoxigenic potential of CNS; (iv) in addition to classical detection methods, the introduction of miniaturized systems and nanomaterials may speed up detection of staphylococci, strain typing, and enterotoxin production.

Staphylococcus: Food Poisoning

Introduction

Staphylococci, and their most prominent food poisoning representative *Staphylococcus aureus*, are probably among the most established foodborne pathogens. It was in 1871 when Recklinghausen, a German scientist, observed cocci in a diseased kidney and called them 'micrococci,' incriminating staphylococci as human pathogens. Later, after several changes in their nomenclature, Sir Alexander Ogston coined the name *Staphylococcus*. The foodborne disease involving staphylococci was for the first time investigated in Michigan (the United States) in 1884 by Vaughan and Sternberg, as a response to the food intoxication involving cheese probably contaminated by staphylococci. Proof of the involvement of staphylococci in food poisoning was first brought in 1914 by Barber who discovered that a toxin substance produced by staphylococci was responsible for staphylococcal food poisoning. The capacity of some strains of *S. aureus* to produce food poisoning was conclusively demonstrated in 1930 by Dack et al. who showed that the symptoms could be produced by feeding culture filtrates of *S. aureus*. Today, it is well established that food poisoning caused by staphylococci is a foodborne intoxication, with staphylococcal enterotoxins (SEs) as etiologic agents. SEs are produced in food during exponential and stationary growth phase of enterotoxigenic strains causing foodborne intoxication after the consumption of contaminated food. *S. aureus* is the species almost invariably involved, although enterotoxin production by several other species has been reported.

Species of Concern in Food

Genus *Staphylococcus* contains 47 species and 24 subspecies as reported in the List of Prokaryotic Names with Standing in Nomenclature as of the full update in 6 August 2013 (http://www.bacterio.net/s/staphylococcus.html). The genus *Staphylococcus* comprises Gram-positive, catalase-positive cocci. Metabolism of carbohydrates may be either oxidative or fermentative. Cells are small (~1 mm diameter) and often form characteristic clumps resembling bunches of grapes. Their classification distinguishes between coagulase-producing strains, designated as coagulase-positive staphylococci (CPSs), and noncoagulase-producing strains, called coagulase-negative staphylococci (CNSs). Staphylococci are predominantly of animal origin, although some species were isolated from the environmental sources. They may be present as part of the normal microflora of humans and animals. *S. aureus* is carried on skin and nasal cavities of about 30% of the healthy human population. Among those, enterotoxigenic species are of potential interest in food safety, although not all of them have been documented in foods. Table 1 shows an overview of reported enterotoxigenic *Staphylococcus* spp. The most important member of genus *Staphylococcus* in relation to food safety is *S. aureus*, followed by *S. hyicus* and *S. intermedius*. Next to the well-established role of CPS in food poisoning, several CNSs have also been potentially involved in foodborne outbreaks. Among CNS isolates reported to produce detectable enterotoxins are those belonging to *S. saprophyticus*, *S. epidermidis*, *S. cohnii*, and *S. warneri*. Recently, following consumers' complaint, a coagulase-negative *S. saprophyticus* was found in an oyster sauce (Rapid Alert System for Food and Feed, RASFF, alert 2012.0605). It is also important to note that CNS isolates play an important role in mastitis etiology and that milk from subclinically infected cows can be hazardous to human health not only because of the risk of pathogen transmission but also because of contamination with enterotoxins.

Regarding the percentage of strains that are enterotoxigenic, widely different percentages have been found depending on the source of isolates. The numbers vary from 10% (of 236 raw milk isolates) to ~60% (200 food isolates). The relative incidence of specific enterotoxins among strains recovered from various sources varies widely, too. The existing data should be critically interpreted as the methods used to determine enterotoxigenic potential differ among studies, including types of SE that were screened for. It is however important to note that one strain can produce multiple enterotoxins.

S. aureus in Foodborne Intoxications

Symptoms

The incubation period and severity of symptoms depend on the amount of enterotoxins ingested and the susceptibility of each individual. However, it is generally understood that all people are susceptible to staphylococcal food intoxication. *Symptoms* are of rapid onset and are commonly described by nausea and violent vomiting. Early symptoms comprise nausea followed by incoercible characteristic vomiting (in spurts) and appear within 30 min to 8 h (about 3 h on average) after ingestion of contaminated food. Other commonly described symptoms include abdominal pain, diarrhea, dizziness, shivering, and general weakness sometimes associated with a moderate fever. In the most severe cases, headache, prostration, and low blood pressure have been reported. In the majority of cases, recovery occurs within 24–48 h without specific treatment, while diarrhea and general weakness can last 24 h or longer. Death is rare, occurring primarily in those susceptible to dehydration (infants and elderly people) and in those affected by an underlying illness. The vomiting symptoms of staphylococcal intoxication are identical to that of *Bacillus cereus* emetic intoxication, caused by cereulide. It is interesting to mention that the symptoms of *B. cereus* diarrheal toxicoinfection are identical to that of *Clostridium perfringens* toxicoinfection. An overview of the symptoms of these toxigenic species is provided in Table 2.

Table 1 Overview of reported enterotoxigenic *Staphylococcus* spp.

Staphylococcus *spp.*	*Coagulase*	*Enterotoxins produced (some of the SE types produced/or* se *encoding genes detected)*
S. aureus	+	+ (All known SE types)[a]
S. caprae	−	+
S. carnosus	−	+ (SEA, SEE, SHE)
S. cohnii		+ (SEA, SEB)
S. chromogenes	−	+
S. delphini	+	+ (SEA, SEE)
S. epidermidis	−	+ (SEA, SEC, SED)
S. equorum	−	+ (SED, SEH)
S. haemolyticus	−	+
S. hyicus	(+)	+ (SEA, SEC, SED)[b]
S. intermedius	+	+ (SEA, SEB, SEC, SED, SEE)[c]
S. lentus	−	+
S. piscifermentans		+ (SEH)
S. saprophyticus	−	+ (SEA)
S. schleiferi subsp. *schleiferi*	−	+
S. sciuri	−	+
S. warneri	−	+
S. xylosus		+ (SEH)

[a]Staphylococcal enterotoxins are members of a family of more than 20 different staphylococcal and streptococcal exotoxins that are functionally related and share sequence homology. Those with established emetic activity, involved in food intoxications, are SEA, SEB, SEC, SED, SEE, SEF, SEG, SHE, and SEI.
[b]Until recently, it has been thought that *S. hyicus* produced SE other than classical SEA–SEE.
[c]Even though *S. intermedius* is known to produce SE (next to *S. aureus* the most often cited as enterotoxigenic staphylococci), only one outbreak has been associated with *S. intermedius* since the identification of this species.

Reservoirs

The staphylococci are ubiquitous in nature, with humans and animals as the primary reservoirs. They are present in the nasal passages and throat, in the hair, and on the skin of many healthy individuals. About 40–45% of healthy individuals are nasal carriers of staphylococci, and 8–22% have them on their skin. In fact, estimates range from 20% to 30% for persistent and 60% for intermittent colonization. Staphylococci can be isolated from animals, with the bovine being the most important because of the involvement of staphylococci in mastitis. The prevalence of subclinical and clinical bovine mastitis caused by *S. aureus* ranges from 5% to 50% in different countries.

Much uncertainty remains about the origin and public health implications of livestock-associated methicillin-resistant *S. aureus* (LA-MRSA), but it is known that it is capable of causing zoonotic infections. Recent reports of MRSA in livestock, particularly pigs, and in humans with contact to livestock provided the first evidence of the existence of a true LA-MRSA reservoir throughout Europe. Since then, LA-MRSA has been identified in Canada, the United States, China, Malaysia, Korea, Thailand, etc.

Although animals and humans are the major source, staphylococci also can be found in the air, dust, water, and human and animal wastes. From these sources, they can be transferred to different types of foods.

Implicated Foods and Outbreaks

Foods that have been frequently incriminated in staphylococcal intoxication include meat and meat products; poultry and egg products; milk and dairy products; salads; bakery products, particularly cream-filled pastries and cakes; and sandwich fillings. In the European Union, the largest proportion of 345 outbreaks caused by staphylococcal toxins in 2011 were attributed to mixed food (40.0%). The second most frequently single food category reported was dairy products (14.3%), followed by bakery products (11.4%). Broiler meat and products thereof, cereal products, eggs and egg products, meat and product thereof, vegetables and juices and other products thereof, and other foods were also implicated. In the United States, pork – particularly baked ham – is the food most frequently involved in outbreaks; poultry, salads (meat, potato, etc.), and cream-filled bakery goods are responsible for many of the outbreaks. Table 3 shows an overview of foods involved in staphylococcal outbreaks in the United States in the period 1998–2008. Salted food products, such as ham, have also been implicated, resulting from the capacity of *S. aureus* to grow at relatively low water activity ($a_w = 0.83$). For a number of dried meat products, *S. aureus* remains one of the main microbial safety issues. In RASFF database, about 83 different notifications were issued on the presence of staphylococci or their enterotoxin in many different foods of different geographic origin. Perhaps, surprising to the common knowledge is that more than 20 of these alerts were related to fish and fishery products and crustaceans and products thereof.

Outbreaks of staphylococcal food poisoning are numerous. *S. aureus*, *B. cereus*, *and C. perfringens* create the group of three most important causative agents of bacterial exotoxin-related foodborne diseases. It is estimated that of 9.4 million foodborne illnesses caused by a known pathogen annually in the United States, 1.3 million are caused by *B. cereus*, *C. perfringens*, or *S. aureus*. Meat or poultry dishes were commonly implicated in *C. perfringens* (63%) and *S. aureus* (55%) outbreaks, and rice dishes were commonly implicated in *B. cereus* outbreaks (50%). Errors in food processing and preparation were commonly

Table 2 Comparison of syndromes caused by toxins of *B. cereus*, *S. aureus*, and *C. perfringens*

		B. cereus		S. aureus	C. perfringens
Bacteria/syndrome/toxin		*Diarrheal syndrome (hemolysin BL (HBL), nonhemolytic enterotoxin (NHE),* B. cereus *enterotoxin T (bceT), and cytK)*	*Emetic syndrome (cereulide)*	*Enterotoxins*	*Enterotoxin (CPE)*
Symptoms		Abdominal pain, cramps, watery diarrhea (secretory type), and occasionally nausea	Nausea, vomiting, malaise, and ultimately a fatal liver failure	Nausea, vomiting, sometimes diarrhea	Intense abdominal cramps, diarrhea, and flatulence
Usual incubation time (h)		8–24 (or longer depending on the dose and host susceptibility)	0.5–5	1–8	6–24
Usual resolution time (h)		12–24 (up to several days in severe cases)	6–24	24–48	Within 24
Intoxication/infection dose		Ingestion of more than 10^5 CFU of diarrheal toxin-producing *B. cereus* strains	$\sim$10 μg kg^{-1} bw, 0.01 μg g^{-1} of food (*B. cereus* concentration more than 10^5 CFU g^{-1} food, depending on the strain, food, and conditions)	100 ng of ingested toxin, 0.05 ng ml^{-1} of food (produced when *S. aureus* counts reach $\sim10^5$ CFU ml^{-1} (g^{-1}))	10^6–10^7 CFU g^{-1} of food (ingested vegetative cells produce CPE during intestinal sporulation possibly under impact of bile and stomach acids)
Toxin produced		In the small intestine of the host	Preformed in the food	Preformed in the food	In the small intestine of the host
Food involved		Milk- and meat-containing products, soups, vegetables, puddings	Rice, pasta, potato puree, noodles, sauces, paella, meat, polenta	Meat- and milk-containing products, creams, chickens salads, canned mushrooms	Meats, meat products, gravy, cooked beans, stews, soups
Toxin stability	Heat	5 min at 56 °C	90 min at 121 °C	SEA 3 min at 80 °C, 1 min at 100 °C; SEB 87 min at 99 °C	5 min at 60 °C
	pH	4–8	2–11	Wide range, resistant to gastric pH	5–10
	Proteinases	Nonresistant	Resistant	Resistant	Increased activity

reported (93%), regardless of etiology; contamination by a food handler was only common in *S. aureus* outbreaks (55%). The incidents involving *S. aureus* are related to different establishments but are very frequent in catering services where food is premade in larger volumes so that cooling is not as fast as required. Moreover, the food is maintained at convenient temperatures for fast serving, and those are temperatures that can support growth and enterotoxin formation. Other studies confirm that the food handler is the principal source of food contamination. In a recent outbreak in Germany, an *S. aureus* isolate from the stool sample was matched to the food isolate and isolate coming from the food handler. Reporting of outbreaks is mandatory and the confirmation of *S. aureus* outbreak, based on the guideline of Centers for Disease Control and Prevention, consists of the isolation of organism of same phage type from stool or vomitus of 2 or more ill persons, or the detection of enterotoxin in epidemiologically implicated food, or the isolation of 10^5 organisms per gram from epidemiologically implicated food. There is an internationally agreed basic set of phages used for typing strains of *S. aureus* of human origin, which is updated regularly to reflect changes in the typability of human clinical isolates. There are problems of nontypability, since 15–20% of isolates may be untypable. Today, more robust, reliable, and convenient molecular typing methods exist, such as pulsed field gel electrophoresis, which is the method of choice in most of the EU member states and is also used worldwide. Also, CDC had published recently a unified pulsed-field gel electrophoresis (PFGE) protocol for Gram-positive bacteria. However, the typing of *S. aureus* is not the common practice in the world. In its report, the European Food Safety Agency states that 19 member states (MSs) and 3 non-MSs currently perform molecular typing for *S. aureus* isolates from animals, food, and feed. Six MSs and one non-MS reported that they neither perform or purchase molecular typing of *S. aureus* isolates.

Control and prevention

As mentioned earlier, humans and animals are usual carrier of *S. aureus*. Consequently, the contamination of foods often happens via the factory or kitchen staff by the hand contact or their respiratory system. Therefore, the good personal hygiene is essential as a preventive measure for *S. aureus*

Table 3 Foods implicated in outbreaks caused by *Staphylococcus aureus*, in the United States, 1998–2008 (for details, see Bennett et al., 2013)

	Staphylococcus aureus *outbreaks*		
Food type	*Confirmed*	*Suspected*	*All Outbreaks*
Outbreak food ethnicity	$n=150$	$n=242$	$n=1074$

contamination. Nevertheless, *S. aureus* is also able to nest itself on the surfaces of process equipment due to inadequate and insufficient cleaning and disinfection. CPSs, which serve as analytic indicator of the presence of toxin-producing *S. aureus*, not only are determined because of their pathogenic nature but also are often detected as an indication of the level of personal hygiene and good manufacturing practice (GMP) performance. Low numbers (100–1000 CFU g^{-1}) can be tolerated, depending on the inherent properties of the food and envisaged storage conditions and length of the shelf life.

It is generally understood and accepted that *S. aureus* as a food intoxicant presents a risk only when the growth to high numbers occurs ($>10^5$ CFU g^{-1}). Since *S. aureus* cannot grow at temperatures below 7 °C and that multiplication of *S. aureus* in raw products is inhibited or slowed down by competing accompanying microflora, these high numbers are normally not reached under the conditions of maintained cold chain. However, the mere presence (and not the growth) of *S. aureus* is associated with the number of cold stored foods and even with ice creams. Nevertheless, problems with *S. aureus* are most often an indication of temperature abuse or postcontamination. With respect to growth temperature, SEB production in ham has been recorded already at 10 °C, as well as lower amounts of SEA, SEB, SEC, and SED in cooked ground beef, ham, and bologna-type sausage.

A simplified scenario in *S. aureus* food poisoning encompasses foods in which production involves a number of manipulations through which the intrinsic factors (especially a_w – given the high salt tolerance of *S. aureus*) have been amended so that the competitive flora becomes inhibited and *S. aureus* is free to multiply at insufficient cooling and produces one or more of its enterotoxins (Figure 1). Similar scenario is when postpasteurization contamination occurs. If in the analyzed food *S. aureus* is found in numbers of 10^5 CFU g^{-1} and higher, then also the presence of SE should to be suspected. However, the SE production is largely strain- and food-dependent, and evidence of SE production at lower numbers and the lack of production at counts even higher than 10^5 CFU g^{-1} exists. Due to the heat stability of enterotoxins, it is possible that *S. aureus* is eliminated in the food, which was heated for the consumption, but that its toxin(s) is still present and active (Table 2). *S. aureus* cells are considerably more sensitive to heat than the SEs, with *D* values ranging from ~2 to 15 at 60 °C. The actual heat stability of each of SE is largely dependent on the environment in which heat treatment occurs.

Knowing that the main source of food contamination with *S. aureus* comes from food handlers, food contact materials, or contaminated raw materials, the main preventive measure is strict application of good hygienic practices and good manufacturing practices. The factors that contribute to staphylococcal food poisoning are inadequate refrigeration, inadequate cooking or heating processing, and poor personal hygiene of infected handlers that results in cross contamination.

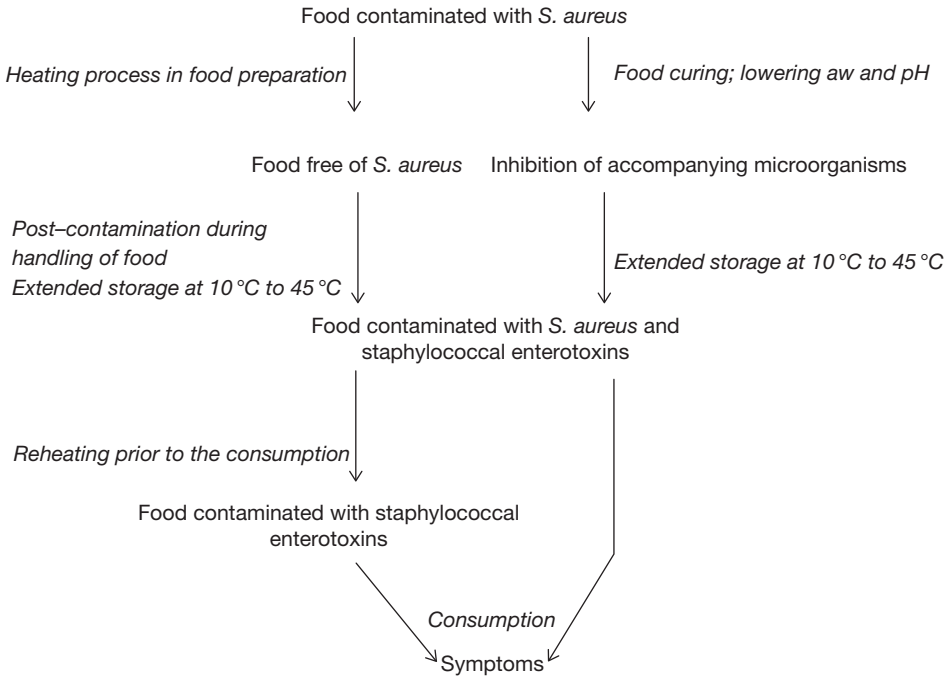

Figure 1 Simplified scholastic representation of usual scenarios leading to staphylococcal foodborne intoxication.

Keeping food below 5 °C and above 50 °C will not allow SE production, nor *S. aureus* multiplication.

Enterotoxins

SEs are the most notable virulence factors associated with *S. aureus*. SEs belong to a great family of staphylococcal and streptococcal pyrogenic exotoxins (PT), characterized with common phylogenetic relationships, structure, function, and sequence homology. SEs function not only as potent gastrointestinal toxins causing emesis but also as superantigens that stimulate nonspecific T-cell proliferation. Although these are two separate functions localized on separate domains of the proteins, certain evidence exists that these two activities can exist independent from each other.

To date, 21 SEs and enterotoxin-like (SEl) types have been described: enterotoxins A (SEA), B (SEB), C1 (SEC1), C2 (SEC2), C3 (SEC3), D (SED), E (SEE), G (SEG), H (SEH), I (SEI), J (SElJ), K (SElK), L (SElL), M (SElM), N (SElN), O (SElO), P (SElP), Q (SElQ), R (SER)[13], S (SES), T (SET) [14], U (SElU), and U2 and V, as reviewed in detail by Hennekinne et al. in 2010 in 'Toxins' (see 'Further Reading' for more information). The incidence of enterotoxin producers among human isolates is reported to be much higher than among nonhuman isolates.

Next to the SEs with demonstrated emetic activity (SEA to SEE, SEG to SEI, and SER to SET), there are also staphylococcal-like (SEl) proteins, which are not emetic in a primate model (SElL and SElQ) or have yet to be tested (SElJ, SElK, SElM to SElP, SElU, SElU2, and SElV). SEs and SEls have been traditionally subdivided into classical (SEA to SEE) and new (SEG to SElU2) types. Several studies attempted to characterize the emetic potential of SEl. In one of them, an emetic potential of SElK, SElL, SElM, SElN, SElO, SElP, and SElQ was assessed using a monkey-feeding assay. All the SEls that were tested induced emetic reactions in monkeys at a dose of 100 μg kg^{-1}. Although a number of affected monkeys were significantly smaller than a number that were affected after consuming SEA (six out of seven) or SEB (four out of four) at the same concentration and the latency periods of the classical SEs seems to be shorter than those of the SEls, these results indicate that SEl may nevertheless play certain role in staphylococcal food poisoning. However, the role of SEls in human food poisoning currently remains unclear, but is it well known that not all of the SEs have equal emetic potential (Table 4). The enterotoxin gene that is most frequently detected in clinical isolates of foodborne staphylococcal intoxications is *sea*. Of note, strains of human origin are highly prevalent in the strains isolated from SFP outbreaks, and *sea* is predominantly carried by human strains. This information does not necessarily correspond to incidence of specific SE genes in food isolates and cow mastitis isolates.

The currently known SEs form a group of serologically distinct, extracellular proteins that share important properties. Among these are the abilities to cause emesis and gastroenteritis in primates, exhibit superantigenicity through an unspecific activation of T lymphocytes followed by cytokine release and systemic shock, and resist heat treatments and digestion by pepsin and structural similarities. SEs are resistant to proteolytic enzymes, hence retaining their activity in the digestive tract after ingestion. Their known heat stability is not the same for all SEs and also depends on the food matrix and toxin concentration. So, for example, *SEA* is more *heat*-sensitive than *enterotoxin* SEB, and SEB is more sensitive than SEC. The biological activity of SEB was retained after heating for 16 h at 60 °C and pH 7.3. Heating of one preparation of SEC for 30 min at 60 °C resulted in no change in serological reactions. The heating of SEA at 80 °C for 3 min or at 100 °C for 1 min

Table 4 Overview of reported SE doses required for intoxication in different hosts

Organism	*Toxin*	*Minimal dose to induce toxic effect or (ED_{50} per kg body weight)/host*
S. aureus	SEA	(25 μg)/rhesus monkey
		(10 μg)/rhesus monkey
		(∼10 mg)/rhesus monkey
		(144 ± 50 ng)/humans
		0.60 ng ml^{-1} of chocolate milk
	SEB	(0.4 μg)/humans
		(0.9 μg)/rhesus monkey
	SEC1	(1.0 μg)/pigtail monkey
	SEG	∼80 μg/rhesus monkey
	SEI	>150 μg/rhesus monkey
	SET	0.05–1.0 ng ml^{-1} milk/humans
		0.1–1.0 μg/humans

resulted in the loss of serological reaction. When evaluating heat inactivation of SE, one should be aware that SE may lose serological activity in detection immunologic assay, but remain biologically active. Crude toxin preparations have been found to be more resistant than purified toxins.

Enterotoxin and enterotoxin-like proteins are globular, single polypeptides with molecular weights ranging from 22 to 29 kDa. They can be encoded in prophages, plasmids, or chromosomal pathogenicity islands. The *seb* gene is carried on the *S. aureus* pathogenicity island, SaPI3, 59 while enterotoxin C (SEC) exists in multiple variants, C1, C3, and Cbov, which are situated on SaPI4, SaPIn1/m1, and SaPIbov, respectively. The *sed* gene is situated on a pIB485 plasmid, likewise *sej*. The expression of *seb*, *sec*, and *sed* genes is induced during the transition from the exponential to the stationary phase, an expression pattern characteristic of proteins encoded by genes regulated by the Agr regulatory system. *Seb* and *sec* undergo a much stronger induction than the plasmid-encoded *sed*. The *sea* gene is carried by a polymorphic family of temperate bacteriophages, and the transcription of sea is linked to some extent to the life cycle of the SEA-encoding prophage. The polymorphic nature of the prophages has been found to affect the amount of SEA produced by the bacterial strain carrying the prophage. Sequence analysis of the *sea* gene and its neighboring genomic regions has further indicated that SEA-producing strains can be grouped into two major groups, SEA_1 and SEA_2. SEA is produced throughout the growth phases. The amount of SEA produced has been related to the group and to the expression level of *sea*. The *see* gene is situated on a (defective) prophage and its expression appears to be unaffected by bacterial growth. It seems that virulence expression of *se* genes is upregulated in iron-depleted environment and in the conditions of the host environment. In other words, *in vivo* expression seems to be higher than *in vitro* expression.

The regulation of production of SE is SE-dependent, as well as strain- and environment-dependent. Under the same conditions, different strains may produce different amounts of SE. Different SEs are synthesized by *S. aureus* in different growth phases. This reflects also in the amounts of different SEs produced by *S. aureus* growing under optimal conditions in laboratory media. For SEB and SEC, the amounts may exceed 100 μg ml^{-1}, compared with 1–10 μg ml^{-1} for SEA and SED. Some indications exist that low amounts of SEB are produced already in early exponential growth phase. Reports exist that show that SEB appears in cultures as early as 4–6 h. However, SEA and SED are produced in foods under a wider range of pH, Eh, and aw than are the other SEs, which explain why SEA and SED are principal toxins involved in staphylococcal food poisoning.

Based on large-scale outbreak data, the intoxication dose of SEs (SEA) can be as low as 94–184 ng, corresponding to about 0.3 ng SEA per ml of chocolate milk.

There are different ways to detect SE in foods, each with its own characteristics. Described assays include those based on animal testing; immunologic, molecular, and biological assays; biosensors; and lately also chromatography-based methods. There are several commercial kits/systems available for SE detection, which are in routine use. ELISA-based kits for enterotoxin detection are commercially available from various manufacturers like 3 M™ Tecra™ (Staph Enterotoxins Visual Immunoassay; screening of the presence of SEA–SEE using AOAC International official method 3 M™ Tecra™ SET VIA and/or specific identification of present SEA–SEE using 3 M™ Tecra™ SET ID VIA; both methods have limit of detection at about 1 ng ml^{-1} of sample extract according to the manufacturer), bioMérieux (VIDAS SET2, which is a reference method for the European screening method of the Committee Reference Laboratory for milk and milk products and is also recommended as the primary screening method for suspect food samples and culture isolates in FDA BAM Chapter 13A and an official method on a variety of foods by AOAC International), Diffchamb AB (Transia Plate SE official methods recommended by Ministere de l'Agriculture, France, Transia Tube SE), R-Biopharm (RIDASCREEN A, B, C, D, and E with sensitivity of below 0.031 ng ml^{-1} in buffer for SEA, SEB, SEC, and SEE and 0.062 for SED and performance equal or better than VIDAS SET2 in cheese), and Toxin Technology (SET-EIA). In the latest years, some very prominent research groups in the field are working on proteomics-based methods, mainly using different formats of LC–MS, to provide new sensitive, robust, and instrumental detection and quantification of SE. Since as little as 100–200 ng of the toxin can cause symptoms of staphylococcal intoxication, the methods are required to have very high sensitivity.

European Legislation

In its latest Commission Regulation (EC) No. 2073/2005 of 15 November 2005 on microbiological criteria for foodstuffs, the European Commission provided two kinds of microbiological criteria, the process hygiene criteria and food safety criteria. The rationale behind is that the safety of foodstuffs is mainly ensured by a preventive approach, such as implementation of good hygiene practice and application of procedures based on hazard analysis and critical control point (HACCP) principles. Process hygiene criteria that can be used in validation and verification of HACCP procedures and other hygiene control measures were set to define the acceptability of the processes. The food safety microbiological criteria set a limit above which a foodstuff should be considered unacceptably contaminated with the microorganisms for which the criteria are set. The food safety criteria were not set for *S. aureus*, but for SEs. This

was done only for cheeses, milk powder, and whey powder, with safety criteria defined as follows: $n=5$, $c=0$, and $m=$absence in 25 g. The criteria are valid for these products placed on market during their shelf life. As for process hygiene criteria, CPSs were defined for cheeses made from raw milk ($n=5$, $c=2$, $m=10^4$ cfu g^{-1}, and $M=10^5$ cfu g^{-1}), cheeses made from milk that has undergone a lower heat treatment than pasteurization and ripened cheeses made from milk or whey that has undergone pasteurization or a stronger heat treatment ($n=5$, $c=2$, $m=100$ cfu g^{-1}, and $M=1000$ cfu g^{-1}), unripened soft cheeses (fresh cheeses) made from milk or whey that has undergone pasteurization or a stronger heat treatment ($n=5$, $c=2$, $m=100$ cfu g^{-1}, and $M=1000$ cfu g^{-1}), milk powder and whey powder ($n=5$, $c=2$, $m=10$ cfu g^{-1}, and $M=100$ cfu g^{-1}), and shelled and shucked products of cooked crustaceans and molluscan shellfish ($n=5$, $c=2$, $m=100$ cfu g^{-1}, and $M=1000$ cfu g^{-1}).

Introduction

Staphylococci are gram-positive spherical bacteria belonging to the Firmicutes phylum. They are mostly facultative anaerobic and catalase-positive bacteria that display a high salt tolerance. To date, the *Staphylococcus* genus comprises 48 species and 21 subspecies. It is divided into two distinct groups: the coagulase-positive staphylococci (CPS), such as *Staphylococcus aureus* and six other species, and the coagulase-negative staphylococci (CNS). Staphylococci are widespread in nature. They are commonly found on human and animal skin and on mucous membranes and are generally considered as commensal microbiota. They can be associated with opportunistic infections. Some species are recognized as human and animal pathogens, in particular *S. aureus*, which can express various virulence factors including enterotoxins that are implicated in food poisoning. The CNS are a vast and heterogeneous group. Some species, such as *Staphylococcus epidermidis*, *Staphylococcus haemolyticus*, *Staphylococcus lugdunensis*, and *Staphylococcus saprophyticus*, produce virulence factors and may be implicated in clinical cases and nosocomial infections. Nevertheless, CNS are not associated with pathogenic risk after food consumption and are considered mostly as food-associated beneficial microbiota. They can be commonly found in foods of animal origin, especially in fermented foods such as cheese and dry fermented sausage where they can be present at high levels (more than 10^6 CFU g^{-1}). Moreover, some species are exploited in the food industry and currently used as meat or dairy starter cultures, as is the case for selected strains of *Staphylococcus carnosus* and *Staphylococcus xylosus*. They contribute to enhance color and flavor formation and to limit the rancidity of meat products. They can also be used as bioprotective cultures and thus contribute to the control of spoilage and pathogenic bacteria. The object of this article is firstly to discuss safety risks associated with the presence of staphylococci in food and secondly to analyze the benefits of staphylococcal ecosystems in foods and of specific species with technological interest.

Risks Associated with Staphylococci in Food

Among all the staphylococcal species, only *S. aureus* belonging to the CPS is considered as a foodborne pathogen. Although CNS isolated from food are generally recognized as safe bacteria, they can nevertheless be sometimes associated with safety hazards such as the synthesis of toxins or biogenic amines and/or the presence of transmissible genes coding antibiotic resistances (Table 1).

S. aureus Involvement in Food Risks

Strains of *S. aureus* that produce enterotoxins can cause staphylococcal food poisoning (SFP) that is one of the leading causes of foodborne illness worldwide. The characteristic symptoms of SPF are severe nausea, projectile vomiting, abdominal cramps, and exhaustion between 2 and 8 h after consumption of contaminated food by preformed enterotoxins. The main reservoirs of *S. aureus* are humans and animals. More than 30% of the humans are carriers of *S. aureus* in their anterior nares and on their hands. *S. aureus* is also commonly found in the nostrils and on the skin of livestock, where it can, for instance, lead to mastitis in dairy cows. It can also colonize food contact surfaces and become a persistent organism due to its capacity to form biofilm. *S. aureus* can contaminate a variety of food products during preparation and processing and has the ability to grow and to produce enterotoxins in a wide range of temperatures, pH, water activities, and sodium chloride concentrations. *S. aureus* can be destroyed by suitable heat treatments commonly used in food processing, but the enterotoxins are extremely resistant to heat and can remain active. Most SFP are caused by unhygienic practices and inadequate refrigeration of foods, allowing the growth of *S. aureus* and production of enterotoxins.

Staphylococcal enterotoxins (SEs) are emetic toxins. They belong to the pyrogenic toxin family because of their superantigenic activities, structural relatedness, and sequence similarities. To date, 11 antigenic types of SE have been reported: SEA, SEB, SEC, SED, SEE, SEG, SEH, SEI, SER, SES, and SET. The detection of genes encoding enterotoxin homologues has further expanded the list of the SE family. These related enterotoxins are designated as enterotoxin-like (SEl) to indicate that their emetic activity has not yet been demonstrated. So far, the majority of SFP involved the five enterotoxins SEA to SEE. Among them, SEA is the most commonly implicated enterotoxin. The role of other SE and SEl could be underestimated because of the difficulty of detecting them in foods. Moreover, the genes encoding SE and SEl are located on mobile genetic elements that can spread among *S. aureus* strains or other staphylococcal species and could contribute to the evolution of SFP.

In addition to the concerns caused by the production of enterotoxins, *S. aureus* can exhibit resistance to antibiotics often encoded on mobile genetic elements. The emergence of antibiotic-resistant *S. aureus* strains constitutes an additional risk due to the potential genetic transfer of these mobile elements including plasmids, transposons, pathogenicity islands, and the staphylococcal cassette chromosomes to bacteria present in foods or in the digestive tract.

CNS Involvement in Food Risks

No clinical cases have been reported to be associated with the consumption of foods contaminated by CNS. Nevertheless, contamination by *S. epidermidis* could be of importance for public health owing to its incidence in nosocomial infections. Moreover, some strains of CNS isolated from food and

S. succinus subsp. *casei*			
S. succinus subsp. *succinus*			
S. vitulinus[b]	–	*S. sciuri*	
S. warneri	–	*S. warneri*	+/– (AR, BA)
S. xylosus[b]	–	*S. saprophyticus*	+/– (AR, BA, SE)

(+), established food risks; (+/–), potential food risks.

AR, potentially transferable antibiotic resistance gene; BA, biogenic amine production; SE, staphylococcal enterotoxin.

[a]Note that the food risks are strain-dependent.

[b]Strains of these species are commonly used as starter cultures or have been tested as potential starter cultures.

belonging in particular to *Staphylococcus capitis*, *S. carnosus*, *Staphylococcus cohnii*, *S. epidermidis*, *Staphylococcus equorum*, *Staphylococcus lentus*, *Staphylococcus gallinarum*, *Staphylococcus piscifermentans*, *Staphylococcus simulans*, and *S. xylosus* have been described as being able to produce enterotoxins, although no case of SFP involving these species has ever been reported. However, recent studies have revealed that the genes coding SE are not present in the majority of CNS strains isolated from food. The low sensitivity and specificity of the methods used for the detection of enterotoxins could explain the discordant results between the ability to produce these toxins and the lack of the corresponding genes. Despite such data, the potential risk due to enterotoxin production by CNS should not be ignored and should be monitored as the genes encoding enterotoxins in *S. aureus* are carried by mobile transferable elements that could be acquired by the CNS.

Like for *S. aureus*, another risk is the increase of antibiotic-resistant strains within CNS. In fermented foods, CNS can be present at high levels and may act as reservoirs of transferable antibiotic resistance genes. The prevalence of CNS resistant to antibiotics is high but varies widely between the different species. The most frequent resistances identified in foodborne CNS are those to ampicillin, erythromycin, penicillin, lincomycin, and tetracycline, and some strains have been described as resistant to multiple antibiotics. CNS can survive the passage through the gastrointestinal tract and exchange mobile genetic elements with gut bacteria. Therefore, it is crucial that the strains of CNS used as starter cultures do not carry transferable antibiotic resistance genes. With respect to the two species currently used as meat starter cultures, most strains of *S. xylosus* exhibit potentially transferable genes encoding resistance to tetracycline and/or erythromycin, whereas these genes are generally absent in the strains of *S. carnosus*.

Among the safety hazards associated with foodborne CNS, the potential production of biogenic amines should also be considered. Biogenic amines are natural compounds of many fermented food products. They are produced mainly by decarboxylation of precursor amino acids by enzymes of bacterial origin. It has been shown that some CNS can be associated with weak productions of biogenic amines such as tyramine, phenylethylamine, putrescine, and cadaverine. The production of biogenic amines is strain-dependent and was detected in some strains of *S. carnosus*, *S. epidermidis*, *S. xylosus*, and *Staphylococcus warneri* isolated from meat products.

Given these data, the selection of strains of *S. carnosus* and *S. xylosus* used as starter cultures should include safety criteria, such as the lack of production of enterotoxins and biogenic amines and of transferable antibiotic resistance genes.

Benefits of CNS in Food

CNS are often present in fermented foods as a part of the indigenous food microbiota. They originate from raw materials such as meat and milk or from the food environment, themselves contaminated by CNS as many staphylococcal species colonize skin and mucous membranes of livestock. Moreover, due to their salt-tolerant characteristics, they are frequently isolated from cured or salted foods. Among all CNS species, only few species are used as starter cultures. *S. xylosus* and *S. carnosus* have a GRAS (generally recognized as safe) status and are currently used as commercial starter cultures in meat fermentation. They have also some applications in dairy or fish fermentation. *S. equorum* not only has been recently introduced in the market as surface starter culture for cheese but also has been used in meat or fish fermentation processes. Some other species such as *Staphylococcus succinus* and *Staphylococcus vitulinus* have been tested as potential starter cultures in dairy or meat fermentation. However, a high species and infraspecies staphylococcal diversity can be found in particular in traditional fermented products. CNS are recognized to play an important role in the flavor of end products, particularly in meat and dairy products.

Biodiversity of CNS in Foods

The development of appropriate molecular methods has allowed reliable identification of the different species of staphylococci isolated from various foods and the characterization of strains within a species.

Meat products

CNS are one of the two main groups of bacteria involved in fermentation and ripening of cured meat products. CNS are recognized to play an important role in flavor and color of meat products such as low-acid fermented sausages. In traditional fermented sausages produced without the addition of starter cultures, many CNS species can cohabit. Species diversity obviously depends on the types of products and the manufacturing process. *S. equorum*, *S. saprophyticus*, and *S. xylosus* are commonly isolated from traditional fermented sausages and are considered as the three most prevalent species. A codominance of these three species has been reported in different types of Italian fermented sausages. *S. xylosus* has been reported as the predominant species in Spanish, German, and certain Italian fermented sausages, while *S. saprophyticus* has been described as the predominant one in some Greek, Argentinean, and Belgian fermented sausages. *S. equorum* was the dominant species in traditional French sausages and in some Spanish chorizo. However, a high diversity of species can be found in some fermented sausages with more than ten species identified in one product. As a nonexhaustive summary, the species *Staphylococcus arlettae*, *S. carnosus*, *S. cohnii*, *S. epidermidis*, *S. haemolyticus*, *Staphylococcus hominis*, *S. lentus*, *Staphylococcus pasteuri*, *Staphylococcus pulvereri*, *Staphylococcus sciuri*, *S. simulans*, *S. succinus*, *S. vitulinus*, and *S. warneri* have been reported in low-acid traditional fermented sausages.

In addition to the cohabitation of various species, infraspecies diversity can be revealed. The characterization by pulsed field gel electrophoresis (PFGE) analysis of isolates of the main species isolated from meat products, *S. equorum*, *S. saprophyticus*, and *S. xylosus*, has shown a genetic diversity within each species. In particular, high infraspecific diversity has been reported for *S. equorum* showing that different strains can survive throughout the manufacturing process and in the final products.

Dairy products

Many species of CNS can be found on surfaces of various types of cheeses such as hard, semihard, soft, and smear cheeses. *S. equorum*, *S. saprophyticus*, *S. simulans*, *S. succinus*, and *S. xylosus* are commonly isolated from cow and goat cheeses of various origins. In addition, many other species such as *S. arlettae*, *Staphylococcus auricularis*, *S. capitis*, *S. carnosus*, *Staphylococcus chromogenes*, *S. epidermidis*, *Staphylococcus fleurettii*, *S. gallinarum*, S. *haemolyticus*, *S. hominis*, *S. lentus*, *Staphylococcus rostri*, *S. sciuri*, *S. vitulinus*, and *S. warneri* can be found in milk and various French and Italian cheeses. This wide diversity of species identified in these products can be attributed to the large variety of cheeses, all manufactured with different processes.

Characterization by PFGE analysis of isolates of the main species isolated from French cheeses, that is, *S. equorum*, *S. xylosus*, and *S. saprophyticus*, has also revealed infraspecies diversity. The comparison of strains isolated from cheeses and dry fermented sausages has revealed that there was no clustering of the strains by type of food sample or geographic origin.

Fish products

CNS of the fish products are less documented as staphylococci do not belong to the usual fish microbiota. Some studies have reported the identification of *S. epidermidis*, *S. haemolyticus*, *S. hominis*, *S. saprophyticus*, *S. simulans*, and *S. warneri* in salted cod fish. Moreover, the species *S. cohnii*, *S. epidermidis*, *S. lentus*, *Staphylococcus nepalensis*, *S. piscifermentans*, *S. saprophyticus*, *S. sciuri*, and *S. xylosus* have been found in fermented fish products. Staphylococci are currently isolated from fish sauce, a fermented fish product. In the process of fish paste fermentation, staphylococci become dominant among halophilic and halotolerant bacteria.

Functional Properties of CNS

CNS have a relevant role in the manufacture of fermented products of animal origin. The functional properties of CNS are particularly well characterized for fermented and cured meat products, where they contribute to the development and stability of the color through their nitrate reductase activity and to the development of flavor (Figure 1). Hence, the role of CNS is fundamental in the final sensorial characteristics of fermented meat products. As opposed to the more unpredictable traditional spontaneous fermentation processes, staphylococcal starter cultures are used in industrial meat fermentations to ensure repeatable and uniform sensory qualities and safety of the end products. They are inoculated at a rate of 10^6 viable germs/g of mixture. *S. carnosus* and *S. xylosus* are the two species commonly used as starter cultures but other species, such *S. equorum* or *S. succinus*, may also be excellent candidates.

Nitrate reduction

Nitrite and/or nitrate is added in meat curing for the development of the characteristic color and unique flavor of cured meat products, for the control of lipids oxidation, and for the inhibition of spoilage and pathogenic bacteria. Nitrite is a reactive compound that is chemically converted in nitric oxide (NO) in meat products. NO reacts with the iron atom of the heme group of myoglobin and metmyoglobin to form nitrosylmyoglobin, a rather stable bright red pigment responsible for the characteristic color (Figure 1). Nitrate is only effective if it is first reduced to nitrite. CNS naturally present in meat or originating from the starter culture play a fundamental role in this reduction. The nitrate reductase activity is widespread among CNS and has been reported in species such as *S. carnosus*, *S. equorum*, *S. lentus*, *S. pulvereri*, *S. saprophyticus*, *S. simulans*, and *S. xylosus*. The genetic determinants of nitrate reductase have been well characterized in *S. carnosus* and are conserved in other staphylococcal species such as *S. xylosus*.

Catalase and antioxidant activities

The formation of hydrogen peroxide due to the growth of lactic acid bacteria (LAB) in meat products can lead to discoloration of nitrosylmyoglobin and lipid oxidation, which can result in the development of rancid off-flavors. Peroxidation corresponds to the chemical reaction between fatty acids and the reactive forms of oxygen, such as superoxide anion ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH^{\bullet}$). *S. xylosus* and *S. carnosus* are well equipped with genes encoding enzymes such as several catalases, one superoxide dismutase, and diverse peroxidases, contributing in synergy to limit the formation of oxygen reactive species (Figure 1). The catalase and superoxide dismutase activities have been notably studied in *S. xylosus*.

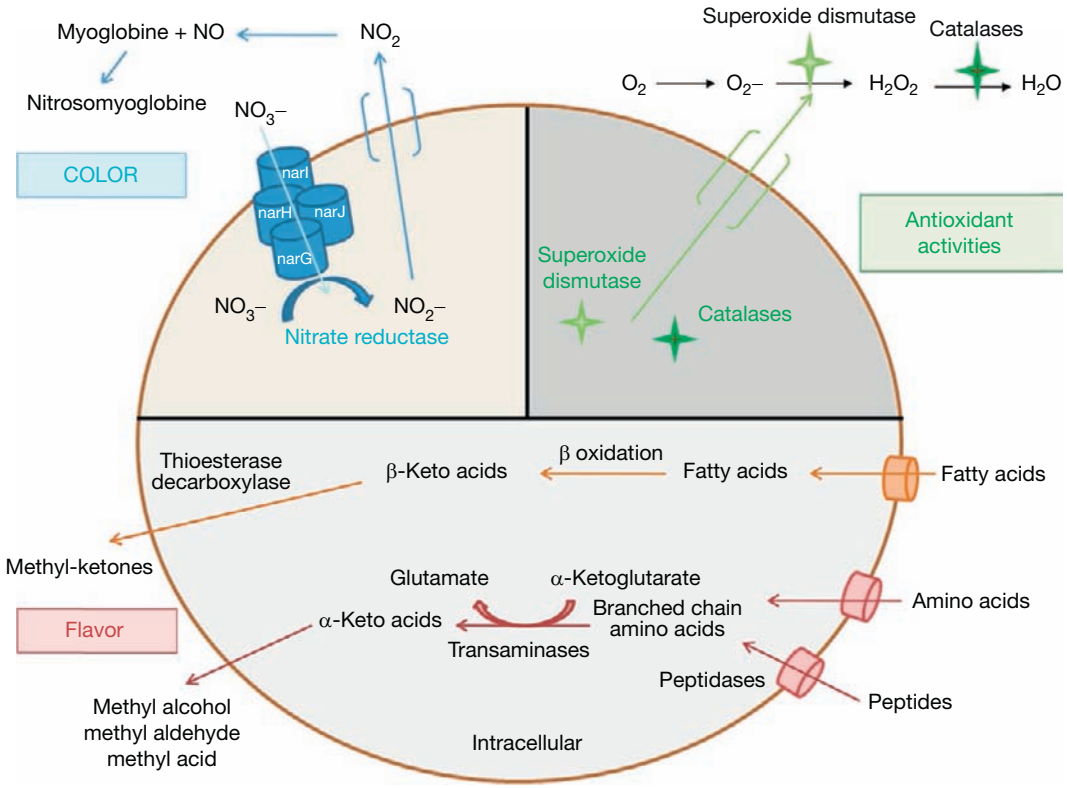

Figure 1 Main functional properties of coagulase-negative staphylococci (CNS) in meat product.

Flavor development

CNS contribute to flavor development through their amino and fatty acid catabolism, leading to the production of volatile compounds such as amino acid catabolites, pyruvate metabolites, and methyl ketones (Figure 1). Catabolism of amino acids is one of the key determinants of flavor development not only in fermented meat products but also in cheeses. The conversion of branched chain amino acids (leucine, isoleucine, and valine) or phenylalanine results in aldehydes, alcohols, and acids with aromatic qualities. The first step of the involved amino acid metabolisms is a transaminase reaction in which the amino group is transferred to an α-ketoacid. *S. carnosus* and *S. xylosus* have, for instance, been associated to the production of volatile compounds such as 3-methyl-1-butanol, 3-methylbutanal, and 3-methylbutanoic acid from leucine. These species thus contribute to the sensorial characteristics of low-acid fermented sausages typical of southern European countries. Moreover, the production of volatile compounds differs per type of CNS, for instance, depending on the use of strains of *S. carnosus* or *S. xylosus* as starter cultures. Fatty acid degradation also plays a role in flavor development. The incomplete β-oxidation of fatty acids leads to the production of methyl ketones. The β-oxidation process usually converts fatty acids into acetic acid by the successive removal of acetyl-CoA groups. However, intermediate CoA esters can be successively converted into β-ketoacids via thioesterase activity and then into methyl ketones via a decarboxylase reaction. In particular, it has been shown that *S. carnosus* has thioesterase and decarboxylase activities and is associated with the production of methyl ketones in fermented sausages.

Competitive growth

Most CNS are good competitors with endogenous bacteria of meat and dairy products due to their ability to grow anaerobically at low water activity, in high concentration of NaCl, and at low temperature. Strains of *S. xylosus* and *S. carnosus* that are used as starter or bioprotective cultures have been selected for their competiveness allowing them to dominate the indigenous microbiota present in the meat during the fermentation process and to survive for long periods in the final products. The use of staphylococcal starter or bioprotective cultures thus contributes to food safety and shelf life of cured meat products because they can prevent the growth of pathogenic and/or spoilage bacteria. However, CNS are poorly competitive in the presence of fast acidifying strains of LAB even if *S. xylosus* and *S. carnosus* starter cultures are also selected for their pH tolerance. Within these two species, the strains of *S. carnosus* are always more resistant to low pH and can survive rather well in these unfavorable conditions. Strains of *S. carnosus* and *S. xylosus* in combination with strains of LAB are currently commercialized as bioprotective cultures for application in meat products to control growth of spoilage and pathogenic bacteria such as indigenous LAB and *Listeria monocytogenes*.

Control of biogenic amines

Strains of *S. xylosus* and *S. carnosus* used as meat starter cultures must be selected based on their inability to produce biogenic amines. When applied, they can help to prevent the formation of biogenic amines by limiting the growth of potential biogenic amine producer bacteria. For instance, a *S. xylosus* starter culture was able to inhibit the formation of histamine and to a lesser extent of tyramine in a salted and fermented anchovy and the use of a strain of *S. carnosus* reduced the accumulation of histamine during fish sauce fermentation. Moreover, it has been shown that some strains of *S. xylosus* and *S. carnosus* can even reduce the level of tyramine, cadaverine, and/or putrescine in fermented sausages. The ability to reduce cadaverine in fermented sausages has also been shown for *S. equorum* strains.

Potential effect in gastrointestinal tract

CNS can be present at levels higher than 10^6 CFU g^{-1} in fermented foods such as fermented sausages or cheeses. These bacteria have the ability to resist to the food processes and to survive in the final products under different environmental conditions. The food matrix can support the survival of bacteria through the gastrointestinal tract. The potential impact of CNS on human health should be considered as some of them could survive gastric conditions and remain alive in the intestinal tract.

Conclusion

Staphylococci are widely spread and are present in various environments and in fermented foods. Among the 48 species belonging to the *Staphylococcus* genus, some species are associated with diseases in humans or animals and others are part of food microbiota and have technological interest, some strains even being used as starter cultures. The yin and yang of staphylococci underline the importance of the accurate identification and characterization of these bacteria at the species and strain levels.

Starch

P Clifton and J Keogh, University of South Australia, Adelaide, SA, Australia

© 2016 Elsevier Ltd. All rights reserved.

Starch Polymers

Starch consists of a mix of amylose and amylopectin. Starch is about 70% amylopectin by weight, though the amount varies depending on the source (higher in medium-grain rice to 100% in glutinous rice, waxy potato starch, and waxy corn and lower in long-grain rice, amylomaize, and several varieties of potato such as russet potato).

Amylopectin

Amylopectin is highly branched, being formed of 2000 to 2 million glucose units. Its inner chains are formed by 20–24 glucose subunits. Glucose (D-glucopyranose) units are linked in a linear way with α-(1→4) glycosidic bonds. Carbon 1 is the aldehyde containing carbon linked to the number 4 carbon in the next glucose. Branching takes place with α-(1→6) bonds occurring every 24–30 glucose units, resulting in a soluble molecule that can be quickly degraded.

Amylose

Amylose is made up of α-(1→4) joined glucose molecules. The number of repeated glucose units is usually in the range of 300–5000 but can be many more. Amylose contains very few α-(1→6) bonds. It reduces the degree of crystal structure of amylopectin and reduces the access of water (and enzyme). There are many more smaller amylose molecules in starch. Amylose can form either a single L-handed helix (and the chains can align) or a double L-handed helix that has extensive hydrogen bonding, which excludes water and is resistant to amylase.

Amylase

In humans, both the salivary and pancreatic amylases are α-amylases. The α-amylases (EC 3.2.1.1) (alternative names: 1,4-α-D-glucan glucanohydrolase and glycogenase) are completely unable to function in the absence of calcium. By acting at random locations along the starch chain, α-amylase breaks down long-chain carbohydrates, ultimately yielding maltotriose (three glucoses) and maltose (two glucoses) from amylose or maltose, glucose, and dextrins (mixtures of polymers of D-glucose units linked by α-(1→4) or α-(1→6) bonds) from amylopectin.

Significance of the Amylose/Amylopectin Ratio in Human Health

The proportion of amylose in the starch is important for humans as it makes the starch less soluble and less easily penetrated by water and amylase. In addition with fewer branch points, there are fewer places for amylase to bind and hydrolyze so digestion is slower. Starch that cannot be digested at all is called resistant starch and may have implications for colonic health and this will be discussed separately. Starch that has been cooked and cooled (particularly potato starch) can become resistant to amylase by virtue of its crystalline structure. The rate at which starch is digested and glucose is absorbed has long-term health implications as rapid absorption and high glucose peaks appear to be associated with chronic diseases. A measure of how rapidly glucose is absorbed is called the glycemic index (GI) that calculates the area of the glucose curve above baseline over 2 h (Figure 1) compared with a standard material (usually glucose but can be white bread). A 50 g bioavailable dose is used (or 25 g if the food has a low carbohydrate amount and the standard is given a value of 100). The method was first developed by David Jenkins in Canada.

The amylose/amylopectin ratio is not the only determinant of GI. How finely milled the food is determines the degree of access of water and amylase to the starch granule so refined starches such as in white bread have easily accessible granules and a high GI, while coarsely ground breads such as pumpernickel have a low GI. In addition, the presence of fat and protein in the food will slow gastric emptying and lower the GI even when white refined starch is used. Sucrose by comprising 50% glucose intrinsically has a low GI so foods with a high amount of sugar combined with refined starch may not have high GI. Thus, in terms of using GI for health promotion, the amount of sugar and fat in the food needs to be limited to make the low-GI symbol reflect the health attributes of the food. Glycemic load is defined as the amount of carbohydrate consumed multiplied by the GI of each of the component foods and this has also been related to disease outcomes.

GI and Health

Heart attack and stroke

Several meta-analyses have looked at the association between GI/GL and heart disease. The most recent one from David Jenkins' group examined ten prospective cohorts. Pooled analyses showed a nonsignificant increase in coronary heart disease (CHD) risk for the highest glycemic load (GI) quantile compared with the lowest, with RR = 1.11 (95% confidence interval (CI) 0.99–1.24) and a significant association for GL, RR = 1.27 (95% CI 1.09–1.49), both with evidence of some heterogeneity. Female cohorts showed significance for GI (RR = 1.26, 95% CI 1.12–1.41) and for GL (RR = 1.55, 95% CI 1.18–2.03), whereas there was no effect in men at all. A more extensive meta-analysis using 15 prospective studies by Fan et al. produced a similar result with a slightly higher RR in women (RR = 1.49, 95% CI 1.27–1.73). Among overweight and obese subjects, dietary glycemic load level was associated with increased risk of CHD (RR = 1.49, 95% CI 1.27–1.76; P for interaction = 0.003). Higher dietary GL, but not GI, was positively associated with stroke (RR = 1.19, 95% CI

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00661-9

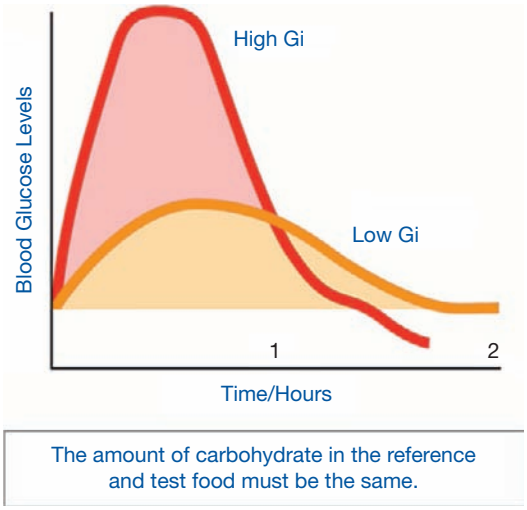

Figure 1 GI index from GI Foundation (http://www.gisymbol.com/).

1.00–1.43). There was a linear dose-response relationship between dietary GL and increased risk of CHD, with pooled RR of 1.05 (95% CI 1.02–1.08) per 50-unit increment in GL level. An earlier meta-analysis of 37 prospective studies showed an overall weak association between GI and CHD (GI RR = 1.25, 95% CI: 1.00, 1.56), but gender was not examined.

Type 2 diabetes

An updated meta-analysis from the Harvard group of their three pooled cohorts showed those in the highest quintile of energy-adjusted GI had a 33% higher risk (95% CI: 26%, 41%) of type 2 diabetes (T2D) than those in the lowest quintile. Participants in the highest quintile of energy-adjusted GL had a 10% higher risk (95% CI: 2%, 18%) of T2D. Participants who consumed a combination diet that was high in GI or GL and low in cereal fiber had an ~50% higher risk of T2D. In the updated meta-analysis including other cohort studies, the summary RRs (95% CIs) comparing the highest with the lowest categories of GI and GL were 1.19 (1.14, 1.24) and 1.13 (1.08, 1.17), respectively. Another meta-analysis of 21 cohorts showed the summary RR was 1.08 per 5 GI units (95% CI 1.02–1.15; $P = 0.01$) and 1.03 per 20 GL units (95% CI 1.00–1.05; $P = 0.02$). In an earlier meta-analysis, the GL was positively associated with RR of T2D of 1.45 (95% CI: 1.31, 1.61) for a 100 g increment in GL ($P < 0.001$; $n = 24$ studies) that is much larger than the estimates in later studies.

Resistant Starch and Health

Although resistant starch contributes to fecal bulking, the evidence for its direct association with disease prevention is lacking; however, total starch intakes are inversely related to the incidence of colorectal cancer, and these cross-country studies are heavily confounded by other lifestyle attributes. Resistant starch increases colonic butyrate that is believed to influence colonic tumor growth by inhibiting histone deacetylase. A randomized trial in young people with familial adenomatous polyps showed no effect of 30 g day^{-1} of resistant starch in polyp growth over 1–12 years.

Whole Grains and Health

There is a very large epidemiological literature relating whole grains (all the components of the grain in the final product regardless of milled particle size) to cardiovascular disease (CVD) and T2D. The most recent meta-analysis showed from seven prospective cohorts that 2.5 servings of whole grain versus 0.21 servings of whole grain were associated with a 21% reduction in CVD events. Intake of refined grain was not significantly associated with CVD events. A whole grain intake of three servings per day was associated with a 32% reduction in T2D in ten cohort studies.

Major Starch Crops

In 2010, world production of cereals was 844 million tons for maize, much for animal production; 672 million tons for rice; and 651 million tons for wheat. Wheat is the leading source of vegetable protein in human food, having a higher protein content than other major cereals, maize (corn) or rice. In terms of total production tonnages used for food, it is currently second to rice as the main human food crop.

In this article, we will not discuss the use of starch for alcohol production or for industrial conversion to glucose and fructose for human consumption nor for use as an animal feed.

We will discuss the various food sources of starch in terms of nutritional value, particularly amount and quality of protein and micronutrients. Most starch crops contain polyphenolic compounds as protection against insects and diseases, but I will not discuss the health implications of the phenolics other than to say that flavonoid intake has been related to protection from CVD. These will be well covered elsewhere in this book. All data on nutritional content are taken from the USDA and crop size data are taken from the Food and Agriculture Organization (FAO).

Rice

Rice is consumed by more than 7 billion people worldwide with an Asian consumption of 103 kg per head with a global consumption of 65 kg per head. Virtually all of this rice is refined polished white rice.

One cup of cooked white rice (210 g) contains 242 cal, 4.4 g of protein, 53.2 g of carbohydrate and 0.4 g of fat, and 0.6 g of fiber, while one cup of brown rice contains 218 cal, 4.5 g of protein, 45.8 g of carbohydrate and 1.6 g of fat, and 3.5 g of fiber. The bran and germ contain much of the fiber in brown rice.

Health Effects of White Rice

When consumed at subsistence levels, white rice is not likely to be associated with adverse outcomes other than nutritional deficiencies. However, as populations become overweight and obese, it is possible that the highly available starch in white rice might contribute to chronic diseases. In an epidemiological study from Shanghai in 117 000 men and women in

whom 70% of total carbohydrates came from white rice and 17% from refined wheat products, the risk of heart disease was nearly three times higher in the highest quartile of intake of carbohydrate after full adjustment ($P < 0.001$). Carbohydrate intake accounted 68% of energy intake. Rice also accounted for the risk of T2D in middle-aged Chinese women by 80% when comparing top to bottom quintiles. Both GI (20% increase) and glycemic load (34% increase) were important. A meta-analysis examined the relationship between rice intake and T2D in seven prospective cohorts. The risk was 55% higher in the highest category of intake in Asian populations but was only 12% higher and not significant in Western populations. The average intake was three to four servings per day in Asian populations and one to two servings per week in Western population. A study in Singapore (the Singapore Chinese Health Study) showed no relationship between total carbohydrate intake and ischemic heart disease mortality in 53 469 participants. However, total starch was weakly related in both men and women with a 3–8% increase in the highest quantile, while fiber intake was protective with a 6–29% reduction in risk with the effect being much stronger in women. Replacement of one serving of rice per day with vegetables, fruit, and whole wheat bread was associated with a 24%, 12%, and 19% lower risk of death, respectively. In contrast, in Japan, rice intake was not associated with heart disease and stroke incidence or total CVD deaths in a cohort of 91 000 men and women aged 40–69 years. In a different Japanese cohort, rice intake was inversely correlated with cardiovascular deaths in men (17–30% reduction in the highest intake) but not in women. It is not clear why there are differences between Chinese and Japanese, but the Chinese body weight increases have been greater than those of the Japanese.

Cancer

Rice takes up inorganic arsenic from soil and water and cooking water and arsenic is a known carcinogen, so in certain high arsenic areas (such as West Bengal and Bangladesh), rice intake may be associated with cancer. It is estimated in China that inorganic arsenic adds 100 cases per 100 000 when the median population cancer incidence is 177 per 100 000.

Eating brown rice once a week cuts the risk of colorectal cancer by 40% in the Adventist Health Study 2. A Japanese study (the Japan Public Health Center-based Prospective Study) found no association of rice or noodles or bread with colorectal cancer risk.

Prostate cancer in Jamaican men is related to a high-GI diet (rice, pasta, sugar sweetened beverages, and sweet baked foods) with a two- to threefold increase comparing tertiles of intake. Similar observations were made in Swedish men with the high-risk foods being low fiber biscuits, cakes, rice, and pasta. Renal cell carcinoma in Italians is associated with high-GI foods bread (94% increase) and pasta and rice (29% increase) comparing quintiles although inverse associations were shown for esophageal cancer (30% reduction) for pasta and rice.

Wheat

Raw wheat can be ground into white flour or, using hard durum wheat only, can be ground into a coarse yellow semolina that is used to make pasta, breakfast cereals, puddings, and couscous. Wheat can be germinated, which produces glucose, maltose (disaccharide) and maltotriose, and maltodextrins (short chains with side chains from amylopectin) from amylase secreted from the aleurone layer, and dried creating malt that is used for drinks, biscuits, and breads; crushed or cut into cracked wheat; and parboiled (or steamed), dried, crushed, and debranned into bulgur (groats). Wheat is a major ingredient in major Western foods as bread, biscuits, pies, cakes, cookies, and breakfast cereals. If the bran (43% fiber) and germ (14% fiber) are retained with the flour from the endosperm, then whole wheat flour is produced.

One hundred grams of whole grain hard red winter wheat contains about 12.6 g of protein, while the same weight of hard red spring wheat contains about 15.4 g of protein.

Much of the carbohydrate fraction of wheat is starch but the protein (gluten) is also important economically. In wheat, phenolic compounds are mainly found in the form of insoluble-bound ferulic acid.

Most of the associations in Western countries of high GI and load and chronic disease are due to refined wheat flour that has only 20% of the fiber level of whole grain wheat. Bread made with 100% whole wheat flour has a GI of about 50, while bread made with white wheat flour has a GI of about 70. The vitamin levels are much the same in both flour types as white flour is fortified. The particle size of whole grain wheat is up to twice that of white refined flour, and this fact plus the fiber that slows gastric emptying accounts for the difference in GI.

Maize (*Zea mays*)

Maize and cornmeal (ground dried maize) constitute a staple food in many regions of the world. Cornstarch (maize flour) is a major ingredient in home cooking and in many industrialized food products.

Virtually, every dish in Mexican cuisine uses maize. Maize is Africa's most important staple food crop. Maize meal is made into a thick porridge in many cultures: for example, from the polenta of Italy to the mealie pap in South Africa. Maize meal is also used as a replacement for wheat flour, to make cornbread and other baked products. In the West, popcorn and cornflakes are the major use of maize. Sweet corn, a genetic variety that is high in sugars and low in starch, is usually consumed in the unripe state. The cooked, unripe kernels may also be shaved off the cob and served as a vegetable in side dishes.

Normal maize starch can be waxy (100% amylopectin) to containing 20% amylase. Special high amylase varieties are available with 50–70% amylase that are usually, but not necessarily, more resistant to digestion, have lower glycemic profile, and offer fecal bulking.

Potato

Potato is a starchy, tuberous crop from the perennial nightshade *Solanum tuberosum* L. It is the world's fourth-largest food crop, following maize, wheat, and rice.

The average annual consumption is about 33 kg of potato. It is an important crop in Europe but increasingly in China and India.

The United Nations FAO reports that the world production of potatoes in 2010 was about 324 million tons.

Potatoes and Health

They contain about 26 g of starch for a medium potato. They are a valuable source of nutrients such as vitamin C, potassium, and fiber. They are relatively low in energy when eaten boiled and unpeeled (276 kJ/100) and low in sodium. However, energy value increases dramatically when potatoes are fried to 800 kJ/100 for homemade chips and 2160 kJ/100 for potato crisps. Salt is often added to potato crisps increasing the sodium content to 620 mg/100 g. Increasing globalization of the food supply and the introduction of fast-food chains mean that potatoes especially eaten as chips are included in the diet of traditionally rice-eating societies such as China and India.

Data from the Framingham Heart Study Offspring Cohort show that over 17 years of follow-up, the percentage of energy from total carbohydrates decreased with the number of weekly servings of carbohydrate foods including potato chips decreasing during that time. Data from the US National Health and Nutrition Examination Survey (NHANES) 2009–10 show that mean total energy intake for the population was 2080 kcal day^{-1}, with white potatoes and French-fried potatoes providing ~4% and ~2% of total energy, respectively. In consumers of white potatoes, they provided ~23% of dietary fiber and ~20% of potassium but only ~11% of total energy in the diet.

The GI of potatoes varies according to type and method of preparation. Boiled white potatoes have a GI of 82 while potato chips have a GI of 51. A new potato cultivar, Carisma with a GI of 53, has recently become available. In a study of the NHANES data, total carbohydrate intakes were not associated with HbA1c, plasma glucose, or serum insulin concentrations. However, diets higher in carbohydrate from potato have been associated with higher levels of HbA1c in people with type 1 diabetes.

Potatoes are included as a separate food group in some but not all epidemiological studies of diet and disease. In a study by Mozaffarian, weight change over 4 years was strongly associated with the intake of potato chips (0.8 kg) and potatoes (0.6 kg). Central obesity was associated with a higher frequency of eating boiled potatoes in a study by Mostad. The authors suggest that a higher frequency of potato consumption that occurred in the presence of lower frequency of vegetable intake might indicate a higher energy density of the main (dinner) meal. In contrast in a study in Chinese participants, a dietary pattern rich in soybeans, grains, potatoes, and flour was associated with reduced triglycerides, fasting glucose, waist circumference, and waist–hip ratio. An increased risk of prostate cancer has been reported in a small study of patients with prostate cancer whose diet was defined as a 'Western diet' and was high in sweets and desserts, organ meat, snacks, tea and coffee, French fries, salt, carbonated drinks, and red or processed meat.

In a prospective cohort study in the Netherlands, a Nutrient-Rich Food (NRF) Index was used to examine associations between the index an incidence of CVD events and all-cause mortality. Food groups that contributed most to the NRF index score were vegetables, milk and milk products, fruit, bread, and potatoes. A high NRF score was inversely associated with all-cause mortality but the score was not associated with incidence of CVD.

Potatoes contain resistant starch that varies depending on the variety and cooking method. Normal cooked potato starch contains about 7% resistant starch that doubles on cooling.

In the United Kingdom, potatoes are not considered by the NHS as counting toward the five portions of fruit and vegetables diet. Chlorogenic acid constitutes up to 90% of the potato tuber natural phenols but its health effects are not clear.

Cassava

Cassava (*Manihot esculenta*), also called manioc or tapioca root, is cultivated as an annual crop in tropical and subtropical regions for its edible starchy, tuberous root. Cassava, when dried to a powdery extract, is called tapioca.

Cassava is the third largest source of food carbohydrates in the tropics, after rice and maize. Cassava is a major staple food in the developing world, providing a basic diet for over half a billion people. It is one of the most drought-tolerant crops, capable of growing on marginal soils.

Like other roots and tubers, both bitter and sweet varieties of cassava contain antinutritional factors and toxins. It must be properly prepared before consumption. Improper preparation of cassava can leave enough residual cyanide to cause acute cyanide intoxication and goiters and may even cause ataxia or partial paralysis.

World production of cassava root was estimated to be 184 million tons in 2002, rising to 230 million tons in 2008.

Cassava is a high-GI crop, but in Congo, consumption of cassava is not related to body mass index (BMI) or insulin sensitivity and β-cell function in people with type 2 diabetes mellitus (DM). Diabetes does not appear to be related to cyanide toxicity from cassava consumption.

Soybean

The soybean or soya bean (*Glycine max*) is a species of legume native to East Asia, widely grown for its edible bean that has numerous uses. The plant is classed as an oilseed rather than a pulse by the UN FAO even though it contains 11% carbohydrate and 13% protein versus 6.8% fat.

Sweet Potato

The sweet potato (*Ipomoea batatas*) has large, starchy, and sweet-tasting tubers. The sweet potato is only distantly related to the potato (*Solanum tuberosum*) and is botanically very distinct from a genuine yam (*Dioscorea*), which is native to Africa and Asia.

Besides simple starches, raw sweet potatoes are rich in dietary fiber and have moderate contents of other micronutrients, including vitamin C and potassium. It is ranked highest in nutritional value per kJ.

Sweet potato varieties with dark orange flesh have more β-carotene than those with light-colored flesh. A study of 10 000 households in Uganda found that 50% of children who ate normal sweet potatoes suffered from vitamin A

deficiency compared with only 10% of those on the high β-carotene variety.

Crop size: World production in 2004 was 127 million tons. Most comes from China and half of this is fed to livestock.

Sorghum

Sorghum bicolor, a grain-bearing grass, is widely cultivated in tropical and subtropical regions and is important in arid regions. In many parts of Asia and Africa, its grains are used to make flatbreads and the grains can also be popped in a similar fashion to popcorn. In India, sorghum is one of the staple sources of nutrition. It is used to make such foods as couscous, sorghum flour, porridge, and molasses.

Crop size: The world harvested 55.6 million tons of sorghum in 2010.

Plantains or Bananas (Musa)

There is no botanical difference between the two and plantains are typically eaten cooked and are usually large, angular, and starchy, in contrast to dessert bananas, which are typically eaten raw and are usually smaller, more rounded, and sugary. *Musa* are indigenous to the tropical regions of Southeast Asia and Oceania.

Plantains are a major food staple in West and Central Africa, Central America, the Caribbean islands, and northern, coastal parts of South America.

Plantain is a carbohydrate source. Its utilizable protein content as percentage of calorie ingestion is higher than sago and cassava, but is much lower than other staples such as maize, rice, and wheat. On per gram consumed basis, plantain's essential amino acid concentrations are very low, even lower than cassava. Cooked green plantain (and cooked green banana) has a low GI, unlike potatoes and many grains. Plantain contains very little β-carotene. The vitamin C content of plantain is very similar to those of sweet potato, cassava, and potato.

In Ghana, a traditional dietary pattern containing fruits, plantains, green leafy vegetables, fish, fermented maize products, and palm oil was associated with T2D with a 54% increase per SD.

Crop size: World production of bananas was 145 M tons.

Yam

Yam is the common name for some plant species in the genus *Dioscorea* (family Dioscoreaceae) that form edible tubers and are cultivated in Africa, Asia, Latin America, the Caribbean, and Oceania.

The protein content and quality of roots and tubers are lower than other food staples. Of all roots and tubers, the protein content of yam and potato is the highest, being ~2% on a fresh weight basis. Yams, with cassava, provide a much greater proportion of the protein intake in Africa, ranging from 6% in East and southern Africa to about 16% in humid West Africa.

Yam, like other root crops, is not a good source of essential amino acids. It is rich in phenylalanine and threonine but limiting in the sulfur amino acids, cysteine, and methionine and in tryptophan. Yam-consuming areas of Africa have a high incidence of kwashiorkor. Except for potassium, vitamin B_6, and vitamin C, yam is a food with moderate nutrient density. Yam generally has a lower GI compared to potato products.

In 2010, the world harvested 48.7 million tons of yam, 95% of which was produced in Africa.

Barley

Barley (*Hordeum vulgare* L.) is a major cereal grain. Barley grain is a staple in Tibetan cuisine and is widely used as whole grain barley meal in the Middle East in soups and stews, porridges, and gruels and in barley bread and biscuits. It is also eaten in Eastern and Central Europe and Africa. Barley grains are commonly made into malt for alcoholic and nonalcoholic beverages. Pearled barley has been steam-treated to remove the bran but still contains the bran.

Barley contains eight of the nine essential amino acids. Whole grain barley eaten at the evening meal can reduce the glycemic response to a standard breakfast compared to white bread or spaghetti and spaghetti plus bran. Fermentation of indigestible carbohydrates was greater with barley with higher breath hydrogen and blood propionate.

Like wheat and rye, barley contains gluten, which makes it an unsuitable grain for consumption by those with celiac disease that is a cell-mediated immunity to gluten that damages the intestinal mucosa and can cause malabsorption.

In a 2007 ranking of cereal crops in the world, barley was fourth in terms of quantity produced (136 million tons).

Oat

The common oat (*Avena sativa*) is a cereal grain. Oats are rolled or crushed into oatmeal or ground into fine oat flour. Oatmeal is chiefly eaten as porridge but may also be used oatcakes, oatmeal cookies, and oat bread and muesli and granola.

Oat β-glucan is a soluble fiber with good cholesterol-lowering properties with at least 3 g day^{-1} reducing low density lipoprotein (LDL) cholesterol by 5–10%. The US Food and Drug Administration (FDA) approved a health claim for β-glucan soluble fiber from oats for reducing plasma cholesterol levels and risk of heart disease in 1997. Similarly, in 2004, the UK Joint Health Claims Initiative (JHCI) allowed a cholesterol-lowering health claim for oat β-glucan for hypercholesterolemic subjects. Reducing the molecular weight of oat β-glucan to 210 000 from 500 000 reduces its cholesterol-lowering ability by 50%.

20 M metric tons is produced each year.

Rye

Rye (*Secale cereale*) is a member of the wheat tribe (Triticeae) and is closely related to barley (*Hordeum*) and wheat (*Triticum*). Rye grain is used for flour, rye bread, rye beer, and crispbread. It can also be eaten whole, as either boiled rye berries or rolled, similar to rolled oats.

Rye bread, including pumpernickel, is a widely eaten food in Northern and Eastern Europe. Rye is also used to make

crispbread. Rye flour is high in gliadin but low in glutenin and has a lower gluten content than wheat flour and contains a higher proportion of soluble fiber.

13.3 M metric tons is produced each year.

Dietary Pulses (Beans, Chickpeas, Lentils, and Peas)

FAO recognizes 11 kinds of pulses: 9 dry beans, 3 dry broad beans, 2 dry peas, and a variety of peas, vetches, lupins plus chickpeas, and lentils.

Pulses are 20–25% protein by weight, which is double the protein content of wheat and three times that of rice. While pulses are generally high in protein, and the digestibility of that protein is also high, they are often relatively poor in methionine, an essential amino acid. Grains are usually deficient in lysine so the two food groups complement each other.

A recent meta-analysis of 26 pulse interventions found that at a median intake of 130 g/LDL, cholesterol was lowered by 0.17 mmol l^{-1}. A meta-analysis of eight trials showed that pulses, exchanged isocalorically for other foods, significantly lowered systolic (MD = −2.25 mmHg (95% CI, −4.22 to −0.28) $P = 0.03$) and mean arterial BP (MD = −0.75 mmHg (95% CI, −1.44 to −0.06), $P = 0.03$).

Chickpeas

Dried chickpeas have 61% carbohydrate (11% sugar and 17% fiber), 6% fat, and 19% protein by weight.

Mature chickpeas can be cooked (or eaten raw) and eaten cold in salads, cooked in stews, ground into a flour (*besan* in India), ground and shaped in balls and fried as falafel, stirred into a batter, and baked to make farinata or paneled or a flatbread.

Chickpeas are widely used in the Mediterranean and the Middle East and Burma. Hummus is the Arabic word for chickpea that is often cooked and ground into a paste and mixed with tahini (sesame seed paste). In India, chickpeas are used in vegetarian curries.

11 M metric ton per year is grown.

Lentils

With about 30% of their calories from protein, lentils have the third-highest level of protein, after soybeans and hemp. Proteins include the essential amino acids isoleucine and lysine, and lentils are important in Asia and India. Lentils are deficient in two essential amino acids, methionine and cysteine.

Lentils are high in amylose, and thus, low-GI red lentils have a GI of 21 and green lentils 22–37. Canned lentils have a higher GI of 42–52. Lentils also have some antinutritional factors, such as trypsin inhibitors and relatively high phytate content. Lentils are a good source of iron, having over half of a person's daily iron allowance in a one cup serving.

The FAO reported that the world production of lentils for calendar year 2009 was 3.917 M metric tons.

Starch: Modified Starches

L Kaur and J Singh, Riddet Institute, Massey University, Palmerston North, New Zealand

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Starch contributes greatly to the textural properties of many foods and is widely used in many industrial applications as a thickener, colloidal stabilizer, gelling agent, bulking agent, and water retention agent. However, its inability to withstand processing conditions (low shear resistance, thermal resistance, and thermal decomposition) and low storage stability (high tendency toward retrogradation) limits its use in some industrial food applications. Starch modification, which involves the alteration of the physical and chemical characteristics of native starch to improve its functional and nutritional characteristics, can be used to tailor starch to specific food applications. Starch modification is generally achieved through derivatization such as etherification, esterification, cross-linking, and grafting of starch; decomposition (acid or enzymatic hydrolysis and oxidization of starch); or physical treatment of starch using heat or moisture (Table 1). The properties of some modified starches and their applications are presented in Table 2. The effects of modifications on thermal, morphological, and pasting/rheological behavior of starches may be quantified using instrumentation such as differential scanning calorimetry, scanning electron microscopy (SEM), Visco-Amylo-Graph/Rapid Visco Analyser, and dynamic rheometer, respectively.

Common Types of Modified Starches

Physically Modified Starches

Physical modification of starch is the preferred form of modification as it does not involve any chemical treatment. Drum drying, extrusion cooking, spray drying, radiation, sonication, annealing (ANN), and heat–moisture treatment (HMT), as well as high hydrostatic pressure (HHP) treatment, are the most commonly employed methods for the physical modification of starch.

Pregelatinization

Pregelatinized starches are the 'instant' starches that provide a desirable texture when dispersed in water at temperatures below the gelatinization temperatures of the parent starch. These starches find applications in convenience foods for a palatable texture and for holding other food components in a uniform suspension. Most of the pregelatinized starches are made by applying starch slurry to a hot drum followed by grinding the thin sheet to a fine powder. The native starch granule structure is completely lost during this process, and no intact granules are generally present in the final product. The limitation of drum-cooked unmodified starch is that upon rehydration, it gives a paste of reduced consistency with a dull, grainy appearance and gels of reduced strength, which is the reason that sometimes chemically modified starches are used as a raw material for drum drying.

Cold water-dispersible starches

Granulated cold water-dispersible or cold water-swellable starches give greater viscosity and smoother texture and have more processing tolerance than traditional pregelatinized starches. The methods used to prepare these starches include heating of starches in aqueous alcohol (sufficient water for gelatinization and sufficient alcohol to maintain granule integrity), high-temperature and high-pressure treatments, and alcoholic-alkaline treatment. The modified starches prepared by these methods differ in their cold water solubility/swellability. These types of starches swell rapidly when added to cold water and are commonly used in cold water-dispersible foods, such as infant foods, ice creams, and dry baking premixes.

Alcoholic-alkaline treatment

Alcoholic-alkaline treatment involves treatment of starch with a mixture of sufficient ethanol and sodium hydroxide to swell starch granules, followed by neutralization with hydrochloric acid, washing with alcohol, and finally drying. The starch granules retain their granular form (depending on starch type and extent of modification, Figure 1) but lose their crystallinity during the process. Solubility has been reported to range between 11.7% and 93.3% for waxy and high-amylose maize starches prepared by different alcoholic-alkaline treatments. However, the effectiveness of the method depends mainly on the starch cultivar, concentration of ethanol and sodium hydroxide, and reaction temperature.

Hydrothermal and pressure treatments

Hydrothermal treatments used for starch modification include extrusion cooking, sonication, and radiation. The modification conditions such as water content, pressure, temperature, and shear forces vary considerably between the different processes. Starch is partially gelatinized during these processes, which results in decreased hydrogen bonding. Extrusion cooking is a popular method of starch modification because of its low cost and continuous mode of processing. The extrusion-modified starch exhibits lower hot paste viscosity and higher water solubility.

HHP treatment offers starch gelatinization at room temperature or even lower. It restricts the swelling of starch granules, resulting in reduced starch paste viscosity. Reduced paste viscosity allows transferring, mixing, and pumping of these starches even at concentrations of 25–30%. Also, HHP-treated starches (at concentrations $>15\%$) produce paste with creamy texture, which can find applications in dietary foods instead of oil.

Annealing and heat–moisture treatments

Two of the other hydrothermal treatments commonly used to modify starch are ANN and HMTs. These treatments modify the physicochemical properties of starch without destroying granular structure. Starch is heated in excess water/intermediate ($>40\%$) water content in case of ANN or at low moisture ($<35\%$) levels for a certain time period, at a temperature above the starch glass transition temperature (T_g) but below its

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00659-0

Table 1 Different starch modification types and preparation techniques

Modification	*Types*	*Preparation*
Physical	Heat–moisture treatment	Heat–moisture treatment – heating starch at a temperature above its gelatinization point with insufficient moisture to cause gelatinization
		Annealing – heating a slurry of granular starch at a temperature below its gelatinization point for prolonged periods of time
	Pregelatinization	Pregel/instant/cold water-swelling starches prepared using drum drying/spray cooking/extrusion/solvent-based processing
Conversion	Partial acid hydrolysis	Treatment with hydrochloric acid or orthophosphoric acid or sulfuric acid
	Partial enzymatic hydrolysis	Treatment in an aqueous solution at a temperature below the gelatinization point with one or more food-grade amylolytic enzymes
	Alkali treatment	Treatment with sodium hydroxide or potassium hydroxide
	Oxidation/bleaching	Treatment with peracetic acid and/or hydrogen peroxide, or sodium hypochlorite or sodium chlorite, or sulfur dioxide, or potassium permanganate or ammonium persulfate
	Pyroconversion (dextrinization)	Pyrodextrins – prepared by dry roasting acidified starch
Derivatization	Etherification	Hydroxypropyl starch – esterification with propylene oxide
	Esterification	Starch acetate – esterification with acetic anhydride or vinyl acetate
		Acetylated distarch adipate – esterification with acetic anhydride and adipic anhydride
		Starch sodium octenylsuccinate – esterification by octenylsuccinic anhydride
	Cross-linking	Monostarch phosphate – esterification with orthophosphoric acid, or sodium or potassium orthophosphate, or sodium tripolyphosphate
		Distarch phosphate – esterification with sodium trimetaphosphate or phosphorus oxychloride
		Phosphated distarch phosphate – combination of treatments for monostarch phosphate and distarch phosphate
	Dual modification	Acetylated distarch phosphate – esterification by sodium trimetaphosphate or phosphorus oxychloride combined with esterification by acetic anhydride or vinyl acetate
		Hydroxypropyl distarch phosphate – esterification by sodium trimetaphosphate or phosphorus oxychloride combined with etherification by propylene oxide

Source: Singh, J., Kaur, L. and McCarthy, O. J. (2007). Factors influencing the physico-chemical, morphological, thermal and rheological properties of some chemically modified starches for food applications – a review. *Food Hydrocolloids* **21**, 1–22.

Table 2 Some properties and applications of modified starches

Types	*Properties*	*Applications*
Pregelatinization	Cold water dispersibility	Useful in instant convenience foods
Partial acid or enzymatic hydrolysis	Reduced molecular weight polymers, reduced viscosity, increased retrogradation, and setback	Useful in confectionery, batters, and food coatings
Oxidation/bleaching	Low viscosity, high clarity, and low temperature stability	Used in batters and breading for coating various foodstuffs, in confectionery as binders and film formers, in dairy as texturizers
Pyroconversion (dextrinization)	Low to high solubility depending on conversion, low viscosity, high reducing sugar content	Used as coating materials for various foods, good film-forming ability, and as fat replacers in bakery and dairy products
Etherification	Improved clarity of starch paste, greater viscosity, reduced syneresis, and freeze-thaw stability	Used in wide range of food applications such as gravies, dips, sauces, fruit pie fillings, and puddings
Esterification	Lower gelatinization temperature and retrogradation, lower tendency to form gels, and higher paste clarity	Used in refrigerated and frozen foods, as emulsion stabilizers and for encapsulation
Cross-linking	Higher stability of granules toward swelling, high temperature, high shear, and acidic conditions	Used as viscosifiers and texturizers in soups, sauces, gravies, bakery, and dairy products
Dual modification	Stability against acid, thermal, and mechanical degradation and delayed retrogradation during storage	Used in canned foods, refrigerated and frozen foods, salad dressings, puddings, and gravies

gelatinization temperature. However, the temperature–time combinations required to achieve desired functionality vary among different starch sources. Although no complete gelatinization of starch takes place, these treatments cause considerable changes in its physicochemical, functional, and digestion characteristics.

Chemically Modified Starches

Chemical modification involves the introduction of functional groups into the starch molecule, resulting in markedly altered physicochemical properties. Such modification of native granular starches profoundly alters their gelatinization, pasting, and

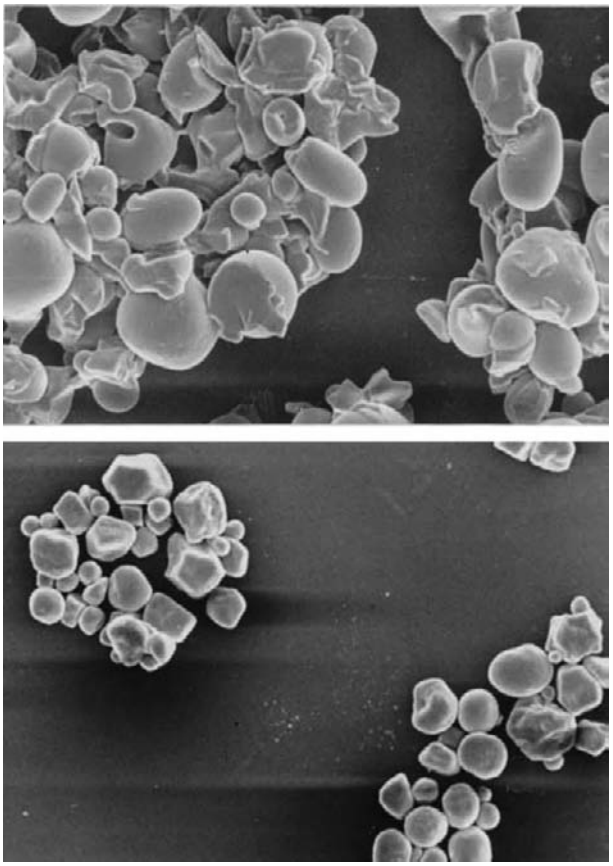

Figure 1 Scanning electron micrographs of granular cold water-soluble potato (top) and corn (bottom) starches prepared using alcoholic-alkaline treatment. Reproduced from Singh, J. and Singh, N. (2003). *Food Hydrocolloids* **17**, 63–72, with permission from Elsevier.

retrogradation behavior. Food-grade starches are chemically modified mainly to increase paste consistency, smoothness, and clarity and to impart freeze-thaw and cold storage stabilities. Some chemical modification reactions of starch are presented in Table 3.

Substitution (stabilization)

The chemical and functional properties achieved when modifying starch by chemical substitution depend, inter alia, on starch source, reaction conditions (reactant concentration, reaction time, pH, and the presence of catalyst), type of substituent, extent of substitution (degree of substitution, DS, or molar substitution, MS), and the distribution of the substituent in the starch molecule. Acetylated starch with a low DS is commonly obtained by the esterification of native starch with acetic anhydride in the presence of an alkaline catalyst, whereas the food-grade hydroxypropylated starches are generally prepared by etherification of native starch with propylene oxide in the presence of an alkaline catalyst. The introduction of (bulky) acetyl groups into starch molecules by acetylation leads to structural reorganization owing to steric hindrance; this results in repulsion between starch molecules, thus facilitating an increase in water percolation within the amorphous regions of granules and a consequent increase in swelling capacity. The hydroxypropyl groups introduced into the starch

chains are capable of disrupting the inter- and intramolecular hydrogen bonds, thereby weakening the granular structure of starch, leading to an increase in motional freedom of starch chains in amorphous regions. The decrease in associative forces within the starch granule due to hydroxypropylation may result in an increased penetration of water during heating that leads to the greater swelling.

Cross-linking

Cross-linking treatment stabilizes and strengthens the starch granule by adding intra- and intermolecular bonds at random locations in the granule. Starch pastes from cross-linked starches are less likely to break down with extended cooking times, increased acidity, or severe shear. Cross-linking minimizes granule rupture, loss of viscosity, and the formation of stringy paste during cooking, yielding starch that is suitable for canned foods and other food applications. Nutritional benefits of cross-linked starch as a new source of dietary fiber have also been reported. Cross-linking is generally performed by the treatment of granular starch with multifunctional reagents capable of forming either ether or ester intermolecular linkages between hydroxyl groups on starch molecules. Sodium trimetaphosphate, monosodium phosphate, sodium tripolyphosphate, epichlorohydrin (EPI), phosphoryl chloride ($POCl_3$), a mixture of adipic acid and acetic anhydride, and vinyl chloride are the main agents used to cross-link food-grade starches. Cross-linking strengthens the bonding between the starch chains, causing an increase in the resistance of the granules to swelling with increasing degree of cross-linking. Higher concentrations of fast-acting cross-linking reagents such as $POCl_3$ result in greater reductions in the swelling potential as compared with slower-acting agents such as EPI. A large concentration of $POCl_3$ cross-links at the surface of the granule causes the formation of a hard outer crust that restricts granule swelling.

Starch phosphates, which are conventionally prepared, have been reported to give clear pastes of high consistency with good freeze-thaw stability and emulsifying properties and may be grouped into two classes: monostarch phosphates and distarch phosphates (cross-linked starches). In general, monostarch

phosphates (monoesters) can have a higher DS than distarch phosphates (diesters) because even a very few cross-links (in the case of diesters) can drastically alter the paste and gel properties of the starch. Starch phosphates are conventionally prepared through the reaction of starch with salts of ortho-, meta-, pyro-, and tripolyphosphoric acids and $POCl_3$.

Dual modification

Dual modification, a combination of substitution and cross-linking, has been demonstrated to provide stability against acid and thermal and mechanical degradation of starch and to delay retrogradation during storage. Dual-modified starches are used widely in salad dressings, canned foods, frozen foods, and puddings. The control of reaction conditions is important during preparation of dual-modified cross-linked/hydroxypropylated starches using different cross-linking reagents with different starch bases such as maize, tapioca, wheat, waxy maize, waxy barley, rice, and sago. The quantity of cross-linking reagent required to prepare a dual-modified starch (with desirable properties) varies with the source of starch, the type of cross-linking reagent, the efficiency of the cross-linking reaction, the DS required, and the specified range of final modified-starch properties. The effects of different reaction conditions such as starch base concentration, temperature, pH, and the concentration of the catalyst salt play an important role during preparation of duly modified hydroxypropylated-cross-linked starch.

Extent of chemical modification

The rate and efficiency of the chemical modification process depend on the reagent type, the botanical origin of the starch, and the size and structure of its granules. This also includes the surface structure of the starch granules, which encompasses the outer and inner surfaces, depending on the pores and channels, and leads to the development of the so-called specific surface. Channels that open to the granule exterior provide a much larger surface area accessible by chemical reagents and provide easier access by the reagents to the granule interior. However, the reagent may diffuse through the external surface to granule matrix in the absence of channels. Although starches from various sources exhibit fundamental structural similarities, they differ in the specific details of their microstructure and ultrastructure. These structural differences have the potential to affect the chemical modification process. The DS and MS of some chemically modified starches prepared from different sources are presented in Table 4.

Morphology of chemically modified starches

Microscopy (light and SEM) has played an important role in increasing the understanding of granular structure of modified starches. It has been used to detect structural changes caused by chemical modifications and the most substituted regions in starch granules. Most of the structural changes upon hydroxypropylation take place at the relatively less organized central core region of the starch granule, that is, where the hydroxypropyl groups are most densely deposited. The 'pushing apart effect' exerted by the bulky hydroxypropyl groups, especially in the central region of the granule, might lead to an alteration in granule morphology upon hydroxypropylation. Another possible explanation is that the starch granule itself is not structurally homogeneous from a physical and chemical point of view, since it has different physical natures (amorphous and crystalline regions) as well as different chemical compositions in each region. The treatment of potato starch granules with propylene oxide (10%, dwb) alters granule morphology (Figure 2(a) and 2(b)). Many of the less affected modified granules develop a depression that later leads to slight fragmentation, indentation, and the formation of a deep groove in the central core region along the longitudinal axis in highly affected granules (Figure 3). These granules appear as folded structures with their outer sides drawn inward, giving the appearance of a doughnut (Figure 3(a) and 3(b)). Moreover, these altered regions have been observed to be apparently larger in large granules compared with small granules in all the potato starches examined; this may be attributed to differences in the native granule architecture and fragility. The peripheral regions and also the outer layer of the less affected starch granules remain unaltered, and the changes remain confined to the central core regions. By contrast, highly affected starch granules develop blister-like appearances, cracks, and small protuberances on their surfaces and a deep groove in the central core region, which suggests that the granule peripheral regions may be the last to be modified (Figure 3(c)).

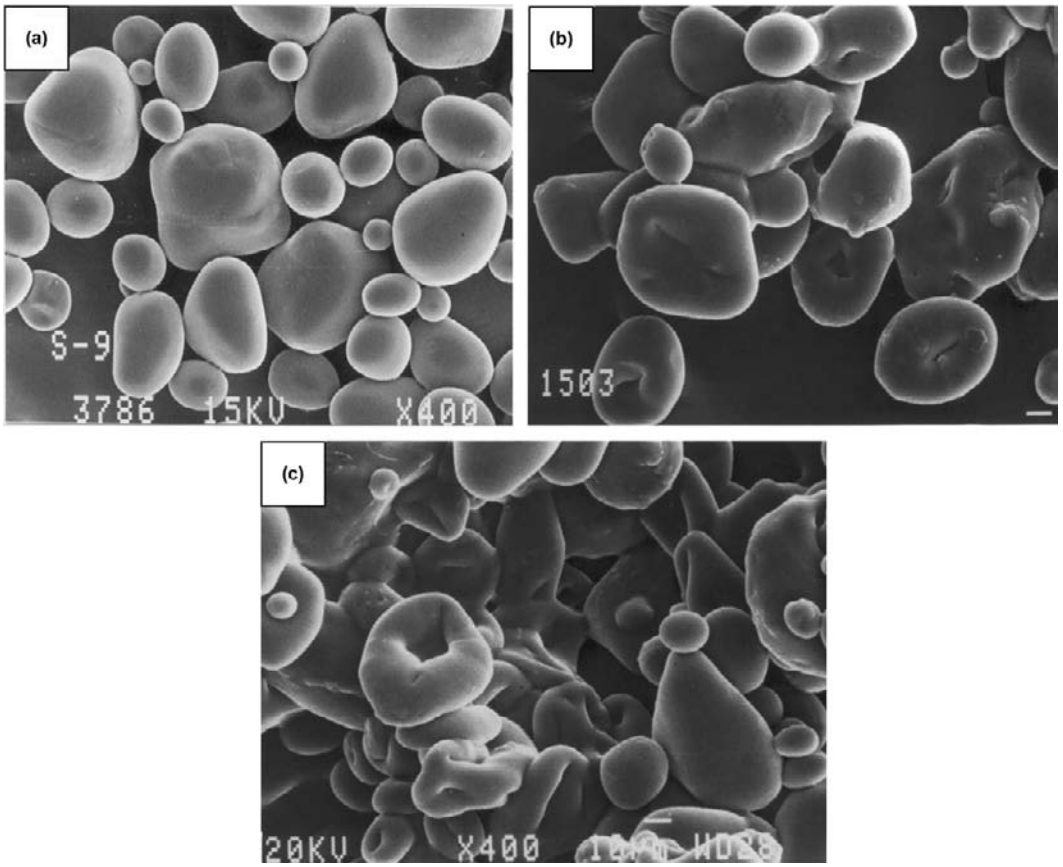

Figure 2 Effects of hydroxypropylation on the granule morphology of potato starches. (a) Native potato starch granules, (b) potato starch granules after hydroxypropylation (at 10% propylene oxide concentration), (c) effect of increased concentration of propylene oxide (15%) on the starch granule structure. Reproduced from Kaur, L., Singh, N. and Singh, J. (2004). Factors influencing the properties of hydroxypropylated potato starches. *Carbohydrate Polymers* **55**, 211–223, with permission from Elsevier.

The granule structure is more substantially altered when the reaction is carried out with a higher concentration of propylene oxide (15% compared with 10%). Highly affected granules appear as if gelatinized, having lost their boundaries and fuse together to form a gelatinized mass (Figure 2(c)). The material within the inner regions of potato starch granules has been reported to be more susceptible to reaction (with propylene oxide) than that in the outer granule layers. Also, as potato starch granules do not possess channels, the reagent diffuses inward through the exterior granule surface. Propylene oxide, being less reactive than other modification reagents, may diffuse into the granule matrix prior to reacting. However, one study on chemically modified pea and waxy maize starches reported that hydroxypropylation occurred uniformly throughout the starch granules. The structural changes in hydroxypropylated starch granules become more evident with increasing MS. Hydroxypropylation leads to alteration in the structure of the gelatinized potato starch gels also, which may be attributed to a weakened granule structure, leading to increased granule disruption during gelatinization. Hydroxypropylated starch gels maintain well the planar structure during storage at 4 °C for 10 days, whereas stored gels of native starches show extensive aggregation of granule remnants. Numerous rod-shaped fuzzy clustered microfibrils appear in hydroxypropylated starch gels (after 30 days' storage at 4 °C) that are easily distinguished from the other starchy materials (Figure 4). The extensive phase separation occurring during long-term storage at 4 °C may be responsible for the formation of these rod-shaped microfibrils. Slow cooling has also been reported to enhance the formation of non-spherulitic morphologies in starch gels.

Acetylation treatment has also been found to alter the granule morphology, although to a lesser extent. It has been observed to cause granule fusion in both maize and potato starches (Figure 5). The granule fusion is more pronounced in potato starches with small size granules. Maize starch granules show a higher resistance toward acetylation treatment than potato starches. The addition of 4% acetic anhydride results in the fusion of granules in potato starches, while maize starch granules tend to fuse at concentrations of acetic anhydride of 8% or higher. The granule surface of maize and potato starch granules has been observed to be slightly rough upon acetylation. The granule surface of rice starches also becomes rough, and the granules tend to form aggregates upon acetylation. However, some granule fusion and deformation and the rough appearance of the granule surface in the acetylated starches could also be the result of surface gelatinization upon the addition of NaOH to maintain alkaline conditions during acetic anhydride addition.

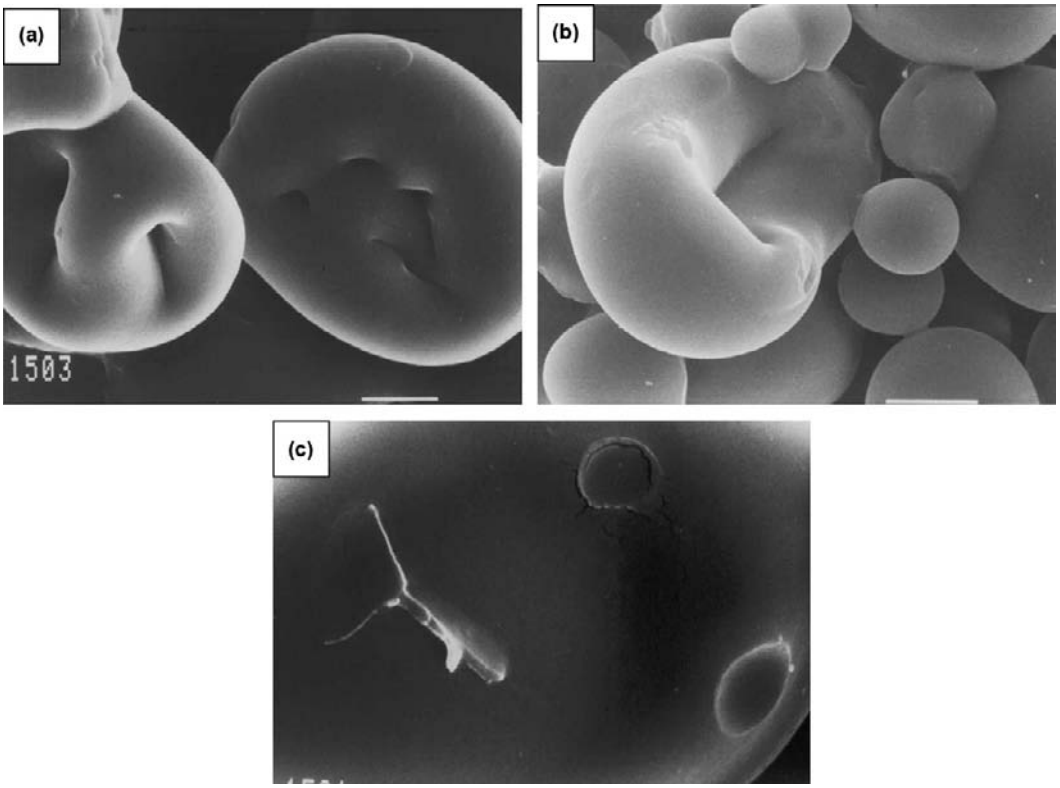

Figure 3 Effects of hydroxypropylation on the granule morphology of potato starches. (a) Formation of deep groove in the central core region, (b) folding of starch granules and formation of doughnutlike appearance, (c) formation of blister-like appearance and cracks on the starch granules. Starch granule size is very responsive to the changes in the DS by phosphate groups; the higher the DS, the larger the granule size. The average increase in granule size has been observed to be higher for rice and maize starches than for potato starch for a given DS. This increase could be due to the substitution by phosphate groups inside the modified granules, building certain repulsive forces that increase the sizes of inter- and intramolecular spaces, allowing more water molecules to be absorbed. Phosphorylation does not cause any detectable change in the general granule shape. After being cross-linked using EPI and $POCl_3$, potato starch granules remain smooth and similar to native starch granules in morphology when viewed under SEM, suggesting that the modification does not cause any detectable morphological change. Some chemical modifications of starch have been reported to increase granule surface area and granule porosity.

Enzymatically Modified/Acid-Modified Starches

Acid modification changes the physicochemical properties of starch without destroying its granule structure. It increases solubility and gel strength and decreases paste viscosity of starches. These starches find applications in the confectionary industry to prepare thin boiling starches. The modification procedure generally involves treating a concentrated starch suspension (36–40%) with acid at a temperature below the gelatinization temperature of the starch for several hours or days (depending on the treatment temperature). In acid modification, the hydroxonium ion attacks the glycosidic oxygen atom and hydrolyzes the glucosidic linkage. Its action proceeds from surface toward the center of the starch granule. The degree of acid hydrolysis increases with increasing amylopectin content in starches from the same species. Acid has been reported to preferentially attack the branched molecules more readily than the linear molecules within the granule. It has also been suggested that acid modification of starches in long-chain alcohols assists in reducing the degree of polymerization of amylopectin more effectively than short-chain alcohols. Alcohols have been reported to be capable of converting the crystalline regions into more amorphous regions that are prone to acid hydrolysis. Different shortcomings of the method include random attack, high yield of glucose, and removal of acid later on, which is the reason for a shift from the acid hydrolysis of starch to the use of starch-converting enzymes in the production of maltodextrin, modified starches, or glucose and fructose syrups.

Enzyme-modified starches are also considered among 'clean label' food products as there is no chemical treatment involved in the process. In enzymatic modification, selective hydrolysis of gelatinized/granular starch is carried out with starch-degrading enzymes, such as α-amylase, isoamylase, and pullulanase. Saccharification and liquefaction are the two major events taking place during starch amylolysis, and the major enzyme-modified products are linear dextrins of varying DE, high-fructose syrups, glucose syrups, dextrose, maltodextrins, and cyclodextrins.

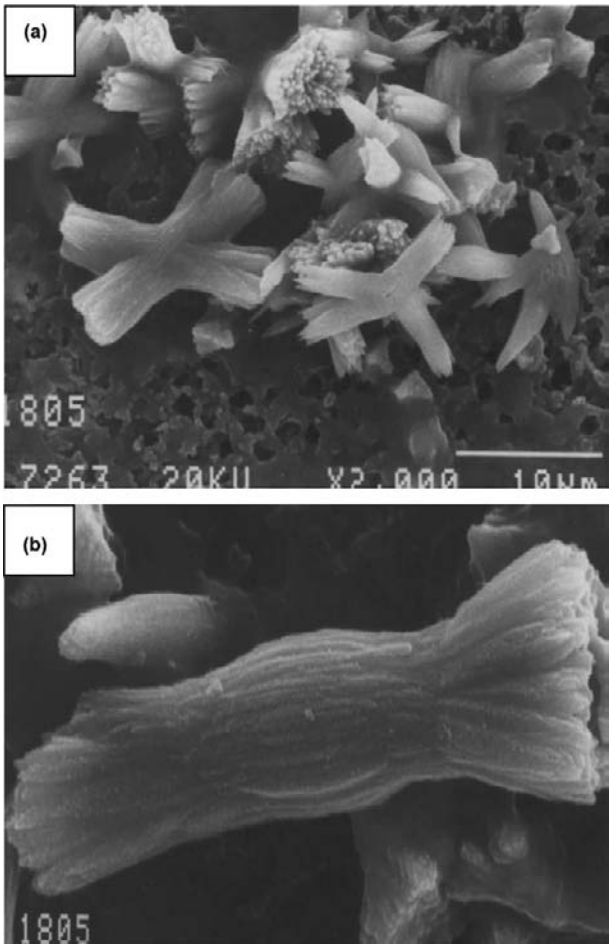

Figure 4 Rod-shaped microfibrils (showing longitudinal arrangement of crystalline structures) formed during long-term storage of hydroxypropylated gelatinized starch pastes. Reproduced from Kaur, L., Singh, N. and Singh, J. (2004). Factors influencing the properties of hydroxypropylated potato starches. *Carbohydrate Polymers* **55**, 211–223, with permission from Elsevier.

High-fructose syrups are considered high-value products in the food industry because of reduced calorie content and good tolerance by diabetics. They can be used as fat mimetics and calorie reducers in flour-based dry mixes, baking systems, fillings, etc. Cyclodextrins are well-known cyclic maltooligosaccharides produced by the enzymatic hydrolysis of starch using cyclodextrin glycosyltransferases from *B. circulans* and *B. macerans*. Cyclodextrins form inclusion complexes with some hydrophobic molecules and find application in food processing, pharmaceutical, and agrochemical industries for preparation, separation, purification, and protection of pharmaceuticals, fragrance, flavors, and steroids.

Modified Starches and Starch Digestibility

Many studies have suggested that the physiological effects of chemically modified starches are affected by the type of modification. There are many reports available that modifications of starch such as hydroxypropylation, octenylsuccinylation, and combinations of cross-linking and substitution reduce the extent of their enzyme-catalyzed hydrolysis. Substitution and oxidation have been suggested to increase the resistant starch content of the maize starches, whereas cross-linking does not affect starch digestibility to a considerable extent (Figure 6). However, some studies on the *in vitro* digestibility of hydroxypropylated and cross-linked waxy and nonwaxy starches have shown no significant changes in resistant starch content compared to control unmodified starch samples. It is important to point out that the general resistant starch assays may not be appropriate to measure the resistant starch content of chemically modified starches. It has been suggested that the pancreatin-gravimetric method involves exhaustive digestion and is therefore more appropriate for the determination of resistant starch in chemically modified starches. The chemical modification of starch by acetylation also improves the satiating, glycemic, and insulinemic properties of the meal. Phosphorylated/cross-linked starches are slowly digestible and are thought to provide nutritional benefits for humans. Also, the slowly digesting modified starches could be used for the treatment of certain medical modalities (e.g., glycogen storage disease and diabetes mellitus). Several studies have highlighted various methods and technologies (other than chemical modification) to modify the starch for the formation of slowly digestible starch (SDS). The prominent methods to produce SDS include ANN and HMT.

Nutritional and Toxicological Aspects

Many modified starches made for food use contain only small amounts of substituent groups and have been used as safe food ingredients. During acetylation and hydroxypropylation of food-grade starches, the level of monosubstitution groups introduced is relatively low. The maximum permitted levels of substitution for starch acetates, starch phosphates, and hydroxypropylated starches are 2.5%, 0.4%, and 10%, respectively. Similarly, cross-linked food starches containing one substituent cross-linking group per 1000 or more anhydroglucose units are considered safe. The legislative approval for the use of novel starch derivatives in processed food formulations is still under debate, but several tailor-made starch derivatives with multiple modifications are being prepared and characterized. Some of the starch derivatives are being increasingly used as fat replacers or fat substitutes. These derivatives are either partially or totally undigested and therefore contribute zero calories to the food on consumption. Starch-based fat replacers find applications in high-moisture food systems, for example, salad dressings, meat emulsions, and some bakery products.

Starch: Sources and Processing

FA Manthey, North Dakota State University, Fargo, ND, USA

Background

Starch is found in green plants. The primary function of starch is to serve as an energy reserve and as a carbon source for *de novo* biosynthesis of macromolecules. As plants mature, starch often accumulates in storage organs such as endosperm or cotyledons of seeds or in fruit, stems, roots, and tubers. Starch is synthesized as discrete granules in amyloplast found in cells of storage organs. Simple starch granules occur when only one granule forms per amyloplast. Compound starch granules occur when many small starch granules form an aggregate structure in an amyloplast.

Starch is composed of two polysaccharides, amylose and amylopectin. Both amylose and amylopectin are long-chain α-1,4 glucans with α-1,6 branches. Amylopectin forms the principal structure of the granule. Amylopectin is a large, highly branched molecule with a degree of polymerization of 10^4–10^7 with 4–5% of the linkages involved with branch points. Amylose is smaller than amylopectin with a typical degree of polymerization of 10^3–10^4 and is nearly nonbranched with only 0.3–0.6% of the linkages involved with branch points. In general, starch granules are composed of 75% amylopectin and 25% amylose.

Starch granules differ in their molecular packing density, which affects their crystalline nature as determined by x-ray diffraction. Starch can be classified based on its x-ray diffraction pattern. Starch found in cereal grains has an A-crystalline type, which indicates densely packed crystals with few water molecules associated with the starch; B-crystalline type is common with starch granules found in tubers and roots and indicates less densely packed crystals with more water associated with the starch. C-crystalline-type starches are often found with legume starches and indicate that the granule contains both A-crystalline and B-crystalline types, where the B-crystalline type is found in the center of the granule, while the A-crystalline type forms the outer layer. The x-ray crystalline pattern, ratio of amylopectin to amylose, and granule size and shape depend on botanical source and can affect the functionality of starch and their subsequent use in food and industrial applications.

Industrial Starch Production

Worldwide, corn, wheat, rice, cassava, and potato are important plant sources for commercial starch production. Together, they represent over 99% of the starch produced. Other plant sources, such as sago palm, sorghum, and legumes, are important depending on geographic area and unique properties of their starch. Starch industry is constantly searching for new starch sources with unique functional properties that can fit niche markets.

Starch Extraction

For grains, starch extraction can begin with the intact grain or with its ground flour. Starch extraction from intact grain begins with steeping, followed by coarse milling to create a coarse suspension or slurry, which undergoes degerming to remove germ and associated lipids, followed by fine milling, screening, and centrifugal separation of starch from protein, fiber, and water-soluble material. Alternatively, grain can be dry-milled and the flour is discharged into a stream of water to form a slurry. The slurry then undergoes similar process steps as described earlier. Very small seeds are often dry-milled first and then defatted since removing the germ during wet milling is difficult due to their small size.

During steeping, the grains are soaked in a warm (40–55 °C), aqueous solution of sulfur dioxide for 24–48 h. Sulfur dioxide enhances the growth of favorable microorganisms, for example, lactobacillus, and inhibits the growth of undesirable microorganisms. Steeping softens the grain, which allows the germ and seed coat to be removed after cracking the seed using a coarse milling process. In cereal grain, starch stored in the endosperm is often embedded in a protein matrix. Metabisulfite, 0.2%; lactic acid, 0.5%; and sodium hydroxide, 0.2% w/w, are added to the steepwater to help disperse the protein matrix that surrounds the starch granules, thus facilitating their release. The germ, which is rich in lipid, weighs less than the other ground seed parts and is removed from the slurry by a hydrocyclone separator. Large pieces of fiber or seed hull are removed by screens. The remaining slurry is generally finely milled and the protein is separated from starch using their differences in density. Germ, oil, fiber, and protein are further refined to add value to 'waste' products associated with starch extraction.

Similarly, starch extraction from vegetative organs such as stems, tubers, and roots involves washing and peeling followed by a grinding or shredding step to form a slurry. Starch in vegetative organs is not embedded in a protein matrix. The slurry is passed through screens and is centrifuged to separate the starch from fiber, protein, and water-soluble material.

Industrial starch extraction processes often use countercurrent washing to conserve water and reduce the amount of wastewater. Countercurrent washing is the process where clean water is introduced to the system at the last washing step. The water contains 0.05% sulfur dioxide in order to control microorganisms. The subsequent wash water flows backward through the extraction system beginning with starch washing and ending as steepwater.

Factors That Affect Starch Extraction

Starch recovery from grain is dependent on starch content, kernel size, and kernel weight. Starch recovery tends to decrease with age of the grain. Separation of starch from protein becomes more difficult with age, increased harvest moisture, high grain drying temperature, and increased levels of starch damage.

Cereal Starches

Corn and sorghum

Corn (*Zea mays*) originated in Central America and is widely adapted to many environments, although it is considered a warm season crop. Corn is monoecious, which means that staminate and pistillate flowers are borne on separate inflorescences on the same plant. Pistillate flowers are located on spikes called ears. An ear of corn contains 8–28 rows of grains with each row having 20–70 grains. There are several types of corn: dent corn, flint corn, flour corn, popcorn, and sweet corn. Dent corn is the most widely cultivated type and is used in corn starch production.

Dent corn has a 1000-kernel weight of 300–360 g and contains about 65–75% starch, 8–15% protein, 3–6% oil, and 10–15% fiber (dry basis). Dent corn consists of an embryo (12%) and endosperm (82%), both of which are surrounded by the pericarp or hull layer (5%). Endosperm cells contain amyloplasts with simple starch granules that contain about 25% amylose. Starch granules range in size from 5 to 25 μm and have round and polygonal shape. The endosperm has two regions, horny endosperm and floury endosperm. The horny endosperm is found near the embryo and along the sides of the kernel. The floury endosperm is found in the middle and top of the kernel. The floury region is characterized by larger cells, large round starch granules, and a relatively thin protein matrix. Horny endosperm consists of a protein matrix surrounding starch granule making the granules angular in shape. Horny endosperm contains only about 1.5–2% more protein than does the floury endosperm. The floury endosperm is opaque, friable, and easily crushed. Starch granules in the horny endosperm are smaller than those in the floury endosperm region.

Sorghum (*Sorghum bicolor*) is a native of Africa, south of the Sahara desert. It is a staple food crop in semiarid tropics. There are seven agronomic groups of grain sorghum based on where they originated. Sorghum inflorescence is a loose to dense panicle having many spikelets. Each spikelet contains two flowers; only one is fertile and sets a seed.

Sorghum has a 1000-kernel weight of 25–35 g and contains 60–80% starch, 9–15% protein, 2–6% fat, and 1–13% fiber (dry basis), all of which depend on cultivar and environment. Sorghum kernel has the same gross morphology as corn. Sorghum has a very hard kernel consisting of bran or hull (6%), endosperm (84%), and germ (10%). Endosperm differs from that of corn only in the relative proportions of floury and horny endosperms. All sorghums have a horny endosperm that surrounds the floury region. The dense horny endosperm layer comprises a larger proportion of the kernel than it does in corn, which results in much greater problems during starch purification. Starch is deposited as simple starch granules in amyloplasts found in endosperm cells. Sorghum starch granules contain about 20–30% amylose and range in size from 3 to 27 μm and have a smooth surface but angular and polygonal shape.

Commercial starch production normally utilizes low-grade or sample grade corn or sorghum. Starch is extracted from corn and sorghum using similar wet milling procedures. The grain is cleaned and steeped for 30–48 h in warm water (45–50 °C) that contains sulfur dioxide. The prolonged steeping is necessary for effective separation of the whole intact germ from the endosperm. The protein matrix that surrounds the starch granules is composed of glutelin protein. Sulfur dioxide weakens the glutelin matrix by breaking inter- and intramolecular disulfide bonds. Zein proteins occur in spherical bodies that are embedded in the glutelin matrix. During steeping, soluble materials including albumins and globulins are extracted (6–6.5%, db) and the kernel softens as the protein matrix begins to loosen and release starch granules.

Steepwater is drained from the kernels and condensed on a multistage evaporator. Softened kernels are coarsely ground using an attrition mill. The cracking of the kernel loosens the hull and breaks the bonds between germ and endosperm. Proper steeping ensures that the germ is freely released intact from kernel by gentle milling with minimal expelling of oil from the germ into the steepwater. The free germ and associated oil that float on the water surface are removed from the steepwater by centrifugal force.

The remaining kernel particles are finely ground, using an impact or attrition mill, to release starch and protein from the endosperm cell walls. A hydrocyclone separator separates the starch from the protein based on their differential weight (density). Protein weighs less and is removed from the top and the heavier starch is removed from the bottom of the separator. The protein is recovered and the starch is washed and centrifuged repeatedly until contaminants have been removed. The refined starch is dewatered, dried, sifted, and packaged.

Wheat

Wheat (*Triticum* spp.) originated in the eastern Mediterranean, Near East, and Middle East areas. Wheat is adapted to cool, dry, and temperate climate. There are five classes of common wheat (*Triticum aestivum*), each with different milling and end use qualities. Wheat inflorescence is a dense spike consisting of multiple spikelets. Each spikelet typically has three florets of which two generally become pollinated and produce a seed.

Wheat has a 1000-kernel weight of 31–35 g and contains about 80% starch, 15% protein, 2.5% fat, and 3.5% fiber, dry basis. Wheat kernel is composed of bran (15%), germ (3%), and endosperm (82%). In the endosperm, starch granules formed in amyloplasts are embedded in a protein matrix. Wheat starch granules contain about 25–28% amylose. There is a bimodal distribution of starch granules based on size, which are designated as A-starch and B-starch granules. A-starch granules are large (20–45 μm) and are lenticular in shape, while B-starch granules are small (2–8 μm) and are spherical in shape.

Starch can be extracted from the wheat kernel. However, wet milling for extracting starch and gluten from wheat kernels is hindered by tendency of gliadin and glutenin storage proteins to agglomerate. Wheat storage proteins tend to entangle with bran particles for which the proteins can no longer be separated. Thus, even though starch yield is reduced by the loss of starch to milling streams and to starch damage, wheat flour is the most common starting material for isolating starch from wheat. Wheat starch generally is isolated from the flour of poor quality wheat using either the dough process (often called the Martin process) or the batter process (often called the Scandinavian process).

The dough process is the traditional method for obtaining gluten and starch from refined wheat flour. In this method, wheat flour is hydrated to 40–60% and mixed to form a dough. The dough is formed as the hydrated storage proteins interact to form a gluten matrix. The resulting dough is continuously kneaded as it is washed with water. Starch and water-soluble compounds are removed from the dough's gluten matrix, creating a starch slurry. Dough strength is reduced by the addition of more water, which causes it to produce suspended curds of gluten particles that contain low levels of residual starch. Gluten curds are recovered on gyrating sieves. The remaining slurry containing starch and water-extractable material is centrifuged, which separates the water-extractable fraction from the starch. The yield of prime grade starch, which has low protein and lipid contents, is about 60% of the weight of flour and contains a high percentage of the large A-starch granules. The A-starch granules are heavier than the small B-starch granules and so precipitate out of the slurry quicker during centrifugation. About 15% low-grade starch is collected, which tends to be rich in pentosans that originate from the cell walls. The starch fractions are separately dried to 12% moisture in a flash dryer using hot air.

In the batter process, wheat flour is continuously discharged into a stream of warm water forming a slurry. The wheat flour slurry is homogenized in a high-speed in-line disintegrator. The homogenized slurry is separated into three fractions using hydrocyclone separators, which takes advantage of the higher density of starch granules compared to gluten particles. The first fraction is the heavy phase that contains A-starch. The second intermediate density fraction contains gluten and B-starch. Subsequently, the B-starch is washed out of the gluten by further centrifugation with hydrocyclones. The third fraction is the light phase that contains water-soluble compounds including proteins and pentosans.

The A-starch is further refined by washing with fresh clean water. Hydrocyclone separators are used to reduce fiber and soluble protein contents to low levels. Purified A-starch slurry is discharged to a centrifuge for dewatering. The dewatered starch is discharged by gravity to a moist starch hopper where it is conveyed into a flash dryer and dried to 12–13% in hot air. Dried starch is ready for storage or for bagging.

Rice

Rice (*Oryza sativa*) probably originated in India or southeastern Asia. Rice can be categorized into two subspecies, *O. sativa indica* and *O. sativa japonica*. Rice thrives in hot humid conditions, with 90% of world production grown in Asia. Rice is able to germinate and thrive in water. The rice plant is able to transport oxygen to the submerged roots from the leaves where oxygen is released during photosynthesis. The rice inflorescence is a loose terminal panicle of perfect flowers. At maturity, the panicle in different varieties may be enclosed in the sheath, partly enclosed in the sheath or fully exposed. Each panicle branch bears a number of spikelets. Rice has one flower spikelet laterally compressed and two short glumes. The rice grain is enclosed by the lemma and palea, which form the hull.

Rice has a 1000-kernel weight of 15–20 g. Rice, after the hull and bran have been removed, contains about 90% starch, 7–8% protein, 0.3–0.5% fat, and 0.2–0.5% fiber. Rice grain consists of a hull composed of lemma and palea (20%), bran layer (10), germ (2%), and endosperm (68%). Brown rice is rice where the hull has been removed but still has the bran layer. White or polished rice is rice where the bran layer has been removed. Endosperm cells contain very little protein matrix but are filled with amyloplasts that contain compound starch granules. Individual rice starch granules contain about 20% amylose and range in size from 3 to 8 μm and have smooth surface but angular and polygonal shape.

Starch is extracted from low-quality rice flour and from broken polished rice grains. Broken kernels are steeped in a warm alkali solution (0.3–0.5% sodium hydroxide) for 24 h and then wet-milled on a pin mill or hammer mill. The resulting ground material is soaked in an alkali solution for 10–24 h. The steeping temperature can range from room temperature to 50 °C. The long steeping time is necessary to remove protein from the starch. Rice protein in the endosperm is tightly associated to the surface of the starch granules and is difficult to remove. Sodium hydroxide is used because at least 80% of the protein in rice is glutelin, which is soluble in alkali solutions. Sometimes, *Bacillus megaterium* is added. *B. megaterium* produces proteases that break down rice protein. After storing the starch suspension for 10–24 h, the fiber is removed by passing the suspension through screens and starch is collected by centrifugation. The extracted starch is washed several times with water to remove impurities and residual sodium chloride. The purified starch is then dried, sifted, and packaged. Solubilized protein can be recovered by neutralization with hydrochloric acid or sulfur dioxide. The precipitate is allowed to settle and is recovered in filter presses or by centrifugation. Isolated protein is mostly used as an animal feed component.

Rice flour can be used in starch production. Flour is added to the alkali solution for 10–24 h, sieved to remove fiber, and centrifuged to collect starch, as described earlier. Starch is dried, reground, and packaged. Wet grinding is preferred to dry as starch damage is more extensive in dry milling. Damaged starch can dissolve in alkali solution.

Rice starch production is limited because of its relatively high product cost associated with long steeping/soaking time and intensive washing procedures needed to remove residual sodium chloride. Alkaline steeping step generates large quantities of alkali and salt, which increases cost for wastewater treatment.

Legume Starches

Pulses

Pulses are dried seeds from plants in the legume family that have relatively low oil content. Dry edible beans (*Phaseolus vulgaris*), dry peas (*Pisum sativum*), lentils (*Lentilla lens*), and chickpeas (*Cicer arietinum*) are the most common pulses. Pulses are cool season crops. Pulse seeds are borne in pods. Each pod contains several seeds. Pods are botanically a fruit, since they contain seeds developed from the ovary of a flower. Pulses can be a good starch source and provide unique functionality due in part on their crystalline structure and relatively high level of amylose (35–40%). Pulse starches generally have B-type x-ray diffraction pattern.

Dry pea is a common source of starch. Dry pea has a 1000-kernel weight of 125–300 g. Seed consists of a seed coat (8–10%), two cotyledons (88–90%), and embryo (1–2%). Dry pea contains about 40–45% starch, 20–27% protein,

1–2% fat, and 19–22% fiber. Cotyledon cells are densely packed with protein bodies and amyloplasts that contain simple starch granules. The total amylose content ranges from 33% to 48%. Starch granules range in size from 8 to 35 μm and are round to elliptical with smooth surfaces.

Dry pea starch can be extracted by dry milling or by wet milling process. Dry fractionation process involves removing the seed coat using a dehuller, followed by milling using a pin mill. The starch-rich and protein-rich fractions are separated based on particle size using an air classifier. Small particles are rich in protein, while large particles are rich in starch (about 65%). Dehulling is easier with peas and lentils than with dry beans.

Wet milling involves dehulling the dry peas, which are then ground using a hammer mill. Pea flour is mixed with a warm alkaline (sodium hydroxide, pH 9–10) solution for 1 h, during which the proteins and lipids are solubilized. The starch is removed by a decanter or ultrafiltration. The solubilized protein can then be precipitated by adjusting the solution pH to 4.5. The protein and starch are then dried in a drum drier. Starch purity is about 98%. Isolation of highly pure starch is difficult due to lipids and proteins associated with the starch and to the presence of highly hydrated fine fiber fraction, which is very difficult to remove from the starch granules.

Tuber and Root Starches

Root crops contain about two-thirds of their weight as water. This affects cost of transportation and shelf life before starch extraction.

Potato

Potato (*Solanum tuberosum*) originated in the Andes highlands of Peru and Bolivia. Potato is a cool season plant and is grown in cool climates found in northern Europe and northern United States. Potatoes form stolons. Stolons start to grow within 10 days of the plant emerging aboveground. Tubers form on the end of the stolon. Thus, a potato tuber is a modified stem, with branches forming from eyes or buds located on the tuber. The interior of the tuber has a pithy central core with branches leading to each bud or eye. Surrounding the pith are parenchyma cells that contain the amyloplasts where simple starch granules are formed. Potato starch has a smooth oval shape and granule size of 5–100 μm with median size of 30 μm. Potato starch granule contains about 20% amylose. The vascular cambium is located toward the outer edge of the tuber, followed by the cortex, suberin epidermis, and periderm. About 20% of a large sound tuber consists of the peel, which is composed of the periderm and part of the cortex. A whole potato consists of about 76% water, 20% starch, 2% protein, 0.2% fat, and 1% fiber. Starch content decreases with storage time.

Cull potatoes, which are those that are too small or large or misshapen or damaged, are used in potato starch production. First, soil and dirt are removed from the potatoes. Next, they are conveyed to a washing drum, which has a low amount of water so that the potatoes do not float. The potato peel is removed by abrasive action of the potatoes rubbing against each other while in the drum. The potatoes are rasped with a rotary saw blade or are sent through a hammer mill where the macerated potatoes are forced against a screen and the pulp passes through the holes. Sulfur dioxide is added to the extraction water to prevent discoloration that occurs once cells are exposed to air. The pulp is screened through a rotary sieve to separate free starch from the pulp. The pulp is often reground in a hammer mill using fine screen opening. Fiber and pulp are removed from starch by the centrifugal force inside a hydrocyclone. The fractionated starch is diluted with freshwater to remove soluble impurities and then concentrated in a continuous hydrocyclone separator. There may be several washings of the starch. The final washing is with freshwater and the starch is concentrated using rotating vacuum filters. The extracted starch is dried to 17–18% moisture in a flash dryer using moderately hot air. The dried starch is sifted and packaged.

Cassava

Cassava (*Manihot esculenta*) originated from tropical regions of Central and South America. Today, cassava is an important staple food crop in sub-Saharan Africa and is an important starch source in Thailand, Brazil, and Malaysia. Cassava typically grows as a perennial woody shrub well adapted to tropical regions and grows well under marginal conditions. Cassava produces a taproot and fibrous roots. Several of the fibrous roots and the taproot will become storage roots. Thus, cassava root is a true root. A cassava plant can produce 3–14 storage roots per plant. Storage roots are composed of periderm, cortex, storage parenchyma, and central xylem bundle. The phloem is located in the cortex. Periderm and cortex make up the peel. About 11–20% of fresh weight of storage root is peel. Storage parenchyma cells are filled with amyloplasts that contain simple starch granules that range from 5 to 25 μm and are truncated in shape. Cassava starch granules contain about 18–25% amylose. Typical composition of the storage root is 70% moisture, 24% starch, 2.2% protein, and 4.5% fiber. Starch in the storage roots can range in color from white to yellow depending on carotene content.

Processing facilities must be close to where the cassava is harvested. Cassava roots need to be processed within 24–48 h of harvest to prevent loss of starch from enzymatic oxidation and rot. Cassava begins to rot within 2 days of harvest. The fresh roots are washed, peeled, chopped, and pulverized in an industrial blender. After disintegration of the pulp, the slurry is washed on screens where the fiber remains and the starch slurry passes through. The fiber can be used as a fertilizer or pressed and dried for cattle feed.

After removing the fiber, crude starch slurry passes through a degritting screen to remove small nonstarch material. The starch slurry is separated into a heavy fraction and a light fraction by a hydrocyclone separator. The heavy fraction is starch and the light fraction contains fine fiber and soluble material. The starch is reslurried and recentrifuged for further purification. Purified starch slurry is dewatered in a continuous vacuum filter or batch-operated basket-type centrifuge. Moisture content of starch after dewatering step ranges from 32% to 45%. The dewatered starch is conveyed to hot air dryers and dried to 12–14%, cooled, and packaged.

Stem Starches

Sago palm

Sago palm (*Metroxylon sagu*) originated in the area extending from Moluccas of Indonesia to New Guinea. Sago palm is a tropical plant grown in Southeast Asia and Oceania where it is able to survive in swampy peat environment. Sago palm

produces an erect trunk about 10 m tall and 75 cm thick. Its vegetative phase lasts 7–15 years during which starch is stored in the trunk. At maturity, an enormous branched inflorescence develops at the top of the trunk. Starch reserves are at their maximum just before flowering and fruiting deplete these reserves. Sago palm dies after mature fruit fall from the tree. The trunk is composed of epidermis, cortex, and pith or conjunctive tissue. Pith contains vascular bundles and storage parenchyma cells. The storage parenchyma cells are packed with amyloplasts that contain simple starch granules that range from 20 to 60 μm and have oval or polygonal shape. Sago palm starch granules contain about 27% amylose. Pith contains 6–12% soluble solids and 79–88% starch and sugars.

Commercially, trees are harvested. The trunks are stripped of leaves and cut into 1 m segments for handling. The segments are split lengthwise and fed into slicers that slice the pith from the bark. Alternatively, the bark is removed from sections of the logs that are then fed into a mechanical rasper that rasps the pith into small pieces. The pith is fed into a hammer mill and discharged into water where a starch slurry is formed. Starch slurry is passed through a series of centrifugal sieves to separate the coarse fibers. The starch can be washed several times to improve purity. The purified starch is dewatered in a rotary vacuum drum dryer and dried with hot air. One palm trunk can yield 180–250 kg dw of sago starch.

Sago starch is known to vary in color from gray to white. It can be bleached with bisulfite but the starch still tends to discolor with prolonged storage. Mature palms are needed for the production of high-quality starch. Immature pith contains impurities, and starch made from it is of inferior quality and has a greater tendency for browning. Starch quality varies with its location in the trunk and growth conditions.

Starch Quality

Starch quality is based on its physical and functional properties. Physical properties include its purity, for example, amount of residual protein, lipid, and fiber and whiteness. Extraction conditions such as holding time and pH and temperature of slurry affect purity and discoloration of starch. Functional properties are generally associated with its pasting properties such as gelatinization temperature and its retrogradation characteristics. Functional properties can be affected by growth environment, genotype, and processing conditions. Steeping additives, for example, sulfur dioxide, lactic acid, and sodium hydroxide, can affect pasting properties by affecting the amount of starch damage and starch purity.

Physical and Chemical Modifications

Starch functionality in industrial and food systems is primarily related to its gelatinization, retrogradation, and pasting properties. Functionality of native starch varies with botanical source, amylopectin fine structure, and amylose–amylopectin ratio and granule size. Starch functionality can be changed through physical and chemical modifications. Physical modifications include pre-gelatinization, annealing, and heat–water treatment. Annealing is a physical reorganization of starch granules when heated in excess water at or below its glass transition temperature. Annealed starch retains its granular structure. Annealing optimizes crystalline order and increases rigidity of amorphous regions. Annealing results in reduced starch swelling, elevated starch gelatinization temperature, diminished gelatinization temperature range, and restricted amylose leaching. Heat–water treatment involves exposing starch with low moisture content (18–27%) to high temperature. The low moisture content limits molecular mobility and gelatinization during treatment. Starch that has been heat–water-treated will have an increased gelatinization temperature. Common chemical modifications involve anionic substitution (carboxymethyl, phosphate, and acetate), cationic substitution (quaternary ammonium), hydroxypropylation, oxidation, cross-linking chains, and depolymerization of chains.

Introduction

Starch is the second largest biomass produced on Earth, next to cellulose, and is synthesized in amyloplasts of higher plants for energy storage. Starch is a major energy source for human and animal diets and an important raw material for industrial applications. Starch granules consist of highly branched glucan, amylopectin, and, a primarily linear glucan, amylose. The amylopectin and amylose molecules are aligned radially in the semicrystalline starch granule. Native starch granules have specific densities around 1.5 g cm^{-3}. Because of the large density, the granular starch can be readily isolated from grains, tubers, roots, and stems by gravity using a wet milling process. The granular structure of starch also facilitates its chemical modifications, which can be washed to remove residues and by-products. Consequently, starch is produced as an economical commodity for food and industrial applications. Major markets of starch are in the corn syrup, paper, textile, food, and bioethanol industries.

The semicrystalline starch granules are not dispersible in water at ambient temperatures. After starch is cooked above its gelatinization temperature, the starch loses its crystalline structure and can then be dispersed to a paste in excess water with continuous heating and stirring. Depending on the composition and structure of starch, such as amylopectin branch chain length, and contents of amylose, lipids, and phosphate monoester derivatives, starch displays different properties. Chemical and physical structures of starch in food determine the enzymatic digestive rate of the starch after the food is ingested, which is reflected as the glycemic response. Prolonged consumption of starchy food with large glycemic index is known to cause insulin resistance, type-2 diabetes, obesity, and other metabolic syndrome. Ingesting of resistant starch (RS) that cannot be hydrolyzed by enzymes in the small intestine and is then passed to the colon, however, reduces the glycemic response and facilitates the growth of microbiota in the colon. Fermentation of the RS in the colon by microbiota can produce short-chain fatty acids to maintain colon health and prevent colon cancer.

This article aims to provide an overview on the composition and structures of starch molecules, morphology and internal structures of starch granules, functional properties of starch, and methods used to determine these characteristics. Other relevant publications, which provide in-depth discussions of the subjects covered in this article, are listed in section 'Further Reading' for information on starch structures and properties.

Composition, Structures, and Analysis of Starch Molecules

Normal starch consists of about 70–80% amylopectin and 20–30% amylose, waxy starch consists of mostly amylopectin and 0–8% amylose, and high-amylose starch consists of 40–90% amylose. In addition to amylose and amylopectin, most cereal normal starches also contain lipids, including phospholipids, which have significant impacts on the pasting, gelling, and digestive properties of the starch. Many tuber and root starches and some cereal starches have phosphate monoester derivatives. Some starches, such as high-amylose maize starch and *sugary-2* starch, contain intermediate component that has branched molecules, however, with smaller molecular weights and longer branch chain lengths than amylopectin. *Sugary-1* starch consists of phytoglycogen, a water-soluble glucan with a highly branched structure and substantially shorter branch chains. Structures of these components are discussed in the following sections.

Amylose

Amylose is a primarily linear molecule, consisting of mainly α-1–4 linked D-glucopyranose with a few α-1–6 branches. The molecular weight of amylose varies from degree of polymerization (DP) 500 in high-amylose maize starch to more than DP 6000 in potato starch. The number of branches increases with the molecular size of amylose.

The α-1–4 glycosidic bonds of amylose chains render a flexible random-coil conformation to the molecule. The presence of hydrophobic hydrocarbon groups and hydrophilic hydroxyl groups on the anhydroglucose units (AGU) prompts two adjacent amylose chains in the aqueous dispersion to fold together and form double-helical crystallites, resulting in the hydrocarbon groups of the AGU folded inside of the double helix, away from the aqueous medium to reach a lower energy state. This crystallization process of dispersed starch molecules taking place during storage of cooked starch is known as retrogradation. The retrograded amylose displays the B-type x-ray diffraction pattern (polymorph), having the amylose double helices packed in a hexagonal unit cell.

Amylose can also form single-helical complexes with many chemicals (complexing agents) that consist of a hydrophobic moiety, such as alcohols and fatty acids. The amylose single-helical complex, also known as an inclusion complex, has the hydrophobic moiety of the complexing agent located inside the hydrophobic cavity of the helix. Depending on the cross-sectional diameter of the complexing agent, amylose can form single helices of different sizes, including six, seven, and eight AGU/turn, to accommodate the diameters linear complexing agents (e.g., *n*-butyl alcohol), branched complexing agents, (e.g., isobutyl alcohol), and bulky ones (e.g., α-naphthol), respectively. The x-ray diffraction pattern of the amylose single-helical complexes is known as the V pattern.

Amylopectin

Amylopectin consists of α-1–4 linked D-glucopyranose linear chains that are connected by α-1–6 branch linkages, about 5%.

The molecule is highly branched and has a molecular size about DP 10^6. Branch chains of amylopectin molecules can be categorized into three groups: the A chain, with its reducing end attached to a B or C chain but not carrying any other chains; the B chain, not only having the reducing end attached to another B or C chain but also carrying other A or B chains; and the C chain, being the only chain of the molecule carrying a reducing end (Figure 1). The A chains are generally short and extend within one cluster. The B chains have different chain lengths, which can extend through one cluster (B1 chain), two clusters (B2 chain), three clusters (B3 chain), or more clusters. The branch chain-length distribution of amylopectin varies with the botanical origin of the starch, which determines the polymorphic form of the crystalline structure and the gelatinization, pasting, and retrogradation property of the starch. Specific properties of starch will be discussed in section 'Properties of Starch.'

Branch chains of amylopectin are arranged in clusters, which are evidenced by wormlike cluster structures remaining after exhaustive acid hydrolysis of granular waxy maize starch at room temperature, as viewed using transmission electron microscopy. The wormlike cluster is attributed to the crystalline structure of outer chains of amylopectin molecules. The amorphous structure of the waxy maize starch, mainly consisting of branch linkages, is hydrolyzed during the acid hydrolysis.

Starches that consist of amylopectin with larger proportions of long branch chains (e.g., B2 and B3 chains), such as potato, high-amylose maize, and *ae* waxy maize starches, display the B-type x-ray pattern. Starches that consist of amylopectin with more short branch chains of A and B1 chains, such as maize, wheat, taro, barley, and rice starches, display the A-type x-ray diffraction pattern, having a monoclinic unit-cell packing.

Extra-long branch chains are present in amylopectin of many cereal normal starches, such as normal wheat, rice, barley, and maize starches, but are not found in cereal waxy starch and potato starch. The extra-long branch chains have amylose-like structures. For example, the extra-long chains of wheat amylopectin have DP ~ 720, which contribute to larger blue values and iodine affinities of the amylopectin of normal wheat starch than that of the waxy wheat starch. The concentration of the extra-long branch chains of wheat amylopectin is positively correlated to the dosage of the waxy gene encoding granular-bound starch synthase that is primarily responsible for amylose biosynthesis.

Intermediate Component and Phytoglycogen

Intermediate component is found in starch of many mutants, including maize *ae* mutant and *sugary-2* mutant. The intermediate component has a branched structure, but its molecular weight is similar to amylose and its branch chain length is longer than amylopectin. After the starch is fractionated using a complexing agent, such as *n*-butyl alcohol, to complex and precipitate the amylose, the intermediate component remains in the supernatant with amylopectin. Gel permeation chromatograms of the mixture collected from the supernatant show that amylopectin is eluted first at the void volume and the intermediate component is eluted later. High-amylose maize starch consists of up to 52% intermediate component. The intermediate component together with amylose of the high-amylose starch forms double-helical crystallites, resulting in a conclusion gelatinization temperature (T_c) up to 130.0 °C. Consequently, the starch remains semicrystalline after cooking and has a large RS content (up to 40%).

Phytoglycogen is another water-soluble glucan, which is found in rice and maize *sugary-1* mutants that are deficient in the starch-debranching enzyme. Phytoglycogen has a smaller molecular weight and shorter branch chain length than amylopectin. The branch chains of the phytoglycogen display a

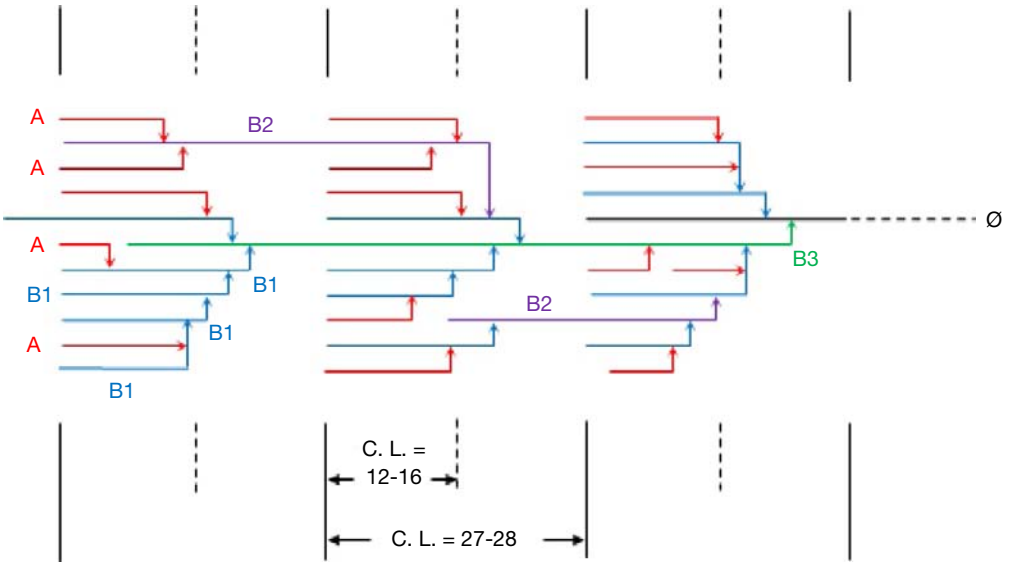

Figure 1 A proposed cluster model of amylopectin with A(–), B1(–), B2(–), and B3(–) chains. The chain carrying the reducing end (Ø) is the C chain. –, α-1–4 glucan chain; →, α-1–6 linkage; C.L., chain length. Reprinted from Hizukuri, S. (1986). Polymodal distribution of the chain lengths of amylopectins, and its significance. *Carbohydrate Research* **147**(2), 342–347.

single-modal chain-length distribution, which is different from the bimodal distribution of amylopectin.

Lipids and Phospholipids

Lipids and phospholipids are mainly found in cereal starches. Cereal normal starch contains up to 1% lipids, and the lipid content is positively correlated with the amylose content of starch. Starches of different botanical origins consist of different species of lipids. For example, normal maize starch consists of mainly free fatty acids, triglycerides, and little phospholipids; normal rice starch contains substantial amount of phospholipids and some free fatty acids; and wheat, barley, rye, and triticale starches consist of exclusively phospholipids. Substantial amount of amylose in normal starch is found in helical complexes with lipids, which were revealed by using solid ^{13}C cross polarization/magic angle spinning NMR. Cereal waxy starches contain little lipids, whereas high-amylose starches contain substantially more lipids. Root and tuber starches contain very little lipids and no detectable phospholipids.

Free fatty acids, monoglycerides, diglycerides, and phospholipids are good complexing agents with amylose and long branch chains of amylopectin. Differential scanning calorimetric (DSC) thermograms show dissociation peaks of the amylose–lipid complex (ALC) at 90 °C or higher. Unlike the retrogradation of starch, which is a slow process and normally takes days for the double helices to develop, the ALC formation is an instant reaction. The dissociation peak of the ALC reappears upon an immediate rescan of the starch sample using a DSC. The ALC present in native starch is amorphous (type 1), which does not give a V-type x-ray diffraction pattern and displays a dissociation peak at a lower temperature (90–100 °C). After cooking, the ALC is reorganized to a lamellar, semicrystalline structure (type 2), which displays a V-type x-ray diffraction pattern and shows a higher dissociation temperature (100–125 °C).

Phosphate Monoester Derivatives

Phosphate monoester derivatives are covalently attached to the amylopectin of potato starch and are also found in many other tuber and root starches. The phosphate groups carry negative charges, which repel one another and, thus, reduce the gelatinization and pasting temperatures and increase the viscosity and clarity of the starch paste. In the presence of salt, the viscosity of the potato starch paste reduces significantly because the negative charges of the phosphate are masked by cations of the salt.

Traditionally, phospholipid and phosphate monoester derivative contents of starch are analyzed by measuring the total phosphorus content after dry ashing of the starch. The method, however, relies on a complete removal of phospholipids by solvent extraction, which is difficult to achieve except by using a 90% dimethyl sulfoxide solution. ^{31}P-NMR spectroscopy has been demonstrated to give unambiguous results for qualitative and quantitative analyses of phospholipid and phosphate monoester contents of starch. Phospholipids, being phosphate diesters, have chemical shifts at 0–1 ppm, whereas phosphate monoesters have chemical shifts at 4–5 ppm at pH 8. Quantitative results can be obtained when adequate acquisition times are programmed to allow spin relaxation.

Structures of Starch Granules

Morphology of Starch Granules

Morphologies of starch granules isolated from different botanical sources and different organs of the plant are different. Images of some starch granules viewed using scanning electron microscopy are shown in Figure 2. Shapes of starch granules include spherical, oval, disk, polygonal, elongated, kidney, and lobe shapes. Starch isolated from leaves has flat and small granules. Starch from wheat, barley, and rye kernels in the triticale family displays bimodal granule-size distributions, the large disk-shaped A-granules, and the small spherical B-granules (Figure 2(g)). Rice and oat have compound starch, resulting from multiple granules being synthesized within a single amyloplast. High-amylose starch from maize and other sources consists of elongated starch granules, and some granule displays a rod shape that is 3 μm in diameter and 30 μm in length (Figure 3(A)). Diameters of common starch granules vary from submicrons to more than 100 μm. For example, the diameters of potato starch are 15–75 μm, wheat starch A-granules 18–33 μm and B-granules 2–5 μm, maize starch 5–20 μm, rice starch 3–8 μm, and amaranth starch 0.5–2 μm.

When viewed under a polarized light microscope, starch granules display birefringence, known as Maltese cross, which reflects the radial arrangement of starch molecules in the starch granule (Figure 2). The center of the Maltese cross, the hilum, is where the biosynthesis of the starch granule initiates. The hilum is not necessarily at the geometric center of the granule; some can be located close to one end of the granule, reflecting the initiating site of the starch biosynthesis (Figure 2(c), 2(f), and 2(h)). Elongated starch granules of high-amylose maize starch (Figure 3) display multiple hila and several Maltese crosses overlapping in a single granule (Figure 3(C) and 3(D)). Confocal laser scanning micrographs also show multiple granules in a single elongated granule (Figure 3(B)). Transmission electron micrographs of developing endosperm tissue reveal that the biosynthesis of the elongated granules is a result of an interaction between amylose molecules of adjacent starch granules initiated in the same amyloplast. The small granules are fused together and continuously synthesized to one elongated granule.

Internal Structures of Starch Granules

Starch of the A-type polymorph consists of amylopectin with large proportions of short branch chains, whereas that of the B-type polymorph consists of amylopectin with more long branch chains that extend through two or more clusters. Starch of the C-type polymorph has amylopectin with a combination of the A- and B-type structures. Because of the large proportion of short branch chains of the A-type polymorphic starch, the short double helices of the branch chains are arranged to a closely packed monoclinic unit cell, resulting in a porous internal structure (Figure 4(a1) and 4(b1)). On the contrary, the B-type starch granules, consisting of more B2 and B3 chains that extend through multiple clusters (Figure 1), maintain a

homogeneous internal structure (Figure 4(a2) and 4(b2)). The porous structure of the A-type polymorphic maize starch granules was first revealed using a nitrogen gas surface adsorption method, which has later been confirmed using a surface-gelatinized technique, and confocal laser scanning microscopy (Figure 4). The porous structure of the A-type starch granules prompts greater susceptibility of the granule to chemical penetration and enzymatic hydrolysis. The A-type starches, such as sorghum and maize starch, display pinholes on the surface of the starch granule, which are open ends of serpentine-like channels likely hydrolyzed by amylases and penetrating into the granule.

Relative locations of amylose and amylopectin molecules in the starch granule have been studied using chemical cross-linking reactions. Results of the cross-linked starch granules show that amylose molecules are primarily cross-linked to amylopectin molecules, an evidence that amylose is interspersed among amylopectin molecules. Amylose is more concentrated at the periphery of the granule than at the hilum as revealed by using the surface gelatinization of starch granules with saturated neutral salt solutions, such as LiCl and $CaCl_2$. This result is consistent with the fact that the amylose content of starch increases with increased size of the starch granule.

The large concentration of amylose at the periphery of starch granules renders a hard shell on the surface of normal starch granules, making it difficult for enzymatic hydrolysis. The hard shell is sometimes misinterpreted as a membrane. But it is known that starch chains on the surface of the starch granule can be elongated with the addition of ADP–glucose, which excludes the presence of a membrane on the surface of the granule. The apparent shell on the surface of starch granules, therefore, can be attributed to tightly associated amylose and amylopectin molecules. It is well known that amylose produces tough films.

Properties of Starch

Starch has versatile properties and applications. It can be used in a granular form for an anticaking agent or facial/baby

powder, a dispersed paste for thickening or sizing agents, a hydrogel structure for puddings or bread, and a crystalline structure (retrograded amylose) for RS (type 3) to improve health. These broad applications are the results of the transformation of starch from semicrystalline granules, to amorphous structures by losing the native crystalline order (gelatinization), to a paste after absorbing water and developing viscosity, to a gel after network formation, and to RS after recrystallization (Figure 5). The transformation and properties of starch are discussed in the following sections.

Starch Gelatinization

Native starch granules can absorb about 30% (w/w) moisture, when steeped in water at an ambient temperature. The water is distributed in the amorphous region of starch granules. When starch is heated to a specific temperature in the presence of water (two times or more), it loses the crystalline structure and the Maltese cross and becomes transparent. This thermal transition is known as gelatinization, and the temperature at which starch loses the crystalline structure is the gelatinization temperature. Gelatinization temperatures of selected A-, B-, and C-type polymorphic starch varieties are shown in Table 1. The gelatinization temperature is a characteristic property of each starch, and it is, in general, positively correlated with the branch chain length of the amylopectin. Phosphate monoester derivatives of starch, however, reduce the gelatinization temperature. For example, potato starch displays a much lower onset gelatinization temperature ($T_o = 58.2\,^{\circ}C$) than the normal maize and rice starches (64.1 °C and 70.3 °C, respectively), despite the fact that potato amylopectin has much longer branch chains than the normal maize and rice starches. This is a result of a high concentration (0.08%) of the phosphate derivatives of the potato starch. The repulsion between negative charges of the phosphate groups destabilizes the double-helical structure of potato starch and decreases the gelatinization temperature.

Starch gelatinization temperature can be determined by observing the loss of Maltese cross using a light microscope equipped with a polarizer and a hot stage, measuring the transparency of a starch suspension during heating, or using a DSC. The DSC can measure both the temperature and enthalpy change of starch gelatinization, which is an endothermic reaction. To obtain a consistent gelatinization temperature of starch, it needs to have at least two times (w/w) water. Without sufficient water, starch is gelatinized at a higher temperature with a broader temperature range. Without the presence of water or other plasticizers, starch will not gelatinize by heat but will be thermally decomposed at a temperature above 250 °C.

DSC thermograms of cereal normal starch show an additional thermal transition peak at temperatures above 90 °C, corresponding to the dissociation of ALC. Dissociation

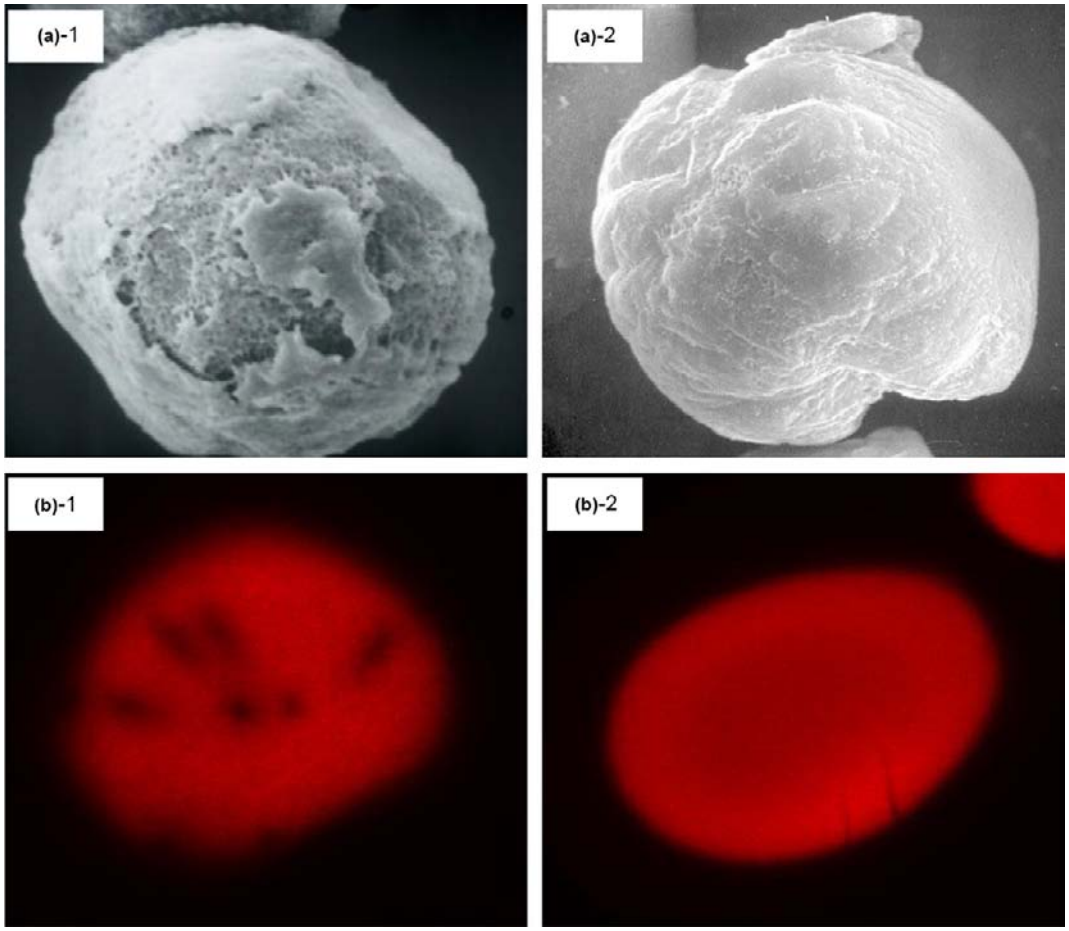

Figure 4 (a) Scanning electron microscopy (SEM) image of surface-gelatinized normal maize starch (1) and potato starch (2). The granules have about 65% surface starch removed. Figure 5 Transformation of starch structures.

temperature of the ALC, in general, increases with increasing chain length of the fatty acid and decreases with an increasing number of double bonds. Among the unsaturated fatty acids, the fatty acids with *trans*-double bonds form ALC with a higher dissociation temperature than those with *cis*-double bonds.

Starch gelatinization can also be achieved by using chemical solutions, such as aqueous alkaline solutions (e.g., NaOH and KOH), dimethyl sulfoxide, and various neutral salt solutions (e.g., KI, KSCN, $CaCl_2$, and LiCl). Aqueous solutions of NaOH and KOH (0.5 M or higher) and dimethyl sulfoxide (90%) are commonly used to gelatinize and disperse starch. A concentrated sodium sulfate solution, however, can be used to increase the gelatinization temperature of starch.

Pasting Property

When gelatinized starch is continuously heated in excess water with shearing, starch granules swell to develop viscosity and some starch molecules are dispersed in the aqueous medium (Figure 5). The viscosity development in this process is known

as the pasting property. Pasting property of starch is very important for many applications of starch, such as for thickening agents and sizing agents, and different starch varieties display different viscosities and pasting temperatures. Pasting property of starch is commonly measured using an amylograph, such as Brabender amylograph, and Rapid Visco Analyzer (RVA).

Pasting properties of common starches analyzed using an RVA are summarized in Table 2. Amylopectin is primarily responsible for the swelling power of starch granules and

viscosity. Amylose molecules, particularly with the presence of lipids, tend to restrict the swelling of granules. Consequently, normal maize starch that has 29.4% amylose and around 1% lipids shows a higher pasting temperature (82.0 °C) and a lower peak viscosity (152 rapid visco units, RVU) than its waxy counterpart (0% amylose, 69.5 °C and 205 RVU, respectively). Amylose molecules, however, are responsible for increasing the setback viscosity upon cooling of the starch paste, resulting from the network formation between amylose and amylopectin molecules. For example, normal maize starch has a setback viscosity of 74 RVU, which is larger than the waxy maize starch, 16 RVU.

ALC formed in starch granules renders entanglements between amylose and amylopectin molecules and restricts the swelling of granules during cooking. Consequently, it increases the pasting temperatures, decreases the pasting viscosities, and results in an opaque appearance of the starch paste. Among all the cereal normal starches, wheat and barley starches display the highest pasting temperatures and the lowest peak viscosities (Table 2) because both have high concentrations of phospholipids, which are readily available for the complex formation. After removal of endogenous lipids using detergents (e.g., sodium dodecyl sulfate), wheat starch shows a pasting temperature and peak viscosity similar to tapioca starch. In contrast, potato starch has a remarkably low pasting temperature (63.5 °C) and great peak viscosity (702 RVU) (Table 2), resulting from its large content of phosphate monoester derivatives. Repulsion between the negative charges of the phosphate monoester groups enhances the swelling of starch granules and increases the peak viscosity and clarity of the paste. The large granule size of the potato starch with a diameter up to 75 μm (Figure 2) also contributes to the great peak viscosity.

Gel Formation

After cooling and storing a paste of 5–15% starch, swollen starch granules in the paste fill up the volume, deform one another, adhered by amylose leached out from the swollen granules, and hold the shape of the mold to form a gel (Figure 5). To maintain the volume of swollen starch granules, amylose and amylopectin molecules must interact with one another to form a network to hold water in the swollen granules. Cereal normal starches, such as normal maize, wheat, and rice starches, are known to retain rigid swollen granules and form strong gels. Waxy starch, normal potato starch, and tapioca starch tend to freely swell and disperse after cooking because of the lack of amylose or lipids to facilitate stable interactions between amylose and amylopectin in the granules. Consequently, those starches cannot form gels. After being thoroughly mixed with lipids, including soy lecithin, oleic acid, and linoleic acid, before cooking, the mixtures of tapioca starch and lipid can develop gels. This result suggests that the formation of ALC facilitates molecular interactions in the starch granules, which restrict the swelling and maintain the integrity of swollen granules for the gel development. Potato starch granules with a prior heat-and-moisture treatment or chemical cross-linking can also develop a gel. Starch gels are formed by storing starch pastes at a refrigeration temperature for a selected period of time, and gel strength can be measured using a texture analyzer.

Starch Retrogradation/Syneresis

After prolonged storage, amorphous starch molecules in the aqueous medium form double-helical crystalline structures and lose their water-binding capacity (Figure 5). This process is known as starch retrogradation, as shown in staled bread and syneresis of gravy. The rate of starch retrogradation can be increased by increasing the concentration of starch in the paste, storing the starch paste at 0–5 °C, increasing amylose (linear molecule) content, having chain length of DP 80–100, and increasing the branch chain length of amylopectin. Cereal normal starch in a paste or a gel tends to retrograde faster than tuber and root starches because of the limited swelling of starch granules. Molecules of cereal normal starch are located in close proximity within the swollen granules, which facilitate the retrogradation.

Chemical derivatives of starch, such as acetyl and hydroxypropyl groups, retard starch retrogradation. When the starch paste or gel is stored below the glass-transition temperature (T_g), the starch retrogradation is retarded because of the lack of molecular mobility. Addition of complexing agents, such as monoglycerides, to bread making can reduce the retrogradation rate of the bread because of the single-helical complex formed with the monoglycerides. When the hydrophobic sides of starch molecules are bound with the complexing agent, it retards the double-helical formation.

Starch Digestibility

Starch, a major energy source, can be hydrolyzed by amylolytic enzymes to generate glucose to support lives of plants, animals, and humans. Starch granules have semicrystalline structures and are less readily hydrolyzed by enzymes. After starch is gelatinized and becomes amorphous, starch molecules can be hydrolyzed quickly.

The enzymatic digestive rate of granular starch is determined by factors including polymorphism/amylopectin structure, amylose content, and size of starch granules. Starch granules with the A-type polymorphs (e.g., normal wheat, rice, and maize starches) are hydrolyzed much faster than those of the B-type (e.g., potato and high-amylose maize starches). Starch with the C-type polymorph (e.g., green banana starch) displays a hydrolysis rate in between (Figure 6). The greater hydrolysis rate of the A-type starch is attributed to the large proportions of short branch chains of the amylopectin (DP 6–12) and the porous structure of the granule (Figure 4). For starch granules with the same type of polymorph, the enzymatic hydrolysis rate decreases with increased amylose content; for example, waxy starches are hydrolyzed fast, whereas high-amylose barley starch and mung bean starch are hydrolyzed more slowly (Figure 6). This could be the result of amylose restricting the swelling of the starch granules and concentrating at the periphery to form a hard shell, which reduces the accessibility of starch granules to enzymatic hydrolysis. Small-granule starches, such as amaranth and rice starches, are more susceptible to enzymatic hydrolysis (Figure 6) because they have a larger relative surface area.

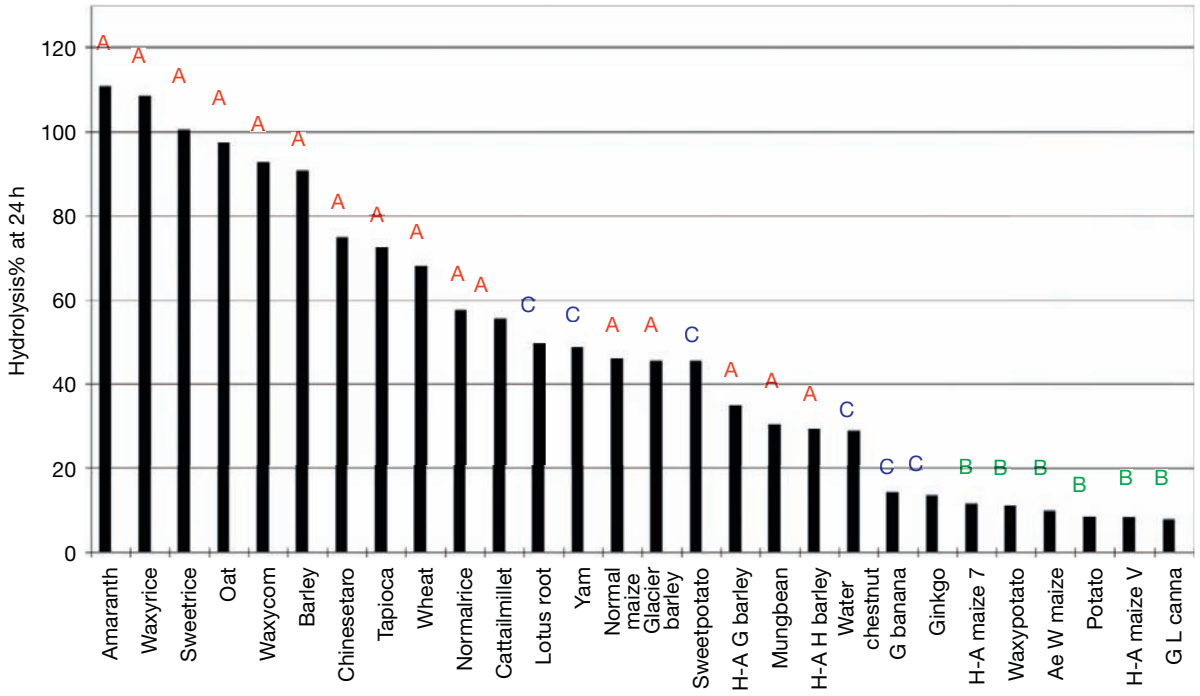

Figure 6 Percentages enzymatic hydrolysis of starches with different polymorphic structures. Porcine pancreatic α-amylase (120 U/20 mg starch in 9 ml phosphate buffer, pH 6.9) was used to hydrolyze starch at 37 °C for 24 h. The percentage enzymatic hydrolysis was determined by measuring the total carbohydrate content in the supernatant using a phenol–sulfuric acid method. The letter above each bar indicates the x-ray diffraction pattern of the starch. Reprinted from Jane, J., Aol, Z., Duvick, S. A., Wiklund, M., Yoo, S. -H., Wong, K. -S., and Gardner C. (2003). Structures of amylopectin and starch granules: how are they synthesized? *Journal of Applied Glycoscience* **50**, 167–172.

The digestive rate of starch in a diet is measured as the glycemic response, which determines the blood glucose concentration. A consistently high blood glucose concentration can cause insulin resistance and type-2 diabetes. The enzymatic hydrolysis rate of starch in a diet is determined by factors including the presence of retrograded starch, chemical derivatives of the starch, formation of ALC, and presence of cellulosic materials and the protein matrix. Retrograded starch is resistant to enzymatic hydrolysis. Chemically modified starch (e.g., cross-linked and octenyl succinic starch) is less hydrolyzable. Lamellar crystallites of ALC are protected from enzymatic hydrolysis. The ALC can also restrict the swelling of gelatinized starch and reduce the enzymatic hydrolysis rate of the starch. Type 5 resistant starch (RS5) is made by complexing high-amylose maize starch with free fatty acids. After human subjects were fed with bread made with 60% of the RS5, it significantly reduced postprandial glucose concentration (55%) and the insulin response (43%) compared with 100% for human subjects fed with white bread.

DSC thermograms and x-ray diffraction studies show no complex formation between amylose and triglycerides, a major component of lipids in foods. Enzymatic hydrolyses of normal- and high-amylose starch cooked with corn oil (triglycerides), however, show substantial decreases in the hydrolysis rate of the starch. The effect is not observed with waxy maize starch. ^{13}C-NMR spectra confirm the formation of the amylose helical complex between amylose and corn oil. Cooking rice with corn oil to prepare fried rice and rice pilaf decreases the starch hydrolysis rate. Surrounding of starch by cellulosic materials and protein matrix also reduces its susceptibility to enzymatic hydrolysis.

Introduction

Nicolas Appert and Louis Pasteur provided the basis for thermal food processing in the nineteenth century, and more than 200 years later, heat processing remains as a reference for food preservation. According to the FDA 'Guidance for Industry: Acidified Foods,' the definition of 'commercial sterility' stands for the condition achieved by "the application of heat which renders the food free of microorganisms capable of reproducing in the food under normal nonrefrigerated conditions of storage and distribution and free of viable microorganisms (including spores) of public health significance." Nonthermal food-processing technologies have become popular during the past 25 years, but most of them need further improvements to be considered at an industrial scale. Even widely accepted novel food technologies such as high-pressure processing lack the broad kinetic databases or standardized procedures developed for thermal food processing, particularly for the canning industry. Most of the theoretical basis for current research and industrial thermal processing design of 'sterile' food products was proposed in the beginning of the twentieth century, remaining as an important guideline for any food engineer.

The first step in the thermal process design is to define the objective. Process objectives are set by prioritizing the effects of a pathogen on human health and the possibility of causing a food-borne disease outbreak. If pathogens are not likely to be present as in the case of most acid foods (pH < 4.5), the processing objective is now defined to control the growth of spoilage microorganisms and enzyme activity or to avoid nutrient degradation or sensorial quality losses. Usually, the objective is defined in terms of the desired number of microbial, enzyme, nutrient, or quality factor decimal reductions (SV). Once the processing objective is defined, kinetic mathematical models are developed to determine the degradation rate of the microorganism, enzyme, nutrient, or quality factor at different temperatures. Temperature evolution of the sample and the heating media must be also analyzed, since variations occur due to the diversity of intrinsic thermodynamic and geometric features of food products and containers. Finally, all the kinetic model and temperature evolution information is analyzed using standardized charts, tabulated data, and/or mathematical procedures developed during the past 100 years to establish the necessary operating conditions to achieve commercial food sterilization. Mastering such an important task requires an in-depth analysis of kinetics, thermodynamics, and transport phenomena, and only the most fundamental aspects to analyze and develop commercial food sterilization processes are briefly presented in this contribution.

Microbial Inactivation Kinetic Models

First-Order Kinetics

The first-order microbial inactivation kinetics states that the change of the microbial population (N) as a function of time (t) at constant temperature is directly proportional to a kinetic rate constant k (eqn [1]). The first-order kinetic model is obtained by integrating from $t=0$ to treatment time t and from $N(t=0)=N_0$ to the microbial population at $N(t)$. The first-order kinetic model can be further modified by changing the Napierian logarithm to a $\log_{10}$ base to report the decimal reductions of a microorganism (eqn [2]). This way, the decimal

reduction time (D_T) is defined as the time required to reduce one-tenth of the microbial population at a constant lethal temperature (eqn [3]). The magnitude of the decimal reduction time determines the thermoresistance of a particular microorganism – the higher the value of D_T, the longer the duration of the heat treatment required to inactivate the microbial population:

$$\frac{dN}{dt} = -kN \quad [1]$$

$$\log_{10}\frac{N}{N_0} = -\frac{k}{2.303}t \quad [2]$$

$$D_T = \frac{2.303}{k} \quad [3]$$

The parameter D_T widely varies among different media, microorganism properties (physiological state, strain, etc.), and the selected processing temperature. Parameters k and D_T are not exclusive for microbial inactivation kinetics and may also be used to describe enzyme inactivation or chemical compound degradation kinetics. Therefore, the processing time (F_T) at a constant temperature required to achieve a defined objective can be found by multiplying the desired number of decimal reductions (SV) by the decimal reduction time (D_T) at a constant temperature (eqn [4]). Twelve decimal reductions (SV = 12D) of *Clostridium botulinum* spores are typically required by agencies validating the food sterilization processes. The main concern about *C. botulinum* is the production of the botulinum toxin that causes severe nerve paralysis that may result in death. *C. botulinum* is commonly found in soil and is capable of germinating in low-acid foods (pH > 4.6). These 12D reductions were set by defining the survival probability of *C. botulinum spores* as 1 spore in 1000 billion containers (10^{12}) and have remained a standard for the canning industry:

$$F_T = SV \cdot D_T \quad [4]$$

Temperature Dependence of Microbial Inactivation Kinetic Parameters

Bigelow established the term 'thermal death time' (D) to describe the amount of time to inactivate the microbial population at a constant temperature and pH. The author was also the first to observe the linear dependence of the thermal death time logarithm with the process temperature (Figure 1). The negative inverse slope of this plot, parameter z_T, is the temperature change required to increase or decrease the decimal reduction time by 10 (eqn [5]):

$$\log_{10}\frac{D}{D_{ref}} = -\frac{T - T_{ref}}{z_T} \quad [5]$$

The reference temperature (T_{ref}) for heat sterilization of low-acid foods is usually set as 121.1 °C (250 °F), since it is the minimum temperature level to eliminate *C. botulinum* spores in most media. These reference conditions usually prevail even if *C. botulinum* spores are not present in the media, reflecting the concern on the possible severe adverse health effects caused by the pathogen. The subscript of both the decimal reduction time and thermal processing time is set as

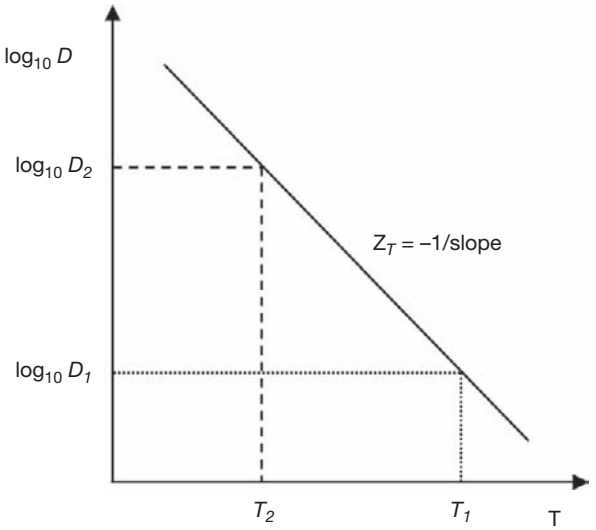

Figure 1 Graphical representation of the thermal resistance constant (z_T).

subscript zero (*0*), to denote that the kinetic parameters were obtained at the reference temperature level (D_0, F_0). Nevertheless, not all food products are able to withstand a thermal process at such high temperature levels, but regulations stood that *C. botulinum* spore destruction should remain as a reference. As a result, food scientists defined the lethality of a thermal process (L, eqn [6]) as the processing time at a temperature level T required to yield the same lethality (microbial decimal reductions) as a 1 min heat treatment at 121.1 °C (250 °F) as shown in Table 1. The *C. botulinum* spores are not capable of surviving at pH < 4.6, for which the biggest concern of thermal processing of medium- or high-acidity foods focuses on microorganisms that are known for food spoilage:

$$L = \frac{F_T}{F_0} = \frac{SV \cdot D_T}{SV \cdot D_0} = 10^{\left(-\frac{T - T_0}{z_T}\right)} \quad [6]$$

Industrial Food Design

General Method

The desired temperature level is not instantaneously reached during heating nor immediately brought back to room temperature on the subsequent cooling cycle. Thus, the complete temperature–time history must be considered when addressing microbial inactivation kinetics to avoid under- or over-processing of foods. Bigelow figured out that the area below the curve of the lethality versus process time plot corresponded to the F value considering the heating and cooling cycles (Figure 2), which can alternatively be represented as the integral shown in eqn [8]. In this case, F values are reported with a superscript related to the thermal resistance (z_T) of the target microorganism, enzyme, or chemical compound and a subscript indicating the temperature level used as a reference to yield a process with equivalent lethality. This procedure was later known as the 'general method' since the calculation applies for any type or shape of either the food product or

Table 1 FDA thermal-resistant data for bacteria in the heat processing of foods

Class of food	*Type of microorganism*	*Microorganism*	*Reference temperature (°F)*	D_T *(min)*	z_T *(°F)*
Low-acid food (pH > 4.6)	Thermophiles	Flat-sour group (*Bacillus stearothermophilus*)	250	4.0–5.0	14–22
	Mesophiles (spores)	Putrefactive anaerobes (*C. botulinum* types A and B)	250	0.10–0.20	14–18
		Clostridium sporogenes group (including P.A. 3679)	250	0.10–1.50	14–18
Acid food and acidified food (pH 4.0–4.6)	Thermophiles (spores)	*Bacillus coagulans* (facultative mesophilic)	250	0.01–0.07	14–18
	Mesophiles (spores)	*Bacillus polymyxa* and *Bacillus macerans*	212	0.10–0.50	12–16
		Butyric anaerobes (*Clostridium pasteurianum*)	212	0.10–0.50	12–16
		Bacillus licheniformis	200	4.5	27
Acid food and acidified food (pH < 4.0)	Yeasts, molds, and mesophilic nonspore-bearing bacteria	*Lactobacillus* species, *Leuconostoc* species	150	0.50–1.00	8–10

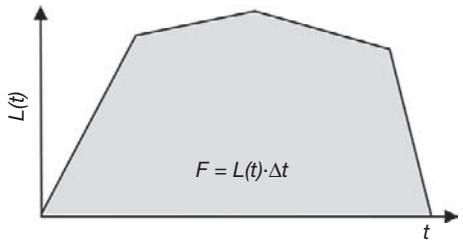

Figure 2 Calculating a heat process lethality with the general method.

container. The only requirements for the 'general method' consist in the knowledge of the temperature profile of the food product and the kinetic values (D_T and z_T) for the microbial, enzyme, nutrient, or quality factor used to design the thermal process. The area under the curve is integrated, and the temperature–time history is modified until it meets the specified F, increasing or reducing the process time. Nevertheless, this main advantage also results in an important drawback, since the predictions will only be available for the currently used temperature profile. If the heat treatment conditions or food or container properties are changed, a new temperature–time profile of the food product must be obtained, and the integration optimized to meet the new processing objectives. Heat processing times vary depending on the type of food and the container size shown for F_0 values ranging from 2 to 15 min (Table 2):

$$F_0^{z_T} = \int_0^t 10^{\frac{T(t)-T_0}{z_T}} dt \qquad [7]$$

Formula Method

The lack of computational tools during the development of the 'general method' made the application of this procedure a laborious, unpractical task for thermal food process design. Colin O. Ball and collaborators partially solved the issue by providing a set of formulas based on experimental data of the unsteady-state heat transfer between the can and the water vapor heating fluid. The formula method is useful in determining a thermal process effectivity using heat penetration data or by defining the correct temperature–time conditions to achieve a certain lethal value F_0.

Table 2 Calculated sterilizing values (F_0) for some current commercial processes according to the American Can Company

Product	*Can sizes*	*Approximated calculated sterilizing value,* F_0 *(min)*

Sausage, Vienna, in brine	Various	5
Chili con carne	Various	6

The heating process is first split into the heating and cooling cycles, and the F_i value given in eqn [9] is expressed as in eqns [9] and [10], going from $t = 0$ to the time in which the heating step is finished ($t = B$) and subsequently cooled down until the food product is at room temperature for $t = t_c$:

$$F_i = F_H + F_C \qquad [8]$$

$$F_i = \int_0^B 10^{[T(t)-T_0]/z_T} + \int_B^{t_C} 10^{[T(t)-T_0]/z_T} \qquad [9]$$

Ball's formula method states that microorganisms have a greater chance of surviving at the region in which the food product has the lowest temperature, which is frequently specified to be located at the center of the food product. Ball assumed that the temperature difference between the retort or heating media temperature (T_R) and the center of the container decays exponentially as a function of time. However, the

assumption where the coldest spot is located in the center of the food product is only true for solid foods with a high thermal conductivity for which heat is only transferred by conduction. In the case of liquid foods, heat is mostly transferred through convection mechanisms that generate fluid flow within the container. Thus, the coldest spot of the food product is not necessarily constant, but may be found near the bottom of the can container.

The semilog plot of the temperature profile in the coldest spot against time will yield fairly straight curves that can be approximated with a linear model (eqn [10]; **Figure 3**). Most parameters of eqn [10] can be obtained with the temperature profile shown in **Figure 3**. The plot shown in **Figure 3** may be constructed with the recorded logarithm of the can temperature on the left y-axis (T_{can}; °F or °C), the logarithm difference of the retort heating medium temperature, and the temperature of the coldest point on the right y-axis ($\log_{10}(T_{retort} - T_{can})$), against the heating time on the x-axis (t_h). The temperature profile is not linear at the beginning of the heating curve, but in most cases, a straight line can be drawn across the majority of the experimental data (**Figure 3**). Parameter (f_h) is of significant importance, since it establishes the time required to cover one log cycle of the straight line drawn across the $\log_{10}(T_{retort} - T_{can})$ data (**Figure 3**). Parameter I_h is defined as the difference between the heating medium and the initial product temperature (T_i; eqn [9]), whereas g_h (eqn [10]) corresponds to the temperature difference between the heating medium and the maximum temperature recorded in the coldest point of the can during the heating cycle (T_{max}). The last parameter of Ball's formula method (j_h) corresponds to a correction factor for the initial nonlinear part of the heating curve. The food product temperature does not instantaneously meet the heating media temperature of the retort, and the time interval in which the heating medium temperature rises from ambient temperature to the desired retort operation condition is known as the come-up time (CUT). In practice, it is considered that only 40% of the value of CUT has a lethality, equivalent to the one it would have if the heating medium temperature process instantaneously reaches lethal temperature levels. If CUT = 3 min, only the heat penetration data beyond 60% of the CUT (0.6 (3 min) = 1.8 min) is considered to be lethal. Therefore, the pseudo-initial temperature (T_{ie}) used to calculate j_h (eqn [12]) can be found by extrapolating the linear portion of the $\log_{10} T_{can}$ curve to $t = 1.8$ min (**Figure 3**), the time at which the heating process is considered to begin its lethality:

$$t_h = f_h \log\left(\frac{j_h I_h}{g}\right) \quad [10]$$

$$I_h = T_R - T_i \quad [11]$$

$$g_h = T_R - T_{can} \quad [12]$$

$$j_h = \frac{T_R - T_{ie}}{T_R - T_i} \quad [13]$$

The lethality factor F_i for the current sterilization process is compared with the lethality factor established under the previously defined temperature and time reference conditions (F_0), to determine its equivalent microbial inactivation through parameter U (eqn [14]). Therefore, parameter U corresponds to the F value at the heating media temperature of the current heat sterilization process:

$$U = F_0 \cdot F_i = F_0 10^{(T_{ref} - T_R)/z_T} \quad [14]$$

Improvements on Ball's formula method. All parameters of Ball's formula method may be calculated from the heat penetration curves except for g_h, since it may be difficult to determine at first glance the maximum temperature the food product must meet to achieve the desired sterilization level. Stumbo and Hayakawa generated charts and tables reporting with different f_h/U, j_h combinations that have been created to quickly calculate $\log_{10} g_h$. Stumbo overcame some of the limitations of Ball's formula method by covering a wider range of microbial thermal resistance parameter (z_T) and heat penetration data (parameter j_h) to determine the g_h value while

200	20.8	6.7	27.1	9.10	32.7	12.1

assuming that the heating and cooling curves remain equivalent. Stumbo calculated the lethality of heat processing for 57 tables containing 18 513 datasets, some of which are exemplified in Table 3. Linear interpolation is a common practice to determine a process lethality not listed in similar tabular data, although error might be introduced in the results due to the rounding of numbers during the calculations. Similarly, parameter g_h can be estimated through plots of factors f_h/U for different j_h values (data not shown).

The original formula method considered the lethality effects of the heating process equal to those of the cooling stage. Furthermore, the formula method was improved by calculating the lethality of the heating and cooling stages separately. Thus, a similar temperature history plot is developed for the cooling cycle, where T_c stands for the cooling media temperature, and the rest of Ball's formula method calculations remain almost the same, with the subindex changing from 'h' to 'c' as in cooling. Once more, a straight line is drawn trying to match most of the $\log_{10}(T - T_c)$ data. The main differences in Ball's formula parameter estimation relate to the initial nonlinear portion of the $\log_{10}(T - T_c)$, since the initial temperature of the cooling cycle corresponds to T_{max}, when the sterilization process has its maximum lethality. Consequently, the hypothesized cooling cycle initial temperature (T_{ie}) is now associated to the intercept of the straight line with the y-axis at $t_c = 0$. After the analysis of the heating and cooling cycles, their corresponding lethal times (F_H and F_C, respectively) are added to calculate the total operating time (F_i; eqn [8] and [9]). Hayakawa made a similar contribution as Stumbo, but tabulated the lethality factors for the heating and cooling cycles separately. Therefore, according to the method proposed by Hayakawa, $f_h \neq f_c$. An additional contribution made by Hayakawa is the simplification of temperature profiles by fragmenting the heating and cooling curves into several linear portions for which the lethality is more easily calculated. Canning industry experts suggest that the general method is more accurate, but Ball's formula method remains as the most popular choice mainly because of its simplicity and quickness.

Concerns of Current Practices for Industrial Food Process Design

Historically, Bigelow's kinetic model based on the D_T and z_T may be the most extensively recognized model in food microbiology. It continues to be used for industrial food process design and remains as a *must* cover topic in conferences and food science courses since it was proposed in the 1920s. However, the first-order kinetic model (eqn [2]) assumes a homogenous microbial population that proportionally reduced for equal time intervals, which is rarely true.

Several nonlinear models have been proposed, among which the cumulative form of the Weibull distribution is one of the most popular, reliable, and easy to use ($G(t)$; eqn [15]). The Weibull model has been employed in other engineering areas to predict the failure time of mechanical or electrical systems. In the case of microbial inactivation kinetics, the Weibull model adapts and determines the time at which the microorganism cells will fail to survive as a result of the applied stress conditions (eqn [16]). Parameter b' determines the rate at which the microorganisms decrease as in the case of the inactivation rate constant of the first-order kinetic model (k). The exponent (n; eqn [16]) reflects the resistance of the microbial population; for $n < 1$, the microbial survival curve shows 'tail formation' (downward concavity) indicating that the microorganisms are resistant to the current processing conditions. Conversely, when $n > 1$, the inactivation curve shows upward concavity suggesting that the accumulated damage makes the microorganisms susceptible to the treatment. If $n = 1$, eqn [16] transforms into the first-order kinetic model indicating a homogeneous inactivation for the microbial population. As in the case of the first-order kinetic model, an equivalent of the decimal reduction time (δ) can be developed as in eqn [17]:

$$G(t) = -\left(\frac{t}{\beta}\right)^{\alpha} \qquad [15]$$

$$\log_{10}\frac{N}{N_0} = -\frac{1}{2.303}\left(\frac{t}{b}\right)^{n};$$

$$b' = \frac{1}{2.303}\left(\frac{1}{b}\right)^{n}; \quad \log_{10}\frac{N}{N_0} = -b' t^{n} \qquad [16]$$

$$\log_{10}\frac{0.1N_0}{N_0} = -1 = -b' \cdot t^{n} \qquad [17]$$

$$\delta = \left(\frac{1}{b'}\right)^{n} = D \qquad [18]$$

Additionally, the linear temperature dependence of $\log_{10} D_T$ is usually seen for narrow temperature intervals. The 12D reductions were set by defining the survival probability of *C. botulinum spores* as 1 spore in 100 billion cans (10^{-12}), but food products

often show traces of spoilage at much lower concentration ($\approx 10^3 - 10^6$ cfu ml^{-1}) of any type of microorganism. The former results in data extrapolation of microbial kinetics that are also assumed to be 'linear' and the incorrect prediction of operating times. Consequently, food scientists and engineers opt to overprocess the food products by indiscriminately elevating the temperature or extending the duration of the treatment, severely affecting the sensorial and nutrimental properties.

Final Remarks

Preservation technologies will continue to play an important role in preserving food as the world population continues to grow. Despite the emergence of alternative nonthermal food technologies, thermal food processing will continue to remain as a standard for industrial needs. The challenge related to thermal food processing include the use of alternative, more environmentally friendly packages. The availability of scientific computational software and the advances in computer science also facilitate the use of more intensive calculation algorithms to enhance the extents of current kinetic, thermophysical, and transport phenomena modeling and to better comprehend these phenomena on foods.

Storage Stability: Mechanisms of Degradation

B Chen, Southwest University, Chongqing, China

© 2016 Elsevier Ltd. All rights reserved.

Background

Food products start to degrade as soon as they enter into the food chain, with the exception of certain dry seeds. The undesirable degradation of foods renders them unacceptable to the consumers due to safety and quality issues. The stability of foods during storage, either fresh or processed, is determined by their degradation rate, which is highly associated with the underlying physical, biological, and chemical causes. Unraveling the corresponding degradation mechanisms could help the food industry in finding effective means to protect food products and to extend their shelf life. Generally, this task is complicated by the large variety of existing food products and their different constituents. As an example, the storage stability of cake is affected by numerous factors, such as microbial spoilage (e.g., development of molds), crumb staling (dryness and other sensory defects), rancidity and other off-flavor development, crystallization of sugars (e.g., grittiness in cream fillings), syneresis of jams and jellies, chocolate bloom, structural weakness, color fade and change, and moisture migration and loss. Such factors are, in their turn, a function of the prevailing process parameters, determining the rate and intensity of the physical, biological, and chemical degradation mechanisms, which are described in this article.

Mechanisms of Physical Degradation

Physical changes include, for instance, softening or toughening, loss of solubility, loss of water holding capacity, wetting, lumpiness, or agglomeration, all of which mainly correspond to water migration and physical damage. Physical change itself results in undesirable textural or appearance changes of food products.

Water Migration and Loss

Water migration and loss, either appearing within the foods (such as staling) or via exchange with the environment (influx or drying), is the major physical mechanism affecting food quality and storage stability. It may result in hardness or in the development of a rubbery soft, spongy, or flabby character of foods, which have a negative effect on consumer acceptance.

Fresh foods, such as leafy vegetables, wither and soften during storage because of the changes in tissue tension upon water loss and turgor pressure, which leads to an increase in the ease of cell separation in many nonlignified tissues. The softening of acidic fruit tissues during heating has been ascribed to acid hydrolysis of cell wall polysaccharides. High-temperature heating of fruit and vegetable tissues causes an initial loss of instrumental firmness due to the fatal disruption of the cell membrane and an associated loss of turgor pressure. Such thermally induced disruption of the cell membrane in fruits and vegetable is linked to the β-eliminative degradation of pectin polysaccharides involved in cell adhesion. The latter degradation process is strongly influenced by pH and is enhanced considerably under increasing alkaline conditions. It is also strongly influenced by ions and organic acids, for example, Ca^{2+}, Mg^{2+}, K^{+} ions, citrate, malate, and phytate. Besides, thermal treatment of fruit and vegetable tissue is often accompanied by wall swelling. This may be due to the thermal degradation of polymers that laterally stabilize the wall, facilitating disruption of the cell membrane, and may also be affected by changes in the ionic composition of the cell wall. The ability of calcium to cross-link pectin, and thereby reduce its solubilization, provides a dual role for this ion as a promoter of pectin degradation through eliminative degradation while enhancing texture through cross-linking.

Water loss will also affect the storage stability of processed foods, predominantly in foods where low water activity is a major conservation hurdle. Crispness or crunchy texture is essential to the quality of a number of cereal and snack products. If the moisture content increases due to the absorption of water vapor or the mass transport of water from other domains, crispness is lost. Dry foods in a package that allows the influx of water vapor can show the transition from glass to rubber as indicated in Figure 1. Crispness is lost if water is gained to reach a water activity (aw) above 0.35–0.50 for crisp snack foods like chips, saltine crackers, and popped popcorn. Similarly, bread crumb, which initially is soft and resilient, gradually loses both of these essential quality attributes, which involves intermoisture migration from crumb to crust and water redistribution between bread components.

Control of moisture migration and loss is thus critical to the storage stability of foods. A wide range of film-forming compounds is now available and facilitates tailoring moisture barriers with optimized functional properties.

Physical Damage

Physical damage, mainly due to physical forces or changes, is another important cause of substantial degradation in food products. Physical forces include the shock, vibration, and compression forces experienced by the food products. Surface deterioration then provides an ideal entry point for many food pathogens and microorganisms, proliferating on leaked nutrients from damaged tissues. Damage also allows water loss, which compromises the quality of the foods and promotes an increase in respiratory rate and an accumulation of secondary metabolites. As a result, ethylene production may be stimulated in plant tissues, which can lead to premature yellowing or ripening of commodities.

For fresh foods like fruits and vegetables, physical damage can arise at any stage. In the earliest stage, when the produce is severed from the mother plant, many fungi invade the produce through the stem end. Bruising can occur, for instance, due to

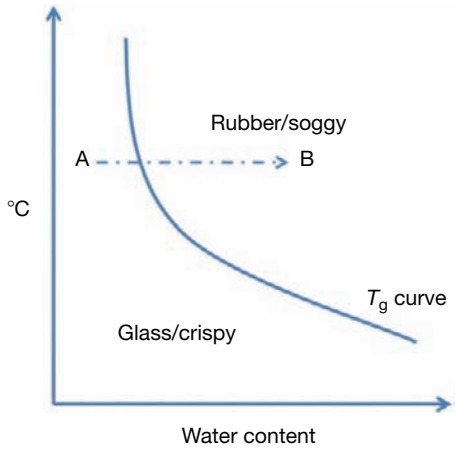

Figure 1 Texture changes as water migration and loss.

dropping or compression, when produce is stacked too high or packs are overfilled. Significant levels of wastage occur in the potato industry due to internal bruising of potato tubers during storage, handling, and transportation. Some fruits and vegetables, such as carrots, will encounter frozen storage, which will then cause the formation of ice crystals. The size of ice crystals may change due to fluctuations in temperature during frozen storage. The number of ice crystals tends to decrease, while their size increases, resulting in progressive physical damage of the vegetable tissue. The technique of osmotic dehydrofreezing has recently been recognized to maintain the texture of fruits and vegetables after freeze-thawing, particularly for carrot and broccoli, with minimal damage to cellular integrity. Moreover, at the retail level, the stability of many fresh food products is considerably reduced by physical damage caused by rough handling, where the produce is loose and can be picked over by the potential customer.

Physical damage will also affect the stability of processed food during storage. Poor packaging of processed food can create problems. Such issues can be related to the lack of padding or underfilling of cartons, allowing movement of processed food within the pack during transport and handling. The processed food in the broken packaging will be exposed into the atmosphere without any protection, thus causing degradation.

Mechanisms of Biological Degradation

Enzymatic effects and microbial metabolism are the two leading biological degradation mechanisms for foods during storage. Fresh foods with natural origin, like fruits, vegetables, cereal grains, fish, and meat, proceed to ripen after harvesting and eventually decay through a process of senescence, which is the normal aging process related to biological degradation. These processes, resulting in reduced storage stability, are usually mediated by several enzymes naturally presented in the food or by enzymes produced by certain microorganisms. Such enzymes, for example, polyphenol oxidase (PPO), peroxidase (POD), and lipoxygenase (LOX), are active during the storage of foods without the control of the synthesizing unit, as is the case before harvesting.

During storage, fresh vegetables and fruits continue respiration through the consumption of oxygen and the generation of carbon dioxide and water vapor until the depletion of energy required for metabolic process. The oxygen level is a key external factor to determine the respiration rate, which controls the rate of senescence. The reduction in respiration rate in response to low oxygen levels is not the result of cytochrome oxidase activity, but rather due to the decreased activity of PPO, ascorbic acid oxidase, and glycolic acid oxidase. In the meantime, the biosynthesis of ethylene will be accelerated, which initiates the ripening of fresh fruits. This ripening process is coded into the genetic makeup of the produce. It can be partially controlled by temperature and composition of the environment (controlled or modified atmosphere). Bananas, for example, are typically harvested green, ripen to a yellow fruit, and finally overripen first to a speckled brown, then to primarily brown, and ultimately to a black appearance. The speed of this process is dependent on the production of ethylene. In addition, the accumulation of ethylene will markedly enhance both PPO and POD activities. Induction of these enzymes can increase browning susceptibility and browning development (Figure 2), which is related to a loss in storage stability. Tissue browning is mainly due to the oxidation of phenolic constituents and degradation of red pigments by PPO, whereas POD may be responsible for deterioration of flavor, color, and nutritional value. Relationships between POD activity and off-flavor development due to oxidation of lipids and phenolic constituents have been established. POD can rapidly oxidize 4-methylcatechol in the presence of H_2O_2 and, thereby, form brown polymeric pigments. Loss of vitamin C is related to ascorbic acid peroxidase, but it can also be linked to the co-oxidation of ascorbic acid with phenoxyl radicals generated by POD. Complementary localization pattern and synergistic roles of POD and PPO in browning reactions have been suggested. Also, an involvement of anthocyanase renders major phenolic constituents (anthocyanin) accessible to POD or PPO.

Another major enzyme group participating in food degradation is constituted by the LOXs. LOXs are a diverse group of enzymes widely spread throughout both the plant and animal kingdoms. They are present in legumes, cereals, fruits, and potato. These enzymes act mainly on polyunsaturated fatty acids containing *cis*, *cis*-1,4-pentadiene systems, and they catalyze the formation of hydroperoxides intermediates similar to those formed by nonenzymatic oxidation. However, LOXs are specific with respect to the substrate and to the positional and stereoisomeric hydroperoxides they produce. The different LOXs present in different plants, or isolipoxygenases in the same plant, vary in their substrate and product specificities, as well as in their optimum parameters (e.g., pH). It is believed that iron, a constituent of LOX, plays a key role in the mechanism by which the enzyme catalyzes hydroperoxides formation. The breakdown of hydroperoxides leading to the formation of volatile and nonvolatile products may also be catalyzed by enzymes (i.e., hydroperoxidases). Obviously, due to the greater specificity in enzyme-catalyzed formation and decomposition of fatty acid hydroperoxides, fewer and more specific oxidation end products are encountered.

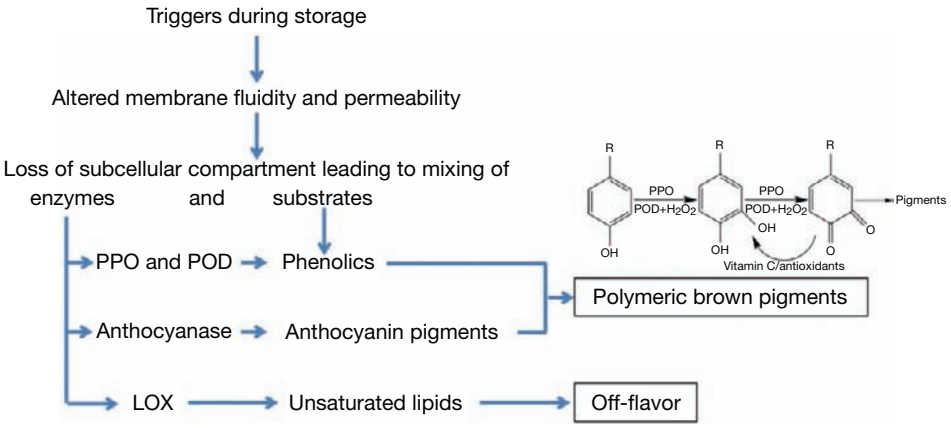

Figure 2 Enzymatic degradation in fresh vegetables and fruits.

Similar to the fresh fruits and vegetables, animal tissue and fish products undergo changes, such as proteolysis, from the moment of slaughter. During chilled storage of meat or fish products, biological changes derived from enzyme action are known to take place, such as changes in the protein, nucleotide, and lipid fractions and the formation of peptides, free amino acids and free fatty acids, and hypoxanthine. Meat that is frozen and then thawed will normally deteriorate rapidly, even at refrigeration temperatures. This deterioration may be due to the physical breakage by ice crystals. Since membranes throughout the tissue will be broken, other compartmentalized proteases may also be released. In general, peptidases active in postmortem muscle have the ability to catalyze the degradation of proteins, such as titin, nebulin, filamin, desmin, and troponin-T, into many of the same degradation products produced in myofibrils during storage. They will cause the meat to become tender but sometimes mushy because of extensive proteolysis, and the resultant low-molecular-weight substrates will facilitate microbiological growth. Fish quality deteriorates after rigor mortis, with proteolytic activity being a causal factor. Proteolytic deterioration of fish meat continues even in the frozen state if the storage temperature is not low enough due to the release of proteinase. Additionally, LOX, found in platelets, microsomal membranes, and other specialized tissues of animals, will also oxidize the polyunsaturated fatty acids. The consequences of these events are the deterioration in sensory quality, a loss of nutritional value, and negative modifications of the physical properties of muscle. These changes are temperature- and atmosphere-dependent and are also influenced by the types of enzymes in the animals and fish.

The action of enzymes could also lead to a decrease in stabilization and consumer acceptability in processed food during storage. In orange juice, the cloud particles, a complex mixture of protein, pectin, lipids, hemicellulose, cellulose, and other minor components, impart the characteristic flavor, color, and mouthfeel. The enzyme pectin methylesterase (PME) in the juice could cause the loss and precipitation of cloud in orange juice through the de-esterification of the methyl groups on the galacturonic acid backbone of pectin and the creation of charged regions that complex with Ca^{2+}, forming gels, which precipitate and clarify the juice. At least three isozymes of PME, which is a heat-resistant enzyme, are known: PME I, PME II, and TS-PME. Elevated pasteurization temperatures are commonly used to inactivate PME and to prevent juice cloud precipitation in the juice industry.

In addition to the actions within the biological system of fruits, vegetables, grains, meat, and fish products, food losses are experienced through the actions of microorganisms. This is universal for both fresh and processed food products during storage. For instance, *Serratia marcescens* isolated from raw milk is found to produce extracellular lipase. This microorganism and its lipase demonstrate lipolytic and proteolytic activity even at 6 °C after 12 h, which could contribute to flavor defects in milk and dairy products. Lactic acid bacteria (LAB) produce lactic acid as acidification to inhibit the growth of spoilage agents. But some LAB species, such as *Lactobacillus sake* and *Lactobacillus curvatus*, have been detected on various types of vacuum-packaged cooked sausages and could deteriorate the storage stability of sausage and sausage slices by forming the undesirable sour aroma sensory attributes and taste.

Traditionally, successful strategies to combat biological degradation include thermal processing (e.g., blanching and pasteurization) and storage at a reduced temperature and under modified packaging (MAP), for inactivating enzymes and controlling microbial growth in fresh foods. Some novel nonthermal technology has been recently introduced as a mild alternative for some conventional pasteurization processes, such as high-pressure and dense-phase CO_2.

Mechanisms of Chemical Degradation

In addition to the physical and biological degradation stated earlier, chemical forces also degrade food. Even in a class of products made commercially sterile and storable at ambient temperature by thermal processing, there can be a wide range of shelf lives because of chemical degradation during storage. Chemical degradation includes thermal degradation, oxidative degradation, nonenzymatic hydrolytic degradation, photodegradation catalyzed by light, and radiation degradation.

Thermal Degradation

Thermal degradation happens for a large variety of food products when applying heat processing. Caramelization is such reaction associated with thermal degradation and can result in complex mixtures of molecules. During storage, thermal degradation is unusual except for foods or constituents that are extremely sensitive to temperature fluctuation or that are distributed in the tropical area. The breakdown of glycosidic bonds in a wide range of carbohydrates is a typical thermal degradation, which will produce mainly acids and other specific compounds depending on the structure and conformation of carbohydrates and processing conditions. Some thermolabile colorants, like anthocyanins, and nutrients, like ascorbic acid, may be vulnerable to such degradation.

Anthocyanins are popular ingredients responsible for the attractive red colors of many fruits and fruit products. Due to thermal instability, anthocyanins readily degrade and form a colorless compound or an undesirable brown color. The storage temperature will determine the thermal degradation rate of anthocyanins in food products and the rate increases during storage as the temperature rises. Many studies have been carried out to investigate the storage stability of anthocyanins in different juices. A recent study suggested a first-order reaction for the degradation of blood orange anthocyanins with half-lives of 55.7, 9.7, and 2.1 days for 45 °Brix samples at storage temperatures of 5, 20, and 37 °C, respectively. The degradation of blackberry juice anthocyanins followed similar first-order reaction kinetics, resulting in half-lives of 330, 32.1, and 11.7 h for concentrated juice (65 °Brix) at storage temperatures of 5, 25, and 37 °C, respectively. The difference of half-lives between juices is primarily attributed to the thermal sensitivity of individual anthocyanin molecules.

Thermal degradation of anthocyanins is primarily caused by oxidation and cleavage of covalent bonds, resulting in a variety of species depending upon the severity and nature of storage temperature. Figure 3 shows the degradation of a typical anthocyanin, that is, pelargonidin, and the formation of various intermediate compounds. The initial degradation step in such degradation mechanism is the hydrolysis of the sugar moiety and aglycone formation due to the formation of cyclic adducts. However, others believe the opening of the pyrylium ring and chalcone formation is the first degradation step for anthocyanins.

Maillard Reaction

The Maillard reaction is of importance for the storage stability of foods, chiefly in commercially available potato chips, potato fries, cereals, coffee, and bread. The Maillard reaction, which induces browning and attractive flavor formation of foods, occurs under both heating processing and storage at room temperature. However, it also has an adverse effect on nutritive value and toxicological implications such as the formation of acrylamide during storage.

The sequences of reactions that make up nonenzymatic browning or Maillard reactions have been extensively studied. In fact, these reactions consist of thousands of subreactions, so that at least 2500 volatile compounds are formed. The Maillard reaction is usually divided into three stages: (i) the condensation between an amino group and a reducing sugar, leading to an *N*-glycosylamine in the case of an aldose sugar that rearranges into the so-called Amadori/Heyns product; (ii) the formation of Amadori/Heyns products, leading to sugar fragmentation products and release of the amino group; and (iii) the generation of all kinds of dehydration, fragmentation, cyclization, and polymerization reactions in which amino groups participate again. Especially in relation to flavor formation, the so-called Strecker degradation is of utmost importance, in which amino acids are degraded by dicarbonyls formed in the Maillard reaction, leading to deamination and decarboxylation of the amino acid.

The degradation caused by Maillard reactions during storage, which involve amino groups, can result in decreased nutritional quality, especially to the extent that the ε-group of lysine is coupled. More importantly, Maillard reaction products are responsible for the appearance of acrylamide, a compound that has been classified as probably carcinogenic in humans. The participants in this reaction are an amino acid

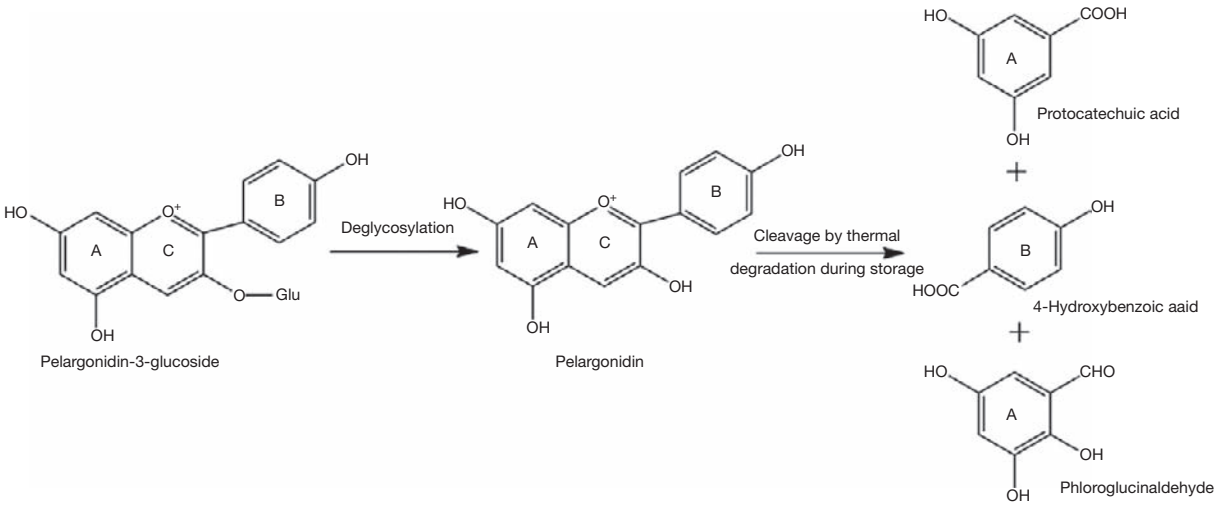

Figure 3 Possible thermal degradation mechanism of pelargonidin.

(asparagine) and reducing sugars (fructose and glucose). In some foods, acrylamide concentrations are reported to increase during storage, probably because of Maillard reactions although the reaction rate may be comparatively slow.

Among the factors that affect browning reactions during storage are temperature, moisture content and water activity, direct reactions of the reactants (either carbohydrates or proteins), and indirect reactions that could affect the pH.

Photochemical Degradation

Basically, a photochemical degradation is a chemical reaction that is induced by light or radiation. Photoexcitation is the first step in a photochemical degradation process, which is initiated by the photosensitizer (Sen). The photon can be absorbed rapidly by the photosensitizer after the exposure to ultraviolet or visible radiation, after which it elevates to a state of higher-energy, unstable, excited, singlet molecule (^{1}Sen*). The excited singlet photosensitizer (^{1}Sen*) loses its energy by internal conversion, emission of light, and intersystem crossing (Figure 4). Internal conversion involves the transformation from a high-energy to a lower-energy state by releasing energy as heat. Emission of fluorescence converts the excited singlet sensitizer to a ground-state singlet sensitizer (^{1}Sen). The excited sensitizer may also undergo an intersystem crossing from the excited singlet molecule to an excited triplet molecule (^{3}Sen*). The ^{3}Sen* may degrade foods through type I or type II pathways. In type I pathway, ^{3}Sen* may react directly with a compound such as linoleic acid or with phenol compounds by donating and accepting hydrogen or electrons and producing free radicals or free-radical ions. In type II pathway, ^{3}Sen* reacts with triplet oxygen ($^3O_2$) to form singlet oxygen ($^1O_2$) and ^{1}Sen by a triplet–triplet annihilation mechanism. The sensitizer returns to ground state (^{1}Sen) and may begin the cycle again to generate singlet oxygen. Both triplet oxygen and singlet oxygen can react with other components, such as lipids, proteins, polysaccharides, colorants, and vitamins, in the food to finally destabilize food during storage. These reactions, as fast as 10^{-9} s, are several orders of magnitude faster than thermal degradation.

Food constituents such as chlorophyll, pheophytins, porphyrins, riboflavin, myoglobin, and synthetic colorants are the common photosensitizers that can absorb energy from light and transfer it to triplet oxygen to form singlet oxygen. The photochemical degradation can thus happen in the foods containing these photosensitizers during storage. Milk, for instance, is susceptible to photochemical degradation due mainly to implication of riboflavin and exposure to fluorescent light to enhance consumer attraction. Therefore, not only the nutritional value but also the storage stability of milk could decrease under such conditions. Similar implications are valid for other dairy products, such as cheese and cream. Packaging materials can effectively protect against photochemical degradation of milk by blocking or reducing the transmission of light. As another example, meat will suffer photochemical degradation because of the presence of myoglobin and other hemoproteins, which are the primary photosensitizers. Both myoglobin and oxymyoglobin have the ability to absorb light energy, resulting in the formation of grayish metmyoglobin.

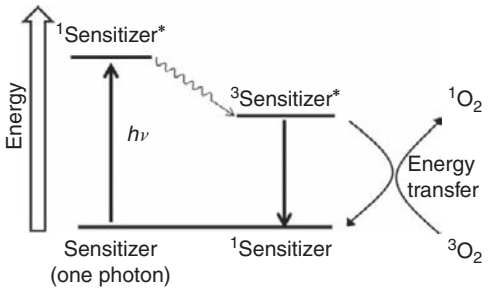

Figure 4 The formation of singlet oxygen in the presence of photosensitizer.

Oxidative Degradation

Oxidative degradation is one of the paramount causes of quality deterioration in natural and processed foods. It is a large economic concern in the food industry because it impairs many quality characteristics such as flavor (rancidity), color, texture, and the nutritive value of foods. In addition, it produces potentially toxic compounds. Thus, oxidative degradation is one of the major processes that limit the shelf life and storage stability of foods. The previously stated chemical degradation mechanisms, for example, heat treatment and singlet oxygen, could initiate oxidative degradation. Oxidative degradation is a general term used to describe a complex sequence of chemical interactions between substitutes, such as lipids, protein, and carbohydrates, in foods with active oxygen species. Each of the substitutes has different degradation mechanisms. Free radicals, however, can participate in all the oxidative degradations as summarized in Figure 5.

Theoretically, the mechanism of lipid oxidation is a free-radical chain reaction between unsaturated fats and oxygen that can occur in an autocatalytic manner. However, lipid oxidation in many food systems is accelerated by prooxidants such as transition metal ions, photosensitizers, UV light, and certain enzymes. The overall mechanism of lipid oxidation involves three stages: (1) initiation, the formation of free radicals; (2) propagation, the free-radical chain reactions; and (3) termination, the formation of nonradical products. A simple scheme for the free-radical mechanism can be summarized as follows:

Initiation:

$$In^{\cdot} + LH \rightarrow In\ H + L^{\cdot} \quad [1]$$

Propagation:

$$L^{\cdot} + O_2 \rightarrow LOO^{\cdot} \quad [2]$$

$$LOO^{\cdot} + LH \rightarrow LOOH + L^{\cdot} \quad [3]$$

Termination:

$$LOO^{\cdot} + LOO^{\cdot} \rightarrow LOOL + O_2 \quad [4]$$

$$L^{\cdot} + LOO^{\cdot} \rightarrow LOOL \quad [5]$$

$$L^{\cdot} + L^{\cdot} \rightarrow LL \quad [6]$$

In the initiation step, a fatty acid radical known as the alkyl radical ($L^{\cdot}$) is formed by abstraction of a hydrogen from a fatty

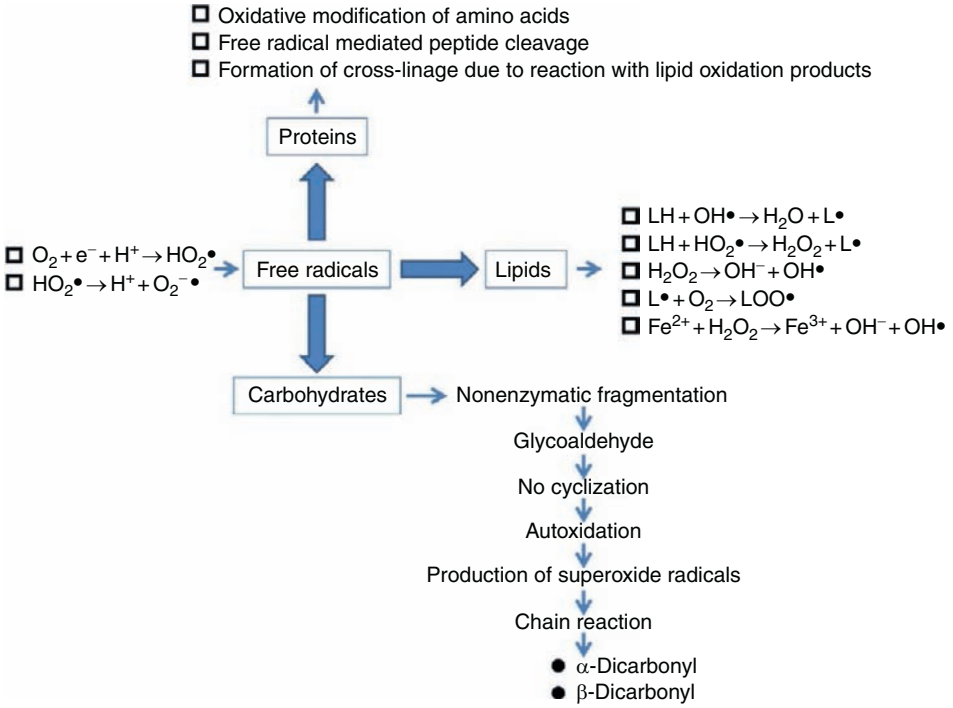

Figure 5 Free radical-initiated oxidative degradation in major food components.

acid in the presence of an initiator ($In^{\cdot}$) (reaction [1]). Once the alkyl radical forms, the free radical can delocalize over the double bond system resulting in double bond shifting and, in the case of polyunsaturated fatty acids, formation of conjugated double bonds. In bulk oils, the ease of formation of alkyl radicals in fatty acids increases with increasing degrees of unsaturation. The first step of propagation involves the addition of oxygen to the alkyl radical, resulting in the formation of peroxyl radical ($LOO^{\cdot}$), which has higher energy than the alkyl radical (reaction [2]). Thus, the peroxyl radical can abstract hydrogen from another unsaturated fatty acid and produce a lipid hydroperoxide (LOOH) and a new alkyl radical (reaction [3]). The interaction of two free radicals to form nonradical species will terminate the process (reactions [4]–[6]). This step is usually less relevant during storage, since the food is already rancid before significant termination reactions take place. An exception is in the low-oxygen environment of frying oils, where the termination reaction can occur between alkyl radicals to form fatty acid dimers.

Rancidity in food occurs when unsaturated fatty acids decompose into volatile compounds. These volatile oxidation products are produced from the decomposition of fatty acid hydroperoxides. The homolytic cleavage of hydroperoxides (LOOH) between these two oxygen molecules is the most likely hydroperoxide decomposition pathway. This reaction yields an alkoxyl radical ($LO^{\cdot}$) and a hydroxyl radical ($^{\cdot}OH$). The alkoxyl radical ($LO^{\cdot}$), which is more energetic than either the alkyl ($L^{\cdot}$) or the peroxyl radical ($LOO^{\cdot}$), can enter into a number of different reaction pathways. Alkoxyl radicals can attack another unsaturated fatty acid, a pentadiene group within the same fatty acid or the covalent bonds adjacent to the alkoxyl radical. This last reaction is known as β-scission reaction and is important to food quality as it causes fatty acids to decompose into low-molecular-weight volatile compounds that cause rancidity.

In the β-scission reaction, the highly energetic alkoxyl radical ($LO^{\cdot}$) is able to abstract a hydrogen from the carbon–carbon bond on either side of the oxygen radical. The decomposition product on the carboxylic acid end of the fatty acid is usually esterified to the glycerol of a triacylglycerol or phospholipids; thus, it would not be volatile and therefore would not contribute to rancidity unless it undergoes further decomposition reactions to form low-molecular-weight compounds. Cleavage of the hydrocarbon chain by alkoxyl radicals on the methyl end of the fatty acid will produce volatile compounds. Upon cleavage of the fatty acid chain, the resulting radicals will interact with a variety of compounds to produce secondary lipid oxidation products such as aldehydes, ketones, alcohols, furans, hydrocarbons, and acids.

The oxidative degradation of protein is common in meat and fish products during storage. In meat, protein oxidation may lead to decreased eating quality such as reduced tenderness and juiciness, flavor deterioration, and discoloration. There are three distinct ways that protein can be oxidatively modified: (1) oxidative modification of a specific amino acid, (2) free radical-mediated peptide cleavage, and (3) the formation of protein cross-linkage due to reaction with lipid peroxidation products.

Physical and chemical changes in oxidized proteins include amino acid destruction, decreases in protein solubility due to protein polymerization, loss of enzyme activity, and formation of amino acid derivatives including carbonyls. One of the consequences of protein oxidation is the reduction of the tenderness of meat by the formation of protein aggregates through both noncovalent and covalent intermolecular bonds. Additionally, intermolecular cross-links formed in

highly oxidative conditions can make proteins less susceptible to enzymatic proteolysis, further reducing development of tenderness by proteolysis in meat. Color deterioration of meat products is another important consequence of protein oxidation that may influence consumer acceptance.

Carbohydrates are quite stable to oxidative degradation, and other components like lipids and proteins are expected to be oxidized before carbohydrates. However, radicals formed in other components are able to react with carbohydrates, producing the formation of carbonyl compounds. Regarding oxidative degradation of carbohydrates, the formation of free radicals could contribute to glycoxidative degradation. During the initial stages of nonenzymatic glycoxidation, the C—H bond of the secondary alcoholic group is cleaved to generate a carbon-centered radical. This radical adds oxygen instantly to produce a peroxyl radical. This radical can either release the hydrogen peroxyl radical to produce oxo-derivatives of sugars or suffer an electronic rearrangement to fractionate the carbohydrate carbon chain and produce a glycolaldehyde and abstract a hydrogen radical to produce an acid and oxygen peroxides after hydrolysis. Different monocarbonyl and dicarbonyl compounds are produced in these reactions, depending on the site of attachment by the lipid peroxyl radical, the carbohydrate involved, and the fractionation or not of the carbohydrate molecule. In fact, 1,2-dicarbonyl compounds are common constituents in many food products that have been described as cytotoxic, mutagenic, carcinogenic, and prooxidative reagents.

Many important factors, such as antioxidants, chemical structure of lipids, oxygen concentration, and temperature, have been found to influence the oxidative stability of lipids, protein, and carbohydrates. A better understanding of these factors could lead to the development of practical strategies for retarding oxidative degradation in food systems.

Conclusions

The quality of fresh and processed products held in storage will degrade over time. Understanding degradation mechanisms is a prerequisite for maximizing nutritional and sensory qualities. Assuming that throughout the storage duration the appropriate conservation temperature is respected, a point in time will be reached when the product quality degrades, perceptively or unperceptively, to a level taken as a cutoff limit. That point in time corresponds to the product shelf life. The quality cutoff limit and the shelf life under specific storage conditions vary over a wide range and depend on the nature of the product, the predominant degradation process, and the mode of storage. Roughly speaking, the degradation processes can be classified as physical, biological, and/or chemical. Major concerns in fresh or minimally processed products are the growth of spoilage microorganisms, enzymatic browning, color deterioration, and rancidity development. Physical degradation, including moisture migration and loss, starch crystallization, and physical damage, some of which significantly affect texture, can determine the shelf life of products in which microbial growth is not a factor. Chemical degradation, primarily the oxidation of constituents in foods initiated by variable factors, such as free radicals, singlet oxygen, and transition metals, generates rancidity and off-flavors perceptively and can determine the shelf life of products when any of the other two is not a major factor. Depending on the susceptibility of the product to one or more of these degradation mechanisms, it would be stored under freezing, chilling, or ambient temperatures or in the presence of certain food-grade additives or types of packaging to maintain a marketable quality for as long as is needed to move throughout the food chain from producer to consumer.

Storage Stability: Shelf Life Testing

E Torrieri, University of Naples Federico II, Portici, Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The quality of most foods and beverages decreases from the moment of the packaging until its consumption due to complex reactions based on biological, chemical, or physical mechanisms. There is a finite length of time after which the product becomes unacceptable. This length of time in which a foodstuff material is stored under specified packaging and environmental conditions is referred to as shelf life. A useful definition of shelf life of food has been available in IFST Guidelines:

Shelf life is defined as the time during which the food product will

- remain safe;
- be certain to retain desired sensory, chemical, physical, and microbiological characteristics;
- comply under the recommended conditions.

Safety and quality are the two main aspects of shelf life of food. While food safety is a legal requirement, the food quality is a choice of the manufacture to respond to consumer requirement. In fact, the words quality, acceptability, and desired characteristics can have several interpretations, depending on the product and on the market. Thus, a proper determination of the shelf life of a product is a critical point for a factory, mainly if one considers that inadequate shelf life will often lead to consumer dissatisfaction and complaints.

The critical factors affecting the shelf life of a food are

- product characteristics (formulation and processing),
- packaging,
- storage conditions.

All the previously mentioned factors are critical, but their relative importance depends on the specific food. In general, for most perishable foods, such as fruits and vegetables, fresh meat, and fish, factors related to initial quality of the product and to packaging and storage conditions are critical for the shelf life, whereas for thermally stabilized foods, such as some beverages, sauce, or cooked ready meal, process parameters, such as pasteurized temperature–time couple, are critical for the ending of their shelf life.

The possible interplay among critical factors must be taken into consideration because they can lead to different storage conditions as a function of the product and package property.

Appropriate shelf life testing is normally required to take into account the different scenarios brought about by this interplay. Once the scenarios are defined, an understanding of the key factors affecting the shelf life of a commodity is the starting point to shelf life prediction.

This article focuses on the methods used to assess shelf life and in particular will focus on the description of the main steps involving shelf life determination by simulation method, in particular

1. identification of the deterioration mechanisms,
2. identification of critical factors for the identified deterioration mechanism,
3. identification of a quality index high related to the deterioration mechanism and its critical level related to the unacceptability of the product,
4. quantification of the evolution of the quality index as function of the time.

Identification of Deterioration Mechanisms

Knowledge on deterioration reactions, which affect food quality, is the first step to determine the shelf life of a specify commodity. Fresh and processed foods deteriorate by a variety of mechanisms including oxidation, browning (enzymatic and nonenzymatic), moisture content changes, enzymatic reactions, microbial attack, structural changes, photodegradation, senescence, loss of carbonation, recrystallization of sugars, and caking. The major modes of food degradation are senescence, microbiological decay, chemical deterioration, and physical degradation. The relation between deterioration mechanisms and quality attributes that change during storage is reported in Table 1.

Although several deterioration modes may occur simultaneously, it is the most sensitive one that limits shelf life. A good understanding of the interaction between the product, the package, and the environmental system can lead to a right identification of the limiting deterioration mechanism.

Factors Influencing Deterioration Process

Many factors can influence the deterioration process and therefore the shelf life of foods. They can be classified as intrinsic factors, related to the final property of the product, and extrinsic factors, related the environment encountered by the product through the food chain (temperature, atmosphere composition, relative humidity (RH), and light). Food deteriorations dependent on environmental factors can be controlled by the package or package technologies.

All these factors are important for the stability of the product. In this section, a brief description of the most important activation factors for foods stability in terms of shelf life is given. In particular, among the intrinsic factor, water activity will be examined, while among the extrinsic factors, temperature and gas composition will be considered. It should be emphasized that loss of quality often occurs by a combination of these factors and, when such interactions are indicated or suspected, consideration must be given to mixed effects. For instance, nonenzymatic browning is a function of food composition, moisture content, and temperature.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00666-8

Table 1 Relationship between deterioration mechanisms and quality attributes that change during storage

Deterioration process	*Mechanism*	*Quality attribute changes*	*Environmental critical factors*
Senescence	Catabolism of carbohydrates	Color, flavor, nutrients, texture, tissue damage	Temperature, oxygen, relative humidity
Microbiological decay	Growth of pathogen or spoilage organism	Off-flavor, visual appearance, unsafe food	Temperature, relative humidity, oxygen
Chemical reaction	Enzymatic or nonenzymatic reaction, lipid oxidation	Color, aroma, taste, off-flavor loss of vitamins, degradation of proteins	Temperature, oxygen, light
Physical degradation	Physical crushing, moisture loss/gain, staling	Texture, sedimentation, creaming	Temperature, relative humidity

Environmental critical factors are also reported for each deterioration process.

Water Activity

Water is the most important diluent of water-soluble food components and plasticizer (softener) of various water-miscible polymeric compounds as well as often the main food components. Chemical reaction, enzymatic changes, and microbial growth may occur readily in foods with high water content, while foods with low water content undergo loss of quality by water absorption. Water has several effects on food stability, palatability, and overall quality, and they are a function of the physicochemical state of water, which is related to water activity.

The parameter water activity is defined as the ratio of vapor pressure above a sample, p_w, and that of pure water (p_{wo}) at the same temperature. Mathematically,

$$a_w = \frac{p_w}{p_{wo}} \quad [1]$$

It describes the degree to which water is free or bound to other components. Water activity depends on the composition, temperature, and physical state of the compounds.

When a food is placed in an environment at a constant temperature and RH, it will eventually come to equilibrium with that environment. The corresponding moisture content at steady state is expressed as the equilibrium moisture content.

The difference between the RH of the surrounding environment and water activity of the food determines whether a food gains or loses moisture during storage.

For the main food product, steady-state relationships between a_w and water content at a constant temperature are described by a sigmoid-shaped curve. This curve is known as sorption/desorption isotherm. Such plots are very useful in assessing the stability of foods and in selecting effective packaging.

Temperature

Temperature is one of the most important factors affecting the shelf life of foods. Raising the storage temperature will accelerate many aging processes, as well as inactivate enzymatic reaction and/or microbiological spoilage. The relationships among temperature, respiration, transpiration, and other deteriorative changes are well documented. The models used to represent the dependence of reaction rate on temperature include the Arrhenius model, the temperature quotient, and Williams–Landel–Ferry (WLF) model.

The most common and generally valid relationship used to describe the influence of a constant storage temperature on the reaction rate is the Arrhenius equation:

$$K = A \exp\left(-\frac{E_a}{RT}\right) \quad [2]$$

where A is the so-called pre-exponential factor, E_a is the activation energy, and R and T are the gas constant and absolute temperature, respectively. The value of E_a is a measure of the temperature sensitivity of the reaction. High activation energy implies that the reaction is strongly temperature-dependent, that is, accelerates greatly with increase in temperature.

An alternative way of expressing temperature dependence of a reaction is to use the concept of Q_{10}:

$$Q_{10} = \frac{K_{(T+10)}}{K_T} \quad [3]$$

It indicates how fast a reaction will occur if the temperature is raised by 10 °C and can be used to predict expected product shelf life.

The last relationship generally used to describe the dependence of food stability from temperature derives from the application of polymeric science principle and theory to food science, which has led to the glass transition temperature (t_g) being put forward as an alternative, potentially preferable parameter, for defining food stability, where the rate of degradation processes is critically dependent on $T-T_g$, particularly at temperature close to T_g. If a change in a quality factor is diffusion-controlled and dependent on viscosity, the observed rate constant may become a function of the true rate constant and diffusivity. In similar studies, the observed rate constant of diffusion-controlled reactions and quality changes in amorphous food matrices have been assumed to be proportional to $1/\eta$, which has led to the direct application of the WLF equation. Mathematically,

$$\log \frac{k_s}{k} = \frac{-C_1 \times T - T_s}{C_2 + T - T_s} \quad [4]$$

where k is the observed rate constant and k_s is the observed rate constant at the reference temperature T_s. C_1 and C_2 are constants for which values of −14,44 and 51,6 are often used, although they are not always applicable. In general, because it is difficult to measure the mechanical parameter at T_g, it is more accurate to use T_g +50 °C as a reference temperature (in place of T_g) and to determine constant C_1 and C_2 graphically

from experimental data. Nelson and Labuza had discussed methods of determining WLF coefficients for assessing the applicability of the WLF equation to the temperature dependence of chemical reactions in food.

Gas Atmosphere

The composition of the atmosphere that surrounds the product affects its deteriorative process. When the food product is packed, the gas composition of the package head space is a function of the packaging properties (gas permeability) and product properties (respiration rate or chemical reaction kinetics). Oxygen is an active reactant in many chemical reactions (oxidation, enzymatic browning, and physiological metabolism). Its availability has detrimental effects on the nutritive quality of foods. Thus, in many cases, removing oxygen from the surrounding atmosphere of a product leads to positive effects on the shelf life of the product. Exceptions are all the respiring products, which, after harvest, keep on respiring, consuming oxygen and sugar, and producing carbon dioxide, water, and energy. If the product has less oxygen available for the metabolic process, it reduces the respiration velocity to preserve itself. Low oxygen content also suppresses the production of ethylene, therefore delaying the onset of ripening. Moreover, concentrations of oxygen lower than the threshold value below which anaerobic condition establishes can be even detrimental for the shelf life of the product. At the same time, it is reported that high concentrations of CO_2 inhibit the respiration rate, and as for oxygen, high levels of CO_2 may affect negatively the quality of the product.

Carbon dioxide and carbon monoxide improve the stability of the foods. In fact, high levels of carbon dioxide lead to a reduction in microbiological activity, especially mold growth, denaturation of some protein by acidification, inhibition of pectin hydrolysis, and a reduction in the cold damage of the vegetable tissue. However, different commodities have different optimum gas composition requirements for maximum shelf life.

Quality Index and Acceptability Level

Once the major deterioration modes are known, and the critical factors for the identified deterioration mechanism have been identified, the following step is to identify quality indexes to quantify the extent of deterioration. Any quality factor should possess three characteristics: measurable, reproducible, and relevant.

Moreover, the quality index has to be correlated to the acceptability of the product and must describe well the kinetic of the degradation process. An index could be a sensory, chemical, or physical parameter, depending on the product and on the degradation process. In Table 2, the main quality indexes used for measuring shelf life are reported.

As a function of the food product, each quality index has a different relative importance. Thus, for bakery product, the water content and mechanical properties are the most important quality indexes, whereas for fresh red meat, microbial count, color, and odor attributes have the main role in defining product acceptability, and for fresh fish, color, odor attribute, and oxidation index are critical for shelf life evaluation.

In order to establish the product shelf life, it is also necessary to define the critical level of each attribute that describes the quality evolution: the critical level must represent the level of the quality under which the product is not anymore acceptable by the consumers. Apart from microbiological quality aspect, for which the legislation provides clear indication (EU regulation (EC) No. 852/2004; 2073/2005), for the other aspects of quality, the critical level must be arbitrarily defined.

Nevertheless, considering that the shelf life of food depends on the interaction of the food with the consumer, a possible approach to define the critical level is to perform a consumer acceptability test. Consumer acceptability test gives a direct measure of liking that can be used more directly to estimate the shelf life. The most common procedure is to ask consumer representative of the target population to scale acceptability on a 9-point category scale, anchored from like extremely to dislike extremely acceptability test. For this kind of test, a large number of consumers are required (minimum of 50 but preferably over 100 consumers), and suitable experimental designs should be used, in conjunction with appropriate statistical analysis.

An alternative method to take consumer response into account is to estimate the probability of a consumer accepting a product beyond a time t using the survival analysis. In this method, samples with different storage times are presented to consumers. Consumers are asked a question such as 'Would you normally consume this product? Yes or No?,' and a survival

Table 2 Main quality indexes used to measure the principal quality change of food during storage

Deterioration process	*Quality index*	*Quality changes*
Senescence	Respiration rate, ethylene, water content, sensory attributes; appearance, flavor, taste/texture, electronic noses	Color, flavor, nutrients, texture, tissue damage
Microbiological decay	Microbial count, pH, acidity, metabolite production, electronic noses	Off-flavor, visual appearance, unsafe food
Chemical reaction	Vitamin concentration, acidity, peroxide value (PV), free fatty acid content (FFA), thiobarbituric acid value (TBA), malondialdehyde content (MDA), hexanal, fatty acid composition, volatile compounds, sensory attributes, color	Color, texture, aroma, taste, off-flavor loss of vitamins, degradation of proteins, loss of essential fatty acids
Physical degradation	Water content, water activity, weight loss, mechanical parameters, sensory attributes, rheological properties, glass transition temperature (T_g)	Texture, sedimentation, creaming

function is defined as the probability of consumers accepting a product beyond a certain storage time. In general a 50% probability can be fixed as level of acceptability. This method has been applied to determine the shelf life of fresh-cut apple, yogurt, pan bread, UHT milk, minced beef, and 'Fuji' apple.

Both methods described are useful to establish in specific package and storage condition the acceptability level in terms of storage days. Then, in order to define the critical level of each quality attribute, it is necessary to know the value of the attribute at the specific time (critical storage days) in the specific condition. For example, if, from the survival analysis, results highlight that after 7 days, the probability that a food product packed in a specific package and a fixed environmental condition can be not anymore acceptable by 50% of the consumers, the corresponding critical level of each quality attribute will be the value of the attribute at 7 days in the same storage conditions. Then, that value will be a reference value for whatever storage conditions, that is, the critical acceptability value of quality index of the specific product.

Quantification of the Evolution of the Quality Index: Shelf Life Test

The knowledge of the main deterioration processes and of the factors affecting food stability is the starting point to measure the shelf life of a given product. With the expression 'simulation of the shelf life,' one refers to a classic approach consisting in representing in laboratory the real storage condition in order to determine at which time the food product loses its commercial quality. This approach is useful when exact knowledge on the deterioration process is not available and the property of a new package is unknown or when their interaction is too complex to be predicted. Moreover, this approach gives the most realistic answer, but data obtained with this method cannot be generalized and are not applicable to different conditions of storage or to different product typologies.

The determination of shelf life by simulation of real storage condition is costly and time-consuming. Efficient design of experiments is important. Commonly, a single batch of product (or replicate batches) is stored under controlled condition and sampled at time zero and at regular time intervals on the bases of the expected shelf life. This type of design has the clear advantage that data related to shelf life are generated at intervals and provide a moving picture of deteriorative change taking place.

An ideal design for evaluating sensory and instrumental properties at different times of storage requires the availability of a large number of samples to be tested all together. In principle, this can be done in three different ways: A possibility is to use samples from successive production batches so that samples with a given shelf life are available on a wide range of time. This approach may suffer if there is fluctuation in production quality and is convenient only in situations in which production consistency can be assured. A variant of this design consists in the use of a single large batch, which is held in conditions that assure that quality changes are effectively zero, for example, frozen storage. Samples are removed from the frozen chamber at appropriate intervals and stored under the desired conditions. The last possibility is that a large batch of the product is sampled and samples are picked up after appropriate time intervals and kept under nonchanging conditions until the required storage has been reached. The main difficulty of the last two experimental designs is to identify appropriate nonchanging storage conditions, since a few foods can be stored at freezing temperature without changes in some important quality attributes.

Once the most appropriate design for shelf life experimental is chosen, the storage conditions need to be chosen carefully, and a good understanding of the storage, handling, and climacteric conditions of the markets in which the product will be sold is essential to the accuracy of shelf life tests. Generally, for chilled foods and frozen foods, temperatures are typically set between 0 and 10 °C and around −18 °C, respectively. For shelf-stable food, shelf life test temperature must be chosen based on climatic conditions: 38–40 °C/80–90 RH for tropical climates and 20–25 °C/50–70% RH for temperate conditions.

Once the storage condition is defined, the quality over time should be monitored. This is done by measuring attributes correlated to the deterioration processes. Chemical, physical, and microbiological analyses are performed according to the product characteristics and the deterioration processes in act (Table 2).

As a function of the expected shelf life, one must decide the time interval of test and the number of samples for each test. Time interval mainly depends on quality degradation kinetics. In the majority of the cases, a constant time interval can be convenient in order to describe the quality changes during time, even if in the same situation, it can be useful to have a high frequency at the end of the shelf life. For example, for microbial growth, the first part of the growth curve is stationary, whereas in the exponential phase, the quality changes are faster.

Then, one must decide the duration of the test. Usually, for highly perishable products, shelf life tests last maximum to 15 days, whereas for more stable product, the duration of a test can range from months to years. In this last case, it can be convenient to follow a different shelf life testing procedure based on shelf life prediction.

Introduction

Strawberry is one of the most economically important berry fruits consumed for its nutrient content and pleasant flavor. Strawberry is a member of the Rosaceae family and one of the most popularly consumed berries in the world. It is commercially cultivated worldwide for its highly appreciated sweet, aromatic, and juicy fruit. The United States is the world's leading producer of strawberries producing over 36 billion pounds in 2012 and accounting for 29% of the total world production. Among the fruits consumed in the United States, strawberries ranks fifth in consumption behind bananas, apples, oranges, and grapes. In the United States, California accounts for the highest commercial production of this berry crop, followed by Florida and Oregon. California's 12-month growing season contributes to higher strawberry yields per acre than any other growing region. Turkey, Spain, Egypt, and Mexico are the other leading strawberry-producing countries. Most strawberries produced are consumed fresh.

Sources and Production

The dessert strawberry, *Fragaria* X *ananassa* L. Duchesne, is the most popular cultivated strawberry and it dominates strawberry cultivation. The cultivated strawberry is a chance hybrid between *Fragaria chiloensis* Duch. and *Fragaria virginiana* Duch. *Fragaria* X *ananassa* is a herbaceous perennial plant that grows from a dense, compressed, central crown. The crown consists of a central core surrounded by a vascular ring. Leaves, stolons, inflorescences, and roots emerge from the crown. In strawberry plants, leaves are trifoliate and arranged spirally around the central crown. The root system of the strawberry plant is relatively shallow. Strawberry flowers typically have five white petals and pink flowers are seen in some varieties. Flowers are borne in clusters known as a cyme and the first flower to appear in the center is the king or the terminal flower. It also produces the largest berry. Honeybees are the primary pollinators in the open field and bumblebee is commonly used as a pollinator in protected cropping.

Botanically, strawberry is an aggregate fruit, originating from the expanded receptacle of the strawberry flower. Receptacle is the flower base that develops into the edible part of the strawberry. A number of ovaries occur on a common receptacle that develops into one-seeded fruits or achenes, attached to the outer surface of the receptacle in spirally arranged rows. The true fruit are the seedlike achenes borne on the surface of the receptacle. Fruit have a central cylinder of pith tissue surrounded by the cortical tissue containing parenchymal and epidermal cells. Horticulturally, the enlarged receptacle with achenes is considered as a berry. The achenes originate at the base of each pistil and are a combination of seed and ovary tissue. The achenes are embedded in the epidermal layer of the receptacle and each berry can have 20–500 achenes depending on the cultivar and growing conditions. Achenes are ovate and each achene contains one ovary. The mature achene is composed of a thick and hard pericarp, a thin testa, an endosperm consisting of one cell layer, and a small embryo. Immature fruits are green in color.

Strawberry plants propagate vegetatively through the production of runners or stolons, which are trailing aboveground stems that can take root at their nodal regions to develop into new clonal daughter plants. Strawberry cultivars are divided into three types based on their photoperiodic response for flower initiation: short-day, long-day, and day-neutral. Short-day types, also called June bearers in the northern hemisphere (single-cropping or non-everbearing strawberries), and day-neutral types are the two main types of strawberries cultivated worldwide. June bearers are suitable for commercial production in colder regions because of the availability of many cold-hardy cultivars that can be overwintered for perennial systems. Short-day cultivars initiate flower buds when the photoperiod is less than 14 h and day-neutral cultivars initiate buds continuously throughout the growing season. Regardless of the photoperiod, most cultivars typically initiate buds at low temperatures (about 10–15 °C). Long-day cultivars are also called everbearing or double-cropping strawberries and often bear fruits more than once. These cultivars never gained popularity and were superseded by day-neutrals.

Production Systems

There are two main management systems in strawberry production. They are matted row and the annual hill system. Strawberries are cultivated under annual or perennial production systems in the field or grown in tunnels or greenhouses. Two methods of cultivation are generally followed: annual plasticulture and a perennial system of matted rows or mounds.

Matted Row System

The matted row system is a perennial system suitable for producing June-bearing strawberries in colder climates. This system is also suited for outdoor field production and not well suited for high tunnel production. In the matted row system, the mother plants are spaced at planting and then allowed to runner freely to form a dense row of plants and trimmed to a specific width. For commercial cultivation, plants are propagated from runners and are distributed as bare root plants or plugs. This system is best suited for June bearers and requires the least amount of labor.

Annual Hill Plasticulture

The majority of strawberries grown worldwide are produced in plasticulture system. In annual hill plasticulture, strawberries are grown as annuals in a high-density system with raised beds

and removed after the fruiting cycle. Each year, raised beds are prepared, fumigated, and covered with plastic to prevent weed growth and to maintain bed shape. Plants are planted through holes punched in the plastic cover and runners are removed from the plants to encourage more and larger crowns resulting in larger berries and higher yields. Single- or double-trickle irrigation lines are laid on the surface of the raised beds to provide water and nutrients. At the end of the harvest, the plastic cover is removed and the plants are ploughed into the ground. The same procedure is repeated for the next production cycle. Initially, plantings are established with fresh-dug plants, partially or fully chilled dormant plants, or plug plants. Dormant plants are commonly used for off-season production systems. These plants can be stored at 0–1.1 °C for 1–9 months prior to planting. Plasticulture has some advantages over the other production systems. In this system, plants are unaffected by summer diseases, drought, or weeds and have an early harvest, large berry size, and shorter time interval between planting and first harvest. Higher initial cost and requirement for excellent management skills are some of the disadvantages of this system. The annual strawberry cultivation system is rather complex. Hill system is the ideal production system for everbearing and day-neutral cultivars because it offers maximum productivity and is well suited to the plant's growth habit.

Strawberry Fruit Development and Ripening

Strawberry fruit development is influenced by a number of factors including the number of achenes and distribution of achenes on the surface of the receptacle and the area of receptacle tissue around the achenes. Growth of the receptacle is primarily controlled by auxin synthesized in the achenes. Several factors including poor pollination and damage to achenes by frost, insects, or diseases that prevent the synthesis of auxins by achenes will result in malformed and distorted fruit development. The nonclimacteric, auxin-dependent strawberry fruit development can be divided into three stages: division, expansion, and ripening during which color shifts from green to white to dark red in about 40 days following anthesis. Growth of the fruit is mainly by cell enlargement with cell size increasing towards the inner part of the fruit. Cells in the cortex primarily contribute to fruit size, while cells in the cortex and pith are responsible for the growth of receptacle. Cell division occurs mostly before anthesis accounting for only 15–20% of the total fruit growth.

Although auxin stimulates the swelling of receptacle, it inhibits the overall ripening process. An important triggering factor for fruit ripening is probably the decline in auxin content that occurs during achene maturation. Green, white, pink, and red are the four consecutive stages of strawberry fruit development. During ripening, a series of physiological and biochemical changes occur that transform the inedible fruit into an edible fruit with favorable organoleptic characteristics. The most notable events associated with ripening involve alterations to fruit size, shape, texture, and pigmentation and the production of aroma and flavor compounds. As ripening progresses, an increase in anthocyanin content is accompanied by a decrease in fruit firmness. The other changes include increase in soluble solids, total sugars, ascorbic acid, reducing sugars, and water-soluble pectins and a reduction in acidity, total phenols, and cellulose. Sucrose is continuously imported from photosynthetic tissue during strawberry fruit development. Sucrose is hydrolyzed into glucose and fructose, the major sugars accumulated in ripe strawberries. The physiological changes associated with ripening result from changes in gene expression and enzyme activities.

Strawberry Consumption and Products

Strawberries are highly perishable and are easily susceptible to mechanical injury, water loss, and microbial decay. So it has a very demanding postharvest handling requirement. For fresh market use, the vast majority of strawberries are hand-harvested. Mechanically harvested berries are only suitable for processing because of extensive bruising during harvesting. Strawberry is a nonclimacteric fruit and has a short shelf life. Strawberries are primarily consumed as fresh but some strawberries are also frozen or processed into other products. Strawberries are often processed into puree, juice, and concentrates and used to make such products as jams, jellies, ice creams, and yogurts. The production of jams and jellies requires heating the fruit puree and the addition of pectin and sugar. Strawberries are also processed into spreads, preserves, syrups, juice blends, nectars, drinks, milk shakes, and fillings for bakery products such as pies, pastries, doughnuts, and cheesecakes.

Generally, strawberries are frozen individually or in block after the removal of cap and stems. Prior to quick-freezing, harvested strawberries are precooled to maintain color, texture, and flavor and graded and quickly rinsed with chlorinated water to remove field debris. Individually quick-frozen strawberries maintain their color and shape and so they are preferred as raw materials for manufacturing value-added products such as freeze-dried or infused dried strawberries. In some cases, sugar is also added to strawberries and the product is stored frozen. These products are added to yogurts and ice creams after pasteurization. Infused frozen strawberries are made by infusing and pasteurizing whole or sliced strawberries in sugar syrup or in other sweeteners. These products are pasteurized and are used in ice creams, sorbets, and bakery products. Infused dried strawberries are made by infusing strawberries to different sweetness levels prior to drying.

Nutritional Profiles of Strawberries

Soluble sugars, organic acid, amino acids, and other secondary metabolites contribute towards the fruit quality and nutritional value of strawberry. Being low in total calories, with a 100 g providing only 32 kcal, strawberry represents a healthy food choice. According to the available data (Table 1), they are a significant source of B vitamins, vitamins C and E, potassium, folic acid, carotenoids, and flavonoids such as pelargonidin, quercetin, and catechin. This fruit is also rich in manganese. Strawberries have also been considered as a moderate source of potassium, iodine, magnesium, copper, iron, and phosphorus.

Phytochemicals

Besides the common vitamin and mineral components, strawberries are exceptionally high in health-supporting

phytochemicals such as polyphenolics. Several research groups have examined the phytochemical composition of strawberry and found them highly variable. The chemical composition of strawberries can be significantly affected by genotype and other factors such as cultivation practices, environment, maturity stage, and postharvest storage. Processing of fresh strawberry fruit into products such as jams, juices, and purees is also associated with some loss of bioactive components.

Phenolic Compounds

The main phenolic compounds in strawberries are anthocyanins, flavonols, flavanols, followed by hydrolyzable tannins (ellagitannins and gallotannins), phenolic acids (hydroxybenzoic acids and hydroxycinnamic acids), and condensed tannins (proanthocyanidins). The polyphenols account for most of the health benefits of strawberries. Anthocyanins are responsible for the red color of strawberries. Prior to maturity, the level of anthocyanins is undetectable in strawberries. As fruits enter the white stage, anthocyanins begin to accumulate and continue until full ripening. Anthocyanins are the best-known polyphenolic compound in strawberries, and more than 25 anthocyanin pigments have been reported in different varieties of strawberries by various research groups. Many studies reported anthocyanin contents ranging from 150 to 800 mg kg^{-1} fresh weight. Cyanidin-3-glucoside, pelargonidin-3-glucoside, 3-rutinoside, and 3-malonyl glucoside are the major anthocyanins in strawberries. Many previous studies reported pelargonidin-3-glucoside as the prominent anthocyanin component in many cultivars. In strawberries, flavonols occur in monomeric (catechins) and polymeric forms called condensed tannins or procyanidins. The most common flavonols in strawberries are quercetin and kaempferol derivatives. Acylated flavonols such as quercetin- and kaempferol-3-malonylglucoside have also been detected in strawberries. Several studies reported that procyanidins possess antioxidant, antimicrobial, antiallergic, and antihypertensive properties.

Most of the ellagic acid in strawberries is in the form of ellagitannins, which are a different class of phenolics. Strawberry ellagitannins are complex and diverse involving different combinations of gallic acid and hydroxydiphenic acid with glucose. The total content of ellagitannins ranges between 7.7 and 18.2 mg 100 g^{-1} FW. Ellagic acid is reported as the main phenolic acid in strawberry. Among the berries, raspberries, and strawberries contain the highest content of ellagitannins. Ellagic acid and ellagitannins also contribute significantly to the total antioxidant capacity and anticarcinogenic property of strawberries. Other phenolic acids have also been noticed in strawberries in small amounts. The derivatives of *p*-coumaric acid and hydroxybenzoic acid have also been detected in

strawberry. Ferulic acid derivatives were also identified in some cultivars. The predominant phenolic acids in strawberries are *p*-hydroxybenzoic acid and *p*-coumaric acid.

Strawberry Volatiles

Strawberries are enjoyed and appreciated for their vibrant color, distinct aroma, sweetness, and characteristic flavor. Volatile compounds are responsible for the unique aroma of fresh strawberries and are also an important quality attribute influencing consumer acceptability. The production of volatiles is one of the noticeable changes that occurs during ripening. Several studies have determined the aroma components of various cultivars of strawberry. Strawberry volatiles are highly complex consisting of several hundred compounds. Although these aromatic compounds are present in very low concentrations of about 0.01–0.001% on a fresh fruit weight basis, individual compounds may have a significant impact on the overall aroma of the strawberry. The volatiles and flavor compounds in strawberry have been studied exhaustively in many genotypes and cultivars. Various studies have detected more than 360 compounds in strawberry. Strawberry aroma compounds can be grouped into several chemical classes, including acids, aldehydes, ketones, alcohols, esters, lactones, sulfur compounds, acetals, furans, phenols, epoxides, and terpenes. However, esters are the main contributors to strawberry aroma. Esters constitute 25–90% of the total volatiles in ripe strawberry. Among the esters, butanoates comprised the predominant proportion. The esters methyl butanoate, ethyl butanoate, methyl hexanoate, ethyl hexanoate, ethyl 2-methylbutanoate, hexyl acetate, and hexenyl acetate are considered as flavor components that contribute to the fruity and green aroma. Normally, terpenes and sulfur compounds comprise less than 10 and 2% of total volatiles produced, respectively. The terpene alcohol, linalool, has been attributed to the floral, fruity, sweet, and berrylike aroma notes of strawberries. Another lactone compound, gamma decalactone, which imparts spicy, floral, and fruity characteristics, has been found in high concentrations in some cultivars. Mesifurane and furaneol give the characteristic caramel-like sweet, floral, and fruity aroma. Hexenal is thought to be responsible for the green or fresh fruit aroma. Strawberry aroma is determined by a complex series of compounds that can be affected by many factors including cultivar or varietal differences, stage of ripeness, and growing conditions.

Strawberry Consumption and Health Effects

The consumption of strawberries has been linked to several health benefits including prevention of inflammation, oxidative damage, cardiovascular disease (CVD), cancers, type 2 diabetes, obesity, and neurodegeneration.

Antioxidant Capacity

Antioxidants could serve a crucial role in disease prevention by reducing the formation of free radicals through free radical scavenging and stimulating the defense system. The antioxidative properties and potentials of polyphenols have been studied including their capacity for free radical scavenging, inhibition of lipid oxidation, and enhancement of the activity of endogenous antioxidative enzyme systems such as superoxide dismutase, glutathione reductase, and catalase. The antioxidant potential of polyphenols is dependent on their chemical structure and is mostly correlated to their polyphenol and vitamin contents. In many studies comparing the antioxidant capacity of fruits, strawberry consistently received higher ranking compared to other fruits and vegetables. Strawberries were ranked fourth among common fruits in total antioxidant and antiproliferative activities on human liver cancer cells. In a study conducted in various strawberry cultivars, vitamin C was shown to be the greatest contributor (>30%) of the total antioxidant capacity of strawberry extracts followed by anthocyanins (contributing 25–40%), ellagitannins, and flavonols. Human intervention studies conducted with fresh, frozen, or freeze-dried strawberries have demonstrated the antioxidant capacity of strawberries to reduce oxidant stress associated with high-fat meals, hyperlipidemia, or metabolic syndrome. Flavonoids of strawberries have been shown to exert its antioxidant action mainly by scavenging free radicals, inducing phase 2 enzymes of antioxidant defense and detoxification, and modulating antioxidant gene expression. An increase in postprandial plasma antioxidant capacity was noticed in healthy subjects or hyperlipidemic volunteers after consuming strawberry or mixed berry. A number of *in vitro* studies have demonstrated the potent antioxidant activities and free radical scavenging ability of phenolic compounds.

Cardiovascular Diseases

Obesity, hyperglycemia, hyperlipidemia, hypertension, inflammation, and oxidative stress are some of the known risk factors for the development of CVD. The oxidation of low-density lipoprotein (LDL) was suggested to be an early event in the development of atherosclerosis. Evidence on the positive effects of the consumption of berries and berry flavonoids on cardiovascular health is available. Only limited epidemiological studies provide evidence for the protective and beneficial effects of strawberry on cardiovascular health particularly in women. A significant reduction in CVD mortality associated with strawberry intake (a mean anthocyanin intake of 0.2 mg per day) was noticed in a study conducted in 34 489 overweight postmenopausal women during a 16-year follow-up period. In another women's health study conducted in female US health professionals ($n = 38\,176$), strawberry intake has also been associated with lower levels of C-reactive protein, which is a stable inflammatory biomarker associated with inflammation and is a high risk factor of CVD. A decreasing CVD incidence was also observed in subjects consuming higher amounts of strawberries during a follow-up study period of 11 years.

Improvement in serum lipid profile through a reduction of total cholesterol, LDL-C, and triglyceride levels was noticed in a study conducted in healthy young volunteers who consumed 500 g of strawberries for 1 month. The nutrients and phytochemicals in the fruit might have favorably affected the plasma lipid profiles. Some human

intervention studies provide evidence for the efficacy of freeze-dried strawberry in the nutritional management of elevated lipid profiles. A few epidemiological studies have shown a positive correlation between flavonoid consumption and reduced risk of CVD.

Anticancer and Cytotoxicity

Evidence is available that supports the anticarcinogenic effects exerted by extracts or purified strawberry phytochemicals mediated via detoxification of carcinogens, protection against DNA damage, antiproliferative effects on cancer cells via apoptosis, and increase in serum antioxidant capacity. Strawberry tannins have also demonstrated anticancer properties through antiproliferative effects on human breast, cervix, and colon carcinoma cells. Purified ellagic acid from strawberries has also shown potent anticarcinogenic benefits in several human cancer cell models. Strawberries treated with thymol, menthol, and eugenol showed stronger inhibition of human HT29 colon cancer cell growth than the untreated berries. The antiproliferative effects of organically and conventionally grown strawberries were evaluated and the organically grown strawberries showed greater antiproliferative activity than the conventionally grown strawberries owing to the higher content of bioactive substances present.

Protection against UV Radiation and DNA Damage

Some *in vitro* studies have suggested that the phytochemicals in strawberry could be helpful in skin protection. Recently, the photoprotective effect of anthocyanin-rich strawberry extracts on human dermal fibroblast exposed to UV-A radiation was studied. Incubation of human dermal fibroblasts in strawberry extract has resulted in an increase in cellular viability and a decrease in DNA damage in a dose-responsive manner when compared to control cells. Consumption of fresh strawberries by young and middle-aged subjects also resulted in significant increase in serum total antioxidant capacity and vitamin C concentrations. A decrease in oxidative biomarkers in urine and blood plasma was also noticed after strawberry consumption for a month.

Bioavailability and Metabolism of Strawberry Phytochemicals

Factors affecting the absorption and metabolism of strawberry phytochemicals (dietary polyphenols) are complex. Bioavailability and metabolism are crucial to the potential health-promoting effect of polyphenols. The bioavailability of phenolic compounds in foods is a complex process influenced by their chemical structure, size, solubility, degree of glycosylation, and conjugation with other compounds. Polyphenols are released from the food matrix during digestion and the amounts of consumed polyphenols available for absorption may undergo modifications before reaching the target tissue. Bioavailability of polyphenols is generally low and in the range of 0.5–1.5% of the amount ingested. Interaction of polyphenols with other structural components such as proteins, carbohydrates, and fibers occurring in food matrices is one of the factors determining the bioavailability of polyphenols.

It was noticed that most polyphenol glucosides in the small intestine are deglycosylated by glucosidases or transported by the lactase–phlorizin hydrolase through the epithelial barrier. After reaching the small intestine, flavonoids in the form of glycoside conjugates are hydrolyzed by lactase–phlorizin hydrolase leading to the release of aglycone. These aglycones pass into the epithelial cells by passive diffusion as a result of its increased lipophilicity. Those flavonoids that are not taken up in the small intestine pass to the colon where they are processed by colonic microflora that hydrolyze glucosides into aglycones and extensively metabolize these aglycones into various aromatic acids. The resultant aglycones are transformed into phenolic acids and hydrocinnamates that are assimilated. In the liver, they are metabolized and excreted in the urine. Flavonoid glucosides that enter the colon from the small intestine are exposed to a microbial population that is capable of modifying the molecular structure of the phenolic compounds through hydrolysis, dehydroxylation, demethylation, ring cleavage, and decarboxylation. Flavonoids undergo glucuronidation in the small intestine by UDP-glucuronyl transferase. But their absorption is relatively low. Some of the ingested flavonoids are possibly absorbed in the stomach.

The absorption and excretion of anthocyanins are influenced by the anthocyanidin structure and the sugar moiety. Anthocyanins are maintained as the stable flavylium cation form under the acidic pH of the stomach, and so only a limited quantity of anthocyanins is quickly assimilated from the stomach. Some of the anthocyanins are absorbed as intact glycosides. The principal anthocyanin in strawberry is pelargonidin-3-glucoside, and it undergoes gastric conversion to pelargonidin glucuronide followed by its conversion to 4-hydroxybenzoic acid. Urinary excretion of pelargonidin-3-glucoside and its metabolites such as pelargonidin and monoglucuronides was observed in human subjects with increased consumption of fresh strawberries. On reaching the small intestine, anthocyanins are converted into some neutral pH forms such as hemiketals, chalcones, and quinonoids. These compounds are partially assimilated in the jejunum and undergo conjugation reactions mostly in the liver, kidney, and also in the intestine. *In vitro* digestion using fecal microbiota has shown that the bacterial metabolism of anthocyanin glucosides involves the cleavage of the anthocyanin heterocyclic rings. The resulting aglycone is further transformed into low-molecular-weight compounds such as phenolic acids. The compound 4-hydroxybenzoic acid has been suggested as a major metabolite of pelargonidin-3-gluciside from strawberry. Protocatechuic acid has been proposed as a potential metabolite from the microbial conversion of cyanidin-based anthocyanidin. Also, coumaric acids, 4-hydroxybenzoic acid, and protocatechuic acid were retrieved from the plasma 8 h after strawberry consumption.

Sucrose: Dietary Importance

J Plaza-Diaz and A Gil, University of Granada, Granada, Spain

© 2016 Elsevier Ltd. All rights reserved.

Definition

Carbohydrates are the world's primary source of food energy. The Food and Agriculture Organization of the United Nations (FAO) and, more recently, the European Food Safety Authority (EFSA) have advised that carbohydrate intake should range from 45% to 60% for both adults and healthy children older than 1 year of age.

Dietary carbohydrates can be in the form of complex molecules (polymers or polysaccharides) or more simple molecules, monomers (monosaccharides) or dimers (disaccharides), commonly referred to as sugars. Sucrose is a disaccharide composed of the monosaccharides glucose and fructose. Sucrose is the organic compound commonly known as table sugar, cane sugar, or beet sugar. Sucrose is an odorless, white, crystalline powder with a sweet taste. It is a nonreducing sugar, which is soluble in water and crystallizes easily. It is used to sweeten foods, improve the sour and bitter taste of many foods, and preserve foods by increasing osmotic pressure, which prevents the growth of many microorganisms.

Sucrose is hydrolyzed in the small intestine via the action of the sucrase–isomaltase enzyme complex, and the resulting monosaccharides are later metabolized, rendering energy or serving as a carbon skeleton for other biological compounds, primarily glycogen, fatty acids, and cholesterol.

Chemical and Physical Characteristics

Chemical Characteristics

Sucrose (α-D-glucopyranosyl-β-D-fructofuranoside) is a disaccharide with the general molecular formula $C_{12}H_{22}O_{11}$, and it has a molecular weight of 342.30. In solution, it is present primarily in the cyclic form, which can be represented in various ways (e.g., a Fischer projection or as a Haworth-type structure; Figure 1). All sugars are fairly reactive but, in sucrose, the reactive sites of glucose and fructose are bonded together. Sucrose is a nonreducing sugar and is stable when heated. Fructose will decompose at temperatures above 103 °C, and both glucose and fructose are unstable in alkaline solutions. In acidic solutions, sucrose will invert or break down to its component monosaccharides. This reaction is accelerated with increasing acidity or temperature. In solution (including in human metabolism), most sucrose reactions begin with the inversion reaction.

Physical Properties

Sucrose is normally used as a solid because it is extremely stable in its crystalline form. Pure sucrose is a colorless, odorless crystalline powder with a pleasing sweet taste without any other flavor or aftertaste; it is the standard reference for sweetness. If sucrose is given a sweetness rating of 100, the relative sweetness of fructose is between 105 and 125, and that of glucose between 65 and 75, depending on the conditions (e.g., acidity, pH, and temperature). The specific gravity of a single sucrose crystal is 1.5879 g ml^{-1}.

Sucrose melts and decomposes at 186–188 °C to form caramel and, when combusted, it produces carbon, carbon dioxide, and water. The heat of combustion is 1351.3 kcal mol^{-1} or 3.95 kcal g^{-1}. Sucrose is, therefore, less caloric than fat (9.3 kcal g^{-1}) and protein (4.1 kcal g^{-1}).

The International Commission for Uniform Methods of Sugar Analysis (ICUMSA) is an international standards body, founded in 1897, which publishes detailed laboratory procedures for the analysis of sugar. Sucrose is extremely soluble in water and alcohol and other polar solvents. Solubility is one of the most studied properties of sucrose because it is such an important factor in production and use. Numerous tables are available to determine the saturation point of sucrose (maximum solubility) under various conditions.

Because the amount of sucrose dissolved in water is important industrially, a series of measuring indexes have been developed to indicate the relative proportions of the two materials. The most important of these is the Brix scale, which provides the percentage of sucrose (by weight) in a water solution. For example, 65° Brix would represent a solution that is 65% sucrose and 35% water. Thus, a Brix reading can be used to obtain the corresponding specific gravity or refractive index of a solution that, in practice, corresponds to a solution of pure sucrose at a set reference temperature, usually 20 °C. This index is very useful for estimating the sucrose content in many foods containing relatively high amounts of sucrose, namely, fruit juices.

Other properties that are commonly measured include viscosity, osmotic pressure, boiling point elevation, and equilibrium relative humidity, because these physical properties are very useful in the food technology field.

Sources and Production

Table sugar (sucrose) comes from plant sources. Two important sugar crops predominate: sugarcane (*Saccharum officinarum* L.) and sugar beet (*Beta vulgaris* L. var. *rapa*). Sugar can account for between 12% and 20% of dry weight. Minor commercial sugar crops include the date palm (*Phoenix dactylifera*), sorghum (*Sorghum vulgare*), and the sugar maple (*Acer saccharum*).

Sucrose is present naturally in many fruits and fruit juices, but it can also be found as added sugar in baby foods, baked products, beverages, breakfast cereals, cereal grains and pasta, dairy and egg products, ethnic foods, fast foods, fat and oil products, finfish and shellfish products, legumes and legume products, meals, entrées and side dishes, nut and seed products, poultry products, pork products, sauces, gravies and soups, sausages and luncheon meats, snacks, spices and herbs, sweets, and vegetables and vegetable products (see Table 1).

Table 1 The sucrose content of foods[a]

	Range in mg per 100 g serving
Baby foods	40–9340
Baked products	160–44 528
Beverages	50–59 896
Breakfast cereals	30–44 357
Cereal grains and pasta	20–1700
Dairy and egg products	10–10 000
Ethnic foods	10–20 081
Fast foods	10–32 098
Fat and oil products	290–6399
Finfish and shellfish products	30–2950
Legumes and legume products	340–8680
Meals, entrées, and side dishes	320–3501
Nut and seed products	340–51 503
Poultry products	20–600
Pork products	40–780
Sauces, gravies, and soups	240–1100
Sausages and luncheon meats	80–1300
Snacks	120–16 508
Spices and herbs	20–4089
Sweets	700–94 546
Vegetables and vegetable products	10–5250

Sugarcane

Most sugarcane comes from countries with warm climates because sugarcane does not tolerate frost. Approximately 80% of the world's sucrose is derived from sugarcane; the remainder is almost entirely from sugar beets.

In 2013, Brazil, India, China, Thailand, and the United States were the major sugarcane-producing countries in the world. Brazil produced approximately 739 million tons of sugarcane in 2013, whereas India produced 341 million tons, China 125 million tons, Thailand more than 100 million tons, and the United States more than 27 million tons. Viewed by region, South America predominates in sugarcane production, providing 44.7% of the global production in 2013. Asia comes in the second place with 39.7% of the global production; Africa and Central America produce 11.2% and Oceania produces 1.5%.

Since the sixth century BC, sugarcane producers have crushed the harvested vegetable material from sugarcane to collect and filter the juice containing the sugar. Sugarcane processing requires two stages: mills extract the raw sugar from the freshly harvested cane and 'mill-white' sugar, which is intended for local consumption, is sometimes produced immediately afterward. Sugar crystals appear naturally white in color during the crystallization process. Sulfur dioxide is added to inhibit the formation of color-inducing molecules and to stabilize the sugar juices during evaporation.

Sugar Beets

Sugar beets come from regions with cooler climates, including northwest and eastern Europe and America; the Russian Federation produced more than 39 million tons in 2013, France 33 million tons, Germany 22 million tons, and the United States over 29 million tons.

White beet sugar is made from beets, which are harvested in the autumn and early winter by digging them out of the ground. The processing begins by slicing the beets into thin chips, which increases the surface area, making it easier to extract the sugar.

The extraction takes place in a diffuser, where the beet is kept in contact with hot water for about an hour before being squeezed in screw presses to extract as much juice as possible. The juice is cleaned up before it can be used for sugar production by carbonatation, where small clumps of chalk are grown in the juice. As the clumps form, they collect many nonsugars; filtering out the chalk also removes any nonsugar molecules.

The juice is evaporated in a multistage evaporator, and the syrup placed in a large pan, typically holding 60 tons or more of sugar syrup. In the pan, water is boiled off until the conditions are right for sugar crystals to grow. Once the crystals have grown, the resulting mixture of crystals and mother liquor is spun in a centrifuge to separate the two, similar to how laundry is spin-dried. The crystals are dried with hot air before being packed and/or stored for dispatch.

Patterns of Consumption

Global Scenario

At the present time, cane sugar and beet sugar are produced in more than 130 countries. As far as the consumption per country is concerned, India, China, Brazil, the United States, and Russia stand out, as they represent 45.2% of global consumption for the 2010–11 sugar cycle. India and Russia showed the

greatest increases in demand at 8.5% and 3.3%, respectively, for the same cycle.

There are six sugar-consuming regions in the world. The first is found in Asia (composed of 36 countries) with a deficit (between production and consumption) of 6.3 million tons and an annual consumption of 14.9 kg per capita. The region with the second highest consumption is composed of the 12 countries of the former Soviet Union, with a deficit of 4.8 million tons. In the third place is North Africa with a sugar consumption deficit of 3.9 million tons. In the fourth and fifth places are North America and Europe with a deficit of 2.8 and 2.4 million tons, respectively. In North America, the deficit region is composed of two countries, Mexico and the United States, which have a population of 422 million inhabitants who maintain a high sugar intake compared with production levels; in per capita terms, the sugar consumption deficit in this region is 2.8 million tons.

Sucrose Intake by Country

Although overall energy intake has steadily increased globally, worldwide trend data do not support the widely held view that refined sugar, as available for consumption, has increased dramatically over the last 40–50 years.

The most comprehensive trend analysis for the National Health and Nutrition Examination Survey (NHANES) 1999–2000 through 2007–08 revealed a decrease in total energy intake (from 2145 to 2070 kcal day^{-1}) for the US population. The absolute intake of added sugars decreased from 100 g in 1999–2000 NHANES to 77 g in 2007–08 (−24%). In addition, the percentage of total energy, via added sugar intake, fell from 18.1% to 14.6%.

In the United Kingdom, there were significant reductions for male children in total sugars (≈9%) and nonmilk extrinsic sugars (NMES) (≈22%) between 1997 and 2008–09, but there was no reduction in the overall total food energy. In female children, the only significant difference was a reduction in the percentage of food energy from NMES, which fell from 16.8% to 14.6%, with no other differences.

In France (INCA surveys), sugar intake only increased significantly in younger men aged 18–34 years (≈10 g day^{-1}, +9.8%) and in middle-aged women aged 35–54 years (≈10 g day^{-1}, +12.7%) between 1998–99 and 2006–07.

In Denmark, between 1999 and 2007, added sugar intake fell by 47% in 2-year-old children and by 62% in 12-month-old children.

In Sweden, the levels of sucrose intake between reports (1989 and 1997–98) increased by 6 g day^{-1} in men but were unchanged in women. The percentage of energy from sucrose between the reports increased marginally in men but was essentially unchanged in women.

In Spain, the daily sugar intake per capita is 111.2 g, according to the 2011 ENRICA study. China's per capita daily sugar consumption is less than 31 g and lower still in rural areas (5.5 g day^{-1}), which is much lower than levels consumed in medium- and high-income countries. In India, the per capita daily sugar consumption is greater than 58 g.

In Australia, the total sugar intake increased significantly between 1983 and 1995 by 14 and 5 g in men and women, respectively. In terms of the percentage of energy contribution, in men, the proportion of energy from total sugars increased between 1983 and 1995 from ≈18% to 20%. In women, it stayed relatively constant at 21% Figure 2 shows the sugar daily energy intake (kcal day^{-1}) in the world.

Digestion, Absorption, and Metabolism of Sucrose

The human body is able to capture some of the chemical energy from carbohydrates through cellular metabolism, resulting in the generation of an intermediate chemical form, adenosine triphosphate, which acts as an energy source for cellular processes. Adenosine triphosphate is regenerated from adenosine diphosphate using energy from food. The brain, nervous system, and red blood cells have an obligatory requirement for glucose as an energy source.

The intestinal digestion of sucrose requires hydrolysis of its α(1,2′)β-linkage, which involves the anomeric carbon of both hexoses, to yield fructose and glucose. In mammalian species, the hydrolysis of sucrose is performed via the sucrase activity of the sucrase–isomaltase complex in the enterocytes of the small intestine.

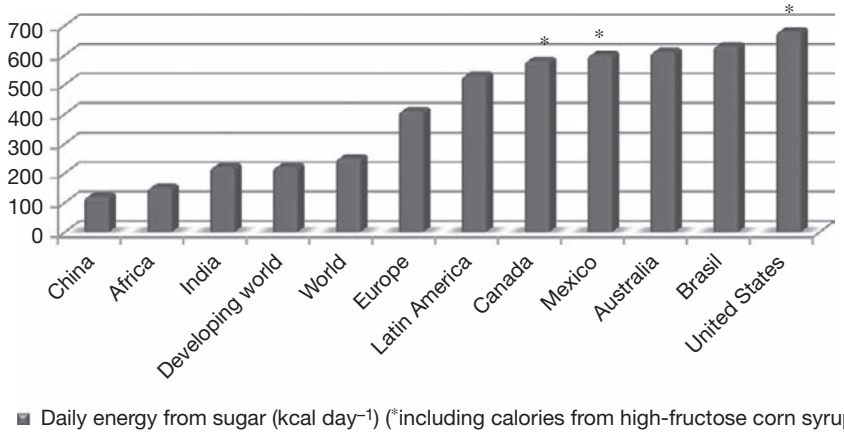

Figure 2 The world caloric intake of sugar. Adapted from USDA-ERS, Conadesuca, OECD, Credit Suisse Research, 2013.

Following absorption, glucose and fructose are transported to the liver by specific transporters, SLGT1 and GLUT-5, respectively. Glucose is phosphorylated to glucose-6-phosphate in the liver by glucokinase, which functions in glycogen synthesis or lipogenesis via the glycolytic pathway, or it reaches the systemic circulation. The plasma concentration of insulin increases immediately after the ingestion of glycemic carbohydrates. A family of glucose transporters mediates the cellular uptake of glucose, while in some tissues (e.g., adipose tissue and skeletal muscle), it is insulin-dependent (GLUT-4).

Fructose is metabolized by conversion to glycolytic pathway intermediates. In the liver, it is phosphorylated to produce fructose-1-phosphate in a reaction catalyzed by ketohexokinase or fructokinase. Fructose-1-phosphate is cleaved by the action of aldolase B to form dihydroxy-acetaldehyde-phosphate (DHAP) and glyceraldehyde. To metabolize glyceraldehyde, it has to be phosphorylated by triose kinase, creating glyceraldehyde-3-phosphate, which enters the glycolytic pathway, along with DHAP, at the triose-phosphate level. Under postprandial conditions, fructose is primarily converted to acetyl-coenzyme A and later to fatty acids and cholesterol.

Glucose is made available to body tissues via the bloodstream, and it is the primary carbohydrate used for energy. The balance between oxidation, biosynthesis, and glucose storage depends on the hormonal and nutritional state of the cells, tissues, and organism. The predominant metabolic pathways of glucose vary indifferent cells depending on the physiological demand. Thus, the liver has a fundamental role in glucose homeostasis in the body.

Glucose can be completely oxidized by hepatocytes to obtain energy, and it can be stored in the form of glycogen, or it can be used to supply carbons for fatty acid and amino acid synthesis. Heart and skeletal muscles can completely oxidize glucose or store it in the form of glycogen. Glucose can be partially broken down in fatty tissues to provide glycerol, which is necessary for triacylglycerol synthesis, or oxidized completely to supply two units of carbon (acetyl-CoA) for fatty acid synthesis.

The brain depends on the continuous supply of glucose, which can oxidize completely to form CO_2 and water. Conversely, erythrocytes, which have a limited capacity for oxidizing glucose because they do not have mitochondria, depend entirely on metabolic fuels for energy production, partially oxidizing glucose to lactate via glycolysis. Other specialized cells such as corneal cells, lens and retina cells, leukocytes, testicular cells, and renal medulla cells are predominantly glycolytic.

Nutritional Aspects of Sucrose

Although at first glance, the sole function of carbohydrates appears to be an energy source for human and animal metabolism, sugars have other significant structural functions in living organisms, such as important components of membrane antigens and proteins that are secreted by many cells.

The release of insulin, in response to sucrose ingestion, maintains blood glucose within a closely regulated range, which is essential for normal functioning of the central nervous system. Sugar does not cause abnormal insulin and blood glucose responses.

Sucrose as a Sweetener

Sweeteners can be categorized as nutritive and nonnutritive. Nutritive sweeteners (NSs) contain carbohydrates and provide energy (4 kcal g^{-1} and an average of 2 kcal g^{-1} for sugar alcohols). Nonnutritive sweeteners (NNSs) offer little or no energy when ingested. They are referred to as high-intensity sweeteners because, as sweetening ingredients, they are many times sweeter than sucrose. NNSs can replace the sweetness of sugar or energy-containing sweeteners. However, they do not have the same functional properties, such as browning, crystallization, and microbial inhibition.

Enjoying a sweet taste is innate, but the perception of sweetness and the preferred level of sweetness vary among individuals. Taste perception begins on the tongue and soft palate, where taste receptors interact with food or beverages. Taste receptor cells are organized into taste buds, which are distributed throughout the tongue and on specialized structures called papillae. A sweet taste is elicited by interaction with a sweet receptor, which is a dimeric G protein-coupled receptor composed of T1R2 and T1R3 subunits with multiple active sites. T1R2 and T1R3 receptors respond to sugars (e.g., sucrose, fructose, galactose, glucose, lactose, and maltose) and NNSs (e.g., acesulfame K, aspartame, cyclamate, dulcin, neotame, saccharin, and sucralose), although their specific preferential binding sites may vary.

Sucrose is an important part of both groups of sweeteners. In the NS group, which includes sucrose, glucose, and fructose, the carbohydrate adds texture, flavor, and color to baked goods; supports the growth of yeast for leavening or fermentation; contributes to volume in ice cream, baked goods, and jams; enhances the creamy consistency of frozen desserts; enhances the crystallization of confectionary products; balances acidity in salad dressings, sauces, and condiments; and helps to maintain the natural color, texture, and shape of preserved fruits. In the NNS group, the carbohydrate is present in a modified form, such as sucralose.

The chlorination of three hydroxyl groups on sucrose produces a modified sucrose that is approximately 600 times sweeter than sucrose (sucralose). Sucralose is used as a sugar substitute in numerous food products, including beverages, baked goods, dairy products, canned fruits, syrups, and condiments, and it is sold direct to consumers as an NS sugar replacement (e.g., Splenda™).

Health Effects

In the last several decades, numerous epidemiological studies have associated a high intake of sugar with higher prevalence of noncommunicable chronic diseases, primarily dental caries, being overweight or obese, diabetes, and cardiovascular disease (CVD). However, recent reviews and meta-analyses do not always support this hypothesis, particularly when the results are adjusted to the energy intake.

Dental Caries

There is consistent evidence of moderate quality supporting a relationship between the amount of total sugars consumed and

the development of dental caries. Dental caries progress with age, and the effects of sugar on dentition are lifelong. Even low levels of caries in childhood are significant to the amount of caries throughout an individual's lifetime. Nevertheless, dental caries, regardless of sugar consumption, has decreased dramatically in developed countries due to increased buccodental hygiene and the use of fluoridated toothpaste and/or water supplies.

Population studies support the dose–response effect between sugar intake and dental caries with 18 of 20 studies showing a positive association, one showing a neutral association and one showing a negative association between sugar intake and the presence of dental caries. Additionally, nine population studies provide evidence of positive correlations between sugar intake and caries levels. There is also evidence of moderate quality showing that dental caries are lower when free sugar intake equates to less than 10% of the total food energy. Indeed, countries with estimated sugar intakes are less than 10% – or even 5% – of the total food energy that do not have lower prevalence of caries. Changes in the sugar supply do not reliably predict the magnitude or trends in the prevalence of caries. Most developed countries have a lower prevalence of caries than many countries with lower sugar intake, despite intakes being greater than 10% of the total food energy. However, the majority of data are for children meaning the situation in regard to adult dental health is unclear.

Obesity

Obesity occurs when energy intake from food and drink consumption is greater than energy expenditure through the body's metabolism and physical activities over a prolonged period, resulting in the accumulation of body fat. Changes in body weight would be expected from any change in macronutrient intake that leads to an overall excess or deficit in food energy compared with the requirements for weight stability. An earlier World Health Organization (WHO)-sponsored expert review stated, "excess energy in any form will promote body fat accumulation."

A recent review and meta-analysis reported that isocaloric substitution of sugars for other carbohydrates does not lead to weight gain. Therefore, there is no consistent or reliable evidence that sugars affect obesity more than any other macronutrient.

Currently, there is no clear evidence of a dose–response gradient for the amount of sugar consumed and body weight. There are a number of short-term intervention studies that focus on increasing or decreasing intakes of sugars and sugar-containing foods, but the majority are unreliable as evidence of the effect of 'free sugars' on obesity because of confounding information on the caloric intake from other macronutrients.

Conversely, there are no randomized controlled trials in children to evaluate the potential effects of sugar on body weight. Therefore, some authoritative reviews have concluded that there is no consistent or reliable body of evidence to support any specific sugar intake level for the avoidance of obesity in childhood.

The overconsumption of food energy, whatever its macronutrient composition, will lead to weight gain. However, there is no convincing evidence to support the widely held view that sugar, including sugars in drinks, is specifically responsible for obesity.

In addition, there is no convincing evidence that sugar is addictive or stimulates overconsumption. Until scientists develop valid and reliable methods for measuring energy intake in individuals and can balance this against energy expenditure, more precise causes of weight gain will remain elusive. Although obesity may be related to morbidity and mortality rates, whether this is predominately a reflection of inadequate physical activity and low physical fitness beyond high energy and dietary sugar intake requires further examination.

Diabetes

Diabetes mellitus (DM) is one of the most prevalent endocrine diseases in the general population. A number of expert reports have considered the possible role of sugar in the causation of DM. In the 1980s, the US Food and Drug Administration Sugar Task Force and UK Committee on the Medical Aspects of Food (and Nutrition) both dismissed the notion that sugar causes DM directly. The EFSA has indicated, "available evidence is insufficient to set an upper limit for sugars based on their effects on type 2 DM risk."

Likewise, the UK recommendations do not consider it appropriate to make specific recommendations for single nutrients, including added sugars. Moreover, the American Diabetes Association suggests minimizing the substitution of sucrose-containing foods for isocaloric amounts of other carbohydrates. Nevertheless, there is moderate evidence that high consumption of sugar-sweetened beverages (SSBs) contributes to an increased risk for type 2 DM. The direction of the association indicates that greater consumption of SSBs is detrimental to health and the association is biologically relevant. However, recent recommendations to prevent DM are focussed on the restriction of total carbohydrate and energy intake and increasing physical activity to allow for weight control, particularly in those who are obese.

Cardiovascular Diseases

There is some concern that increased consumption of carbohydrates (particularly sugars and especially fructose), as may occur on a low-fat high-carbohydrate (LFHC) diet, could result in increased plasma triacylglycerols and reduced High density lipoproteins (HDLs) cholesterol (HDL-c), which are both independent risk factors for CVD. A number of in-depth reviews have examined the effects of carbohydrates on triglycerides and factors that may influence any effect on CVD.

These reviews have shown that in controlled isocaloric feeding studies, LFHC diets are associated with marginally reduced HDL-c (although it often results in an improved total cholesterol: HDL ratio) and slightly increased triacylglycerols. The authors found no adverse effects on cardiovascular risk factors (i.e., blood lipids, glucose, and insulin) when sucrose replaced starchy foods at the levels of at least 25% of total energy intake.

Hypocaloric diets (not ad libitum), which can be low or high in sucrose, have been shown to reduce serum triacylglycerol levels. Consumption of fructose within the range

observed across the US population is not associated with hyperlipidemia in normal, overweight, or obese individuals, although high consumption may result in nonalcoholic fatty liver disease.

A low-fat (particularly low in saturated fat) high-carbohydrate diet, adequate physical activity/cardiorespiratory fitness, and abstinence from tobacco use are the current recommendations to reduce the risk of CVD. Although changing to a high-carbohydrate diet may increase blood triacylglycerols, the implications for CVD risk are unknown, and outcomes are moderated by many factors that require further study. Thus, currently, there is insufficient evidence to conclude that sugar directly or indirectly increases the risk of CVD.

Sucrose: Properties and Determination

M Peris, Polytechnic University of Valencia, Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Sucrose occurs in many foodstuffs. This disaccharide forms a major element in confectionery and desserts. Cooks also use it for sweetening – its fructose component, which has almost double the sweetness of glucose, makes sucrose distinctively sweet in comparison to other food carbohydrates. Furthermore, it can act as a food preservative when utilized in sufficient concentrations. Sucrose is important to the structure of many foods, including biscuits and cookies, cakes and pies, candy, and ice cream and sorbets. Finally, it is a common ingredient in many processed foods and the so-called junk foods, which include salted snack foods, gum, candy, sweet desserts, fried fast-food, and sugary carbonated beverages. That is why knowledge of its quantitative distribution in those foodstuffs and in dairy products, meat and meat derivatives, and other natural matrices is essential, since they are involved in very important characteristics, such as flavor, maturity, quality, authenticity, and storage conditions.

Definition and Properties

Sucrose is a carbohydrate (sugar). A white, odorless, crystalline powder with a sweet taste, it is best known for its role in food. The molecule (molecular weight 342.30) is a disaccharide composed of the monosaccharides glucose and fructose (both are $C_6H_{12}O_6$) with the molecular formula $C_{12}H_{22}O_{11}$. Sucrose is a molecule with nine stereocenters and many sites that are reactive or can be reactive. The molecule exists as a single isomer.

In sucrose, the components glucose and fructose are linked via an ether bond between C1 on the glucosyl subunit and C2 on the fructosyl unit. The bond is called a glycosidic linkage. Glucose exists predominantly as two isomeric 'pyranoses' (α and β), but only one of these forms links to the fructose. Fructose itself exists as a mixture of 'furanoses,' each of which having α and β isomers, but only one particular isomer links to the glucosyl unit. What is notable about sucrose is that, unlike most disaccharides, the glycosidic bond is formed between the reducing ends of both glucose and fructose and not between the reducing end of one and the nonreducing end of the other. This linkage inhibits further bonding to other saccharide units.

Physical Properties

Sweetness is probably the main characteristic of sucrose. In fact, sucrose is the standard sweetener to which all other sweeteners are compared. For this purpose, the relative sweetness of sucrose is set to 1. A growing number of alternative sweeteners exist on the market, all of them with somewhat different sweetness compared to sucrose. In this sense, sweeteners are divided into two main groups: bulk sweeteners (sorbitol, glucose, fructose, etc.), with a relative sweetness lower or slightly higher than sucrose, and high-intensity sweeteners (such as saccharin, aspartame, and acesulfame K), with a relative sweetness considerably above 1.

Sucrose crystallizes in the monoclinic space group $P2_1$ with the following room-temperature lattice parameters: $a = 1.08631$ nm, $b = 0.87044$ nm, $c = 0.77624$ nm, and $\beta = 102.938°$. It should also be remarked that the specific rotation at 20 °C using yellow 'sodium D' light (589 nm) is +66.47°.

The solubility of sucrose in water increases with increasing temperature. This relatively high solubility is an important parameter for its bulking effect in many foods and beverages. The dissolved sugar increases the viscosity of water-based solutions or mixtures, resulting in enhanced mouthfeel. On the other hand, dissolved sucrose lowers the freezing point of ice cream by preventing the water molecules from combining to form ice crystals, which slows down the freezing process. The frozen water crystals no longer in solution increase the sucrose concentration in the remaining solution and lower the freezing point even further.

Finally, sucrose does not deteriorate at ambient conditions. It does not melt at high temperatures. Instead, it decomposes – at 186 °C – to form caramel.

Chemical Properties

When dissolved in water, sucrose ($pK_a = 12.51$ at 25 °C) is chemically incapable of altering the amount of protons or hydroxide ions in solution. Therefore, the solution will exhibit no change in pH.

Like other carbohydrates, it combusts to carbon dioxide and water. Mixing sucrose with the oxidizer potassium nitrate produces the fuel known as rocket candy. The simplified reaction is

$$C_{12}H_{22}O_{11} + 6\,KNO_3 \rightarrow 9\,CO + 3N_2 + 11H_2O + 3K_2CO_3$$

Sucrose burns with chloric acid, formed by the reaction of hydrochloric acid and potassium chlorate:

$$8HClO_3 + C_{12}H_{22}O_{11} \rightarrow 11H_2O + 12CO_2 + 8HCl$$

On the other hand, sucrose can be dehydrated with sulfuric acid to form a black, carbon-rich solid, as indicated in the following idealized equation:

$$H_2SO_4(\text{catalyst}) + C_{12}H_{22}O_{11} \rightarrow 12\,C + 11\,H_2O + \text{Heat (and some } H_2O + SO_3 \text{ as a result of the heat).}$$

Since the molecule of sucrose contains no anomeric hydroxyl groups, it is classified as a nonreducing sugar. This absence of redox properties plays a capital role in the fundamentals of the different chemical methods proposed for the determination of this disaccharide.

Hydrolysis breaks the glycosidic bond converting sucrose into glucose and fructose. This process is also called inversion,

since sucrose is dextrorotatory, whereas the resulting mixture of glucose and fructose (a.k.a. inverted sugar) is slightly levorotatory. Hydrolysis is, nevertheless, extremely slow, but, if the enzymes sucrase and invertase are added, the reaction will proceed rapidly. Hydrolysis can also be accelerated with some acids, such as diluted HCl or monochloroacetic acid. Likewise, gastric acidity converts sucrose to glucose and fructose during digestion.

Determination

Sample Preparation

Regardless of the food product – and prior to the analysis – sucrose in the food sample must be dissolved in water (extraction) and separation or fractionation of food components may be necessary to remove interfering substances (cleanup).

For a general purpose, perhaps the most widely utilized method consists of using clarifying agents, whose function is to eliminate colored compounds (which might interfere with the passage of light through the solution), the rest of optically active substances, and other potentially interfering constituents (proteins, fatty acids, etc.). These clarifying agents should not affect the chemical nature of sucrose in the final solution. Moreover, any excess of clarifying agent must be removed to avoid undesirable interferences. The clarifying agents most frequently used in the analysis of sucrose in foodstuffs are lead acetate, zinc ferrocyanide, activated charcoal (for qualitative analysis), ion-exchange resins (used to remove potential acidic or basic interferents), and phosphotungstic acid.

Another alternative, solvent precipitation, is often used when the extraction solvent chosen has been water alone, since in this case, polar compounds such as salts and amino acids may contaminate the extract. Precipitation with an appropriate solvent, for example, a mixture of acetate buffer/acetonitrile, is then required.

In the case of chromatographic analyses of sucrose, the presence of some high- and low-molecular-weight ionic species in the food material (and hence in its extract) may seriously interfere. For example, the risk of overlapping peaks increases when salts and/or amino acids occur in the sample, since some of them under certain chromatographic conditions may elute very near to sucrose. In most of these cases, the use of a mixed-bed ion-exchange resin permits the complete removal of all these interfering species with no loss of analyte.

Apart from ion exchange, the use of chemically modified silica (e.g., C_{18}) has also become a common chromatographic procedure for extract cleanup, either in an open column or – as usually preferred – in the form of a Sep-Pak cartridge attached to the end of a syringe. In this last way, once the aqueous extract is forced through the cartridge, any nonhydrophilic molecules will be retained and sucrose will pass straight through with no decrease in its concentration.

Methods of Analysis

Traditional methods

Physical methods of analysis

Refractometry Refractive index of a solution depends on the concentration of solute. Therefore, it can be used to determine the concentration of sucrose solutions and the corresponding instruments (refractometers) may be calibrated with refractive index or directly with sugar concentration scales. For example, they are often calibrated in Brix, a parameter that is numerically equivalent to %sucrose w/w; in this case, these instruments are utilized only with sucrose solutions. When only refractive index scales are available, tables are required to obtain sucrose concentration. Unlike older instruments, modern refractometers are electronically controlled and (theoretically) free from operator error. Measurements are usually made at 20 °C using the sodium D line as the light source. Sucrose is most frequently utilized as the calibration medium for the instruments and the readings expressed as %sugar w/w 'as sucrose' in the food. Obviously, such instruments are only accurate for pure sucrose solutions, although they are also widely used for foods containing other sugars such as glucose syrups or invert sugar, since the reading obtained may be corrected if required; usually, the reading is used as a reference value to the sugar content (total soluble solids) of the solution. On the other hand, refractive index is heavily influenced by changes of temperature and wavelength of the light source; thus, control is necessary. Nevertheless, this drawback has been overcome by modern instruments, since their reading is temperature-compensated.

Polarimetry Polarimetric determinations are one of the common methods utilized in sucrose analysis, especially in the case of milk and dairy products. In this sense, special equipment (saccharimeter) exists that quotes the optical rotation in international sugar degrees (°S). 100°S (34.620°) is defined as the polarization of a sucrose solution of 26.000 g/100 ml in a 200 mm tube at 20 °C with white light filtered by potassium dichromate. Alternatively, yellow sodium light can be used.

Temperature is a major factor to be controlled since it may influence optical and specific rotations. For example, with an invert sugar solution (glucose + fructose) using sodium light, specific rotation is 0 at 90 °C and −20 at 20 °C.

In the case of the determination of sucrose in food samples, high-molecular-weight compounds such as proteins and polysaccharides must be removed, as well as reducing sugars.

When other sugars such as common monosaccharides occur in the food sample, the optical rotation must be recorded before and after hydrolysis, which is carried out with either diluted HCl or the invertase enzyme. From the difference in the optical rotation before and after hydrolysis, the concentration of sucrose can be determined, following the well-known Clerget method.

Isotope dilution Despite its widespread use in the analysis of sucrose in foods, polarimetry is known to be unreliable in the presence of optically active nonsucrose constituents. Instead, the isotope dilution technique is not affected by interferences from other species in solution. This technique measures the yield of a nonquantitative process. A small amount of radioactive sucrose is added to a sucrose solution (it is then an internal standardization method). After a nonquantitative purification of sucrose (regardless of its origin, various procedures have been developed for this purpose), the radioactivity is

measured. The extent of dilution of the radioactive tracer indicates the amount of sucrose originally present.

Liquid scintillation counting techniques have been applied in isotope dilution studies with no loss of accuracy over gas-flow proportional counters, but with an increase in the number of samples that can be analyzed.

Chemical methods of analysis

Classical methods What we know as 'classical methods' are related to the determination of reducing sugars, but sucrose – although a nonreducing carbohydrate – may also be determined by some of these procedures using modified versions of them. For example, according to the Lane and Eynon method, boiling Soxhlet reagent (Fehling A+Fehling B) is titrated with the sample using methylene blue as an indicator. Although this titration only determines reducing sugars, a simple modification enables it to measure sucrose. After the initial determination of reducing sugars, a sample of the carbohydrate solution is hydrolyzed using either hydrochloric acid or invertase. This converts sucrose into a mixture of glucose and fructose (invert sugar), and by remeasuring reducing sugars, the percentage of sucrose can be calculated.

The basic method has also slightly been changed by making use of alkaline copper citrate rather than tartrate, with Na_2CO_3 providing the alkaline environment. It is then known as the Luff–Schoorl method: An excess of the reagent is added to the carbohydrate solution, and after the reduction reaction is complete, the excess copper citrate is reacted with excess KI and the liberated iodine is titrated with $Na_2S_2O_3$ using starch as indicator. By subtraction of a blank, the amount of copper solution reacted with the sugar solution can be obtained.

Colorimetric methods According to the anthrone method, sucrose reacts with anthrone (9,10-dihydro-9-oxoanthracene) under acidic conditions to produce a blue/green color. The reaction takes place between the dehydration products of the sugar – furfural and hydroxymethylfurfural – forming condensation products with the anthrone. A modification to the standard technique, known as the Clegg's anthrone method, is based on the previous digestion of the food with $HClO_4$. Thereafter, sucrose will be hydrolyzed to their component reducing sugars and these react with the anthrone reagent.

Another typical colorimetric assay, the phenol–sulfuric acid method, involves two stages: dehydration of sucrose to furfural and hydroxymethylfurfural with concentrated H_2SO_4 and condensation of these substances with phenol to produce a yellow color. This method has a high sensitivity and is therefore utilized when microgram quantities of sucrose occur.

An alternative procedure is based on the addition of 3,5-dinitrosalicylate in alkaline solution. This compound reacts with reducing sugars, the resulting product being measured colorimetrically at 540 nm; in this case, two measurements are required: before and after acid hydrolysis of sucrose. Its percent is then calculated from the difference in absorbance before and after the inversion.

Finally, sucrose also reacts with picric acid (2,4,6-trinitro-1-phenol) in alkaline solution to produce red picramates, which can also be monitored spectrophotometrically at 490 nm. This procedure is known as the picric acid method.

Modern methods

Near-infrared (NIR) reflectance

Spectroscopic measurements in the near-infrared region of the electromagnetic spectrum have often been used in quantitative analysis of sucrose in a wide range of foodstuffs including soybean, chocolate, sugar cane, and beet. This technique (which relies effectively upon chemometrics, since it develops statistical models for the spectral data to predict the sucrose content in the food samples analyzed) is straightforward with a great potential, given its advantages in terms of minimal sample preparation. Nevertheless, further improvement in the sensing configuration and calibration methods is needed in some cases.

Chromatography

In the determination of sucrose in foods, high-performance liquid chromatography (HPLC) and gas chromatography (GC) provide rapid analyses with greater precision and specificity. These features are notably enhanced if these techniques are coupled to others, mainly mass spectrometry. Several factors are involved in the comparison between both methods; the general conclusion – according to the bibliography – is that GC gives better selectivity, higher sensitivity, and a wider range of compounds analyzed but that, in simpler (in fact more frequent) cases, HPLC of the underivatized samples is more recommendable. In global terms, HPLC methods are preferred for the analysis of syrups, honeys, and foodstuffs containing major amounts of sucrose, for example, jams, biscuits, and confectionery products, whereas the greater sensitivity of GC methods can be used to advantage for the determination of sucrose where it may be present in only minor or trace amounts.

Both techniques need a careful sample treatment, as mentioned earlier in the text. In particular, GC requires the use of dual solid-phase columns, hexamethyldisilazane and o-trifluoroacetyl, and other procedures for extraction purposes, as well as derivatization of sucrose (preparation of a volatile derivative in quantitative yield). In this last case, o-trimethylsilyl (TMS) derivatives are predominantly used for the analysis of this disaccharide, although both acetates and trifluoroacetates have occasionally been utilized.

High-Performance Liquid Chromatography

HPLC is one of the most commonly employed methods in the determination of sucrose in foods, especially in fruits and fruit juices, vegetables, yogurt, beverages, and cereals. Partition systems (partition chromatography) employing polar-bonded phases are now the cornerstone of HPLC analysis of sucrose in foodstuffs. Amine-bonded silica gels are the most frequently utilized systems for sucrose separations, silica being usually bonded by a primary amine. Nevertheless, care must be taken to avoid or minimize the formation of Schiff bases. Additionally, the lifetime of these amino-bonded phases remains quite short because of a certain degree of phase hydrolysis, although this problem may be overcome by using trifunctionalsilane (e.g., 3-aminopropyltriethoxysilane) or, alternatively, an eluent recycling system to extend the column life.

Theoretically, a wide range of polar mobile phases could be used with these polar amino-bonded phases, water being a

major component to ensure adequate solubility of sucrose. Nonetheless, the eluent is usually an acetonitrile/water mixture, the relative proportions of which can alter the retention times (the less complex the carbohydrate molecule, the more percentage of acetonitrile is required).

As far as detection is concerned, the refractive index detector (RID) is still the most widely used detection method for sucrose, in spite of its lack of sensitivity (although this does not offer a big problem in most foodstuffs, since sucrose often occur as a major component). However, RID is nonspecific and its response may be altered by changes in environmental conditions as well as any dissolved solute (e.g., salt) that will produce a peak irrespective of its nature, which may appear near sucrose. Furthermore, its principle of operation with a reference cell for the mobile phase rules out any possibility of making use of gradient elution. All in all, some steps must be taken when using RID, namely, (a) solvent delivery must be degassed and pulse-free, (b) isocratic elution has to be employed, (c) the detector must be carefully thermostated, and (d) the temperature of the column must also be kept constant to ensure the equilibrium of the solvent components between both phases and therefore the composition of the eluate.

The evaporative light-scattering detector (ELSD, 'the mass detector') is also gaining popularity; it is an evaporative analyzer in which the mobile phase is removed by nebulization and evaporation prior to the determination of nonvolatile carbohydrates (such as sucrose) by light scattering. ELSD offers sensitive detection and allows gradient elution (eluent is removed before detection). Another important advantage is its great flexibility of use given the absence of baseline drift and its rapid equilibration. And last but not least, it is not sensitive to temperature changes nor to variations in the mobile-phase flow.

The use of a pulsed amperometric detector (PAD) should also be remarked; it allows specific electrochemical detection without derivatization, by direct oxidation on a gold electrode in a highly alkaline medium. It is based on an extremely fast three-step potential cycle; the −OH groups can be oxidized at the first potential and the gold electrode surface is then oxidized to remove reaction products and then finally reduced to its initial state by the application of the third voltage.

This detection system is coupled with high-performance anion-exchange chromatography (HPAEC), which has the same alkaline pH requirements. The sensitivity of PAD is considerably higher than that yielded using RID. Moreover, this technique requires no sample derivatization and is compatible with gradient elution; these features make anion-exchange chromatography with PAD especially suitable for the analysis of sucrose in foodstuffs.

Finally, other detectors have been proposed for the HPLC determination of sucrose in foodstuffs, such as Fourier transform infrared spectroscopy, Raman spectroscopy, and charge aerosol detector (CAD). The latter is based on the nebulization of the solution leaving the column and the evaporation of the mobile phase as the aerosol goes through a heated tube, but unlike the ELSD, it measures charged particle flux.

Gas chromatography

GC methods have been applied to a wide range of determinations of both naturally occurring sucrose and that added during food manufacture, for example, in honey, bun mix, or soybean. The first essential step is the preparation of a volatile derivative in quantitative yield. A second requirement is that a mixture of derivatives, for example, mono- and disaccharides, be completely resolved upon analysis. Anyway, there is no universally applicable procedure for the preparation of sucrose for GC, which is suited to all types of sample and all possible carbohydrate mixtures.

As regards detection systems, in most sucrose analyses, the flame ionization detector (FID) has been used, although mass spectrometry (MS) has also found interesting applications. Both detectors have a high sensitivity. In many cases, even the sensitivity of thermal conductivity detectors (0.01–0.001 times the sensitivity of a FID) would be adequate. In this sense, sucrose in several beverages has successfully been determined as its TMS derivatives using thermal conductivity detection. The determination of sucrose as acetate or TFA derivative presents no detection problems, but combustion of TMS derivative produces silica that accumulates on the ion collector of the FID and gives rise to a gradual decrease in detector response.

In the analysis of sucrose in foodstuffs, it is unlikely that greater sensitivity than that obtained by the use of the FID will be required. However, in some cases, much greater sensitivity can be achieved by the use of selective detectors, such as nitrogen-selective alkali FID or the combination of a glass capillary column and an electron capture detector.

Enzymatic methods of analysis

They are in theory very specific, but in practice, their specificity depends on the purity of the enzymes used. On the other hand, enzymatic determinations require very small quantities of material and sampling is therefore important. Anyway, and unlike many chemical and physical methods, enzymatic methods represent a sensitive, rapid, and reproducible means of measuring sucrose in foods, although costs may be higher than for conventional techniques. Nevertheless, the use of immobilization techniques contributes to cheapen this type of analysis. Furthermore, since enzymes are so specific, there is no need for elaborate cleaning up procedures to remove interfering compounds, although trace metals may cause some problems.

The main enzymatic method for the determination of sucrose in foodstuffs is based on the following reactions:

$$\text{Sucrose} \xrightarrow{\text{Invertase}} \text{Glucose} + \text{Fructose}$$

$$\text{Glucose} + 2\ \text{ATP} + \text{Fructose} \xrightarrow{\text{Hexokinase}} \text{G6P} + \text{F6P} + 2\ \text{ADP}$$

$$\text{G6P} + \text{NAD} \xrightarrow{\text{G6PDH}} \text{NADH} + 6 - \text{Phosphogluconate}$$

where ATP = adenosine triphosphate, G6P = glucose-6-phosphate, F6P = fructose-6-phosphate, ADP = adenosine diphosphate, NAD = nicotinamide adenine dinucleotide, G6PDH = reduced form of G6P, and NADH (measured spectrophotometrically) = reduced form of NAD.

Test kits are also commercially available for the enzymatic determination of sucrose in foodstuffs such as bread and bakery goods, cereal products, dietetic food, meat products (sausages and hamburger), and potatoes.

Finally, combined instrumental–enzymatic methods have also been developed. In particular, a spectrophotometric method for determining sucrose in green and roasted coffee beans has been proposed. Sucrose is hydrolyzed by invertase and the resulting glucose is oxidized by means of glucose oxidase; then, the produced H_2O_2 reacts with phenol-4-sulfonic acid sodium salt and 4-aminoantipyrine in the presence of peroxidase, yielding a pink dye with an absorption maximum at 505 nm. This method has recently been enhanced by adapting it to enzyme-linked immunosorbent assay (ELISA) plates, which enables large-scale, low-cost analyses to be carried out.

Flow injection analysis

Flow injection analysis (FIA) is an automated method in which a sample (analyte) is injected into a continuous flow of a carrier solution, which mixes with other flowing solutions (reagents) before reaching a detector. This technique is straightforward with very low sample and reagent consumption and high sampling frequencies. In the case of sucrose, each food sample is analyzed in duplicate for its content in reducing sugars: before and after inversion of sucrose. The difference between both results yields the content of sucrose.

Three automatic FIA methods have been proposed for the determination of reducing sugars in beverages based on classical reactions (the picric acid method, the Cu(II)–neocuproine method, and the Nelson–Somogyi method). The first one presents a dual-channel configuration, with pH being adjusted with NaOH at a confluence point. The same manifold is utilized for the Cu(II)–neocuproine method, whereas the automation of the Nelson–Somogyi method makes use of a reversed FIA system, in which the sample flows continuously and then is mixed with the NaOH stream. In all cases, the reactor in which the chemical reaction takes place is immersed in a thermostatic bath at a suitably high temperature. Additionally, and in the case of colored samples, the use of a dialysis unit (inserted between the injection valve and the reactor) permits to avoid tedious decolorizations with charcoal.

Different scientists have also been working on the flow injection automation of the previously mentioned enzymatic determinations of sucrose. In this sense, several biosensors have also been designed on this basis. For instance, a specific sucrose electrode has been developed for the determination of this disaccharide (in fruit juices) in a FIA system without interference from glucose, fructose, or any other carbohydrate present in the food sample. This osmium-based biosensor is based on an enzymatic cascade coupled to electrocatalytic detection of NADH; it is incorporated into a FIA system with piperazine-*N*,*N*′-bis(2-ethanesulfonic acid) as a carrier.

Capillary electrophoresis

Capillary electrophoresis (CE) is straightforward with low sample consumption, high speed of analysis, high resolution, and efficiency; nevertheless, in the case of sucrose analysis, it is still limited by the lack of functional groups containing chromophores and charges.

High electric fields are used in CE to force ionic solutes to migrate through a buffer- or gel-filled capillary. The injected species are separated along the tube on the basis of charge, size, or both and are subsequently detected near the capillary end.

The separation of sucrose (a 'neutral' carbohydrate) by CE requires the *in situ* conversion of this polyhydroxy compound into charged species via (a) complex formation with other ions such as borate and metal cations and (b) ionization of the hydroxyl groups at extremely high pH using appropriate electrolyte solutions. Besides, several detection strategies have been developed including indirect UV spectroscopy, laser-based refractive index measurement, laser-induced fluorescence (LIF) detection, electrochemical detection, dynamic labeling via complexation with absorbing or fluorescing ions, and precolumn derivatization with a suitable chromophore and/or fluorophore. More recently, other detection modes such as capacitively coupled contactless conductivity (CCD) have also been used for the CE analysis of sucrose, for example, in the detection of adulterations in instant coffee by the addition of coffee husks and corn or the analysis of sucrose in soft drinks, isotonic beverages, and fruit juices. On the other hand, it should also be noticed that several applications utilize micellar electrokinetic capillary chromatography as separation mode. Finally, in the case of determining sucrose in honey, a suitable alternative has turned out to be the amperometric detection at constant potential after a strong dilution of the sample with an appropriate buffer.

Sensors

A first example could be a prototype of amperometric biosensor for sucrose determination based on electrochemical polymerization of m-phenylenediamine onto a platinum electrode. Enzymes invertase, mutarotase, and glucose oxidase are employed for biomembrane formation and entrapped into the polymer film during the electropolymerization process. An important advantage of this sensor is the reduction in interference from ascorbic acid due to the mechanism of selective partitioning and diffusion within the polymer film.

Sucrose sensors based on pH alteration generated by a series of boronic acid derivatives have also been proposed. In this sense, a recent development configured a pH indicator and boronic acid ensemble array with extended diversity of boronic acids and applied the probe selection process to optimize the system for quantitative dose–responses sucrose from soft drinks.

Another type of electrochemical sensors for sucrose analysis has been prepared by using graphene, due to its excellent electrical conductivity and electrocatalytic activity. For example, a recent graphene–copper nanoparticle composite paste electrode was successfully applied for the determination of this disaccharide in milk, peach, and banana. The advantages of this type of sensors include higher sensitivity, satisfactory stability, surface renewability, bulk modification, and low expense of fabrication.

Finally, a selective electrochemical sensor has been developed for the determination of sucrose in sugar beet juices by integrating electropolymerization of molecularly imprinted polymer with multiwall carbon nanotubes. The sensor was prepared by electropolymerization of o-phenylenediamine in the presence of template, sucrose, on a multiwall carbon nanotube-modified glassy carbon electrode. Hexacyanoferrate (II) was used as a probe to characterize the sensor using electrochemical impedance spectroscopy, cyclic voltammetry, and differential pulse voltammetry. Capturing sucrose by the

modified electrode causes a decrease in the response of the electrode to $Fe(CN)_6^{4-}$. This sensor provides an efficient way for eliminating interferences from compounds with similar structures to sucrose.

Other techniques

Apart from the earlier-mentioned leading analysis techniques of sucrose in foods, other developments are also noteworthy. For example, a simple and fast procedure was developed for the direct determination of sucrose in beetroot samples through attenuated total reflectance Fourier transform infrared (ATR-FTIR) absorbance measurements. The method only requires a previous crushing or liquefaction of samples and it is free from matrix effects and from the interference of minority of carbohydrates.

A promising approach is also a relatively rapid and inexpensive enzymatic–fluorometric microtiter plate assay for sucrose quantification in sugar beetroot dry matter. As expected, refractometric analysis generally overestimated sucrose content, whereas enzymatic–fluorometric analyses reasonably correlated with HPLC results.

Some work is in progress concerning sonic-spray ionization (SSI), a liquid chromatography–mass spectrometry interfacing technique in which a liquid flow is sprayed from the tip of a capillary under atmospheric pressure with a gas flow coaxial to the capillary. In contrast to the electrospray or atmospheric pressure chemical ionization techniques, SSI forms charged droplets without heating the capillary or applying an electric field to the tip of the sprayer. Therefore, it is ideally suited for the analysis of thermally unstable compounds such as sucrose.

Finally, surface plasmon resonance (SPR) has also been used in the detection of food carbohydrates. It monitors biospecific interactions that occur on a surface of a metal layer between the immobilized ligand and the free analyte, by measuring changes in resonance angle due to an increase of the mass concentration of the analyte in the vicinity of the surface. Recent improvements in the instrumentation have enabled the detection of smaller carbohydrates, including sucrose, in foodstuffs.

Future developments

The outstanding features of the many modes of CE analysis – including capillary electrochromatography (CEC) – are driving many chemists to further explore its unique capabilities in the field of sucrose analysis in foods.

Considerable progress has been made in HPLC in such a way that it is now routinely used for quantitative analysis of sucrose in foodstuffs. Some separations still remain to be improved, but the development of new bonded phases with various organic loadings (mainly from different amino–alkyl silanes) together with the establishment of ELSD as an alternative to RID will offer much scope in enhancing the resolution of sucrose in the presence of other carbohydrates.

A promising approach for the indirect determination of sucrose in carbohydrate-rich foods such as caramel syrup or mint syrup is the coupling of FIA systems to an HPLC. The method is based on postcolumn derivatization of reducing sugars with *p*-aminobenzoic acidhydrazide in an alkaline medium following elution from the chromatographic column with an acetonitrile/water gradient as mobile phase. The manifold also allows nonreducing sugars (such as sucrose) to be hydrolyzed prior to insertion into the chromatograph, thus making them compatible with the derivatization reaction and with continuous decolorization of the sample on an activated carbon column.

Finally, many highly purified enzymes are now commercially available for the specific detection and quantification of sucrose. As foods become more complex and new sugars and their derivatives are employed in their formulation, there is no doubt that enzymatic methods will be increasingly used to determine specific compounds, such as sucrose. The widespread use of immobilized enzymes, including their use in enzyme electrodes, should allow the continuous assay of this essential component of some foods, not only for the purpose of classical on-line analysis but also with a view to on-line and in-line monitoring of food production processes. The latter is already a well-established analytic procedure and the growing availability of biosensors will open a promising path. Additionally, the increasing stability of many enzymes that can be achieved by cross-linking and immobilization techniques will extend the range of such determinations.

Introduction

Sugar alcohols are white crystalline, non- to slightly hygroscopic powders and clear syrups. They are generally stable to heat and do not take part in Maillard-type browning reactions. Chemically, sugar alcohols are hydrogenated mono-, di-, and oligosaccharides. The more important compounds in these groups have the structures shown in Figure 1, and their main physical properties are summarized in Table 1. Erythritol is described separately further in the text.

Sensory and Nutritional Properties

Compared with sucrose, sugar alcohols have slightly reduced sweetness values, as shown in Table 2. Sugar alcohols produce a characteristic mouth-cooling effect that is directly related to their heats of solution and their solubility in water (Table 1). Sugar alcohols, also known as polyols, may give particular advantages with regard to diet control and dental health (Table 3). The benefits that polyols can give in reducing caloric intake are due to their different metabolic behaviors after oral ingestion compared with other carbohydrates. Because polyols may have a mono-, di-, or oligosaccharide carbohydrate structure, small differences can occur with regard to their metabolic fate in the human body.

Except for maltitol-containing syrups (55–75% maltitol), in which a small fraction of oligomeric structures occur, polyols are not degraded by saliva enzymes (amylases) upon oral ingestion. In the stomach, slight acid hydrolysis of the di- and oligosaccharide polyols may occur. However, once the small intestine is reached, extensive hydrolysis by α-amylases of the

mucosa occurs, and up to 60–80% of the maltitol and isomalt are hydrolyzed. A 50% glucose/50% sorbitol or a 50% glucose/25% sorbitol/25% mannitol mixture, respectively, is obtained. The other disaccharide polyol lactitol is almost unchanged because the required β-galactosidase is only present in trace amounts. Sorbitol, mannitol, and xylitol reach the small intestine unchanged.

In the small intestine, the monosaccharide polyols are partly absorbed into the bloodstream by a passive diffusion process at rates depending upon their molecular weight (Table 3). Also, the applied dose and the actual intestinal transit time affect the rate of absorption. The absorbed fraction of sorbitol and xylitol is channeled into the normal liver metabolism and contributes energy to the same extent as glucose.

The unabsorbed polyols finally reach the large intestine where the microflora ferments them almost completely to volatile fatty acids (VFAs). From the energy contained in the fermented fraction, 20% is used by the bacteria for growth. The remainder is absorbed from the gut as VFAs, which are then transported in the blood to be metabolized by the liver into fat constituents. In total, about 50% of the energy of the fermented polyols is available to the human body.

Based on the earlier metabolic behavior, the calorific value of polyols can approximately be calculated (Table 3). However, depending upon the methodologies used, values vary over a wide range. Therefore, and because many polyols are used in combination with each other, a European Union Directive has laid down an average calorific value of 2.4 kcal g^{-4} for all polyols.

Because of the reduced digestibility of polyols, their intake level is recommended to be restricted to 40–50 g day^{-1} (adults) and 30 g day^{-1} for children in order to avoid gastrointestinal discomfort. Higher doses may cause osmotic diarrhea or increased flatulence due to slow absorption and extensive fermentation, respectively, but tolerance levels improve upon adaptation. On the other hand, polyols are very suitable for diabetics, because rapid glycemic or insulinemic response is avoided. For the same reason, sorbitol and xylitol are often applied in parenteral nutrition to provide a more controllable carbohydrate energy source compared with glucose or fructose.

Concerning dental health, polyols have long been known to have no adverse effect on teeth. This is due to the fact that mouth bacteria are unable to ferment polyols, thereby avoiding the production of enamel solubilizing acids. With the intraplaque pH telemetry test, it was shown that eating polyol-based sweets did not decrease the plaque pH below the critical value of 5.7. Additionally, for xylitol, there is ample proof of a cariostatic effect. In several studies, of which the Turku study (Finland) is most famous, the incorporation of xylitol in a normal diet was proved to reduce the occurrence of dental caries. Most probably, xylitol selectively discriminates against the growth of *Streptococcus mutans*, the major organism involved in dental caries.

Occurrence and Methods of Production

Polyols like sorbitol, mannitol, and xylitol have been well known over the last 30 years due to their occurrence in a number of fruits, vegetables, and cereals. Although they occur in nature, their concentration in plant material is too low for a simple, economic commercial extraction, as practiced with sucrose. A more complicated process is therefore needed for the production of sugar alcohols.

Several techniques have been described to produce polyols, but only a few of them are of industrial importance. These are mainly based on catalytic hydrogenation of easily accessible carbohydrates, for example, dextrose, glucose syrups, maltose syrups, invert sugar, isomaltulose, xylose, and lactose. These carbohydrates are obtained by either hydrolysis or isomerization of natural raw materials like starch, sucrose, milk (whey), and straw (Figure 2).

The carbohydrate raw material is hydrogenated in an aqueous solution at elevated temperatures (120–190 °C) and hydrogen pressure (20–200 bar) using an activated nickel catalyst. Hydrogenation can be performed in either a batch process or a continuous process and results in the addition of hydrogen to the carbohydrate precursor. Hydrogen pressure, temperature, pH value, and type of catalyst are the most

Table 3 Absorption characteristics of sugar alcohols

Polyol	Absorbed from the small intestine (%)	Excreted (%)		Fermented (%)	Calorific value (kcal g^{-1})
		Urine	Feces		
Xylitol	25–40	0	<1	60–75	2.9
Sorbitol	15–20	0	<1	80–85	2.6
Mannitol	15–20	15–20	<1	80–85	1.9
Maltitol	45–60	0	<1	40–55	3.2
Lactitol	<1	0	<1	99	2.3
Isomalt	35–45	0	<1	55–65	3.0

important parameters influencing reaction time and selectivity. They have to be well adjusted to obtain a high-purity product in high yield. Purity of the raw material is also of importance in this respect. The hydrogenated carbohydrate (polyol-containing) solution is subsequently refined by filtration, carbon, and/or ion exchange resin treatment to remove salts and colored by-products formed during hydrogenation.

Sorbitol and maltitol are available as aqueous solutions and also as crystalline material. Mannitol, xylitol, lactitol, and isomalt are available as crystalline material. All crystalline polyols are produced by crystallization, solidification, or spray drying of an aqueous solution at an appropriate concentration.

Uses in Foods

Substitution of sugars in food to achieve specific nutritional objectives is not a new practice. Initially, polyols like sorbitol and mannitol were used to sweeten food for diabetics. To cope with sensorial and technological requirements for noncariogenic food, the range of polyols has been extended to include products such as maltitol, xylitol, isomalt, and lactitol.

For the production of polyol-based foods, most conventional types of food manufacturing equipment are used. However, manufacturing conditions (temperature, vacuum, etc.) very often need to be adapted. As some polyols are moderately hygroscopic, the relative humidity of air during production and storage conditions require careful control. It is also necessary to assure good protection by careful wrapping and/or packaging. When necessary, the sweetness of polyol-based foods can be enhanced by adding the necessary amounts of intense sweeteners like aspartame, acesulfame K, cyclamate, and saccharin.

In addition to the production of sugarless foods, polyols, for example, sorbitol, can also be used in conventionally sweetened food products in order to give specific sensorial effects

such as texture and reduced color. There are also technological advantages such as plasticity, workability, and shelf life. In particular, sorbitol is widely used for its humectancy power to extend food products shelf life.

The main uses of polyols in food products are outlined in the succeeding text.

Sugar-Free Confectionery

This is the most important application field for polyols.

Hard Confectionery

Hard confectionery is produced by boiling polyol solutions or syrups to a very high dry matter content (98–99.4%), followed by cooling, molding, and wrapping. The boiling temperature for such polyol confectionery varies between 155 and 170 °C, depending on the type of polyol. Severe vacuum conditions are needed. With the exception of mannitol, all the polyols can be used alone. However, for technical and economic reasons, very often, combinations of polyols are applied. It should be kept in mind that the solubility of polyols strongly influences crystallization and graining.

Soft and Chewable Confectionery

The main component in this application is a polyol or a polyol blend (65–70% dry matter) that is presolubilized and cooked together with vegetable fat (about 6%), emulsifier (about 0.8%), gelatin (about 1.4%), and other minor components, for example, food-grade acid, flavor, and color. After cooling, the mass is formed and wrapped. Chewability of the sweets can be obtained by acration of the cooked mass after partial cooling using conventional acration techniques such as pulling and continuous foaming.

Gums and Pastilles

Maltitol syrups, alone or in combinations with either lactitol or isomalt, are very suitable for the production of gelatin gums. For some compositions, it is necessary to adapt the gelatin type and level and the cooking conditions in order to obtain gum properties equivalent to those obtained with conventional sweetened gums.

In pastilles, a gum arabic/polyol ratio of 50/50 on a dry-weight basis is advised. This composition is cooked to 70–72% dry matter content, molded in starch, and dried to 90% dry matter. After demolding, the gums are waxed. Maltitol syrups give good pastilles with optimal shelf life properties.

Tableting

Although all powdered polyols can be compressed on rotary machines to give tablets, sorbitol is the most common polyol used in this field.

Powdered sorbitol has excellent flow properties for tableting. Good flowability is very important to provide a uniform tablet weight. Compared with other directly compressible materials, powdered sorbitol gives a high increase of tensile strength as a function of compression force and is therefore very suitable for direct compression. Due to their rather high hygroscopicity, sorbitol-based tablets should be protected or stored under relatively dry conditions in order to avoid softening due to moisture pickup. The priability of sorbitol tablets, even those compressed at low pressure, is extremely low and is improved further by storage at close to equilibrium relative humidity. The overall performance of sorbitol powder in tableting depends upon different factors, such as particle size and distribution, crystal morphology, and compression conditions.

Chewing Gum

The main components of sugar-free chewing gums are gum base (25–30%), polyol powder as solid phase (45–63%), and sorbitol or maltitol syrups as liquid phase (10–30%). The solid phase can be sorbitol powder, but more often, a combination of sorbitol and xylitol is used. The main advantages of xylitol are its excellent cariostatic properties, high sweetness, and a pleasant cool taste due to its negative heat of solution. The addition of a small quantity of glycerol improves the plastifying properties; mannitol addition prevents stickiness.

Chocolate

Total replacement of sucrose by polyol powder in both bitter chocolate and milk chocolate is possible provided the powder has an optimum purity, crystal morphology, and granulometry. A bitter chocolate consists of 40–50% cocoa mass, 40–50% polyol powder, and 5–10% cocoa butter.

Originally, only sorbitol was used for sugar-free chocolate. Recent trends are toward the use of maltitol, isomalt, and lactitol.

Dragée Coating

Coating consists in covering cores, for example, chewing gum with a syrup that is close to its saturation point, and then inducing crystallization by evaporation. Generally, a lot of layers (40–50) are needed. The temperature of polyol syrups, drying air, centers, and core bed are very important processing parameters. Sorbitol is the most common sweetener for sugarless coating, but maltitol, xylitol, isomalt, and lactitol can also be used.

Bakery Products

Polyols can be used in bakery products due to their specific properties, which are lacking in many other bulk sweeteners. The sugar alcohols contribute to softness and storage capacity. They also regulate moisture, taste, and sweetness. A combination of polyols or a polyol combined with another sweetener is preferred. If browning is too light, the baking temperature can be raised or a small amount of fructose can be added.

The baking industry uses crystalline sorbitol and sorbitol solutions in products for special dietary use. It is also employed as a humectant to extend the shelf life of baked goods. The stability of baked products can be improved by partial substitution of sucrose by sorbitol, for example, in cakes. Sorbitol is

used in sponges and cakes at between 5% and 8% of flour weight. In biscuits and cream fillings, it is used up to 10%. The freshness of gingerbread is improved by adding only 5% sorbitol. It is also used to substitute sugar in classical formulations for low-sugar products.

The use of the other polyols in bakery is rapidly developing. The level of sugar replacement with these sweeteners depends on the type of polyol and the application objective. While, for some polyols, rather high usage levels can be achieved, for example, for maltitol, lactitol, and isomalt, for others, for example, xylitol and mannitol, usage levels are generally low. These differences are also related to the specific sensory and physicochemical properties of the polyols used. An important contribution of the other polyols is, as for sorbitol, the humectant properties that control the moisture level in bakery products when stored for long periods. In some cases, combinations of polyols can give interesting complementary effects. The main applications in the bakery field are cakes, biscuits, pastry, fillings, and icings. In the last two products, xylitol and mannitol can be an asset due to their perceptible cooling effect.

Other Areas of Application

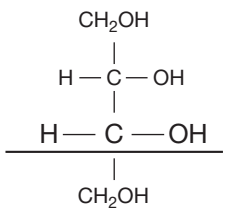
Polyols can also be used in sugarless jams and ice creams. Sorbitol-containing jams and preserves have a clear taste and good texture. A sufficiently high solids content can be obtained in order to inhibit microbiological activity, thereby protecting the jams against mold development. In order to avoid crystallization during storage, the solubility of the polyol(s) should be checked before formulating the food.

Erythritol

Chemical and Physical Properties

Erythritol is a linear carbohydrate molecule of four carbon atoms, each carrying one hydroxyl group. The molecular structure is shown in Figure 3.

Chemically, erythritol therefore belongs to the class of monosaccharide polyols like sorbitol, mannitol, xylitol, and glycerol. Erythritol is also a symmetrical molecule and therefore, it exists in only one form, the mesoform. It forms anhydrous crystals with a moderately sweet taste without off-tastes or off-odors. The powder has a transparent white brilliant appearance and dissolves in water to give a colorless nonviscous solution. Crystals melt at 122 °C to form a colorless and brilliant nonviscous melt.



1,2,3,4-butanetetrol

Figure 3 Molecular structure and chemical formula of erythritol.

Erythritol's chemical properties are similar to those of other polyols in that it has no reducing end groups and thus has excellent heat and acid stability. It differs in having a low solubility (37% ww at 25 °C), a property that among these simple polyols it shares with mannitol and isomalt. The heat of solution is very low ($-181\ J\ g^{-1}$), a property shared with xylitol. However, compared with the group of polyols presently used as sugar replacers, erythritol has the lowest molecular weight (122), which of course provides different properties, such as higher osmotic pressure and lower water activity in solution. It has also a high freezing point depression and boiling point elevation.

Compared with sucrose, erythritol has a sweetness value of 60–70%. It has a clean, sweet taste, similar to sucrose, and a strong cooling effect and shows many synergies with intense sweeteners.

Occurrence and Methods of Production

Erythritol occurs in several foods at levels up to 0.13%. It is also present in human and animal tissues and body fluids.

Briefly, erythritol is produced from wheat or cornstarch by enzymatic hydrolysis yielding glucose, which is fermented by a safe and suitable yeast-like fungus, *Moniliella pollinis*. Once erythritol is separated from the sterilized fermentation broth, it is purified by ion exchange resin, active carbon, ultrafiltration, and crystallization. The final crystalline product, which looks very similar to sugar, is more than 99.5% pure.

Uses in Foods

The main uses of erythritol in food products are outlined in the succeeding text.

Tabletop Sweeteners

In tabletop applications, erythritol will be used at levels up to 99.9% as a noncaloric, noncariogenic carrier for intense sweeteners. In these applications, the sensorial profile-modifying properties of erythritol are of great importance, resulting in sweetness synergy, improved mouthfeel, and masking of off-flavors. In addition, due to erythritol's crystalline structure and nonhygroscopic property, it offers excellent flowability and stability as carrier.

Beverages

The synergies that erythritol shows when used in combination with intense sweeteners are also very useful in low-calorie beverages. Also, at use levels of 3.5% or less, erythritol can mask certain off-flavors in beverages like coffee, tea, and grapefruit juice.

Chewing Gum

Good-quality noncaloric and noncariogenic chewing gum can be formulated by using solely erythritol (use level up to 60%).

Most of the sugar-free chewing gum produced today has a tendency to become brittle and harder during aging. This can be avoided, and a sugar-free chewing gum with softer texture, greater flexibility, and improved shelf life can be obtained by partial replacement of the other sugar alcohols using erythritol.

Chocolate

The use of erythritol in chocolate compositions allows a dry conching process at high temperatures. Due to the good heat stability and low-moisture pickup of erythritol, it is even possible to work at higher temperatures than traditionally used. This results in enhanced flavor development.

Erythritol-based chocolate is not only easy to produce but also considered a true 'reduced-calorie' product.

Candies

Sugar-free fudge with texture and shelf life properties equivalent to conventionally sweetened fudge can be produced using erythritol (up to 40%) in combination with maltitol syrup (75% maltitol) to control crystallization.

Depending on the cooking temperature and seeding level with erythritol, the texture can be varied from soft to hard. In hard candies, erythritol in its crystalline form is used up to 50% for its cooling effect as sherbet filling in die-formed hard candies or 'sandwiched' in between two layers in deposited hard candies.

Fondant

Using erythritol, it is possible to obtain sugar-free low-calorie noncariogenic fondant with identical technical properties to classical products. Previously, this was impossible with the other low-calorie bulking agents currently available. Pure erythritol induces too high a crystallization, but 60% erythritol in combination with maltitol syrup as a liquid phase helps to control this phenomenon.

Lozenges

Research has shown that lactitol, crystalline maltitol, and erythritol are the only suitable materials to produce a lozenge with a lower calorie content than the conventional sugar-based lozenges, but are otherwise identical. In addition to the lower calorie content and pronounced cooling effect, erythritol has the added advantage over lactitol and crystalline maltitol of requiring a shorter drying time to obtain the required texture at low residual moisture content. Lozenges based on solely erythritol (up to 99%) have excellent shelf life properties, even when stored under high-humidity conditions.

Bakery (Pastry) Products

In fat cream, a very good texture is obtained with erythritol at a use level of 60% and a particle size distribution below 300 μm. The manufacturing process and shelf life properties of the erythritol-based fat cream are similar to those for conventional fat/sucrose compositions. Erythritol has an effect of masking the fatty mouthfeel, giving a more refreshing and attractive product. In addition, the calorie content of the composition is also reduced.

Reduction of calories in bakery products is particularly difficult if only the sugar moiety is replaced. Erythritol can reduce the caloric content by more than 30% (dependent on the application) without introducing undesirable side effects. Additionally, erythritol improves the shelf life of bakery products. Erythritol can be applied successfully in cookies, biscuits, and cakes, where it improves baking stability and shelf life at an addition level of about 7%.

Abbreviations

EFA	Essential fatty acid
HDL	High-density lipoproteins
HOSO	High-oleic-acid sunflower oil
HOHSSO	High-oleic-acid–high-stearic-acid sunflower oil
HSSO	High-stearic-acid sunflower oil
LDL	Low-density lipoproteins
SFA	Saturated fatty acids
SFA/MUFA/PUFA	Saturated fatty acids/monounsaturated fatty acids/polyunsaturated fatty acids ratio
U-AMDR	Upper value of acceptable macronutrient distribution range

Origin and Systematics

The cultivated sunflower (*Helianthus annuus* L.) is a plant of the family Asteraceae (Compositae). The term *Helianthus* is derived from the Greek *Helios*, meaning sun, and *anthos*, meaning flower, and from Latin *annuus*, meaning annual. The property of this flower 'turning with the sun' is clearly expressed by the French and Spanish languages when naming this plant. The flower is appreciated through the world (e.g., it is the national flower of Ukraine and the state flower of Kansas; it is used as a symbol by green ideologies, Spiritualist church, and also vegans). The genus *Helianthus* comprises 51 species, most of them perennial. The genus is distinguished technically by the fact that the ray flowers, when present, are sterile and by the presence of a pappus on the disk flowers that is of two awn-like scales that are deciduous (i.e., easily detached and falling at maturity). Some species also have additional shorter scales in the pappus or the pappus is not even present.

The domestic sunflower possesses a single large inflorescence (flower head) at the top of an unbranched stem. It is an annual species, which has an erect rough hairy stem, reaching heights of 2–3 m. The flowers in the center of the head are called disk flowers. The disk flowers are arranged spirally, following a Fibonacci number arrangement. This pattern produces the most efficient packing of seeds mathematically possible within the flower head. These disk flowers mature into fruits, containing the sunflower 'seeds.' *H. annuus* grows best in fertile, moist, well-drained soil with heavy mulch and needs full sun. In commercial planting, seeds are planted 45 cm apart and 2.5 cm deep. The *H. annuus* is diploid with a base chromosome number of 17 and an estimated genome size of 2871–3189 million base pairs (Mbp), although some references suggest that its true size is around 3500 Mbp.

Archeological evidence indicates the occurrence of heads and achenes of domesticated types of sunflower as early as the first millennium BC, and it has been suggested that cultivation began as early as 2600 BC probably in Tabasco, Mexico. Many indigenous American peoples such as Aztecs and Otomi in Mexico and Incas in South America employed sunflower as a solar deity symbol. In 1510, Spanish explorers encountered the sunflower and carried and introduced its seeds to Europe. It was grown initially as an ornamental plant and later for food and medical purposes. The sunflower was developed as an important source of oil during the early 1800s in Russia. More recently, wild species have been used in breeding programs. They have been found useful in improving disease and insect resistance of cultivars. The success of breeders, most from the former Soviet Union, in improving the oil content of seeds from less than 30% to over 50% was a major factor in the development of the sunflower as a major world oilseed crop.

Oils and fats present great importance in the field of health and industry. *H. annuus* is mostly grown as a crop for its edible oil and seeds, but new promising applications have made sunflower a premium seed. 'New' sunflower oils have appeared in the market as a consequence of researches and methodology applications. Some of these oils can be used for general food preparation and dressing, but some of them are specifically designed for manufacturing margarines, pastries, and confectionaries due to their high plasticity and also in deep frying due to the high thermal stability of some types (see succeeding text).

World Sunflower Crop

Sunflower ranks among the most important annual field crop grown in world for the production of edible oil. During the last few decades, the total production has increased a lot. Thus, in 1989–91, it was estimated at about 22.3 million metric tons. In 1998–99, world production was about 26.7 million tons, and at the 2013, it was about 44.7 million tons (Figure 1(a)). The increase in efficiency production and the new applications of this oil seed (e.g., biodiesel production) seem related.

Although sunflower is grown primarily for its 'conventional oil production,' there is limited cultivar production for 'new' sunflower seeds or non-oilseed or confection purposes. Sunflower grows well in most regions of the world, with significant production occurring in just few countries (Table 1 and Figure 1(b)). Europe and America are the leading producers of sunflower seed, accounting for about 50% of the world's total production. Recent data show that the ex-USSR (Russia plus Ukraine), the EU-27, and Argentina are the largest producers (Table 1 and Figure 1(b)). Other leading producers are also shown. However, because production depends on cultivars and in many countries, efficiency is determined by the weather, the leading order can change. In some countries, a

high percentage of sunflower comes from dry-ground cultivars; thus, sunflower seed production may change dramatically from a wet year to a dry year (by about half a million tons).

Figure 1(a) clearly shows that the cultivar surface has increased during the last decade; however, the trend increase was much lower than that observed for the seed production, clearly suggesting the efficiency improvement of cultivars all over the world.

World Sunflower Oil Production

Sunflower oil is the fifth in production among edible vegetable oils in the world. World edible oil and fat production has increased in the last few years with an estimated total seed production of about 400 million metric tons in the year 2014. Oil production is highly dependent on the crop and, thus, is changeable from season to season. The total world sunflower oil production since 2001 is presented in Table 1. This was set considering the accepted approach that 42 g sunflower oil can be obtained from 100 g sunflower seed. World production of sunflower seed oil in the 2014 season is currently forecast at about 21 million metric tons.

Conventional vegetable oils, such as sunflower, are main raw materials to elaborate biodiesel. The use of sunflower oil for biodiesel production was initiated in South Africa in 1979 and presently is opened all over the world, contributing to the increase of seed prices all over the world and that of sunflower oil in particular (Figure 2).

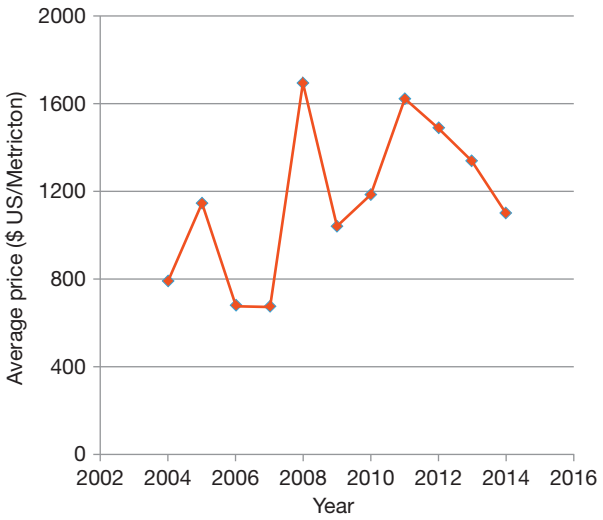

Figure 2 Top ten producer countries of sunflower oil. Estimated productions in million tons for 2014 are given.

Although sunflower oil is considered premium oil, with a correct equilibrium between linoleic acid and tocopherols, the benefits of monounsaturated fatty acids to health have encouraged the production of new sunflower oils. Thus, recently, several new variants of sunflower oils have appeared with the aim of catering to the demand for oils richer in oleic acid, such as the high-oleic-acid sunflower oil (HOSO), and with much lower price than olive oils. Moreover, because it has greater oxidative stability than the conventional sunflower oil (see succeeding text), HOSO is expected to significantly expand food and industrial uses of sunflower oil all over the world. Moreover, due to both the 'neutrality' under the lipoprotein metabolism point of view and the stability at high temperature of stearic acid, new sunflower oils have appeared in the market, such as high-stearic-acid sunflower oil (HSSO) and high-oleic-acid–high-stearic-acid sunflower oil (HOHSSO), with very promising properties.

Market and Prices

Sunflower derives most of its economic value from the oil extracted from the seeds; the remaining value is from the meal. The oil is considered to be of very high quality and generally sells for a premium in world markets, over soybean, palm, and rapeseed oils. In the period of 1999–2001, sunflower oil price ranged between US$ 400 and 600. The year 2002 prices for crude and refined sunflower oil were 700 € per metric ton and 733 € per metric ton, respectively. After 2004, the sunflower oil price has greatly changed with top pick at 2008 and 2011, where the average yearly price was about US$ 1600 per metric ton (Figure 2).

Oil Extraction

Before oil extraction, sunflower seed (c.30% hulls) is usually dehulled to 8–12% because of the high wax content in the hulls. An outline of the extraction procedure is shown in Figure 3. Before pressing, other manipulations are necessary, such as delinting, cracking, breaking, conditioning, and structuring. Nowadays, the presses used on an industrial scale are screw presses or expellers. The pressure applied in pressing can be as high as 3000 kPa but is commonly around 150 000 kPa. Capacities of expellers used for pressing are usually 100–200 t per day, but equipment exists that can handle up to 500 t per day. The solvent extraction is mainly carried out by percolation through the platelets of prepared seed using nontoxic solvents that are powerful solvents for oils and nonsoluble in water, low in price, and also nonflammable and nonexplosive.

Treatment of Crude Oil

In some countries, the oil from the first pressing of seed is used directly. However, refining the oil to change its color, odor, flavor, and physical properties has become a common procedure to satisfy consumer demands.

Refining

Fats and oil contain minor compounds that must be removed because they confer taste and smell that can diminish consumer acceptance. Steps in the chemical and physical refining are, in general terms, similar to the ones processed in other vegetable oils (Figure 3).

Composition

Conventional and Wild Sunflower Oils

Triacylglycerol species and fatty acid composition

The chemistry and properties of natural fats and oils are mainly dependent on their overall composition and especially on the relative composition of the fatty acid constituents. Furthermore, the structures of the fats, in terms of the relative proportions of different molecular species or of the stereospecific distribution of fatty acids on the glycerol moieties, have a bearing on their properties.

Table 2 shows the characteristics that conventional sunflower oil has to have in order to be an acceptable edible oil according to international regulations. In addition, specific aspects for other sunflower oils are also given. The different fatty acid fractions contained in the conventional oil may be quite variable. Nevertheless, polyunsaturated fatty acids predominate. The percentage of oleic acid (C18:1, $n-9$) plus linoleic acid (C18:2, $n-6$) is rather constant (85–87%) because both fatty acids originated in the same biosynthesis chain. The linoleic acid is produced from oleic acid by desaturation carried out by the seed Δ^9 desaturase enzyme. The major $n-6$ fatty acid is linoleic acid, ranking 48–74%. This edible oil also contains about 11–12% of saturated fatty acids (SFA) (mainly palmitic and stearic acids). Oleic acid represents about 14–39.4% and only minor amounts of linolenic acid are present. Sunflower oils from cold climates are poor in oleic acid and very rich in linoleic acid (about 15% and 75%, respectively) with an iodine value of 125–136 and do not require winterization. Southern US oils have been found to

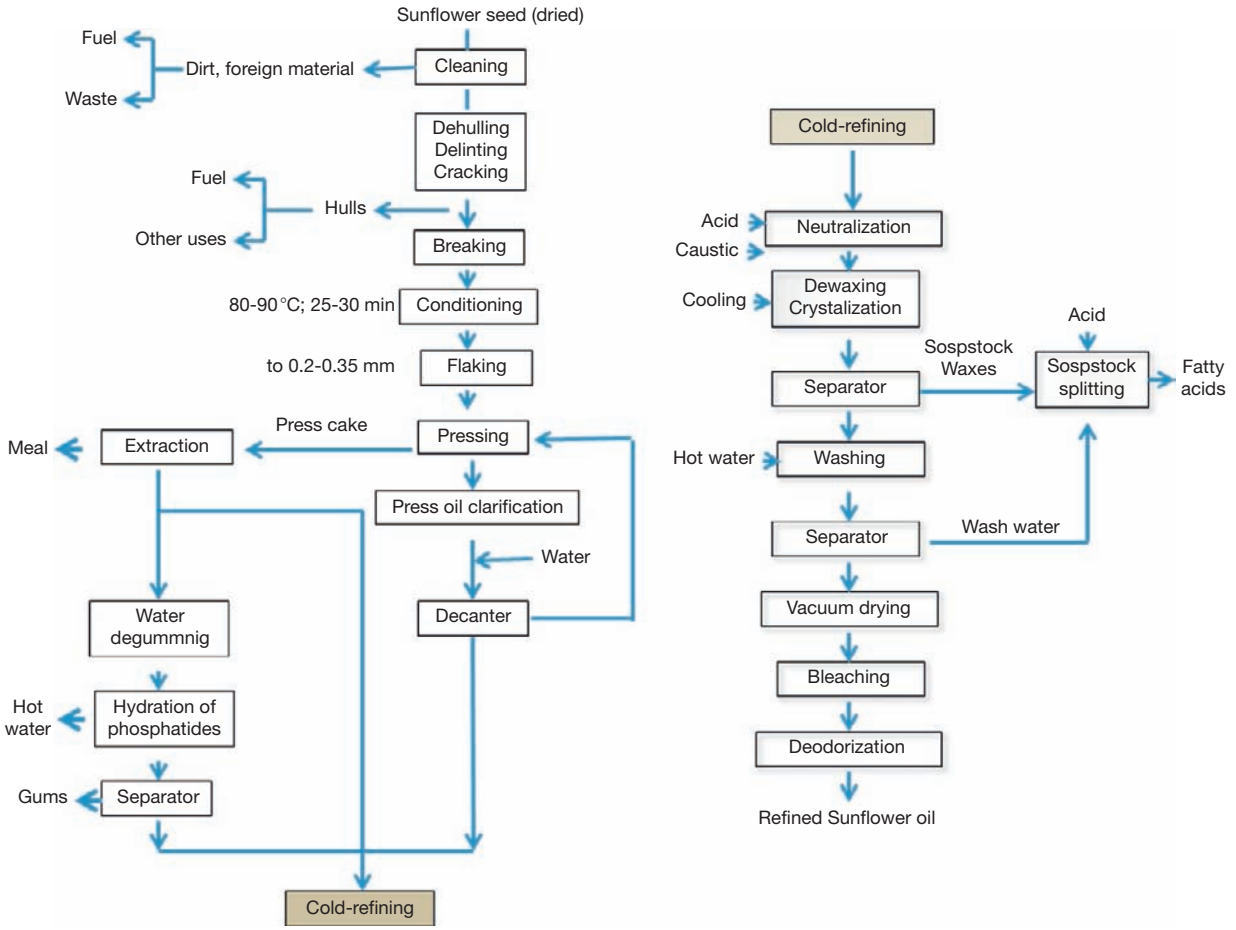

Figure 3 Sunflower oil extraction and refining procedure scheme. General lines have been set in the scheme. Modified from Sánchez-Muniz, F. J., Cuesta, C. (2003). Sunflower oil. In: Caballero, B., Trugo, L., and Fligas, P. (eds.) *Encyclopedia of food science and nutrition* (2nd ed.), pp. 5672–5680. Amsterdam: Elsevier Science Ltd. and completed following general accepted procedures.

contain about over 50% of oleic acid and as little as 35% of linoleic acid with an iodine value of ~106.

Wild *H. annuus* has been defined also as a potential source of palmitic and stearic acids. Compared with many edible vegetable oils, the SFA concentration of 12 g 100 g^{-1} in sunflower (*H. annuus* L.) oil is considered moderate, with the principal SFA being palmitic and stearic acids. A reduction of SFA in sunflower oil to the 6.0–8.0 g 100 g^{-1} level would enhance the acceptability of sunflower oil when looking for sunflower oils low in saturated fatty acids. Reports have indicated that the wild *H. annuus* populations from North Dakota tend to have the lowest average stearic and palmitic acid concentrations, while the highest stearic and palmitic concentrations were observed in wild populations from Kansas.

The stability of the reduced SFA trait for a selected population of wild *H. annuus* has been confirmed by growing the progeny of the original population in a habitual greenhouse environment (22–25 °C and 16 h of daylight). Interspecific F1 hybrids were produced in the field using a nuclear male sterile analog as the female parent and the wild *H. annuus* population as the male parent.

New Sunflower Oils

As previously mentioned, the industry requires an ample range of oils and fats, some of them solid or semisolid at room temperature, to prepare some foods. These 'new oils' can be a suitable and healthier alternative to animal fats and some tropical fats such as palm oil, palm kernel, and coconut oil and hydrogenated vegetable oils. Similarly to the techniques used to produce HOSO, mid-oleic-acid sunflower oil and other sunflower oils such as the HSSO can be obtained. Hybridization is the main mechanism to obtain high-quality HOSO and HSSO seed producers.

Biotechnology has taken advantages of the knowledge of biochemistry reactions and pathways occurring in the sunflower seed. To get linoleic acid (the major fatty acid of conventional sunflower oil) from other shorter and less unsaturated fatty acids, a cascade of enzyme reactions take place in an organelle of the seed called 'plastidial.' Thus, from acetyl CoA after its conversion in acetyl-acyl carrier protein (acetyl-ACP) and malonyl-ACP, through successive condensation of two carbon units, it can obtain palmitoyl-ACP by the

[a]BOE (2013). Real Decreto 308/1983 de 25 de *Enero, por el que se aprueba la Reglamentación Técnica Sanitaria de Aceites Vegetales Comestibles*. BOE-A-1983-5543.

Source: Codex Alimentarius Commission. JOINT FAO/WHO FOOD Standards Programme CODEX Alimentarius Commission. ALINORM 03/17. Twenty-Sixth Session. Rome, Italy, 30 June–7 July 2003. *Report of the eighteenth session of the CODEX committee on fats and oils*. London, United Kingdom, 3–7 February 2003.

action of an enzymatic complex entitled fatty acid synthases I and III (FASIII/I). After a new condensation addressed by the FAS II, a new fatty acyl moiety is produced, the stearyl-ACP. This unit is a substrate of the first desaturation that induces the production of oleoyl-ACP. Both stearoyl-ACP and oleoyl-ACP are the main products synthesized into the plastidial. Following that, enzymes called thioesterases hydrolyze and transport outside the plastidial both ACP-bound moieties that are transformed in stearyl-CoA and oleoyl-CoA, now available to esterify hydroxyl groups of the glycerol molecule and to produce specific triacylglycerols. Available cytoplasmic oleic acid can be unsaturated to linoleic acid, after binding to a molecule of phosphatidylcholine.

International research institutions have developed by conventional mutagenesis and hybridization a collection of new oils. Original seeds have been modified by alkylating agents and later selected according to their fatty acid profile. From initial seed lines through crossing and selection, commercial seeds, richer in specific fatty acids, were obtained. In addition, autofecundation and crossing with common sunflower lines have permitted to increase the specific content of oleic or stearic acids. Seeds from which HOSO should be obtained must have the enzyme expression of the oleoyl-desaturase depressed. Several mechanisms have been proposed; however, high temperatures have been shown to highly depress the linoleic acid content of sunflower seed. When talking about high-stearic-acid sunflower oils (HSSO), the key reaction to be partially inhibited should be catalyzed by the thioesterase that transforms the stearic acid to oleic acid.

Although the individual proportion of fatty acids in the 'new' oils changes with respect to that of the conventional one, fortunately, no other fatty acids than those existing in the conventional sunflower oils are produced in partial blocking of the thioesterase and/or desaturase. In addition, the amount of SFA in the β-position of the triglyceride is also modified. According to the available information, commercialized HOSO, HSSO, and HOHSSO should cover all international requisites for conventional sunflower oil (Table 2), except those related to fatty acid composition, the iodine index value, and the SFA content in the β-position of triglycerides, as oleic acid and stearic acid have been deeply modified. At present, several studies have been performed with HOSO showing the suitability of this oil under several health and technological aspects (see succeeding text). With respect to HSSO and HOHSSO, although nonexhaustive toxicity evaluation of these oil types has been performed, the available information suggests that nondeleterious effects can be suspected, as they are being produced through conventional mutagenesis and hybridization techniques. Moreover, the information provided on the qualitative composition of these oils does not demonstrate the presence of new fatty acids deriving from the obtaining process. The content of the rest of the fatty acids is within the approved ranges established for other edible vegetable oils. Despite the Scientific Committee not having performed an exhaustive assessment and the lack of available epidemiological data, no possible adverse effects can be deduced from the information provided.

The HOSO shows a fatty acid composition similar to other monoenoic oils, such as olive oil (Tables 2 and 3). The HOHSSO is enriched in stearic acids. Also, some new variants are enriched in palmitic acid (Table 3). The conventional sunflower oil is rich in trilinolein, while the HOSO is rich in triolein. HOHSSO and other 'new' sunflower oils are richer in tristearin or tripalmitin (data not shown).

Table 3 Major fatty acid composition of different sunflower oil types available at the market

Acid type	*Palmitic*	*Stearic*	*Oleic*	*Linoleic*

Source: Martínez Force, E. and Garcés Mancheño, R. (2004). New sunflower oils: the future for a more healthy food industry. CTC Alimentacion **21**, 49–54.

Due to more and more production and commercialization of those new oils every day, their identification and clear classification to avoid misleading and fraudulent uses are of great importance. Near-infrared reflectance spectroscopy has been proposed to this aim; however, some oils, very similar in composition, do not completely permit their identification.

Minor Components

In the last two decades, certain minor constituents of oils have been extensively studied because of their antioxidant properties and because they can modulate the dietary cholesterol absorption, the fatty acid metabolism, and thus the serum cholesterol levels. Table 2 shows the accepted rank composition of minor compounds of the different main variants of sunflower oils. Large amount of phytosterols and tocopherols is present. It is remarkable that, although conventional sunflower oil has a different fatty acid composition than HOSO, the profile of minor compounds (in absolute and relative amounts) of these two oils is quite similar. The stability in minor components of the different sunflower oils is also evident and can be related with the fact that neither new sterols nor new molecules have been detected in the HSSO and HOHSSO production.

Other Aspects

In the few last years, new regulations and norms have been stated, as the one originated after detecting contamination risk in sunflower oil by mineral oil. Thus, the European Food Safety Authority has set that sunflower oil imported into the community shall not contain more than 50 mg kg^{-1} mineral paraffin. This has to be certified according to EN ISO/IEC 17025 taken in accordance with the provisions of Regulation (EC) No 333/2007 and the international standard ISO 5555:2003.

Food Uses and Applications

Conventional sunflower oil is appreciated among vegetable oils because of its bland flavor, light color, high smoking point, high level of linoleic acid, and very poor linolenic acid content.

Sunflower oil is primarily used as a salad dressing and cooking oil. Furthermore, it is extensively used as a major ingredient in some margarine and shortening products. For some decades, population living near to the Mediterranean coast continues consuming a relatively large quantity of olive oil, mainly for frying purposes. However, other cheaper oils, mostly sunflower oil, have largely substituted olive oil. Economic reasons have promoted the production and consumption of sunflower oil. However, at present, some 'new' variants of sunflower oil are been produced and commercialized, mostly for culinary uses that have to be performed at relatively high temperatures.

Margarines and Spreads

Margarines were originally obtained from lard first and from other fat sources such as seed oils later. However, the association of saturated and *trans*-fatty acids with coronary and other cardiovascular diseases led to the development of new margarines from vegetable origin. In fact, most margarines and spreads are presently obtained by transesterification that permits the specific enrichment of the oil in a given fatty acid.

Sunflower oil is one of the oils employed in the formulation of fat blends to achieve an adequate product. High polyunsaturated margarines should contain no less than 45% of *cis*, *cis* linoleic acid or less than 50% PUFA. Thus, in order to reach 45–50% in PUFA, 70–80% sunflower seed oil was demanded. Nonetheless, as previously mentioned, the generation of different types of sunflower oils, in particular that of HSSO and HOHSSO, has changed the facilities of bakery and margarine industries, permitting obtaining new foodstuffs, due to the plasticity and thermostability conferred by those oils.

Deep Fat Frying

Deep fat frying is one of the quickest cooking elaboration procedures of food with cultural and economic importance. Sunflower oil is being extensively used for deep frying, at home and fast-food restaurants and in the industry.

Frying is a relative complex process, consisting in browning, dehydration, and heat and mass transfer. During frying, the culinary fat is exposed to the action of moisture from the foodstuff, oxygen from the atmosphere, and high temperature at which the operation takes place. Thermally oxidized and hydrolytic compounds are present in different quantities depending on a considerably high number of frying variables. Finally, apart from migration of lipids from the food into the frying oil, the presence of some compounds from the foods can substantially affect the thermal oxidation reactions.

Oil entrance can increase some organoleptic properties of the food (texture, flavor, aroma, taste, and crispiness) and improve or impair the fatty acid profile giving rise to a most balanced saturated fatty acids/monounsaturated fatty acids/polyunsaturated fatty acids (SFA/MUFA/PUFA) ratio. Thus, the level of linoleic acid in the food can be deeply increased by frying with sunflower oil. Moreover, lipophilic compounds (such as tocopherols) can also access the food. This seems very convenient when the oil is used for the very first times when oil is unaltered or slightly altered or in industrial cooking, where there is a high turnover of fresh oil. However, usually, the frying is performed on demand, mostly at home, bars, and small restaurants with non-turnover or very low turnover of fresh oils.

The global alteration of oil (thermal oxidation plus hydrolysis) can be evaluated measuring the percentage of total polar artifacts (as polar content) by column chromatography. Also, polymer determination is extendedly used. The 22–25% polar material or the 10–12% polymers' cutoff points have been accepted for oil discarding. Frying potatoes in sunflower oil following domestic conditions shows that polar content increased in oil and frying potatoes. However, when frying is performed with frequent oil turnover, the amount of polar material in sunflower oil is substantially below the critical level (Figure 4). The amount of polymers (dimers + oligomers) formed in sunflower oil during frying is also lower in the frequent turnover of fresh oil than in the null turnover one (Table 4). The benefit of the high turnover has been found in the frying of frozen foods (potatoes, fish fingers, croquettes, tuna pastries, etc.) under domestic conditions at 180 °C. More recently, we found that the frequent turnover together with lower frying temperature (160 °C) permits to use the oil longer, keeping the thermal oxidation in the sunflower oil used 40 times to fry different foodstuffs reasonably low (Table 4).

HOSO is a rather stable oil. Our studies using HOSO to fry potatoes following a domestic frying model suggest that the frequent replenishment of used HOSO with fresh HOSO permits the frying of sets of fresh potatoes at a very high rate (Figure 4). Moreover, HOSO performs much better than the conventional sunflower oil in the frying of frozen prefried

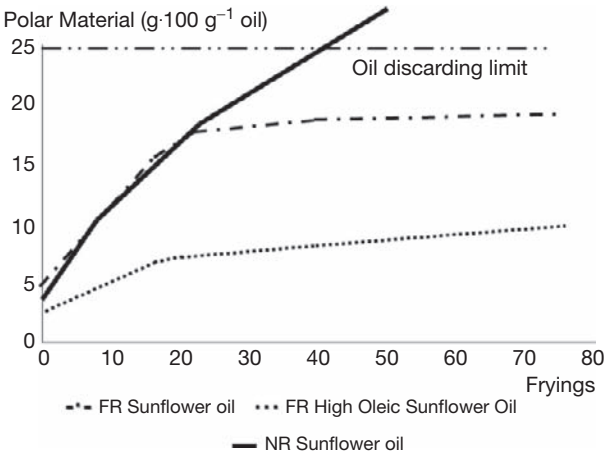

Figure 4 Sunflower oil and high-oleic-acid sunflower oil behavior in potato frying. Influence of frequent or null turnover of fresh oil. Polar fraction (mg 100 mg^{-1} oil) change. NR, null turnover; FR, frequent turnover. Modified from Sánchez-Muniz, F. J., Cuesta, C. (2003). Sunflower oil. In: Caballero, B., Trugo, L., and Fligas, P. (eds.) *Encyclopedia of food science and nutrition* (2nd ed.), pp. 5672–5680. Amsterdam: Elsevier Science Ltd.

Table 4 Total polar content and polymers in different oils before and after frying frozen prefried foods with null or frequent fresh oil addition to the fryer oil at different temperatures

					Polar (mg 100 g^{-1} oil)		Polymers (mg 100 g^{-1} oil)	
	Temperature	*Food*	*Frying number*	*Oil addition*	*Initial*	*Final*	*Initial*	*Final*

foods, at both frequent or null turnover techniques. Interesting results were found frying with HOSO at 160 °C. The higher stability (lower polar artifact and polymer formation) of HOSO at high temperature, with respect to conventional sunflower oil (Table 4), seems related to differences in the fatty acid composition (mainly more oleic acid and less linoleic acid).

Among natural sunflower oil antioxidants, tocopherols seem to be more relevant. In this way, it is interesting to note, in continuous frying operations, a regular turnover of fresh oil maintains the level of antioxidant in the oil. However, data from some publications suggest that the addition of the antioxidant exerts little influence in extending frying life of the oil used in frying but it can extend the shelf life of the food reducing the rate of oxidation of the absorbed oil. According to others, peroxidative degradation of frying highly increases when the tocopherol is lacking in the oil. Recent publications suggest that the addition of concentrates of carob fruit fiber (very rich in nonextractable tannins) significantly increases the frying shelf life of sunflower oil and olive oil–sunflower oil blend, reducing the thermal oxidation and polymerization and decreasing the tocopherol content losses.

As previously mentioned, frying performance with HOHSSO offers very promising results as it, first, permits keeping the alteration of the oil low and, second, enriches the food in oleic and stearic acids, with potential benefits under a cardiovascular disease point of view. Nonetheless, further research is demanded.

Other Food Uses

Sunflower 'whole seed' is sold as a snack food, raw or after roasting in ovens, with or without salt, and/or with seasonings added. In Germany, it is popular to make Sonnenblumenkernbrot, sunflower butter mixed with rye flour. It is also sold as food for birds and can be used directly in cooking and salads. American Indians had multiple uses for sunflowers in the past, such as in bread, medical ointments, dyes, and body paints. The sunflower meal, obtained after the oil extraction, displays high protein content (about 42% for the hulled seed meals) and is used primarily in food rations for livestock and poultry. Compared to soybean, sunflower meal contains lower energy and lysine but higher fiber and methionine content. Variants of sunflower seeds with low oil content (non-oilseed sunflower) are primarily used as a snack food; as an ingredient in baked foods, salads, and candies; and for feeding birds and small animal pets. During the last decades, a flowering market has grown round these seeds.

Finally, sunflower hulls present potential uses as litter for livestock or poultry and as a source of roughage in animal feeding. Building or insulation boards and fireplace logs are other potential applications.

Due to its higher price than other seed oils, sunflower oil is not widely employed for industrial purposes. Some paints, varnishes, and plastics take advantage of its semidrying properties without the yellowing problems associated with oils rich in linolenic acid. In some eastern European countries, the oil is used by detergent and soap manufacturers. Like other vegetable oils, it has potential value for uses in the production of adhesives, agrochemicals, surfactants, additional plastics and plastic additives, fabric softeners, synthetic lubricants, coatings, and other products. HOSO has extra value in industrial products where oleic acid and related chemicals are currently utilized. It can be used as a source of oleic acid in the spread and margarine industry, as an ingredient in infant food formulas, which require stability, bland flavor, and specific fatty acid composition. Its fatty acid profile together with its high oxidative stability is valuable for cosmetic and pharmaceutical

manufacture. This should also be more evident in the case of HOHSSO.

Dietary Importance and Health Effects

Sunflower Oil as Energy Source

While carbohydrates and protein provide 17 kJ g^{-1} (4 kcal g^{-1}), long-chain triglycerides provide 38 kJ g^{-1} (9 kcal g^{-1}). The fatty acids are used for energy production in the cell mitochondria and peroxisomes. Present recommendations for fat are between 20 and 35% of total energy (45–78 g day^{-1} in a 2000 kcal diet). Due to a large percentage of total fat (more than 50% in some Mediterranean populations) being used in the form of oils for food cooking and dressing, the fatty acid composition of a diet largely depends on the culinary oil/fat used.

Research data suggest that a unit of energy from fat may be more fattening than a unit of energy from most carbohydrates. This fact can be related to the limited body capacity to convert carbohydrate into fat and the faster adaptation to oxidize excess carbohydrate than excess fat. Moreover, body capacity for storing carbohydrate as glycogen is limited, whereas in adipose tissue, fat store is virtually unlimited. Long-term signals regulating food intake and energy homeostasis suggest that both insulin and leptin act in the central nervous system to inhibit food intake and to increase energy expenditure. Insulin, through increasing oxidative glucose metabolism in adipocytes, stimulates leptin production from adipose tissue. Dietary fat (mostly saturated fat) does not stimulate insulin secretion and therefore does not increase leptin production. This suggests the convenience of decreasing saturated fat consumption and substituting saturated fat for a more unsaturated one.

Sunflower Oil as Essential Fatty Acid Source

Linoleic and linolenic acids are the two parent members of omega-6 ($n-6$) and omega-3 ($n-3$) fatty acid families, respectively. Both are essential and must be supplied by the diet because humans and animals have lost the ability to synthesize them. Moreover, other fatty acids of the $n-6$ family such as γ-linolenic acid (18:3, $n-6$), dihomo-γ-linolenic acid (20:3, $n-6$), and arachidonic acid (20:4, $n-6$) or from the $n-3$ family as eicosapentaenoic acid (20:5, $n-3$) and docosahexaenoic acid (22:6, $n-3$) cannot be formed.

The major $n-6$ fatty acid in the Western diet is by far linoleic acid. Although other oils are richer in linoleic acid, sunflower oil appears to be the primary source of this fatty acid, at least in Europe and particularly in Mediterranean countries. The importance of linoleic acid consumption is detailed elsewhere (see 'Essential Fatty Acids').

Deficiency of this fatty acid is called essential fatty acid (EFA) deficiency; it is well documented in rodents and can be produced in several animals, including humans. The disease is characterized by skin symptoms such as dermatosis. Growth is retarded, reproduction is impaired, and there is degeneration or impairment of functions in many organs of the body. EFA deficiency is characterized by changes in the fatty acid composition of many biological membranes, depending on the profile of the fat consumed. Overt EFA deficiency is only seen when linoleic acid provides less than 1% of dietary energy (about 2 g day^{-1} in 2000 kcal diet). Present recommendations for linoleic acid have been set in adults (2.0–3.0%En for adequate intake (AI); 2.5–9% upper value of acceptable macronutrient distribution range (U-AMDR)). In 6–12- or 12–24-month-old children, AI has been set in 3–4.5%En, while the U-AMDR in <10%En.

Sunflower Oil as Antioxidant Source

Sunflower oil contains valuable amount of minor compounds such as α-tocopherols, γ-tocopherols, and phytosterols (Table 2). The correct equilibrium between PUFA and antioxidants protects lipoprotein membranes from oxidative stress. Among other properties, phytosterols act not only as free radical scavengers but also as antipolymerization agents in frying oils.

Influence of Linoleic Acid on Cholesterolemia and Lipoproteinemia

It is currently recommended that dietary total fat, SFA, and cholesterol should be reduced, while the intake of PUFA and MUFA should be increased. As a result of these considerations, the consumption of unsaturated oils has been recommended, and margarines rich in PUFA and MUFA, called healthy margarines, have been developed. Linoleic acid had been considered for many years to be the unique fatty acid that had hypocholesterolemic effects (at serum and lipoprotein levels). Recent investigations suggest that oleic acid also presents such an effect on low-density lipoprotein (LDL) particles. On the other hand, a large intake of linoleic acid (higher than 10%En) would decrease high-density lipoprotein (HDL) cholesterol and increase the oxidation of LDL and HDL particles. Due to its fatty acid profile, HOSO presents similar cholesterolemic effects as olive oil. However, differences in minor compounds would clearly explain differences observed in some studies with respect to the effects on lipoproteinemia and LDL oxidation of these two oils.

Influence of Polyunsaturated Fatty acids $n-6$ on Other Physiological Processes

$n-6$ fatty acids have been proven to exert important roles in cytokine production and monocyte chemotaxis and in eicosanoid production. Platelet aggregation, inflammation, and cellular immunity are processes modulated by metabolic products derived from $n-6$ fatty acids. Because sunflower oil contains large amounts of linoleic acid (the fatty acid mother of $n-6$ family), the intake of this fatty acid should be adequate, avoiding low and very high intakes that would induce EFA deficiency or $n-6$ biomembrane saturation. In some circumstances, the capacity to transform linoleic acid into arachidonic acid is largely depressed (e.g., small for gestational age neonates, aging, diabetes, high alcohol, saturated fat, and cholesterol intakes) by decreasing the activity of $\Delta-6$ desaturase.

Like other fats, sunflower oil may modulate all these previously cited processes because of its ability to change the fatty

acid composition of membrane phospholipids. As a consequence, membrane fluidity may change and also, when cytokines act on target cells, the amount and types of prostaglandin and leukotriene originated are modified. Dihomo-γ-linolenic acid and arachidonic acid derive from linoleic acid and are precursors of eicosanoids. These fatty acids can be metabolized via different enzymatic pathways, giving rise to thromboxanes, prostacyclins, prostaglandins, leukotrienes, hydroxy and hydroperoxy fatty acids, and lipoxins, which have been proved to modulate cellular growth, angiogenesis, inflammation, cellular immunology, thrombosis, cardiovascular disease, cancer, etc.

According to recent recommendations, linoleic acid consumption must be $<9\%$En (20 g in a 2000 kcal diet). Other scientific societies had previously recommended that linoleic acid should contribute 3–6%En in the diet. However, the effects of linoleic acid on cell properties and health are highly dependent on the $n-6/n-3$ ratio and personal conditions. Thus, the adequate amount for linoleic acid, and sunflower oil, should be individually considered taking into account age, sex, and physiological status together with possible nutrigenetic, nutrigenomic, and epigenetic characteristic interactions.

Future studies should be addressed to avoid potential misleading and fraudulent uses of these new oils. Clearly identifying and defining their composition and properties and regulating their production and uses are demanded. The absence of adverse effects of new sunflower oils consumption must be assessed throughout epidemiological studies. In addition, the negative impact of all these new cultivars on the conventional ones has also to be checked and controlled.

Supercritical Fluid Extraction

E Ibáñez, JA Mendiola, and M Castro-Puyana, Institute of Food Science Research (CIAL-CSIC), Madrid, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Supercritical fluid extraction (SFE) is a technique based on the use of solvents at temperatures and pressures above their critical points. SFE can be a fast, efficient, and clean method for the extraction of natural products from several matrices. The ease of tuning the operating conditions in order to increase the solvation power makes this technology a good option for the selective recovery of several types of substances.

The discovery of the critical phenomena is attributed to Charles Cagniard de la Tour in 1822. SFE was first introduced in 1879 by Hannay and Hogarth. Despite the advantages associated to the use of supercritical fluids (SCFs) as extracting agents, it was not until around 1960 that this technique started to be thoroughly investigated as an alternative to conventional extraction methods. The field of critical phenomena has thrived and now forms a keystone of modern science, both experimental and theoretical, and its development exemplifies how a topic of purely fundamental research can diversify into initially unanticipated directions.

On the pressure–temperature diagram (see Figure 1), the point at which critical temperature (T_c) and critical pressure (P_c) meet is called the critical point of the substance. As the substance approaches its critical temperature, the properties of both, gas and liquid phases, converge, resulting in only one phase at the critical point: a homogeneous SCF. Physical properties of SCFs are between those of a gas and those of a liquid. Density is close to liquids, and viscosity and surface tension are close to gases. This is one of the key features of SFE since the solvating power (quantified using Hildebrand solubility parameter, δ) of the fluid can be strongly influenced by small changes in pressure and temperature favoring either the extraction of the target compounds or the precipitation of the solutes dissolved in the SCF. Many other physical properties such as relative permittivity and solvent strength, highly related to density, show large gradients with pressure above the critical point. Changes in those properties are crucial when dealing with extraction since they are related to changes in solubility and mass transfer ratios and, therefore, in the selectively of the solvent.

Despite every single substance having a critical point, not all of them are used in SFE, and green solvents (generally recognized as safe, GRAS) with mild critical properties are preferred. Among them, carbon dioxide (critical conditions = 31.2 °C and 7.38 MPa) is undoubtedly the most commonly employed. CO_2 is cheap, environmentally friendly, and GRAS. Another advantage is that CO_2 is gaseous at room temperature and pressure, which makes extract recovery very simple and provides solvent-free extracts. Also important for food and natural products' extraction is the ability of SFE using CO_2 to be operated at low temperatures using a non-oxidant medium, which allows the extraction of thermally labile or easily oxidized compounds. Its main drawback is its low polarity, which can be overcome by adding small amounts of polar cosolvents (methanol, ethanol, and water).

Due to the absence of toxic residues in the final product, among other advantages, SFE has been used in different fields such as food, pharmaceutical, chemical, and fuel industries. The widest application of SCFs is extraction, especially with carbon dioxide. The first patent dealing with SFE was published in 1943, although the first industrial application was developed in 1978.

In the food and health areas, SFE can be employed

- to extract valuable bioactive compounds such as flavors, colorants, and other biomolecules, or
- to remove undesirable compounds such as organic pollutants, toxins, and pesticides.

Basic Instrumentation for SFE

The SFE general extraction procedure might be divided into three phases. At the beginning of the extraction process, the supercritical solvent diffuses into the matrix and decreases the mass transfer resistance; after this step, soluble compounds are dissolved into the SCF and are further transferred by diffusion first into the surface of the solid and later to the bulk of the fluid phase. The extraction process ends with the transport of the solute and the bulk fluid phase and their removal from the extractor.

A basic scheme of the equipment used to perform SFE is shown in Figure 1. It consists of a container of the extraction solvent (A) (usually CO_2), a pump to pressurize the fluid (B), an oven containing the extraction vessel (C), and a restrictor to maintain the high pressure inside the system (D). Due to the action of the oven and the pump, the CO_2 changes from liquid to supercritical conditions. The recovery consists on a trapping vessel (E), where pressure is reduced to a gas equivalent pressure. Optionally, it can include a second trapping vessel (F), a CO_2 recycling system (G), and a modifier pump (H). Nevertheless, from this starting point, the instrumentation employed might be more or less sophisticated.

Parameters of SFE

In order to optimize extractions using SCFs, different parameters should be considered:

- *Raw material*: It is normally imposed by the process, but in general, it is recommended to increase the surface contact among the matrix and the SCF to increase the mass transfer ratio. For solid samples, factors such as particle size, shape, and porosity of the solid material are of crucial importance. Small particles increase extraction rates, but too small particles must be avoided since their use can compact the bed,

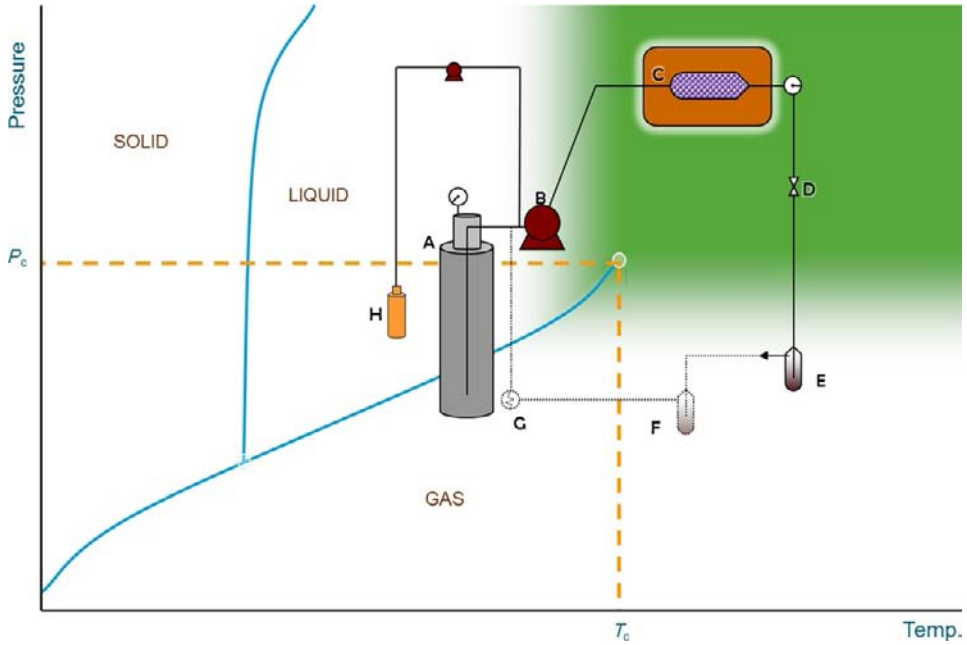

Figure 1 Scheme of the typical supercritical fluid extractor superimposed into the CO_2 phase diagram. The different parts of the SFE are named as liquid CO_2 cylinder (A), CO_2 pump (B), heated extraction cell (C), static/dynamic valve (D), collection vessel 1 (E), collection vessel 2 (F), CO_2 recycling system, and modifier container (H).

increasing the internal mass transfer resistance and causing channeling inside the extraction bed; as a result, the extraction rate may decrease due to a nonhomogeneous extraction. Sometimes, it is necessary to use dispersing agents (e.g., sea sand) to avoid sample clogging or to adsorb/retain interfering compounds present in the matrix, such as water or lipids; some examples are the employment of silica gel or sepiolite for water adsorption or C18 for lipids retention. In the case of liquid samples, countercurrent SFE (CC-SFE) is usually carried out. Extractions under CC conditions are performed using columns (normally packed) where the solvent (supercritical CO_2) is pumped from the bottom and the liquid matrix is pumped from the top; both streams contact each other in opposite directions (countercurrent flow), which increase the number of equilibrium steps and therefore the mass transfer ratio. In this case, factors such as size of the column, type of packing material, and solvent/feed ratios are the main parameters to be considered to increase the extraction rate.

- *Solubility*: One of the main advantages of using SCFs is the possibility of tuning the solubility, which is highly dependent on the pair pressure–temperature and therefore on the density of the fluid. Solubility of most components in SCFs increases with the increase of the SCF density, which can be accomplished by increasing the extraction pressure. Other important aspects influencing solubility of components in the SCF are their polarity and molecular weight and the extraction temperature. In SFE processes using CO_2, the component solubility is lowered as the polarity and/or the molecular weights of the solutes are increased. Increasing the temperature, at constant pressure, promotes two opposite effects: It reduces the solvent power of CO_2 by a decrease of the density, and, on the other hand, it increases the vapor pressure of solutes that can be more easily transferred to the supercritical phase. Depending on the working pressure, different effects can be observed: In fact, near the critical pressure, the fluid density is the predominant effect, and a moderate increase in temperature leads to an important decrease in fluid density and, therefore, to a decrease in solute solubility. At high pressures, the vapor pressure is the most prevalent effect; thus, the solubility increases with the temperature. This phenomenon is known as retrograde behavior.
- *Modifiers* (*cosolvents*): Since CO_2 is the main fluid used in SFE, and due to its low polarity, the addition of modifiers to CO_2 can improve the extraction proficiency by raising the solubility of polar solutes. As a general rule, the amount of modifier used is lower than 10–15%. The most used modifiers are methanol, ethanol, and water. It is important to consider that the critical point of the mixture CO_2: modifier is different from that of the pure compounds (it also depends on the proportions of CO_2 and modifier in the mixture). Since cosolvents are not gases at room conditions, liquid residues are obtained in the extracts and the remaining matrix after SFE.
- *Solvent-to-feed ratio*: It must be high enough to provide a good extraction yield in a short time, but it should also grant enough contact time among solvent and solutes. But it must be taken into account that higher solvent rates increase operational costs. In general, it is common to use solvent-to-feed ratios around 25–100:1 for analytic processes and 5–15:1 for large-scale processes.

Due to the high amount of parameters affecting SFE, the process optimization can be a highly tedious work. In order to

optimize SFE process, two main strategies are followed: phase equilibrium engineering and experimental designs. The first one is based on thermodynamic calculations; it is very useful and accurate, but not easy to carry out, mainly when dealing with complex matrices. The use of experimental designs offers a framework where researchers create an experiment, controlling experiment factors so as to predict or establish a result based on dependent and independent variables. Experimental designs give the possibility to evaluate interactions between factors while limiting the number of experiments. Optimization based on experimental design is based on statistical calculations.

Applications

SFE has been used since the end of 1970s to isolate compounds; however, for a long time, applications were focused only on a few of them. Nowadays, a high amount of research works has been published dealing with the use of SFE as a powerful extraction technique for recovering a wide variety of bioactive compounds from different natural sources such as plants, marine sources, and agricultural and food by-products. Although CO_2 is the main fluid used in SFE, its low polarity limits seriously its ability to extract polar components from natural products. To address this drawback, small amounts of cosolvents are added to CO_2. This fact increases the CO_2 polarity, enabling SFE to be also applied to extract from slightly polar to polar bioactive compounds.

On the other hand, the use of chemometric tools to determine the optimum values of the different parameters involved in the SFE process is of great interest to set up a robust SFE extraction procedure. Thus, Taguchi, Box–Behnken, or central composite experimental designs have been used, among others, for the optimization of variables. Along with these methodologies, response surface methodology has also been employed since it allows not only the choice of the best extraction parameters but also the graphical observation of the influence of these parameters on the studied factors (response variables).

Plants

SFE has been extensively employed as extraction technique for recovering bioactive compounds from plants. A wide variety of solid materials have been employed as natural sources to extract compounds possessing a particular bioactivity. Table 1 gives details of different works for the recovery of valuable compounds, mainly with antioxidant activity. Although optimum extraction conditions obviously depend on the sample, normally, pressures from 9 to 30 MPa and temperatures from 35 to 100 °C have been employed.

As can be observed in Table 1, the bioactive compounds extracted by SFE from plants belong to a wide range of chemical structures covering a broad range of polarities. Considering the low polarity of CO_2, it has been mainly used to extract nonpolar bioactive compounds. For example, neat CO_2 has been used to isolate the less polar bioactives from essential oils. The extraction of low-polar compounds, such as carotenoids, has been performed employing two different strategies: using pure CO_2 at higher pressures (60 MPa) and using small proportion of a modifier (see Table 1). Both strategies enable us to improve the extraction rate of medium to nonpolar compounds. On the other hand, fractions enriched in polar bioactive compounds (phenolic compounds) were also isolated by using SFE with cosolvent (see Table 1). Although the most frequent modifiers are ethanol and methanol, others, such as diethylamine and water, have been also investigated, for instance, for extracting alkaloids.

Marine Products

Marine environments have been pointed out as an extraordinary source of high added value products due to their wide range of chemical structures and biological diversity. In this regard, organisms like algae, microalgae, crustaceans, and fish often possess highest concentration of bioactive compounds suitable for human health. Moreover, the conversion of waste and by-products discharged by fisheries, such as fish heads, viscera, skin, and tails, into valuable materials, through, for instance, extraction of high added value compounds, is a goal for a sustainable and ecological production and can provide enormous benefits from an environmental and economic point of view.

Table 2 gathers different applications of SFE dealing with the extraction of bioactive compounds such as ω-3 polyunsaturated fatty acids (ω-3 PUFAs), carotenoids, and phenolic compounds from marine sources. The possibility of obtaining ω-3 PUFAs, mainly eicosapentaenoic (EPA) and docosahexaenoic acids (DHA), from marine sources has been intensively studied taking into account its important potential biological properties (anti-inflammatory, antithrombotic, antiarrhythmic, etc.). Fish oil and fish by-products usually present higher amounts of PUFA than seed oils or microalgae. This fact makes them the major natural dietary source of ω-3 PUFAs. Due to the characteristic of this kind of compounds, their extraction by SFE using CO_2 is especially appropriate. SFE has demonstrated to be especially useful for fish oils' fractionation, operating under different temperatures and pressures. For instance, it has been recently demonstrated how the probability of fractionating the triacylglycerols with respect to EPA and DHA from fish oil is improved using fish oil with lower ω-3 fatty acids content as the basis. On the other hand, the use of SFE to add value to waste products of the fish industry has been also demonstrated by using different fish by-products and some marine invertebrates as raw materials to obtain bioactive compounds. In this case, the addition of ethanol to improve the extraction yields of, for instance, lipids and astaxanthin from red-spotted shrimp waste compared to the extraction without a cosolvent is sometimes necessary. Increasing the proportion of ethanol also produced an increase in the concentration of the ω-3 fatty acids in the lipids of the obtained extract.

On the other hand, SFE technology has been used to obtain carotenoids, isoflavones, polyphenols, and flavonoids from algae and microalgae as natural sources. As it can be observed in Table 2, carotenoids have been mainly extracted adding ethanol or methanol, although a study has demonstrated the possibility of extracting astaxanthin or canthaxanthin without cosolvent. Besides extraction, another interesting recent application is the purification of carotenoids by supercritical antisolvent precipitation. This technology has been applied, for

Table 1 Details of some works for the recovery of valuable compounds from plants using SFE

Group of compounds	*Compounds of interest*	*Plant material*	*Related bioactivities*	*Extraction conditions*
Lipids	Fatty acids	*Borago officinalis*		CO_2 + methanol, 35 MPa, 65 °C, 10 min static + 10 min dynamic
	Fatty acids and antioxidants	*Camellia sinensis*	Antioxidant activity	CO_2, 32 MPa, 45 °C, 90 min (static)
	Essential oils	*Lamiaceae* plants	Antimicrobial activity	CO_2, 30 MPa, 40 °C, 90 min (dynamic, 2.4 kg h^{-1})
	Essential oil	Spearmint (*Mentha spicata* L.)		CO_2, 9 MPa, 35 °C, 30 min (static)
	Essential oil	Spearmint (*Mentha spicata*)	Antioxidant activity	CO_2, 30 MPa, 50 °C, 180 min (dynamic, 0.3 kg h^{-1})
	Hernandulcin and other sesquiterpenes	*Lippia dulcis*		CO_2, 12 MPa, 35 °C, 60 min (static) + dynamic period
	Oleuropein	Olive leaves	Antioxidant activity	CO_2 + 20% methanol, 30 MPa, 100 °C
	Lutein, zeaxanthin	*Hemerocallis disticha*	Antioxidant activity	CO_2, 60 MPa, 80 °C, 30 + 30 min (static + dynamic, 0.01 l min^{-1})
	Tocopherols, lycopene, and β-carotene	Sea buckthorn	Radical-scavenging activity	CO_2, 40 MPa, 35 °C, 60 min (static)
	Lutein	Spinach	Antioxidant activity	CO_2 + ethanol, 30 MPa, 50 °C, 90 min (static)
Phenolic compounds	Polyphenols, flavonoids	Kale, spinach	Antioxidant activity	CO_2 + 5% methanol, 25.8 MPa, 50 °C, 30 min (static)
	Phenolic compounds	Olive leaves	Cytotoxic activity	CO_2 + 6.6% ethanol, 15 MPa, 40 °C, 120 min (static)
	Phenolic compounds	Rosemary (*Rosmarinus officinalis*)	Antioxidant activity	CO_2, 30 MPa, 40 °C, 300 min (dynamic, 3.6 kg h^{-1})
	Phenolic compounds	Rosemary (*Rosmarinus officinalis*)	Antioxidant activity	CO_2 + 6.6% ethanol, 15 MPa, 40 °C, 120 min (static)
	Phenolic compounds	Rosemary (*Rosmarinus officinalis*)	Anti-inflammatory activity	CO_2, 35 MPa, 80 °C, 30 static + 90 min dynamic
	Total phenols	Strawberry	Antioxidant activity	CO_2 + 19.7% ethanol, 60 MPa, 48 °C, 60 min (dynamic, 15 g min^{-1})
	Phenolic compounds Volatile compounds	Rosemary, oregano, chamomile, marigold	Antioxidant activity	Phenolic: CO_2 + 17–40% ethanol, 10 MPa, 35–40 °C, 20 min (dynamic 0.001 l min^{-1}) Volatile: CO_2 + 0–10% ethanol, 10–17 MPa, 35–40 °C, 10–20 min (dynamic 0.001–0.002 l min^{-1})
	Phenolic compounds	Clove buds (*Syzygium aromaticum*)	Antioxidant and antibacterial activities	CO_2, 10 MPa, 40 °C, 300 min (dynamic, 0.62 kg h^{-1})
Alkaloids	Alkaloids	*Mitragyna speciosa*		CO_2 + 28.8% ethanol, 30 MPa, 65 °C, 45 min (dynamic)
	Alkaloids	*Nelumbo nucifera*	Several bioactivities	CO_2 + 10% diethylamine and 1% water, 30 MPa, 70 °C, 120 min (dynamic, 1.1 kg h^{-1})

example, to the purification of zeaxanthin from the ultrasonic extract of *Nannochloropsis oculata*. Other antioxidant compounds different from carotenoids, such as isoflavones, polyphenols, and flavonoids, have been also extracted by SFE using methanol or ethanol as cosolvents.

Agricultural and Food By-Products

SFE has been widely used to value agricultural and food by-products generated as food waste during food manufacturing. The generation of a large variety of by-product wastes during the industrial activities makes imperative to find new uses for these materials in order to reduce their environmental impact. In this sense, SFE processes are being developed to recover high valuable products from food wastes. As Table 3 shows, SFE has been used to obtain from different agricultural and food by-products a huge variety of bioactive compounds, from fatty acids, essential oils, and tocopherols to carotenoids and polyphenols with antioxidant properties. This fact once again demonstrates the versatility of SFE toward the extraction of lipophilic and hydrophilic compounds when a cosolvent is added to CO_2.

Different SFE methodologies have been developed to extract lycopene, which has the highest antioxidant activity among all dietary antioxidants and represents the most abundant carotenoid in tomatoes, accounting for more than 80% of

Table 2 Examples of SFE procedures for the recovery of valuable compounds from marine sources

Group of compounds	*Compounds of interest*	*Marine source*	*Related bioactivities*	*Extraction conditions*
Lipids	ω-3 PUFAs	Fish oil	Anti-inflammatory, reduce risk of certain heart diseases	CO_2, 20 MPa, 33 or 40 °C (static 30 min + dynamic, 0.8 l min^{-1})
	ω-3 PUFAs Astaxanthin	Brazilian red-spotted shrimp waste (shell and tail)	Antioxidant activity	CO_2 + 15% ethanol, 30 MPa, 50 °C, 100 min (dynamic, CO_2 at 3 l min^{-1} and ethanol at 0.001 l min^{-1})
	ω-3 PUFAs Astaxanthin	Brazilian red-spotted shrimp waste (heads, shell, and tail)	Anti-inflammatory, reduce risk of certain heart diseases Antioxidant activity	CO_2, 30 MPa, 50 °C (static 20 min + dynamic 200 min, 1.5 l min^{-1})
	ω-3 PUFAs	Fish by-products (trout heads, spines, and viscera)	Anti-inflammatory, reduce risk of certain heart diseases	CO_2, 50 MPa, 60 °C (dynamic,0.6 kg h^{-1})
	ω-3 PUFAs	Northern shrimp by-products	Anti-inflammatory, reduce risk of certain heart diseases	CO_2, 35 MPa, 40 °C, 90 min (dynamic, 3–5 l min^{-1})
	ω-3 PUFAs	Shellfish by-products (abalone gonad)	Anti-inflammatory, reduce risk of certain heart diseases	CO_2, 28 MPa, 50 °C, 80 min (dynamic, 0.42 l min^{-1})
	Lipids Zeaxanthin	*Nannochloropsis oculata*	Anti-inflammatory, reduce risk of certain heart diseases Antioxidant activity	CO_2 + 16.7% ethanol, 35 MPa, 50 °C (dynamic, CO_2 at 0.01 l min^{-1})
	Lipids	*Schizochytrium limacinum*	Anti-inflammatory, reduce risk of certain heart diseases	CO_2 + 95% ethanol, 35 MPa, 40 °C, 120 min (static)
	Astaxanthin	*Haematococcus pluvialis*	Antioxidant activity	CO_2 + ethanol (2.3 ml g^{-1} sample), 43.5 MPa, 65 °C (static 60 min + dynamic 180 min, CO_2 at 10 l min^{-1} and ethanol at 0.03 l min^{-1})
	Astaxanthin	*Monoraphidium* sp. *GK12*	Antioxidant activity	CO_2 + ethanol (biomass/ethanol ratio, 1/20), 200 bar, 30 °C, 15 min (static)
	Lutein	*Chlorella vulgaris*	Antioxidant activity	CO_2 + ethanol, 40 MPa, 40 °C, 45 min (dynamic, CO_2 at 0.003 l min^{-1} and ethanol at 3×10^{-4} l min^{-1})
	Canthaxanthin and astaxanthin	*Chlorella vulgaris*	Antioxidant activity	CO_2, 30 MPa, 40 °C, 30 min (dynamic, 0.04 kg h^{-1})
	Astaxanthin, β-cryptoxanthin	Pink shrimp	Antioxidant activity	CO_2, 30 MPa, 60 °C, 25 min (dynamic, 0.798 kg h^{-1})
Phenolic compounds	Polyphenols and flavonoids	*Chlorella vulgaris C–C*	Antioxidant activity	CO_2 + 50% ethanol, 31 MPa, 50 °C, 20 min (static)
	Isoflavones	Sea and freshwater algae and cyanobacteria	Antioxidant activity	CO_2 + 3% methanol/H_2O (9:1 v/v), 35 MPa, 40 °C, 60 min (dynamic, 0.75–0.85 l min^{-1})
	Phlorotannins	*Sargassum muticum*	Antioxidant activity	CO_2 + 10% ethanol, 15.2 MPa, 60 °C, 90 min (static)

the pigments present in fully red ripe fruits. Although its SFE extraction has been mainly carried out from tomato by-product, it can be also extracted, for instance, from guava by-products. Several works have demonstrated an increase in the extraction yield of lycopene when a vegetable oil (roughly crushed hazelnut or tomato seed oil) is added as cosolvent.

As it can be observed in Table 3, the addition of a moderately polar modifier is critical for extracting polyphenols from agricultural and by-products. Usually, the extraction efficiency of SFE extraction of polyphenols is measured by the total phenolic content, although it can also be performed by measuring the levels of a specific compound, such as resveratrol.

Conclusions

In this work, the interest of SCFs to extract bioactive compounds from natural sources such as plants, marine, and food by-products is discussed. Although most of the applications presented have been performed at small scale, they are

	Proanthocyanidins	Grape seed	Antioxidant activity	CO_2 + 15–20% ethanol, 25–30 MPa, 30–50 °C, 60 min (dynamic 0.3 kg h^{-1})
	Resveratrol	Grape by-products (seeds, stems, skin, and pomace)	Antioxidant activity	CO_2 + 5% ethanol, 40 MPa, 35 °C, 180 min (dynamic, 0.048 kg h^{-1})
	Phenolic compounds	Brewery waste	Phenolic compounds	CO_2 + 6% ethanol (flow at 0.0002 l min^{-1}), 14 MPa, 40 °C, 30 min (dynamic, 0.18 kg h^{-1})
Alkaloids	Caffeine	Coffee husks		CO_2, 30 MPa, 100 °C, 300 min (dynamic, 197 kg CO_2 kg^{-1} husk)

important from the process development point of view and as a first step toward the possible establishment of the technology, for each particular application, at large scale. To do so, more realistic economic studies are needed to extend the degree of application of the SFE technology at industrial scale. We intend to demonstrate the possibilities of SCFs as an alternative technology to improve sustainability through the development and launch of initiatives dealing with the extraction and recovery of valuable compounds from non-costly sources. By doing so, new products intended for human health improvement will be developed ranging from new foods to new bioactive ingredients and pharmaceuticals mimicking the possibilities offered by nature.

Sweeteners: Classification, Sensory and Health Effects

A Das and R Chakraborty, Jadavpur University, Kolkata, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

For most of human history, sweetness has provided a reliable orosensory cue to a food's energy content. Sweet-tasting foods are more calorically dense than less sweet foods, making sweetness a valid predictor of subsequent energy availability. The fondness of humans for sweet foods is inborn: studies have shown a preference for sweet-tasting nutrition in newborns. Therefore, mankind has always added sweet substances to their food. The first recorded sweetener was honey, which was used in the ancient cultures of Greece and China. Honey was later replaced by saccharose, common sugar, which was originally obtained from sugarcane. During the World Wars, sugar beets were the major source of saccharose. Saccharin was the first artificial sweetener, which was synthesized in 1879 by Remsen and Fahlberg in Baltimore, the United States. It was well accepted during World Wars I and II because of its low production costs and the shortcoming of regular sugar. As economies recovered and living standards increased after the wars, sugar became affordable. Artificial sweeteners are currently being used as sugar substitutes in considerable and increasing amounts in food and beverages, especially for those who are diabetic and/or obese. There are numerous known intense sweeteners that provide little or no energy, but only a few of them are approved for use in the food industry. They have also been used in other personal care and pharmaceutical products such as toothpastes. Although, from the beginning of their use, there has been a controversy over their risk as potential carcinogens, these sweetener compounds are generally considered to be safe for use in foodstuffs. Some of the low-calorie sweeteners currently approved by different international authorities as direct food additives include acesulfame, aspartame, cyclamate, saccharin, and sucralose. Over the past 30 years, the incidence of obesity has increased dramatically, which led to consumer awareness of a healthy lifestyle, maintaining normal body weight by consumption of a balanced diet and adequate physical activity. Sucrose, the most well-known carbohydrate, is present in numerous food products in which it affects their taste, texture, and consistency. However, as the main cause of obesity, as well as diabetes and dental cavities, sucrose is often replaced with alternative sweeteners. In order to find adequate replacement for refined white sugar, the food industry is intensively promoting its artificially sweetened products (frequently called 'diet' or 'light'), highlighting their benefits. Intense sweeteners are among the most controversial food additives due to concerns of adverse health effects. On the other hand, there are a wide range of natural, unrefined sweeteners that, aside from providing sweetness to the product, contain various bioactive compounds, such as vitamins, minerals, or polyphenols that are known to exhibit positive health effects and contribute to the concept of functional foods.

Classifications

Consumers have a wide range of choice in sweeteners. One distinguishing characteristic of sweeteners is the provision of energy. Sweeteners can be grouped in various ways. For the purpose of this article, sweeteners will be grouped as nutritive and nonnutritive. Nutritive sweeteners provide a sweet taste and a source of energy; nonnutritive sweeteners (NNS) are sweet without energy. Nutritive sweeteners contain carbohydrates and provide energy; they may be further classified into monosaccharides or disaccharides, which impart 4 kcal g^{-1}, or sugar alcohols (polyols), which provide an average of 2 kcal g^{-1}. Different terms are used to refer to nutritive sweeteners, including *sugars*, *sugar*, *caloric sweeteners*, and *added sugars*. Sugars occur naturally (intrinsic) in all fruits, vegetables, and dairy foods or are added (extrinsic) to foods during processing or in preparation for consumption by an individual. Sugars commonly found in foods include glucose, fructose, galactose, sucrose, maltose, corn-based sweeteners, and agave nectar. *Sugar* often refers to sucrose, which is derived from sugarcane or sugar beet. The US Department of Agriculture uses *added sugars* to refer to sugars and syrups added to food during processing and preparation or before consumption. In addition to imparting a sweet taste, sugars have the following functions that are important to the safety and quality of foods:

- Inhibit microbial growth by binding water in jams and jellies.
- Add texture, flavor, and color to baked goods.
- Support the growth of yeast for leavening or fermentation.
- Contribute volume in ice cream, baked goods, and jams.
- Enhance the creamy consistency of frozen desserts.
- Enhance the crystallization of confectionery products.
- Balance acidity in salad dressings, sauces, and condiments.
- Help to maintain the natural color, texture, and shape of preserved fruits.

Existing evidence does not support the claim that diets high in nutritive sweeteners *by themselves* have caused an increase in obesity rates or other chronic conditions (e.g., hyperlipidemia, diabetes, dental caries, and behavioral disorders). Nonetheless, consumers who want the taste of sweetness without added energy may select NNS to assist in the management of weight, diabetes, and other chronic diseases. NNS offer little to no energy when ingested. They are referred to as high-intensity sweeteners because, as sweetening ingredients, they are many times sweeter than sucrose. NNS can replace the sweetness of sugar or energy-containing sweeteners. However, they do not have the same functional properties such as browning, crystallization, and microbial inhibition. NNS also have the potential to assist in dental health and dietary quality. Scientists have responded to consumer demand by developing, researching, and producing a number of energy-reduced or NNS.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00677-2

The use of nutritive and NNS is evaluated by governing bodies throughout the world; these include the Food and Drug Administration (FDA) of the United States and the European Food Safety Authority (EFSA) of the European Union and expert scientific committees such as the Joint Expert Committee on Food Additives (JECFA) of the United Nations Food and Agriculture Organization (FAO) and the World Health Organization (WHO). In the United States, some sweeteners are considered generally recognized as safe (GRAS) ingredients, and others are food additives as defined by the 1958 Food Additives Amendment to the Federal Food, Drug, and Cosmetic Act. GRAS sweeteners have scientific consensus on their safety based on a history of use prior to 1958 or on well-known scientific information (21 CFR, parts 182 and 184). Some, but not all, GRAS substances are listed in 21 CFR 182 and 184. Manufacturers often determine that use of a substance is GRAS and sometimes will notify FDA of their conclusions. Because substances whose use is GRAS are not subject to FDA approval, manufacturers may market on the basis of their own determination, provided that such a determination is correct.

Nutritive Sweeteners

Sucrose and fructose, which are GRAS substances, are primary sugar sweeteners that occur naturally or are added to foods. In addition to their sensory qualities, nutritive sweeteners add functional properties to foods through their effects on the physical (e.g., crystallization and viscosity), microbial (e.g., preservation and fermentation), and chemical (e.g., caramelization and antioxidation) characteristics. Sucrose is a disaccharide composed of glucose and fructose that provides 4 kcal g^{-1} ($\sim$16 kcal per teaspoon). Commercially, sucrose comes by processing sugarcane or sugar beets. Refinement removes the yellow-brown pigments of unrefined sugar to produce the white crystal form of table sugar. Molasses is the least refined form of sucrose. The monosaccharide fructose also provides 4 kcal g^{-1}. Fructose is present in fruit (also known as fruit sugar or levulose) and is added to foods and beverages as high-fructose corn syrup (42–55% fructose) or in the crystalline form. Fructose has replaced sucrose in many foods and beverages because of its sweetening power, lower cost, and functional properties that enhance flavor, color, and product stability. Fructose also synergizes the sweetness potential of sucrose and certain NNS. Polyols or sugar alcohols have been used in food products for many years to decrease the intake of carbohydrates that raise blood glucose levels. Polyols can be used alone but are more often used in combination with other polyols or NNS because of the bulking property of some polyols. Many polyols are found in nature but may be manufactured from monosaccharides or polysaccharides to be used as food ingredients. Foods containing polyols and no added sugars can be labeled as sugar-free. Trehalose and D-tagatose are other sweeteners used in food. Trehalose is found naturally in foods such as honey and unprocessed mushrooms. The enzyme trehalase is present in the brush border membrane of the small intestine and hydrolyzes the α-1,1 bond of trehalose into two glucose molecules. D-Tagatose is similar to fructose in structure other than an inversion of the hydroxyl and hydrogen groups at the fourth carbon and is found in many foods, including dairy products. Thus, consumers should base their selection of nutritive sweeteners on sensory or functional properties and not on misconceptions of differences in nutrient value.

Nonnutritive Sweeteners

Up to nine in ten consumers in the United States buy or use low-calorie products, including sugar-free and reduced-fat foods and beverages. NNS have also seen increased use in European countries (due to the growing interest in health and an aging population) and in developing countries (with interest in making limited diets more palatable). High-intensity sweeteners can offer consumers a way to enjoy the taste of sweetness with little or no energy and/or glycemic response. NNS may assist in weight management, control of blood glucose, and prevention of dental caries. The trend is to blend high-intensity sweeteners with other nonnutritive and nutritive sweeteners to create new sweet taste profiles. Blending can cause sweetness synergy (i.e., the combination is sweeter than the individual components), which can decrease the amount of sweetener needed and can improve the overall sweet taste profile.

Since the discovery of saccharin in the late 1800s, NNS have been used by consumers to achieve a sweet taste, for reasons of economics, blood glucose control, or energy control. NNS approved for use in the United States have been tested and determined to be safe at levels that are within the acceptable daily intake (ADI). Food products may contain a blend of different NNS, which further complicates estimation of intake. Although consumption of NNS in foods and beverages has increased since 1965, only about 15% of the population reported consuming any foods or beverages with NNS in 2003–2004. A systematic review of NNS intake data indicated that average intakes by adults are consistently well below their ADIs.

The FDA has approved five NNS and regulates them as food additives: saccharin, aspartame, acesulfame K, sucralose, and most recently neotame. NNS, like other food ingredients, appear on the food label in the ingredient declaration. Other NNS include alitame, cyclamate, stevia, and thaumatin.

Acesulfame K

Acesulfame K has been developed as a sweetener by Hoechst. This high-intensity sweetener is a potassium salt of 6-methyl-123-axathiazine-4 (3H)-one 2,2-dioxide with molecular formula $C_4H_4KNO_4S$ and molecular weight of 201.24. It is a white crystalline powder and $\sim$120 times sweeter than sucrose and has high water solubility. Acesulfame K is heat-stable so it can be used in cooking and baking. It may have a bitter aftertaste when used alone to sweeten food or beverages. Ace K is often blended with other sweeteners (usually sucralose or aspartame) whereby each sweetener masks the other's aftertaste and exhibits a synergistic effect by which the blend is sweeter than its components. The European Commission's Scientific Committee on Food (SCF) reevaluated this sweetener and supported its safety but recommended an ADI from 0–9 mg kg^{-1} to 0–15 mg kg^{-1}

body weight per day. The amount of acesulfame K added to food products is very small because of its intense sweetening power and because it is often used in combination with other sweeteners. The estimated daily intake is estimated at 20% of the ADI because of its intense sweetening power. Estimated intakes in children are below the ADI (ranges from 3 to 9 mg kg^{-1} body weight per day).

Alitame

Alitame is composed of L-aspartic acid, D-alanine, and a novel C-terminal amide moiety and is 2000 times sweeter than sucrose without the bitter or metallic qualities of high-intensity sweeteners. The JECFA reviewed safety data on alitame in 2002. The committee concluded that there was no evidence that alitame is carcinogenic. An ADI of 0–1 mg kg^{-1} body weight was allocated on the basis of the no-observed-adverse-effect level of 100 mg kg^{-1} body weight per day to an 18-month study in dogs. Alitame has already been approved in Mexico, Colombia, and China and Australia and New Zealand.

Aspartame

Aspartame, a dipeptide (L-aspartyl-L-phenylalanine methyl ester), is 160–220 times sweeter than sucrose. Intestinal esterases hydrolyze aspartame to aspartic acid, methanol, and phenylalanine. These components are found in much greater amounts in the normal diet in fruits, vegetables, meat, and milk. For example, a serving of nonfat milk provides about 6 times more phenylalanine and 13 times more aspartic acid, whereas a serving of tomato juice has about 6 times more methanol than an equal volume beverage sweetened 100% with aspartame. In 1981, the FDA approved aspartame as a sweetener for a number of dry uses (e.g., tabletop sweetener, cold breakfast cereal, gelatins, and puddings) and in chewing gum. This approval was expanded in 1983 to include carbonated beverages. The Council on Scientific Affairs of the American Medical Association in 1985 concluded that "Available evidence suggests that consumption of aspartame by normal humans is safe and is not associated with serious adverse health effects." In EFSA's first ever full risk assessment of the food additive aspartame, the experts concluded that aspartame and its breakdown products are safe for human consumption at current levels of exposure. Aspartame does not have any carcinogenic effect, and there are no possible effects of aspartame on the development of the unborn organism (fetus). The sweetener is authorized in the European Union for use in drinks, desserts, sweets, dairy products, chewing gums, and energy-reduced and weight control products and as a tabletop sweetener. This assessment was carried out as part of the reevaluation of the safety of all previously authorized food additives in the EU. The first safety assessment of aspartame carried out in Europe was published by the SCF in 1984, and an ADI for aspartame of 40 mg kg^{-1} body weight per day was established.

Cyclamate

Cyclamate was discovered in 1937. It was used as a low-calorie sweetener in the United States in the 1950s and 1960s. It is a salt of cyclohexylsulfamic acid. Sodium cyclamate is used as an NNS, and the analogous calcium salt is used especially in low-sodium diets. Cyclamate is 30 times sweeter than sucrose. It has a bitter aftertaste but has good sweetness synergy with saccharin. It is soluble in water and its solubility can be increased by preparing the sodium or calcium salt. It is approved by the JECFA and SCF and is in use by more than 50 countries worldwide. The JECFA set an ADI for cyclamate at 11 mg kg^{-1} body weight per day. Cyclamates were banned by the FDA as a food ingredient in 1969 because the saccharin/cyclamate mixture was shown to cause cancer in experimental laboratory rats. The primary concern was that it could be toxic to some individuals who appear to metabolize cyclamate to cyclohexylamine.

Neotame

Neotame is a derivative of a dipeptide compound of the amino acids – aspartic acid and phenylalanine. Neotame has been developed as a sweetener with a high degree of sweetness and is obtained by N-alkylating aspartame. Its degree of sweetness varies according to the kind of food and blend composition. It is 7000–13 000 times and about 30–60 times sweeter than sugar and aspartame, respectively. Globally, neotame is approved for use in multiple countries in North America, South America, Europe, Africa, Asia, and Australia. In June 2003, the JECFA confirmed the safety of neotame and granted an ADI of 2 mg kg^{-1} body weight per day.

Saccharin

Saccharin was discovered by Remsen and Fahlberg in 1878 at the Johns Hopkins University, Baltimore. It is an NNS of 1,2-benzoisothiazol-3-(2H) on 1,1 dioxide. Saccharin has an unpleasant bitter or metallic off-taste. As the parent compound is only sparingly soluble in water, the sweetener is usually used as the sodium or calcium salt. Both salts are highly water-soluble, 0.67 g ml^{-1} of water at room temperature. It is about 300 times sweeter than sucrose. The FDA has approved saccharin (in the ammonium saccharin, calcium saccharin, and sodium saccharin forms) as a sweetener in beverages in amounts not to exceed 12 mg per fluid ounce, as a sugar substitute packaged in amounts not to exceed the sweetening power of 1 teaspoon of sugar (20 mg) for use in cooking or at the table, and in processed foods in amounts exceeding 30 mg per serving. The label must state saccharin in the ingredient declaration, the amount of saccharin listed per fluid ounce for beverages, milligrams in the dispensing unit for cooking or tabletop use, and milligrams per serving for processed goods. The FDA lists the ADI for saccharin at 5 mg kg^{-1}.

Stevia

Stevia (stevioside), derived from a South American shrub, imparts a sweet taste but cannot be marketed or sold as a sweetener in the United States. It is a natural herb. This zero-calorie sweetener mainly contains steviol glycoside, which is 10–15 times sweeter than sucrose. The human body does not metabolize these sweet glycosides and so obtains no calories from stevia. Unlike artificial sweeteners, the sweet glycoside does not break down in heat, which makes stevia an excellent sweetener for cooking and baking. Studies have indicated that stevia tends to lower elevated blood pressure. The ADI is

4 mg kg^{-1} body weight expressed as steviol equivalents based on GRAS notification. It also significantly improves the nutritional status of diabetic patients.

Sucralose

Sucralose was discovered in 1976. This NNS is made from sucrose by a process that substitutes three chloride atoms for three hydroxyl groups on the sucrose molecule. Sucralose is 450–650 times sweeter than sucrose and has a pleasant sweet taste, and its quality and time–intensity profile are very close to that of sucrose. It has a moderate synergy with other nutritive and NNS. Sucralose was approved in April 1998 by the FDA as a tabletop sweetener and for use in a number of desserts, confections, and nonalcoholic beverages. In 1999, sucralose was approved as a general purpose sweetener. The FDA concluded from a review of more than 110 studies in human beings and animals that this sweetener did not pose carcinogenic, reproductive, or neurologic risk. According to the EFSA, the ADI of sucralose is 40 mg kg^{-1} body weight per day.

Thaumatin

Thaumatin is a sweet-tasting basic protein extracted from the fruits of a tropical plant, *Thaumatococcus daniellii* Benth., found in rain forests of Western Africa from Sierra Leone to Zaire, Sudan, and Uganda. The first description of this plant was made in the mid-nineteenth century. It is a mixture of proteins with tight disulfide bonds, imparts an intensely sweet taste, and acts as a flavor enhancer. In the United States, thaumatin is GRAS as a flavor adjunct for a number of categories. Thaumatin at a recommended use range of 1–5 mg kg^{-1} complete feed is safe for all animal species with a considerable margin of safety. Consequently, thaumatin can be administered simultaneously via feed or water for drinking. Thaumatins are highly digestible proteins and no residues in edible tissues/products are expected. Consequently, there are no concerns for consumer safety.

Sugar Alcohols

Sugar alcohols are neither sugars nor alcohol; it includes lactitol, xylitol, maltitol, polydextrose, mannitol, isomalt, polyols, palatinit, sorbitol, polyol syrups, hydrogenated starch, and hydrolysates. They are used to sweeten foods labeled 'sugar-free' or 'no added sugar.' Small amounts of sugar alcohols are found naturally in fruits and vegetables. They can also be manufactured. They are only partly absorbed by your body, have fewer calories than sugar, and have no major effect on blood glucose. Consumption of more than 10 g of sugar alcohols a day can cause side effects such as gas, bloating, and diarrhea.

Sensory and Health Aspects of Sweeteners

The sense of taste mainly consists of saltiness, sourness, sweetness, bitterness, and umami, the so-called five basic tastes. These basic tastes indicate different biological signals. Saltiness, which is basically caused by salt, is a signal of the electrolyte balance in foods and beverages. Sourness and bitterness are good indicators of rottenness and poisons, respectively. Umami is a signal of proteins and certain amino acids. Sweetness is a signal of nutrient sources, such as sugars and sugar alcohols. In human taste sensing, each basic taste is perceived on taste buds, which are sensory organs on the tongue. Taste buds consist of about 50–150 taste receptor cells. The mechanisms of sweetness and umami taste perception were clarified by the discovery of sweetness receptors and umami receptors, which have broad selectivity to the corresponding tastes and are capable of detecting substances with various chemical structures in spite of only one type of heterodimeric receptor in each cell. In a biological taste system, the signal responses to sweeteners are initially coded in taste buds of the epithelium by action potentials. It is known that all sweeteners are mediated by heterodimeric G protein-coupled receptors in type II cells in the bud, which have a plurality of binding sites to correspondingly identify sweet stimuli of different structures. However, studies have suggested that there are two kinds of sweetness signal transduction models that are different but interdependent to conduct different types of sweet stimuli. One is the cyclic adenosine monophosphate pathway utilized by natural sugars such as sucrose to elicit membrane depolarization, and the other is the inositol triphosphate (IP3) and diacylglycerol pathway used by artificial sweeteners for signal transduction. Many researchers have pointed out that receptor activities toward the artificial sweeteners greatly depend on residues in the amino terminal domains of the sweet taste receptors as ligand binding sites. This means the signal responses of taste receptor cells to natural sugars and artificial sweeteners may be different and can be used to characterize different sweeteners.

The worldwide demand for high-potency sweeteners is expected to increase, especially with the new practice of

Table 1 Properties of some nutritive sweeteners

Sweetener	*Glycemic index*	*Type*	*Source*
Glucose	100	Monosaccharide	Hydrolyzed starch
Fructose	19–23	Monosaccharide	Enzymatically isomerized glucose
Lactose	46	Disaccharide	Milk sugar
Lactulose	0	Disaccharide	Alkaline isomerization of lactose when milk is heated
Maltose	105	Disaccharide	Enzymatic hydrolysis of starch
Mannitol	0	Sugar alcohol	Hydrogenation of invert sugar or fructose
Sorbitol	9	Sugar alcohol	Hydrogenated glucose
Sucrose	61–65	Disaccharide	Cane and beet
Tagatose	0	Galactose isomer	Hydrolyzed lactose, galactose converted by alkali
Xylitol	7–13	Sugar alcohol	Hydrogenated xylose

combining different sweeteners. The properties of some nutritive sweeteners are given in Table 1. Among naturally derived sweeteners, stevia and licorice root are likely to become prevalent sources of high-potency sweeteners for the growing natural food market in the future. Rebaudioside A derived from stevia is the least astringent and the least bitter, has the least persistent aftertaste, and was judged to have the most favorable sensory attributes of the four major steviol glycosides. Both stevioside and rebaudioside A are synergistic in mixtures with other high-potency sweeteners and are, like glycyrrhizin, good candidates for inclusion in various food products. Sweet substances are compounds with diverse chemical structures and sizes, for example, sugars (sucrose), sugar alcohols (xylitol), sulfonyl amides (saccharin), peptides (aspartame), D-amino acids (D-tryptophan), and proteins (thaumatin). Sweetness receptors are heterodimeric proteins that consist of two kinds of G protein-coupled receptors (T1R2 and T1R3). T1R2 + T1R3 heterodimeric receptors are activated by all sweeteners. Sweetener potency is defined as the number of times that a sweetener is sweeter than sucrose. The potency of a sweetener is compared with sucrose mainly in the threshold levels of the sweetener and sucrose. Sugars and sugar alcohols, such as sucrose and xylitol, are low-potency sweeteners, whose sweetener potencies are about 1 and under. On the other hand, sweeteners that have a sweetener potency exceeding 10 are called high-potency sweeteners, such as saccharin and aspartame. Interestingly, low-potency sweeteners, such as sucrose, exhibit higher sweetness intensity than high-potency sweeteners at very high concentrations. That is why low-potency sweeteners are also called high-intensity sweeteners. Some approved NNS are given in Table 2.

Sweetness is not the only relevant sensory characteristic when evaluating sucrose replacement by low-calorie sweeteners. Other sensory characteristics, such as bitterness, aftertaste (metallic, sour, etc.), texture attributes (viscosity and mouthfeel), and freshness, should also be taken into account. Bitterness and metallic off-flavors have been one of the most common problems of low-calorie sweeteners. The dynamic of these sensory characteristics throughout consumption, particularly onset and linger, is also relevant for the performance of these ingredients. Temporal dominance of sensations (TDS) is a new dynamic methodology that consists of presenting a list of attributes to the assessors, who are asked to continuously select the attribute that is perceived as dominant at each time of the evaluation. Considering that TDS is focused on dominant attributes, instead of quantifying attribute intensity, results from this methodology could better explain consumer's perception and more accurately identify the sensations that determine their hedonic perceptions.

In sensory evaluations of foods, beverages, or pharmaceutical products, well-trained sensory panelists actually taste samples to evaluate them; therefore, sensory tests have some problems such as low objectivity and reproducibility and the stress possibly imposed on panelists. In addition, it is very costly to select and train panelists. In particular, in the medical and pharmaceutical industries, it is difficult to perform sensory tests because of the potential for side effects. Though quantitative analysis is conducted, it cannot estimate the strength of each basic taste. Thus, taste evaluation methods without using human sensory systems have attracted attention. The development of taste evaluation methods should contribute greatly to the palatability of drug products and the quality of foods and beverages. To solve the problem, electronic tongues (e-tongues) have been introduced and used successfully to evaluate the taste. e-Tongues primarily use metal and ion-selective electrodes in a potentiometric multisensor system; therefore, principal component analysis and partial least squares are generally used to analyze taste information obtained by sensor outputs with low selectivity.

Over the years, the effects of nutritive and NNS use on human health have been a concern among health professionals and the public for a variety of reasons. One area involves the safety of sweeteners for use by children, when sweetener intakes are high relative to body weight, and pregnant women, when the goal of the diet is to support maternal and fetal health. The use of nutritive sweeteners is acceptable during pregnancy. Recommendations for NNS use during pregnancy must be based on well-designed and approved clinical investigations to ensure healthy pregnancy outcomes. Women who consumed one or more NNS-sweetened soft drinks per day were significantly more likely to deliver preterm. The association was stronger for carbonated than for noncarbonated drinks. At the time of the study, aspartame and acesulfame K were used most often for carbonated drinks, and saccharin and cyclamates were more often used for noncarbonated drinks. From the survey, it was concluded that daily intake of beverages containing NNS may be associated with an increased risk of preterm delivery. It is important to point out that the incidence of preterm birth was low, and the increased risk was primarily as a result of

Table 2 Some approved nonnutritive sweeteners

Type	*Regulatory status*	*Description*
Acesulfame K	Approved as a general purpose sweetener	200 times sweeter than sucrose, noncariogenic, and produces no glycemic response
Aspartame	Approved as a general purpose sweetener	160–220 times sweeter than sucrose, noncariogenic, and produces limited glycemic response
Neotame	Approved as a general purpose sweetener	8000 times sweeter than sucrose, noncariogenic, and produces no glycemic response; sweetening power is not reduced during heating
Saccharin	Approved as sweetener for beverages and as a tabletop sweetener in food with specific maximum amount allowed	200–700 times sweeter than sucrose, noncariogenic, and produces no glycemic response
Sucralose	Approved as a general purpose sweetener	600 times sweeter than sucrose, noncariogenic, and produces no glycemic response

medically induced preterm birth. This finding has not been confirmed in other studies.

Dental caries are the localized destruction of dental hard tissue by acidic material from bacterial fermentation of dietary carbohydrates. Factors that influence the development of dental caries include microbiological shifts in the biofilm, salivary flow, buffering capacity of saliva, frequency and kind of dietary sugars consumed, length of time the oral bacteria have to ferment the fermentable carbohydrate and make organic acids, tooth susceptibility, and preventive behaviors such as cleaning of teeth. A child who consumes more than three between the meals nutritive sweetener-containing snacks or beverages per day is considered at increased risk for dental caries. Xylitol is considered cariostatic and anticariogenic and aids in the prevention of dental caries. It is very soluble in water and sparingly soluble in ethanol. Human tolerance studies indicate that consumption exceeding 50 g per day leads to diarrhea. Excess body fat arises from the energy imbalance caused by taking in too much energy and expending too little energy. Recent concerns have been expressed regarding high intakes of sweetened foods and beverages and the possible association with the increasing prevalence of overweight and obesity across the population, including children. Of particular interest is consumption of high-sugar, low-nutrient dense foods, specifically sweetened sodas and drinks. There is speculation that high intakes of fructose (particularly in the form of sweetened liquids) increase energy intake and obesity risk through the blunting of circulating insulin and leptin levels. Obesity is another complex problem, and its cause cannot simply be attributed to any one component of the food supply such as sweeteners. Troiano and colleagues found higher intakes of energy from sweetened soft drinks among overweight than nonoverweight youths, yet they suggest that physical inactivity may be more significant to the secular increase in weight within this population. Nutritive sweeteners containing fructose and sucrose are of primary interest related to hyperlipidemia. Diets high in these sweeteners have been shown to increase serum triacylglycerol and low-density lipoprotein cholesterol levels in short-term studies, particularly if the diet is low in fat, with fructose being more hyperlipidemic than sucrose. It should be emphasized that not all studies show a positive association. LDL concentrations have been shown to rise with increases in sugar intake. The effects on high-density lipoprotein levels are inversely related to sugar intake. As part of the FDA approval process, toxicology testing can examine the impact of NNS on behavior. The approved NNS did not show significant effects on behavior, especially when consumed within the ADIs. Attention has been paid to the association between aspartame and a range of central nervous system and behavioral conditions including headaches, seizures, cognitive impairment, and mood disorders; a recent critical review of the scientific literature refutes all such associations.

Conclusion

Nutritive and NNS add to the pleasure of eating. Consumers can enjoy a wide range of sweeteners in a wide variety of foods and beverages. Consumers can incorporate nutritive sweeteners into a healthful eating plan and meet current guidelines for healthful diets. The range of nutritive and NNS allows choice in the type and amount of sweeteners to include in the diet. NNS are safe for use within the approved regulations. They can increase the palatability of fruits, vegetables, and whole grain breads/cereals and thus have the potential to increase the nutrient density of the diet while promoting lower energy intakes. The trend in sweetener blending will maximize the sweetening potential and support intakes of NNS well within the acceptable levels.

Introduction

Taints and Off-Flavors

The presence of unacceptable flavors in food products is the utmost motive for its rejection. In this regard, every year the food industry receives a lot of complaints from consumers concerning taints or off-flavors in fresh, processed, and packaged foods. Basically, a taint is defined as an unpleasant odor or flavor conferred to food through external sources (e.g., packaging or storage). An off-flavor is a typical odor or taste resulting from a compound formed by internal food deterioration, such as microbiological spoilage or lipid oxidation. Even though they have different origins, both are frequently caused by trace amounts of volatile organic compounds not usually present in that food, giving to the consumer the impression of poor food quality. Occurrence of taint and off-flavor affects the quality, causing financial loss to food industries and thus damaging their reputation because the product could be even rejected by the consumer.

The description of a taint by the consumer is in general notoriously variable, partly for an absence of any training in analytical descriptive methods but mainly for unfamiliarity with chemical species responsible for taint. The most frequently unacceptable taints and off-flavors detected by the consumer are described as disinfectant, moldy, musty, earthy, fecal, metallic, fishy, painty, and plastic-like between others. The occurrence of these unpleasant aromas in products of individual industries is highly variable and is related to low concentration levels of different analytes. However, the monitoring of compounds is important as an integral component of the product quality control previously done to its introduction to the market.

Taints and off-flavors can originate from several sources, including microbiological degradation, migration from packaging, contaminated process water, or an unsuitable storage environment of ingredients or finished products. The origins of some chemicals responsible for taints and off-flavors and the detail of several specific events during their formation have been described and are out of the scope of this article. A compilation of compounds causing typical organoleptic defects with their taint descriptors, odor thresholds, and the possible origin is presented in Table 1. In general, the perception threshold for the majority of compounds is at the level of low nanogram per liter emphasizing the necessity of reliable analytical methods for its analysis and identification.

Cork taint: a particular case

An organoleptic defect that has captured the attention in recent years and is one of the most well-known food taints refers to the cork taint. It is considered as a key organoleptic defect in wine, producing a moldy and musty aroma. The main compounds responsible for this defective aroma are haloanisoles, although there are other analytes causing the same fault. Haloanisoles are also known to cause off-flavor in food and beverages, but they are specially associated with defective wines.

The manufacturing of cork stoppers for wine bottles involves several stages including cork ripening. In this step, the cork can suffer deterioration because it is exposed to the environment that is susceptible to the proliferation of fungi and bacteria. To overcome this problem, wood preservatives are added to the cork in order to minimize its trouble. The most efficient wood preservatives are based on halophenols, particularly chlorophenols. However, these compounds are biomethylated by fungi present in the cork, yielding their respective haloanisoles that are mainly responsible for cork taint in wines. Furthermore, the chlorination of lignin degradation products in the presence of free chlorine or anionic species containing chlorine also produces different chlorophenols, suffering the same microbiological degradation. Besides, wood pollution in winemaking procedures such as washing of oak barrels (hypochlorite bleaching) or transportation, storage, and handling of wine or packing materials could also increase the cork taint concentration in the final product.

The incidence of cork taint in wines of individual wineries is highly variable. However, the monitoring of haloanisoles in wines is important as an integral component of the strategies of product quality control prior to the introduction of the wine to the market.

Analytical Methods

Compounds causing taint in foods are commonly present at trace levels (ng l^{-1} or ng g^{-1}). Nevertheless, the appearance of these defects raises the question if there is any risk to human health based on risk assessment studies. Generally, a food with taint or off-flavor does not represent a safety risk for the consumer, although the perception of low quality, brand damage, and adverse publicity can be exceptionally costly to the food industry. Consequently, the selection of the most suitable

Table 1 Compilation of some compounds responsible for taints and off-flavors, odor thresholds, and taint description

Compound	*Taint aroma*	*Odor thresholds (ng l^{-1})*
2,4,6-Trichloroanisole	Mold	0.03–50
2,4,6-Tribromoanisole	Mold	3.4–7.9
2,3,4,6-Tetrachloroanisole	Mold–dust	5–15
Pentachloroanisole	Dust	10 000

methodology for the identification and quantification of taints and its occurrence in foods is crucial.

The analysis and identification of compounds causing taints and off-flavors are similar to those of volatile compounds contributing positively to the flavor of food. Due to the low concentration levels of analytes and considering the food samples, complexity, the determination of these compounds represents a challenge for the analytical chemists being necessary the application of sample preparation tools prior to the instrumental analysis. Also, highly selective and sensitive analytical techniques are required for the unequivocal identification and determination of taint compounds. In this sense, considering that most of compounds causing taints in food are volatile, gas chromatography (GC)-based techniques have been the choice for its analysis. Mass spectrometry (MS) is the selected analytical technique for taint investigations when identification and quantification of trace amounts of unknown contaminants are required. Currently, modern MS detectors can achieve suitable identification of nontargeted analytes, increasing the spectrum of identified compounds and the applicability of methods. Besides, other detectors including electron capture (ECD), atomic emission (AED), and olfactometry (O) were reported for the analysis of the compounds of interest. During recent years, the instrumental techniques used for the identification of food volatiles have been efficiently shared with sensory methods to determine the relative odor influence of unknown components in food. The sensory descriptor of a taint can often be the key point to performing targeted chemical analysis. In this way, sensory panels trained in give objective assessments and descriptions of taints can provide an insight when a consumer has complained that the foodstuff tastes spoiled.

Since the concentration of taints is usually low, it is necessary to count on highly efficient extraction/preconcentration techniques for its evaluation. Thus, with the developing interest in miniaturization in analytical chemistry for solvents and sample savings, innovative miniaturized techniques have been also reported and successfully applied for odor analysis.

Techniques for Chemical Analysis

Sample Preparation Strategies: Isolation and Preconcentration

Sample preparation is a critical step in the identification and quantification of analytes. The majority of separation and detection techniques require different extraction and cleanup procedures to minimize matrix effects, mainly when complex food samples are analyzed. The techniques used for sample preparation of volatile compounds, particularly taints and off-flavors, have been changing during the last 20 years. Liquid–liquid extraction (LLE) has been progressively replaced, and efforts were placed on the miniaturization of LLE by significantly reducing the required organic solvent amount, increasing the sustainability of the analytical process. The proposed techniques include simultaneous steam distillation solvent extraction, static headspace, dynamic headspace, solid-phase microextraction (SPME), headspace sorptive extraction (HSSE), and stir bar sorptive extraction (SBSE). The most recently developed techniques include liquid-phase microextraction approaches such as dispersive liquid–liquid microextraction, ultrasound-assisted emulsification microextraction, and single-drop microextraction, as well as the novel QuEChERS (quick, easy, cheap, effective, rugged, and safe) method.

Liquid–liquid extraction

Some methods have been reported for taints and off-flavors in foods that use direct solvent extraction. High concentrations of androstenone and/or skatole in pig carcasses are associated with unpleasant odors in meat, the so-called boar taint. Most of the described methods to quantify boar taint compounds employ LLE to extract the compounds from adipose tissue. The muscle is heated prior to extraction, and liquid fat is mixed with the organic solvent. The extracts are often frozen and centrifuged or filtered to remove insoluble material. Different organic solvents, such as methanol, ethanol, hexane, ethyl acetate, or petroleum ether, and solvent mixtures have been used to extract androstenone and/or indolic compounds from these matrices with satisfactory recoveries (98.9% and 93.8% recovery of skatole and indole).

Due to the differences in polarity of steroids and indole compounds, it is a difficult challenge to select an extraction

solvent that can be used to simultaneously extract both groups with high extraction yields. Methanol has shown to be suitable for parallel extraction of androstenone and indole compounds, achieving recoveries closer to 100%. However, most laboratories perform extraction of steroids and indole compounds separately.

Solvent extraction methods have the drawback that the complexity of obtained extracts makes necessary the application of some additional sample preparation step such as preconcentration and purification in order to isolate compounds of interest previous to instrumental analysis. The preconcentration step simplifies the collection of chromatograms that allow a correct identification and quantification of analytes. The purification allows the removal of potential interfering compounds present in complex matrices being a crucial step of any method. Solid-phase extraction (SPE) is the most commonly used technique for the cleanup of food samples during taint and off-flavor analysis. Different authors have employed C_{18} or HLB sorbents for cleaning up samples and for preconcentrating compounds such as haloanisoles and halophenols with satisfactory results. The advantage of SPE is that for liquid samples such as wine, high extraction efficiencies could be achieved by using small sample and elution solvent volumes.

Indole compounds can be retained by both polar and nonpolar extraction mechanisms. So, a strongly polar extraction column, like Bond Elut 20H Diol, has been used, whereas the hydrophobic stationary C_{18} phases show good efficiency to remove lipids and fatty acids in meat samples.

Supercritical fluid extraction

An alternative to traditionally used LLE is supercritical fluid extraction (SFE) that has been applied for the extraction of boar taint compounds in porcine samples. SFE employs the unique properties of supercritical fluids to facilitate the extraction of organic analytes from solid samples. A supercritical fluid is a substance above its critical temperature and pressure that has a good solvating power (like liquid), high diffusivity, low viscosity, and marginal surface tension. Due to these characteristics, SFE permits a rapid mass transfer in the supercritical phase and an improved ability to penetrate the pores in the sample matrix, achieving a fast and efficient extraction. SFE may be an environmentally sustainable alternative to the conventional organic solvent extraction because it avoids the use of large amounts of toxic solvents, being also rapid, automatable, and selective.

SFE using supercritical carbon dioxide has been used to isolate androstenone from fat, achieving extraction efficiencies as high as 97%, although the efficiency obtained for skatole was 65%. This fact could be related to the polarity difference between both compounds. In order to improve the extraction of a wide spectrum of analytes, the addition of a cosolvent could be a suitable alternative for future developments.

Solid-phase microextraction

The most common sample preparation technique reported for extraction/preconcentration of taint and off-flavor compounds is SPME. It has the advantage, when compared with other techniques, that it is solvent-free and can be easily automated.

The application of SPME in the field of food taints and off-flavors is mostly explored for compounds that are important for the food industry and frequently befall those that cause musty–earthy off-flavors (haloanisoles, halophenols, geosmin (GEO), and methylisoborneol (MIB)), those that cause medicinal off-flavors (phenolic compounds and sulfur-containing compounds), and carbonyl compounds that produce food spoilage due to oxidative changes in lipids.

There are various SPME approaches combined with different detectors for the determination of the compounds of interest. The HS-SPME is the most extensively used extraction design for these compounds. Direct extraction of halophenols from water provides higher peak areas than HS extraction. On the other hand, in the case of wine, HS-SPME yields an approximate fourfold increase in peak areas compared with direct immersion (DI). Additionally to the reduced sensitivity reported by using the DI mode of SPME fibers applied into wines, increased contamination of the injector system and shorten lifetime of the SPME fibers and analytical GC column are observed. When the equilibrium is reached, the amount of analyte extracted on the fiber should be the same, either the fiber is immersed in liquid matrix or extraction is performed from the HS. Consequently, differences in the quantity of extracted analytes in DI and HS extraction can be a result of the different phenomena to reach equilibrium for both extraction methods. During HS, the analytes have to diffuse from liquid to gaseous phase and then from gaseous phase to the fiber coating. In the case of DI, they have to transport from liquid phase to the fiber coating. In addition, the DI extracts a lot of matrix coextractives that could affect selectivity and sensitivity of the methodology; and also, the fiber has a reduced lifetime.

The extraction temperature is also an important factor during SPME method development because it affects the extraction efficiency. An increase of temperature causes an augment of extraction yield because of the enhancement of mass transfer; however, high temperature decreases the efficiency of extraction due to a decrease of the distribution constant. Furthermore, the application of stirring could increase the extraction efficiency for haloanisoles. Stirring accelerates the transfer from liquid matrix to HS, and the equilibrium is achieved much faster in the stirred system than in nonstirred ones.

In view that the fiber coating is the 'heart' of the extraction, it is very important to select the right fibers for the desired application. The nonpolar polydimethylsiloxane (PDMS) and the combined adsorbent capacity of divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) were the most used coating for cork taint compound extraction from wine samples. Additionally, polyacrylate fibers were also used with good performance. The DVB/CAR/PDMS fibers were more utilized in the analysis of a wide range of cork taint compounds, including haloanisoles, halophenols, MDMP, MIB, 1-octen-3-one, 1-octen-3-ol, geosmin, and guaiacol; meanwhile, PDMS was more used for the analysis of haloanisoles. Based on the reported methods, DVB/CAR/PDMS-based SPME techniques showed an increased extraction efficiency (between 50% and 100%) related to PDMS. However, some authors reported low reproducibility of DVB/CAR/PDMS fibers, justifying the selection of PDMS as coating.

The lipophilic boar taint compounds interact strongly with the interfering fat matrix, and thus, the sample preparation

must overcome such fat-associated matrix effects. HS-SPME using PDMS/DVB fiber and an extraction temperature of 100 °C after cross validation revealed comparable results to previously reported methods using the same separation and detection technique.

Taking this into account, the development of a successful SPME method needs a reproducible agitation, suitable control of sample temperature and headspace volume, and the extraction time. The variability of ionic strength and levels of polymeric materials (e.g., polysaccharides and tannins) in wines significantly affect the headspace concentration of volatiles. Thus, the quantitation by external calibration method is generally not suitable, and the use of a labeled internal standard (IS) or the method of standard additions may be required for an accurate quantitation of analytes.

The most accurate, precise, and robust method to determine the levels of important compounds in problematic matrixes and eliminate matrix effects is the application of stable isotope dilution analysis (SIDA). In any analysis, the applied IS should be as similar as possible to the measured analyte, without being present originally in the matrix. The isotopically labeled ISs are ideal because they have almost identical physicochemical properties to their unlabeled analogs and nevertheless can be easily discriminated from the analyte of interest by MS. In this sense, the accuracy of analysis is not reduced by inefficiency in isolation or by analyte decomposition because the labeled IS is virtually chemically identical to the substrate being assayed. This fact avoids the necessity of an exhaustive extraction of the analyte of interest from the matrix, improving the applicability for equilibrium extraction techniques such as SPME or SBSE, extensively used for taint and off-flavor analysis. Another advantage is that methods can be simplified, being possible the determination of several analytes (even though compounds with different chemical properties) in a single extraction and GC–MS run.

Hence, SIDA is the method of choice, especially when the quantitation of low concentrations of odorants is desired. In this sense, it has been reported for quantitation of boar and cork taint compounds using SPME-GC–MS.

Stir bar sorptive extraction

During SBSE, analytes are extracted from a liquid phase of an aqueous matrix into a magnetic stir bar covered with a polymeric phase. As for SPME, HSSE can also be used for specific analytes. In contrast to extraction with adsorbents, whereby the analytes interact with active sites on a surface, in SBSE, the solutes migrate into the sorbent phase. In comparison with SPME, SBSE has much higher amount of sorbent available resulting in higher sample capacity. Also, SBSE leads to more rapid methods with a sensitivity improvement, being able the determination of taint compounds with extremely low sensory thresholds (ng l^{-1}), even in the presence of large matrix components. However, taking into account the nonselective sorption capability of sorbents, a coconcentration of undesirable matrix components from the sample could be possible. In this sense, SBSE could produce analyte preconcentration in the sorbent, but, sometimes, the achieved cleanup is not satisfactory for complex samples.

The SBSE technique has been applied for the extraction of taint compounds in different samples, principally cork and wines achieving similar or better analytical performance than SPME.

As SPME, SBSE is not an exhaustive extraction technique, and likewise for all equilibrium-based techniques, it is necessary the utilization of ISs or standard additions for quantitation.

Comparison of taint extraction/preconcentration techniques

Taking into account the principles and reported applications for taint analysis using the mentioned techniques, some comparative comments can be given. For the analysis of volatile compounds, the most efficient and convenient approaches refer to SPME and SBSE. These approaches have the advantages of proved extraction of a wide scope of taint and off-flavor compounds, reduced sample extraction time, and excellent analytical figures of merit. Also, the use of organic solvents is practically avoided being also sustainable alternatives to LLE methods. An indisputable advantage of SPME is its possibility of complete automation of analytical process, increasing the reproducibility and accuracy of the obtained results. It also allows the reduction of the analysis time during routine analysis and method development, which increases the sample throughput of the technique, a requirement for methods to be applied in the industry.

Recently, numerous LLE miniaturizations have been reported particularly for the analysis of cork taint compounds. These methods appear as suitable alternatives, especially the methods determining simultaneously haloanisole and halophenol families, by coupling novel one-step extraction and in situ derivatization strategies. In general, microextraction techniques are faster than SPME; however, the last has the advantage of allowing the full automation of methodology. In addition, SPME has found a wide application for taint analysis being very simple and the only real solventless sample preparation technique reported for these compounds.

Derivatization

Due to the polar nature of some taint compounds such as halophenols, some chemical modification of the analytes is necessary prior to instrumental analysis in order to enhance its detection. Derivatization is commonly used for the determination of chlorophenols due to the poor GC response and peak tailing generally obtained for these compounds. Also, the derivatization step allows the simultaneous determination of different groups of compounds (i.e., haloanisoles and halophenols), improving the applicability of the technique. There are different strategies to achieve satisfactory derivatization of polar analytes. Some authors proposed the in situ derivatization reaction, providing a one-step derivatization and extraction/preconcentration technique, particularly for polar chlorophenols that simplify the operability and shorten the analysis time. These approaches were successfully applied in microextraction techniques using acetic anhydride as derivatization reagent. In SPME techniques, on-fiber derivatization of halophenols using *N*-methyl-*N*-trimethylsilyltrifluoroacetamide after a preconcentration on a SPME fiber has been proposed.

Instrumental Techniques

Taking into account that the majority of taint and off-flavor compounds are volatile or semivolatile, the selected analytical instrumentation for its analysis is GC-based techniques. However, there are other compounds such as those causing boar taint (skatole, indole, and androstenone) where the utilized technique is high-performance liquid chromatography.

GC is coupled with different detectors including MS, MS/MS, high-resolution (HR) MS, ECD, AED, and O. GC–MS has the advantage of achieving a practically unequivocal identification, particularly when MS/MS or HRMS is used. In the specific case of cork taint compounds in wine samples, some authors reported difficulties to produce reliable data in certain trace levels (low ng L^{-1}) due to severe coelution problems of haloanisoles and halophenols. Thus, the selection of MS/MS methods unique for each analyte combined with SIDA quantitation strategies permitted to avoid ambiguous identification of compounds. Besides, MS/MS methods could evade some matrix interferences remaining after sample preparation step, increasing the selectivity and sensitivity of the analytical methodology. In fact, the reported MS/MS methods for cork taint compounds showed lower Limits of detection (LODs) than MS methods. GC-HRMS was reported for the determination of 2,4,6-TCA and 2,4,6-TBA with higher selectivity. This technique showed similar sensitivity than MS/MS methods, giving the exact mass of analytes but having the disadvantage of a high purchase and maintenance cost.

The use of multidimensional GC (MDGC) coupled with ECD was recently reported, allowing the reliable quantification of different groups of cork taint compounds at sub-ng L^{-1} level avoiding coelution problems and without necessity of extensive sample preparation previous to instrumental analysis. This strategy gives benefits from the additional separation achieved using MDGC and using SIDA deprived of the utilization of MS detectors. In this way, some authors explained the selection of ECD because of its relatively low purchase and maintenance costs, combined with its relatively good sensitivity. Nevertheless, ECD is only suitable for halogenated taint compounds being the principal disadvantage compared to the most used GC–MS detectors. In this sense, the variety of detected compounds is reduced, and the determination of other minor or less common analytes and the nontargeted analysis are not possible. So, future developments using MDGC combined with MS detectors appear as appropriate options to reach the detection of a wide spectrum of analytes.

A valuable analytical instrument for the detection and identification of new aroma compounds in wine or other foods is GC-O detection. It is based on coupling to GC a human nose as a detector for sensory evaluation of the eluate from the chromatographic column with the aim to discerning the active odor compounds present in a particular sample. This allows establishing whether a particular compound is sensory active at a given concentration (i.e., whether it appears in the sample at a higher level than the sensory detection threshold). The presence of a special attachment, named olfactometric port, connected in parallel to conventional detectors such as MS, due possible the determination of the analyte's odor. GC-O can be useful in correlating odors to compounds and can be used as an initial screening of volatile compounds or to confirm the presence of a specific taint compound. The flow of the eluate is split in such a way that the analytes reach both detectors at the same time, so both signals could be compared. The combination of the O detector with MS is particularly useful, allowing not only the evaluation of the odor compounds but also its identification with mass spectral information. Taking into account that aroma thresholds and descriptors vary from person to person, each sample should ideally be run more than once and evaluated by more than one sniffer to avoid nonobjective results. GC-O could be a useful tool to establish the importance of each aroma component. However, one of the main limitations of GC-O is that some compounds that are detected at the heated sniffing cup of the O detector are not normally detected by the human nose. In GC-O detection, many compounds that are not essentially volatile in the matrices in which they occur are normally vaporized in the injector of the GC. In this sense, this detection strategy can overestimate the significance of an aroma compound and change the perceived aroma character in a real-life situation. The use of reference standards with GC-O is important for both matching retention times and odor characteristics; quantification can be performed subsequently using instrumental techniques such as GC–MS.

Other separation/detection techniques have been applied for taint and off-flavor identification. Ion mobility spectrometry (IMS) is a technique that characterizes molecules by their gas-phase mobility, offering high sensitivity, instrumental simplicity, low cost, analytical flexibility, and real-time monitoring capability. Due to these advantages, IMS is a suitable possibility for the detection of volatile compounds. However, it experiences a limited selectivity, which has been overcome by the separation of the analytes using gas capillary chromatographic columns or multicapillary columns (MCCs). This approach has been proposed for the determination of 2,4,6-TCA, and the use of MCC allowed an increase of selectivity of IMS detection.

Other promising detection techniques are the immunoanalytical technologies, which involve a specific antibody raised against the analyte. These analytical tests are based on the specific interaction between the antibody and the antigen. Because of their high sensitivity and selectivity, immunoassays have been successfully used for both qualitative analysis and quantitative analysis of several compounds at trace levels. The disadvantages of these techniques are the low sensitivity and selectivity and the unfeasibility of determination of more than one analyte at the same time. This new generation of analytical tools appears as suitable alternatives for future developments in this matter.

Conclusions and Future Trends

The avoidance of taints and off-flavors is crucial to ensure food quality and will be achieved by controlling processes, packaging, and storage conditions. The application of different analytical methodologies for the analysis and identification of taint compounds varies between laboratories and the needs of specific quality control of each industry. The selected analytical method depends on many factors such as

instrument accessibility and analyst experience. Likewise, the sensitive and selective detectors required for taints, sample preparation as extraction, and preconcentration play a critical role in the development of methods for taint and off-flavor analysis. SPME poses substantial advantages, which prompts this technique for this type of analysis. It is sensitive and selective being useful for screening and targeted analysis of compounds. Besides, the possibility of total automation of analytical process, promises successful developments for the future. The use of conventional techniques such as those based on LLE is time-consuming and requires high volumes of organic solvents and solvent concentration steps. These facts emphasize the utilization of sustainable alternatives for this type of analysis.

Although these are well-established techniques that can be effectively applied for the analysis of taint and off-flavor compounds at concentrations lower as their human detection threshold, there are only a small number in which two or more families of analytes have been determined at the same time. Consequently, the challenge for analytical chemists will be the developments of consistent methods that can thoroughly cover the variety of taint compounds present in foods, achieving their simultaneous determination through more sustainable sample preparation approaches.

Introduction

Phenolic compounds or polyphenols are the most abundant and ubiquitous secondary metabolites present in the plant kingdom with more than 8000 phenolic structures currently known with highly diverse structures and molecular masses ranging from <100 Da for simple phenolic compounds to >30 000 Da for highly polymerized structures. They possess a common structure comprising an aromatic benzene ring with one or more hydroxyl substituents. They represent a large and diverse group of molecules including two main families: the flavonoids based on common C_6–C_3–C_6 skeleton and the non-flavonoids. Phenolic compounds play an important role in plant growth and reproduction, providing protection against biotic and abiotic stress such as pathogen and insect attack, UV radiation, and wounding. Polyphenols are widely distributed in the human diet mainly in plant-derived food and beverages (fruits, vegetables, nuts, seeds, herbs, spices, tea, and red wine) and can influence multiple sensorial properties such as flavor and color and contribute to the aroma and taste, for example, astringency and bitterness.

In this article, phenolic compounds, particularly tannins and more particularly the proanthocyanidins and hydrolyzable tannins, will be emphasized. Their structures, biosynthesis, and occurrences will be described. The term 'tannins' is etymologically derived from the ancient keltic lexical root 'tann-' meaning oak and was first used in 1976 in tanneries. This word has also been used to designate the substance of vegetable origin capable of transforming fresh hide into leather. In 1962, tannins were defined by Bate-Smith and Swain as "water soluble phenolic compounds having molecular weights between 500 and 3000, and besides giving the usual phenolic reactions, and they have special properties such as the ability to precipitate alkaloids, gelatin and other proteins." Indeed, in tannin-rich food and beverages, this latter capacity is easily recognized as an astringent character once tannins precipitate with salivary proteins. The definition was later expanded by Edwin Haslam at the molecular level by adding structural and polyphenolic character. Besides the water-soluble properties and molecular weights already defined, tannins also possess some 12–16 phenolic groups and 5–7 aromatic rings per 1000 Da of relative molecular mass. Depending on the monomer structure, tannins are classically divided into four groups: condensed tannins or the proanthocyanidins (i.e., polymers of flavanol unit), the hydrolyzable tannins (i.e., gallotannins and ellagitannins), the complex tannins (tannins composed of hydrolyzable tannin moieties and flavonoid moieties), and the phlorotannins found in algae (oligomers of phloroglucinol unit).

Proanthocyanidins

Nomenclature and Structures

Proanthocyanidins or condensed tannin compounds are derived from the oligomerization of flavan-3-ol units such as catechin and/or epicatechin and epigallocatechin. Apart from lignin, they represent the most abundant class of natural phenolic compounds and the most common flavonoid. Indeed, flavonoids are the major constituents with more than 4000 compounds having been characterized. They share a common flavan core consisting of fifteen carbons with two aromatic rings (A and B), bounded by three carbon atoms, which form an oxygenated heterocycle (ring C) (Figure 1(a)). The flavonoid skeleton C_6–C_3–C_6 can have numerous substituents and occurs naturally as glycosides rather than aglycones. Due to differences in the oxidation state and substitution on ring C, flavonoids can be further be divided into different subgroups comprising flavones, flavonols, flavan-3-ols, isoflavones, flavanones, and anthocyanins (Figure 1(b)).

Unlike flavones, flavonols, isoflavones, and anthocyanidins, which are planar molecules, flavan-3-ols, proanthocyanidins, and flavanones have a saturated C_3 element in the heterocyclic C-ring and are thus nonplanar. The two chiral centers at C_2 and C_3 of the monomeric flavan-3-ol produce four isomers for each level of B-ring hydroxylation. (+)-Catechin and (−)-epicatechin are widespread in nature, whereas (−)-catechin and (+)-epicatechin are comparatively rare (Figure 2).

An important feature of the flavan-3-ols is their ability to form polymers, which are often referred to as proanthocyanidins or even condensed tannins as opposed to hydrolyzable tannins (gallotannins and ellagitannins). Although usage of the term 'oligomeric' varies somewhat, dimers, trimers, and up to heptamers are generally assigned to as oligomeric ($n = 2$–5), whereas longer chains are generally attributed to as polymeric procyanidins or tannins ($n = 6$–∞). Oligomeric and polymeric proanthocyanidins have an additional chiral center at C_4 in the upper and lower units, and their structures vary in function of the nature of their constitutive subunits, mean degree of polymerization (mDP), and linkage position. Proanthocyanidins composed mainly of (epi)catechin units are called procyanidins and these are the most abundant type of proanthocyanidins in plants. Other oligomeric tannins contain (epi)afzelechin and (epi)gallocatechin subunits and are called propelargonidins and prodelphinidins, respectively (Figure 2).

The current valid nomenclature for oligomeric procyanidins was defined by Hemingway et al. in 1982 after being first introduced by Weinges et al. in 1968 and later extended

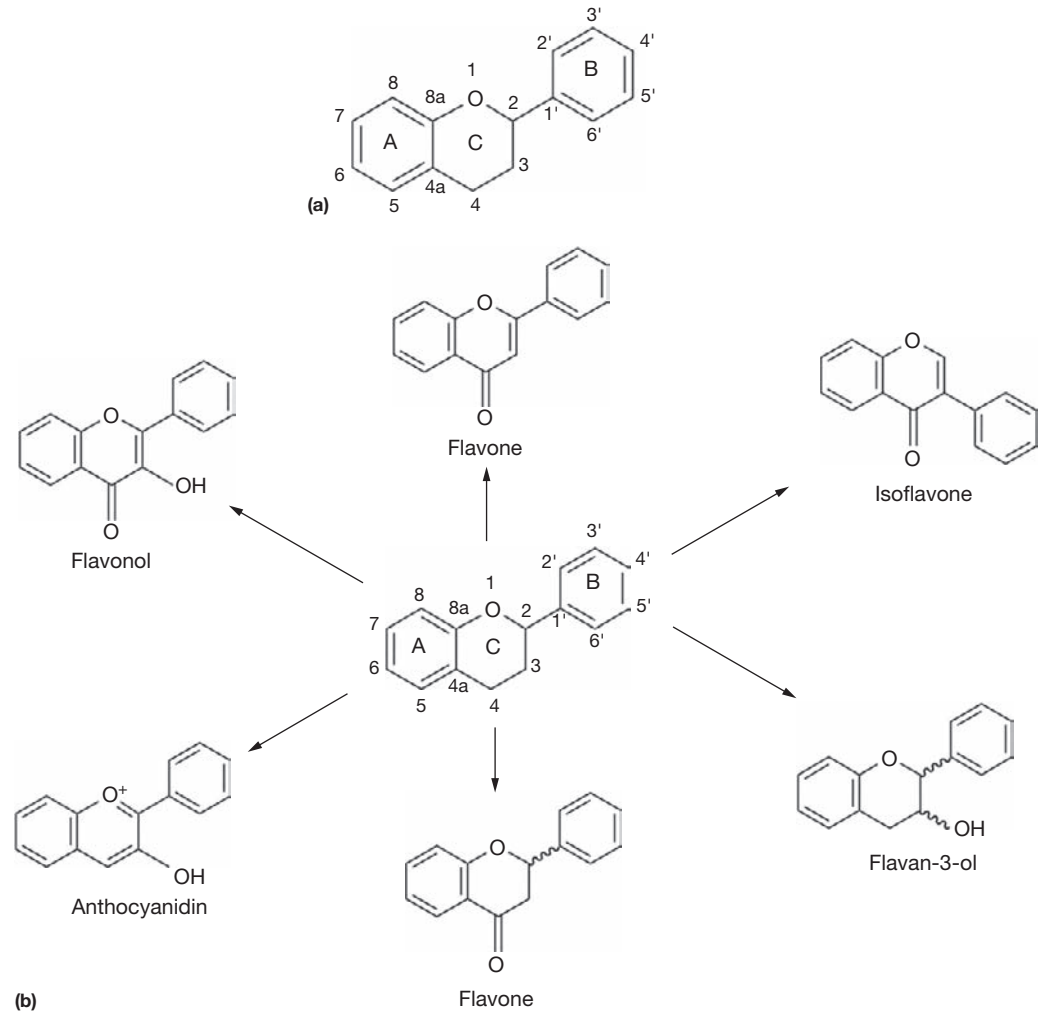

Figure 1 (a) Flavonoid ring structure and numbering system and (b) structure of the flavonoid skeleton.

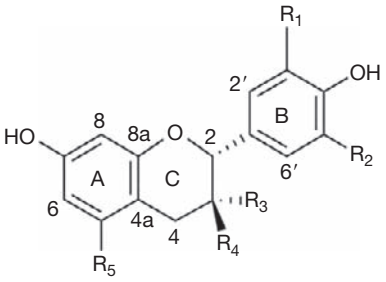

2*R* Flavan-3-ol monomers	R_1	R_2	R_3	R_4	R_5
(+)-Afzelechin	H	H	H	OH	OH
(–)-Epiafzelechin	H	H	OH	H	OH

(–)-Epicatechin	H	OH	OH	H	OH
(+)-Gallocatechin	OH	OH	H	OH	OH
(–)-Epigallocatechin	OH	OH	OH	H	OH

Figure 2 2*R* isomer flavan-3-ols structure.

by Thompson et al. in 1972. The IUPAC system also works in naming proanthocyanidins and proves to be useful in cases that absolute stereochemistry at all chiral centers have to be described. Proanthocyanidins have high structural diversity based on four possible monomer units, (2*R*, 3*S*)-catechin, (2*S*, 3*R*)-ent-catechin, (2*R*, 3*R*) -epicatechin, and (2*S*, 3*S*)-ent-epicatechin, with the diastereomeric monomers (2*R*, 3*S*)-catechin and (2*R*, 3*R*)-epicatechin being predominant (Figure 2). Regarding the stereochemistry of the C_2–C_3 bond, they exhibit *cis* [(2*R*, 3*R*) (−)-epicatechin] or *trans* [(2*R*, 3*S*) (+)-catechin] configuration. Because most common flavan-3-ols exist as 2*R* isomers, the prefix 'ent' is used to label less common 2*S* isomers. The interflavanol linkage and its direction are indicated in parentheses with an arrow (4→) and its configuration at C_4 is described as α or β. Moreover, proanthocyanidins possessing a glycone are given a qualifying ending of '-in,' while those lacking a glycone are qualified with an ending of 'idin.'

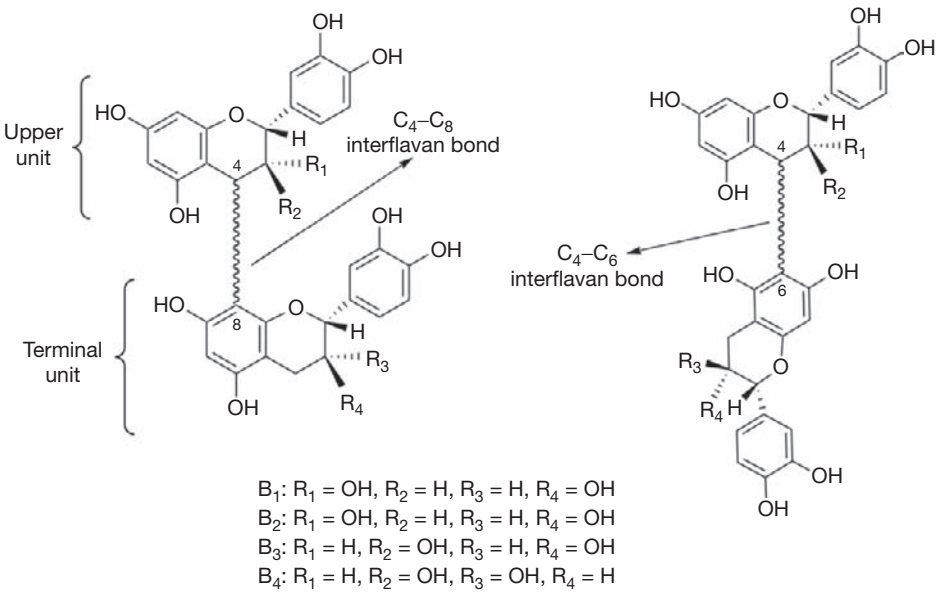

Figure 3 Type B procyanidin structures and C_4–C_8/C_4–C_6 interflavan bonds.

Stereochemistry at C_4 is strongly influenced by the hydroxylation on the A-ring. Procyanidins and prodelphinidins with 2,3-*cis* stereochemistry frequently adopt 3,4-*trans* stereochemistry during interflavanoid bond formation with $C_4 \rightarrow C_8$ or $C_4 \rightarrow C_6$ interflavanoid linkages occurring in relative proportion of 3:1. Type B proanthocyanidins are dimers resulting from these types of linkage between two units of flavan-3-ols (Figure 3). The four most common B-type proanthocyanidin dimers are the B_1, B_2, B_3, and B_4 (Figure 3). A-type proanthocyanidins are dimers that, in addition to the C–C interflavan linkage, that is, $C_4 \rightarrow C_8$ or $C_4 \rightarrow C_6$ interflavan bond, also have a C–O bond between the C_5 and C_7 carbons of the upper units. This subclass lacks two hydrogens compared to the B-type linkages. Trimers or C-type proanthocyanidins, such as C_1, consist of three flavan-3-ol units linked by two $C_4 \rightarrow C_8$ interflavan bonds. Table 1 illustrates the most common proanthocyanidins.

Besides, proanthocyanidins can also be distinguished depending on the nature of the liberated anthocyanidins in acidic conditions. Proanthocyanidins that are composed of (+)-catechin and (−)-epicatechin release cyanidins and prodelphinidins and those composed of (+)-gallocatechin and (−)-epigallocatechin liberate delphinidins.

Table 1 Common proanthocyanidins and their structures

Proanthocyanidins common name	*Structures*
Procyanidin B_1	(−)-Epicatechin-(4β→8)-(+)-catechin
Procyanidin B_2	(−)-Epicatechin-(4β→8)-(−)-epicatechin
Procyanidin B_3	(+)-Catechin-(4α→8)-(+)-catechin
Procyanidin B_4	(+)-Catechin-(4α→8)-(−)-epicatechin
Procyanidin B_5	(−)-Epicatechin-(4β→6)-(−)-epicatechin
Procyanidin B_6	(+)-Catechin-(4α→6)-(+)-catechin
Procyanidin B_7	(−)-Epicatechin-(4β→6)-(+)-catechin
Procyanidin B_8	(+)-Catechin-(4α→6)-(−)-epicatechin
Procyanidin A_1	(−)-Epicatechin-(4β→8,2β→O→7)-(+)-catechin
Procyanidin A_2	(−)-Epicatechin-(4β→8,2β→O→7)-(−)-epicatechin
Procyanidin C_1	(−)-Epicatechin-(4β→8)-(−)-epicatechin-(4α→8)-(−)-epicatechin
Procyanidin C_2	(+)-Catechin-(4α→8)-(+)-catechin-(4β→8)-(+)-catechin

Biosynthesis of Flavan-3-ol and Proanthocyanidin

The flavonoid biosynthetic pathway has largely been characterized, especially not only in *Arabidopsis thaliana* but also in *V. vinifera*. Proanthocyanidins are synthesized along the phenylpropanoid pathway by the activity of a cytosolic multienzyme complex. The upstream pathway consists of the formation of the core, the basic skeleton of all flavonoids, starting from three molecules of malonyl-CoA and one of 4-coumaroyl-CoA. Chalcone synthase (CHS) and chalcone isomerase (CHI) are the enzymes involved in the two-step condensation, producing a colorless flavanone named naringenin. The latter is a central intermediate as from this point onward, the flavonoid biosynthetic pathway diverges into several side branches each resulting in the production of different classes of flavonoids including isoflavones, flavanones, flavones, flavonols, flavan-3-ols, and anthocyanins. The oxidation of the latter compound by flavanone 3-hydroxylase (F3H) yields the dihydrokaempferol that subsequently can be hydroxylated on the 3′ by flavonol 3′-hydroxylase (F3′H) producing dihydroquercetin. Dihydroflavonol reductase (DFR) then converts dihydroflavonols to leucoanthocyanidins with the synthesis of leucocyanidin from dihydroquercetin. Indeed, leucoanthocyanidins are key intermediates in the formation of flavan-3-ols, proanthocyanidins, and anthocyanidins. The enzyme leucocyanidin 4-reductase (LAR) is responsible for the conversion of leucocyanidin to the flavan-3-ol (+)-catechin, whereas leucocyanidin

deoxygenase (LDOX) catalyzes the synthesis of cyanidin, which anthocyanidin reductase (ANR) converts to (−)-epicatechin. Figure 4 shows the schematic pathway and enzymes involved in the production of flavan-3-ols and proanthocyanidins.

Occurrences in Grapes and Wines

It is well known that grapes and red wines contain oligomeric procyanidins and prodelphinidins. The content of proanthocyanidins in grape berries depends on genetics, stages of ripeness, climatic geographic factors, and cultural practices. These compounds are mainly localized in the solid part of grape bunches (skins, seeds, or stems).

In the berry skins, they are found as a free form in the vacuolar sap or bound to proteins and polysaccharides in the internal face of the tonoplast and to the cell wall, respectively. Some authors have described a decrease in the content of flavan-3-ol monomers and proanthocyanidins after veraison and a concomitant increase or decrease of proanthocyanidin mDP in grape skins. Grape seeds are composed by an outer integument including a soft outer parenchymatous layer covered by a cuticle and an inner layer of hard, lignified, brown cells (hard, brown 'hull'). The endosperm constitutes the white soft tissue inside the inner integument. The majority of both monomeric and polymeric flavan-3-ols are localized in the outer seed coat with two to five times higher concentrations than the endosperm, which is mainly composed of monomeric flavan-3-ols. A considerable amount of proanthocyanidins can also be found in seed hull. The accumulation of flavan-3-ols in seeds can be delayed when compared to skin, and maximal concentration is reached a few weeks after veraison. The concentration of flavanol monomers then decreases sharply, while slight accumulation of procyanidin oligomers is observed.

The major flavan-3-ol monomers in grapes are (+)-catechin and its isomer (−)-epicatechin and, to lesser extent, (+)-gallocatechin, and (−)-epigallocatechin (Figure 2). Moreover, their galic acid ester (−)-epicatechin-3-*O*-gallate and (+)-gallocatechin-3-*O*-gallate have also been identified. Grape seed proanthocyanidins comprise only procyanidins, whereas grape skin proanthocyanidins include both procyanidins and prodelphinidins. Skin proanthocyanidins have a higher mDP and a lower proportion of galloylated subunits than seed ones.

During red wine making, grape proanthocyanidins are extracted from seeds and skins and concentration depends not only on the original grape profile but also on the extraction and winemaking techniques employed. Extraction kinetic depends on the solubility of the compounds and on their accessibility within the berry tissues, which can be modulated by physiological factors such as the maturation stage. It is further influenced by other technological factors, including the concentration of alcohol and of sulfur dioxide in the liquid phase, the temperature, and the extent of must homogenization. Consequently, the wine flavonoid composition is also influenced by the duration of pre- and postfermentation maceration phases and by treatments enhancing cell wall or berry degradation.

Condensed tannins can be found in grapes with different degrees of polymerization with two or more units of flavan-3-ols, reaching as high as 80 units of flavanol. Degrees of polymerization between 3–83 and 2–16 have been reported in grape skins and grape seeds, respectively. In red wine, their degree of polymerization changes continuously during aging as a result of the chemical transformations. The concentration of flavan-3-ols and proanthocyanidin in red wine ranges from ~500 to 5000 mg l^{-1} and in white wines between 100 and 300 mg l^{-1}. Proanthocyanidins are of great importance to sensory quality of red wine due to their astringent and bitter properties and their role in the long-term color stability via some chemical reactions with anthocyanins (copigmentation and/or condensation).

Molecular size of proanthocyanidins reflected in the mDP affects the mouthfeel properties, especially their relative bitterness and astringency. Indeed, monomers are more bitter than astringent, whereas the reverse is true for large-molecular-weight derivatives.

Hydrolyzable Tannins

Classification and Structures

Hydrolyzable tannins are synthesized by a wide variety of plants and trees where they occur in wood, bark, leaves, and galls. Some species produce either gallotannins or ellagitannins, while others produce complex mixtures containing gallo-, ellagi-, and condensed tannins, for example, *Acacia*, *Acer*, and *Fagaceae*. The designation 'hydrolyzable tannins' for gallotannins and ellagitannins is due to the fact that these compounds can be hydrolyzed, releasing gallic acid and/or ellagic acid, by treatment with dilute acid, whereas condensed tannins are not. Indeed, hydrolyzable tannins are esters of gallic acids and a polyol, mainly D-glucose, but fructose, xylose, saccharose, and structures like hamamelose are also found. Gallic acid is the base unit of gallotannins, whereas gallic acid and hexahydroxydiphenoyl (HHDP) moieties are both subunits of the ellagitannins. Regarding these facts, a large variety of gallotannin and ellagitannin structures derive from these two basic moieties (i.e., glucose unit and gallic acid).

A classification was first introduced by Haslam and coworkers and the two known subclasses of hydrolyzable tannins were subdivided into three groups A, B, and C. However, because of the great abundance of newly identified structures, a new classification with four groups was proposed by Okuda and coworkers in which hydrolyzable tannins are classified on the basis of the oxidation level of their galloyl ester groups and modeled on a plausible progressive biogenetic elaboration of hydrolyzable tannins, first hypothesized by Schmidt and Mayer. Gallotannins are defined as type I hydrolyzable tannins. Type II gathers the HHDP-bearing ellagitannins such as the monomeric tellimagrandins II and I, and type III those featuring the dehydrohexahydroxydiphenoyl (DHHDP) unit (i.e., dehydroellagitannins), as exemplified by geraniin (Figure 5). Ellagitannins in which the DHHDP unit has suffered additional transformations, such as the aforementioned chebulagic acid and ascorgeraniin, constitute the type IV group (Figure 6).

Besides this classification, many monomeric ellagitannins that result from chemical transformation need to be taken into account such as important structural modifications involve the opening of the D-glucopyranose core, the formation of *C*-aryl

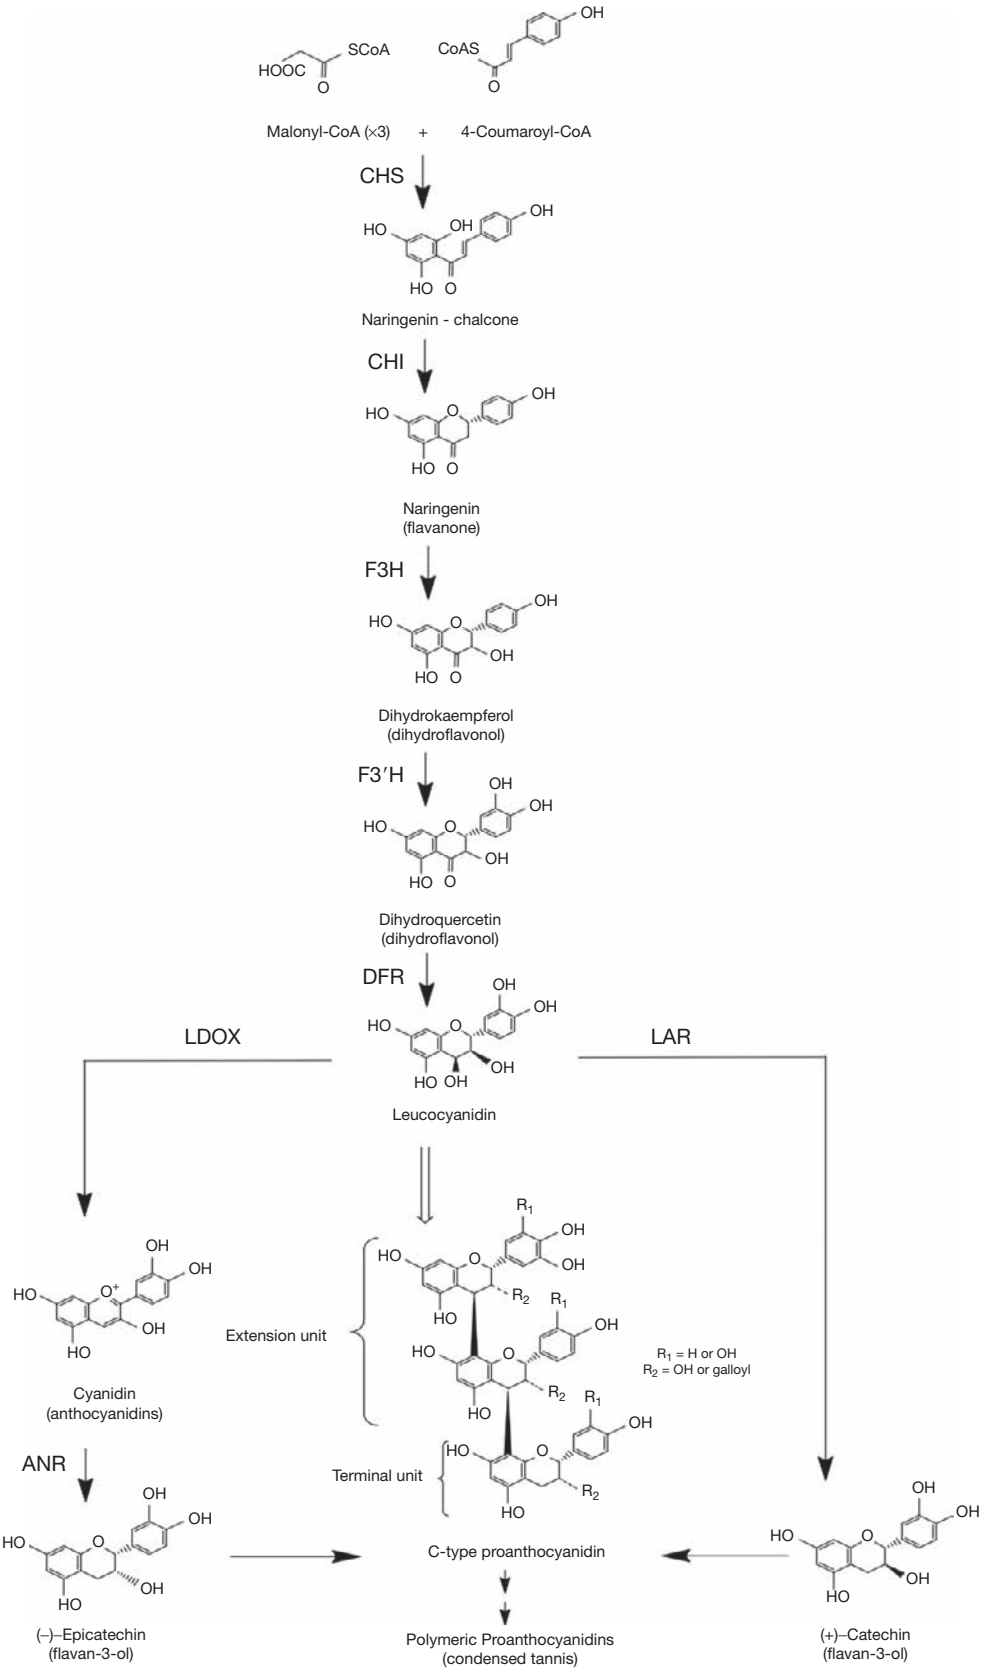

Figure 4 Schematic pathway and enzymes involved in the production of flavan-3-ols and proanthocyanidins. Enzyme abbreviations: CHS, chalcone synthase; CHI, chalcone isomerase; F3H, flavanone 3-hydroxylase; F3′H, flavonol 3′-hydroxylase; DFR, dihydroflavonol 4-reductase; LAR, leucocyanidin 4-reductase; LDOX, leucocyanidin deoxygenase; ANR, anthocyanidin reductase. (eds.) *Natural products*. Berlin, Heidelberg: Springer.

glucosidic bonds, and the condensation reactions taking place at the glucose C_1 locus. Since these ellagitannins still mostly display the characteristic structural features of compounds belonging to primary types II–IV, further classification takes into account these structures as II to IV+ types.

As ellagitannins of essentially types II and II+ oligomerize via various modes based on oxidative coupling reactions between free and C–C-coupled galloyl groups (i.e., HHDP units) on different glucopyranosic ellagitannins, as well as on condensation reactions at the C_1 center of *C*-glucosidic ellagitannins, classification becomes further complicated. After a first proposal based on the structures of the constituting monomers, Okuda and coworkers instead classified oligomers into five types according to the nature of the interunit linkage

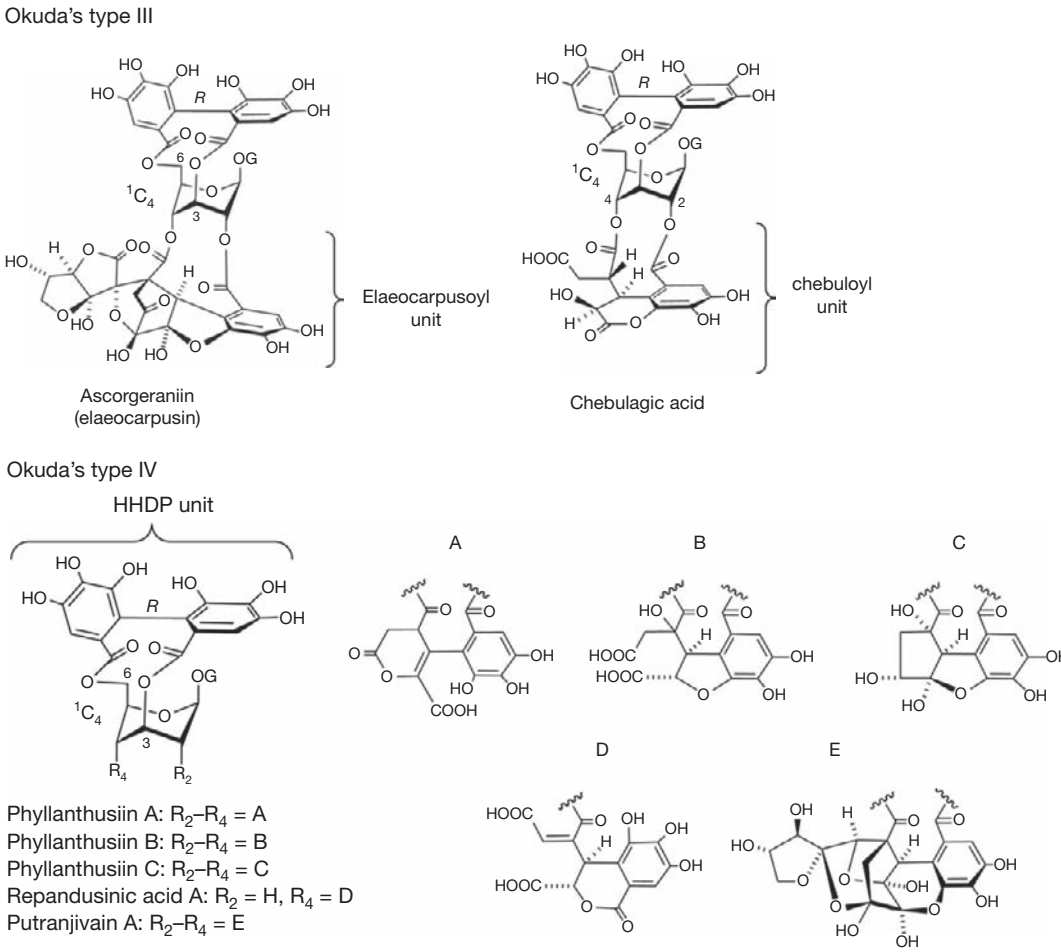

Figure 6 Examples of Okuda's type III and type IV ellagitannins. Adapted from Jourdes, M., Pouységu, L., Deffieux, D., Teissedre, P.-L. and Quideau, S. (2013). between monomers: (1) GOG (and GOGOG), (2) DOG, (3) GOD, (4) D(OG)2, and (5) C-glucosidic type, for which G = galloyl, O = oxygen, and D = HHDP. A more comprehensive and extensive information concerning the structures, descriptions, and examples of these oligomeric hydrolyzable tannins can be found in different reviews.

Biosynthesis

Gallic acid appears to be formed primarily via the shikimic acid pathway from 3-dehydroshikimic acid. Enzyme studies with extracts from oak leaves have shown that gallic acid is converted to β-glucogallin, which, in turn, is converted via a series of position-specific galloylation steps to penta-*O*-galloyl-glucose (β-PGG). Penta-*O*-galloyl-glucose is a pivotal intermediate that leads to the synthesis of gallotannins and ellagitannins. Figure 5 illustrates the biosynthetic pathway of hydrolyzable tannins.

Gallotannins are the result of further galloylations of β-PGG and are characterized by the presence of one or more meta-depsidic digalloyl moieties, as exemplified by hexagalloyl-glucose 2-*O*-digalloyl-1,3,4,6-tetra-*O*-galloyl-β-D-glucopyranose (Figure 5). On the other way, β-PGG can evolve through intra- and intermolecular phenolic coupling processes leading to the formation of covalent bond such as C–C biaryl and C–O diaryl ether bonds between two spatially adjacent galloyl groups. The intramolecular coupling leading to the formation of HHDP biaryl unit is the characteristic structural motif that defines ellagitannins since during acidic hydrolysis, it will lead to the formation of ellagic acid. Moreover, the ellagitannins harboring this characteristic HHDP biaryl unit belong to the hydrolyzable tannins classified as Okuda's type II. The nature of the atropisomeric form of these chiral biaryl motifs, such as the (*S*)-HHDP unit of the tellimagrandins or the (*R*)-HHDP unit of geraniin, is determined by the position of the galloyl motifs on the glucopyranose core in either its $^{4}C_{1}$- or its $^{1}C_{4}$-conformation. Moreover, the HHDP motif can go through additional oxidation transformation leading to the DHHDP unit that featured hydrolyzable tannins classified as Okuda's type III (i.e., dehydroellagitannin) such as geraniin. Furthermore, the DHHDP unit can also undergo many additional transformations leading to the formation of the chebuloyl and elaeocarpusoyl ester groups, which characterized hydrolyzable tannins classified as Okuda's type IV.

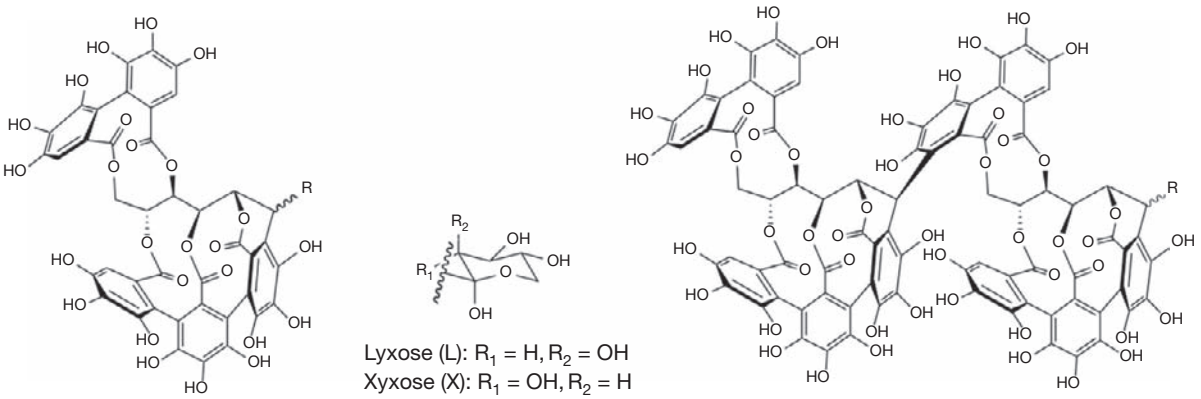

Figure 7 Structure of main monomeric ellagitannins vescalagin, castalagin, as well as the grandinin and roburin A–E isolated from *Castanea* (chestnut) and *Quercus* (oak) species.

Occurrences in Wines

As noted earlier, the primary source of wine tannins is grape berry seeds and skins, which contain proanthocyanidins in their vacuoles and cell walls. Another important source of tannins is the oak heartwood used to make barrels in which red wines are stored or aged.

The main *C*-glycosidic ellagitannins extracted by wine during its aging in oak barrels are the two monomers vescalagin and its C_1 epimer castalagin (Figure 7) that have been first isolated and characterized from *Castanea* (chestnut) and *Quercus* (oak) woody species by Mayer and coworkers in 1967. Indeed, these two molecules represent between 40% and 60% by weight of the ellagitannins in *Quercus petraea* and *Q. robur* heartwoods, which are the two main oak species used to make barrels along with the American species *Q. alba*. Furthermore, six other *C*-glycosidic ellagitannins, isolated from fagaceous *Quercus* and *Castanea* hardwood species, that is, the lyxose/xylose-bearing monomers grandinin and roburin E, the dimers roburins A and D, and the lyxose-/xylose-bearing dimers roburins B and C were also found in wines. Once in the wine, these ellagitannins slowly but continuously transform through condensation, hydrolysis, and oxidation reactions.

Moreover, it has also been observed that ellagitannins can affect red wine organoleptic properties such as color stability, perception, and sensory profile and also protect red wine against oxidation. Implications of ellagitannins on red wine are further described in a review.

Conclusion

Actually, some tannins have been identified and quantified in different vegetable origins including grapes and beverages, but more investigations need to be done to elucidate more structures and to explore their occurrence and concentrations in food and beverages as well as their biodisponibility and functional activity after ingestion. This family of compounds possesses several potent beneficial health effects and could be used as daily diet additive with a defined oral daily requirement. Another aspect of study concerns structural elucidation of tannin evolution during food processing (chocolate, wine, teas, fruits, etc.) and their implication in color evolution and sensory aspects of foods and beverages.

Tea: Analysis and Tasting

The Flavor of Tea

Types of Made Teas

Next to water, tea is the second most popular beverage in the world. According to processing procedures, tea that is currently made in the world can be classified into six main types including black, green, white, yellow, oolong, and reprocessed teas. Green tea is a nonfermented tea as the first step in its processing is to inactivate enzymes by dry heating or steaming. Most of the chlorophyll is preserved, and oxidation of catechins is limited. In contrast, black tea is a full-fermented tea because catechins are oxidized to theaflavins (TFs) and thearubigins (TRs), which are responsible for the typical color and taste of black tea. Oolong tea is a semifermented tea. During manufacturing of oolong tea, young shoots are allowed to wither for a short time (<8 h) before parching to inhibit the enzyme activity. Oxidation of catechins occurs during processing but to a much less extent than for black tea (Table 1). The yellow tea processing is very similar to that of green tea except with an additional step known as 'men huang' or literally 'heaping until it turns yellow,' while white tea is produced with only withering and firing. Additionally, reprocessed teas (e.g., scented tea and compressed tea) are usually processed with a series of postprocessing, such as scenting and compacting. The principal types of tea produced and consumed in the world are black and green teas, with small amounts of other types.

Theoretically, fresh young shoots of tea plants can be processed into any types of tea. However, in practice, young shoots from a specific cultivar may only be suited for processing into one of the six types of tea depending on physical, chemical, and biological characteristics of the young shoots. For example, tea cultivars suitable for black tea (generally belonging to *Camellia sinensis* cv. *assamica*) are not considered a good choice for green and oolong teas because of the high polyphenol contents. The latter two types of tea are usually produced from *C. sinensis* cv. *sinensis*. Good quality oolong tea requires cultivars with thick leaves, medium to dark leaf color, and medium polyphenol contents.

General Concept of Tea Flavor

The quality of tea is determined by its appearance, its color, and most importantly by its flavor. The flavor of tea comprises taste and aroma. Taste is characterized by astringency, bitterness, mellowness, and slight sweetness. Aroma is often described as fresh, fragrant, flowery, or dull and grassy. However, the factors that determine quality differ somewhat between black and green teas (Table 1). TFs, TRs, catechins, and caffeine are responsible for black tea quality. In contrast, green tea quality depends more on the content of amino acids, catechins, and caffeine. In addition, the appearance of the made tea and the color of the brew play major roles in the evaluation of green tea; young leaves and a clear brew with a pale green-yellowish tint indicate high quality. The quality of a green tea declines with signs of cloudiness and brown-reddish pigments.

Chemical Composition Related to Tea Flavor

The flavor of tea is principally determined by the chemical components it contains. Volatile compounds contribute to the aroma and nonvolatile compounds to the taste. These compounds are either direct metabolites that have accumulated in young shoots during growth or products of various reactions using these metabolites as substrates during processing. Thus, the flavor of made tea is largely affected by the abundance of chemical constituents and their relative composition in young shoots. Table 2 presents the most important constituents related to tea flavor and their typical concentrations in fresh young tea shoots. The chemical composition of tea depends on the following factors: genetic strain, climatic conditions, soil, growth altitude and horticultural practices, the plucking season, sorting (grading) of the leaves, the processing, storage, etc. Some parameters are more important than others. For example, the best green teas are usually plucked during the first flush in April or May (there are three main plucking times: spring, summer, and autumn).

Relish Origin Compounds in Teas

Amino acids and amides

Concentrations of total free amino acid (including amides) in tea range from 1% to 5%. The most abundant components are theanine (Thea), glutamine (Gln), glutamic acid (Glu), and arginine (Arg). Each free amino acid (or amide) has its own taste that may be sweet, salty, sour, bitter, and umami (Table 3). Free amino acids infused in a green tea brew have been recognized as the principal contributor to the taste of mellowness. Some volatile compounds found in made tea are derived from free amino acids. Amino acids can be transformed to aldehydes by decarboxylation and deamination. In the presence of flavonoids and carbohydrates, amino acids can undergo Strecker degradation to form aldehydes, alcohols, and carboxylic acids. Under heated conditions during the manufacturing process, free amino acids and especially L-arginine and L-theanine may react with sugars to form furan, pyrazine, and pyrrole (Maillard reaction), which contribute to the roast aroma of green tea.

Polyphenols

Flavonoids, which were previously called tea tannins or tea polyphenols, are the main phenolic compounds comprising 20–40% of dry matter in young shoots of tea plants. The characteristics of made tea, including color, taste, and aroma, are directly or indirectly associated with these phenolic compounds.

Table 3 (Continued)

Taste and Odor	*Chemical component*	*Threshold (μmol l^{-1})*	*Other tastes (in different concentrations)*
	Serine	30 000	Umami
	Alanine	8000	Umami
	Glycine	30 000	
	Proline	26 000	Intensively bitter
	Threonine	40 000	
	Hydroxyproline	0.5 g l^{-1}	Bitter
	Lysine HCl	0.5 g l^{-1}	Bitter
	Glutamine	0.05 g l^{-1}	Umami
Umami-like	Aspartate/Na	4000	
	Glutamate/Na	3000	
	Adenosine monophosphate (AMP)	2000	
	Guanosine monophosphate (GMP)	300	
	Theanine	6000	Sweet, astringent
Salty	Sodium	7500	
	Potassium	15 000	
	Magnesium	4000	
Odor	Hexanol	92–97 μg l^{-1}	Green, grassy
	Hexanal	10 μg l^{-1}	Green, grassy, metallic
	Trans-2-hexenal	190 μg l^{-1}	Green, fruity
	Cis-3-hexenol	13 μg l^{-1}	Fresh, fruity green
	Methyl jasmonate	–	Sweet, floral
	Linalool	0.6 μg l^{-1}	Floral, citrus-like
	Linalooloxides	–	Sweet floral, citrus, and fruity
	Geraniol	3.2 μg l^{-1}	Floral, roselike
	2-Phenylethanol	1000 μg l^{-1}	Flowery, roselike, honey-like
	Benzyl alcohol	–	Sweet, fruity
	Phenylacetaldehyde	–	Honey-like
	Coumarin	0.02 ppb	Sweet, camphoraceous
	β-Ionone	0.2 μg l^{-1}	Woody, violet-like
	Damascenone	0.004 μg l^{-1}	Honey-like, fruity

The predominant flavonoids in tea are catechins (flavan-3-ol) and their gallates, which include the following and generally account for up to 30% of dry weight: (-)-epicatechin (EC), (-)-epigallocatechin (EGC), (-)-epicatechin gallate (ECG), and (-)-epigallocatechin gallate (EGCG).

For black tea production, catechins are oxidized and catalyzed by polyphenol oxidase to form pigments TFs and TRs, which provide the typical color and flavor of black tea. This characteristic structure produces yellowish and bright reddish colors and provides a bright and yellowish appearance to the beverage. The content of total TFs in black tea is usually less than 2.5%. Pure TFs have a very fierce astringency, inducing a mouth-drying and rough-astringent oral sensation. The taste thresholds of TFs (between 13 and 26 μmol l^{-1}) are much lower than those of their precursor catechins (Table 3).

Catechins and their oxidation derivatives are the principal contributors to astringent and bitter tastes of tea beverages, especially of green teas. The taste thresholds of individual catechins range from 18.1 to 51.0 mg/100 ml or from 190 to 930 μmol l^{-1} (Table 3). Galloyl esters show lower taste thresholds than nongalloylated catechins. Catechins are responsible for the astringent taste and strength of green tea infusion. Quality green tea is characterized by high contents of free amino acids with appropriate concentrations of catechins and caffeine.

While not influencing the color of tea, other polyphenols, such as flavonols, gallic acid, and chlorogenic acid, and their glycosides, have been linked to the taste of astringency. Some flavon-3-ol glycosides, which usually do not undergo significant changes during processing, induce a silky, mouth-drying, and mouth-coating sensation with extremely low taste thresholds spanning from 0.001 to 19.8 μmol l^{-1}. The sensory activity of these flavon-3-ol glycosides is influenced by the structure of aglycon, sugar moiety, and sequence of the individual monosaccharides in glycosidic chain.

Caffeine

Caffeine (1, 3, 7-trimethylxanthine) is one of the major alkaloids in tea. Its content in young tea shoots ranges from 2% to 5% (Table 2). Other important alkaloids in tea are theobromine (3, 7-dimethylxanthine) and theophylline (1,3-dimethylxanthine). Generally, alkaloids undergo minimal changes during processing. Pure caffeine tastes unpleasantly bitter (threshold is approximately 3 mg l^{-1} in water), but its bitterness diminishes in the presence of catechins and TFs. This is because in tea brew, a portion of caffeine can form complex

with catechins, TFs and TRs, and alleviates astringency of the latter compounds. The quality of tea positively correlates with the concentration of caffeine, which contributes to briskness of black tea infusion. In cooled black tea brew, cream is formed as a complex of caffeine, catechins, theaflavin-3′-gallates, polysaccharides, protein, and some other compounds. The creaming property is an important indication of black tea quality.

Carbohydrates

Free sugars in young tea shoots consist of mainly glucose, fructose, sucrose, raffinose, and stachyose. Starch is low in young shoots but occurs in a high concentration serving as the main reserve polysaccharide in roots. Pectin substances consist of galactose, arabinose, galacturonic acid, rhamnose, and ribose. With heating during the green tea processing, sugars can react with free amino acids to produce compounds with roast aroma. The slight sweetness of tea brew may be partly accounted for by the existence of sugars.

Tea polysaccharides (TPSs) were found to be mostly glycoconjugates in which a protein carries one or more carbohydrate chains covalently attached to a polypeptide backbone, usually via N- or O-linkages. The contents of TPSs are usually higher in old than in young leaves and varied greatly among tea varieties, during harvest seasons and during processing.

Flavor Origin Compounds in Tea

Volatile compounds

The aromatic property of teas is being intensively investigated. Compounds contributing to tea aroma are primary products present in fresh leaves, which are biosynthesized by plants and do not undergo changes, or are secondary products formed during the manufacturing process from substrates (such as lipids, amino acids, and carotenoids) through enzymatic and nonenzymatic reactions. More than 600 volatile compounds associated with tea aroma have been identified, and the number is still increasing as new compounds are continuously reported. These compounds are often classified into groups including hydrocarbons, alcohols, ketones, aldehydes, lactones, phenolic compounds, acids, esters, nitrogenous and sulfur compounds, and miscellaneous oxygenated compounds. Alcoholic compounds such as geraniol, linalool, and its oxides are the main sources of the floral flavor of teas. In fresh tea shoots, only a limited proportion of these alcoholic compounds exist in free states, while most of them are present as glycosides, which can be hydrolyzed either enzymatically or nonenzymatically. During processing of oolong tea and black tea, the enzymatic hydrolysis occurs strongly and the liberated volatile compounds contribute greatly to the floral aroma of these teas.

The aromatic property of a specific tea is determined by the manufacturing process, tea variety, developmental stage of the fresh young shoots, climatic conditions, and agronomical management. The three major types of tea, that is, green tea, black tea, and oolong tea, have different aromatic profiles. The green tea flavor includes freshness, flower, and roast. The fresh and greenish odors are characteristics of green tea and are mainly due to (Z)-3-hexenol, its esters, and (E)-2-hexenal. The distinct roast aroma of pan-firing green tea (such as most Chinese green tea) is generated by pyrroles, pyrazines, and furans. In contrast, black tea often has large contents of linalool and its oxides, geraniol, methylsalicylate, (E)-2-hexenal, (Z)-3-hexenol, and (E)-2-hexenyl formate. Oolong tea has a great proportion of (Z)-jasmone, jasmine lactone, methyl jasmonate, and indole but comparatively little hexenol and hexenol esters. Linalool and geraniol are considered as the principal compounds contributing to flowery odor of all three types of teas.

Carotenoids

Carotenoids are the substrates of many of the volatile compounds present in made tea. During processing, carotenoids degrade via oxidation during withering and fermentation or paralytic reaction during firing. In green tea, a change of structure occurs through the conversion of violaxanthin to auroxanthin. Volatile compounds of ionine series are formed as primary oxidation products of carotenoids. These compounds smell sweet floral aroma and are believed to have a major effect on the aroma of tea.

Lipids

Glycolipids are the most abundant constituent accounting for more than half of the total lipid content, followed by neutral lipids (c. 35%) and phospholipids (c. 15%). Linolenic, linoleic, and palmitic acids are the major fatty acids. Linolenic acid is rich in glycolipids, while a high proportion of linoleic and palmitic acids are present in phospholipids. Neutral lipids contain high contents of lauric, myristic, palmitic, stearic, oleic, and linoleic acids. The lipid content increases from bud to third leaf and is low in the stem. This variation is related to the maturity of chloroplast. Compounds such as (Z)-3-hexenol, its esters, and (E)-2-hexenal, which principally contribute to the fresh and greenish odor of green tea, are oxidation products of free fatty acids formed during manufacturing.

Color Origin Compounds in Tea

Chlorophyll epimers and pyropheophytins are not in young shoots. Most of the chlorophyll is preserved during manufacturing of green tea, thereby creating a green color. In black tea, chlorophyll degrades and transforms either to pheophytin or first to chlorophyllide, catalyzed by chlorophyllase, and finally to pheophorbide. Pheophytin is a darker pigment with 10% higher specific absorbance at 665 nm compared to pheophorbide. Pheophytin is black and pheophorbide is brown; therefore, their relative proportion determines the blackness, an important criterion in the evaluation of made black tea. Nevertheless, some chlorophyll remains unchanged, and the residual chlorophyll has been linked to dull infusion and grassy taste of black tea.

However, some studies have suggested that the influence of chlorophyll and breakdown products on black tea quality might be dependent on the levels of other chemical compounds, such as TRs and TFs. At high concentrations, TFs can alleviate or mask the negative influence of chlorophyll on the appearance of black tea infusions. Oolong tea, a semioxidation tea, contains pheophytin b and high concentrations of pyropheophytin a but low concentrations of chlorophyll a and chlorophyll b.

Chemical Analysis of the Flavor-Related Compositions

Determination of Nitrogen-Containing Compounds

Amino acids

Amino acids form a purple complex with ninhydrin (pH = 8.0) under heating/derivatization conditions. The total content of amino acids is then determined by spectrophotometer at 570 nm. The components of amino acids are analyzed both quantitatively and qualitatively after preseparation with paper chromatography, thin-layer chromatography, or high-performance cation exchange chromatography. Another popular method is pre/postcolumn derivatization with reversed-phase high-performance liquid chromatography (RP-HPLC). Different sensitivities have been obtained by various precolumn derivatizations such as o-phthalaldehyde and the AccQ●Tag technology developed by Waters Corporation. In AccQ●Tag derivatization, primary and secondary amines are transformed into highly stable fluorescent derivatives, which can be completed within 10 min, and the dramatized products can be stored at room temperature for a week. The detection limit of fluorescence and ultraviolet detector (UV) absorption were 50–300 fmol and 0.1–0.30 pmol, respectively (Table 4). The AccQ●Tag technology has also been used in conjunction with ultra high-performance liquid chromatography or MS. Gas chromatography–mass spectrometry (GC–MS), capillary electrophoresis (CE), and anion exchange chromatography with pulsed amperometric detection are also used for amino acids analysis. In GC–MS analysis, tallow fatty acid, pentafluorophenol, n-propanol, and heptafluorobutyric acid silanization reagents are commonly used as derivatization reagents. The advantages of these methods are short separation time and high column efficiency. The disadvantage is that the derivative reaction can be easily interfered.

Alkaloids

The alkaloids (caffeine, theobromine, and theophylline) in tea have a conjugate structure, which can absorb strong UV. Therefore, alkaloids can be simply and rapidly determined by spectrophotometry. High-performance liquid chromatography (HPLC) coupled with a UV detector is popularly adopted (Table 4). The alkaloids can be separated and detected synchronously with catechins in C_{18} column by gradient elution with acetonitrile and water. Caffeine can also be extracted, preconcentrated, and analyzed by dispersive liquid–liquid microextraction and gas chromatography/nitrogen–phosphorus detection as the simple, fast, and green method. The limit of detection (LOD) and limit of quantity are 0.02 and 0.05 μg ml^{-1}, respectively.

Determination of Phenolic Compounds

The first step for measurement of phenolic compounds in teas is extracting them completely without chemical modifications. Boiling water and aqueous organic solvents (aqueous methanol, acetone, ethanol, and dimethylformamide) are among the most frequently used agents. For example, in ISO 14502, the ground tea is extracted twice with 70% aqueous methanol at 70 °C for measurement of total polyphenol and catechins. The total tea polyphenol content in extracts is detected by spectrophotometry. For example, in ISO 14502-1, the determination of total polyphenol content is based on the Folin–Ciocalteu assay, in which Folin–Ciocalteu reagent is added to the extract after dilution along with a Na_2CO_3 solution and the blue color is evaluated photometrically at 765 nm.

The catechins (flavan-3-ols) and flavonols in extracts are detected by HPLC, GC, and CE (capillary zone electrophoresis and micellar electrokinetic capillary chromatography). HPLC with UV or diode array detector (DAD) is the most frequently used method (Table 4). The chromatographic columns are mainly C_{18} and OD column, and the most common mobile phases are methanol and acetonitrile. A small amount of acid (acetic, formic, or phosphoric acid) is added in the mobile phase to prevent catechins from oxidation and complexion, to adjust the retention time, and to improve the peak shape of some compounds. Recently, the near-infrared spectroscopy (NIRS) was used to determine polyphenols/catechins and showed advantages in speed, efficiency, nondestructiveness, and environmental friendliness. However, low sensitivity, big relative error, and a requisite correction model (calibration) limit its widespread application. In the case of the flavonol and flavone glycosides, hydrolysis is performed followed by independent determinations of the aglycones and individual glycosides after a suitable cleanup. Analysis of flavonol and flavone glycosides in teas has always been a challenge due to the number components and the lack of commercial standards. Mass spectrometry especially high-resolution mass spectrometry coupled with liquid chromatography has been increasingly adopted for qualitative and quantitative determinations of flavonoids in teas.

The separation of major and minor TFs is accomplished by isocratic or gradient RP-HPLC. A stabilization solution consisting of EDTA and ascorbic acid is added to the samples to maintain stability of analytes. TRs are the most abundant but complicated group of phenols in black tea. Isolation of compound and purification and structural elucidation of TRs have long been the challenges, and direct quantification of TRs is currently not possible. There are two approaches to isolate TR fractions. One employs liquid–liquid extraction with ethyl acetate and *n*-butanol to separate the TRs in three fractions, the SI, SII, and SIa. Another approach to isolate TR fractions is precipitation by the addition of caffeine, yielding the formation of a TR–caffeine complex, which precipitates. Some recent researches employed matrix-assisted laser desorption/ionization-time of flight to get molecular mass distribution and structural information of TR fractions.

Analysis of Sugars

The total sugar content can be easily determined by anthrone chemical methods. However, careful operation is required due to the use of concentrated sulfuric acid. Sugar components such as fructose, glucose, and sucrose can be separated by HPLC, high-performance anion exchange chromatography, and GC–MS (Table 4). Special HPLC columns, for example, aminopropyl silica- or potassium-bonded, are necessary for the separation of sugars as their chemical and physical properties vary only slightly. The UV absorption of sugars is low. Therefore, evaporative light-scattering detector and MS are frequently used as detectors.

Qualitative and quantitative determination of polysaccharides in teas is currently rather hard due to their complex

Table 4 Brief introduction to representative analysis methods of chemical compounds in teas

Compounds	*Separating technology*	*Detecting technology*	*Pretreatment (extraction, derivatization, etc.)*	*Detecting condition*	*Validity and LOD*
Amino acids	TLC	Spectrophotometry	Ninhydrin (pH = 8.0)	570 nm	
	GC	MS	Tallow fatty acid, pentafluorophenol, and *n*-propanol		
	CE	UV/MS			μmol level
	UHPLC	MS		Coupled with postcolumn derivatization using ninhydrin	
	HAEC	PAD	Without derivatization		pmol–fmol level, interfered by carbohydrates
	HPCEC	Spectrophotometry	Postcolumn derivatization with ninhydrin	440 nm and 570 nm, 1 h	Automatic amino acid analyzer
	RP-HPLC	Fluorescence, UV	Dansyl-Cl	35 min	1×10^{-12} mol
			6-Aminoquinolyl-*N*-hydroxysuccinimidyl carbamate	10 min	1×10^{-13} mol
		Fluorescence	o-Phthalaldehyde	1 min	fmol 1×10^{-15} mol
			9-Fluorenylmethyl chloroformate	1 min	fmol, 1×10^{-15} mol
		UV	Phenylisothiocyanate	20 min, 254 nm	1 pmol, 1×10^{-12} mol
			2,4-Dinitrofluorobenzene	365 nm, 60 min	1×10^{-12} mol
Alkaloids	HPLC	UV/MS	C18 column	220–280 nm	
	TLC	Fluorescence	Extraction with methanol or water	GF_{254}, thin-layer chromatogram scanner	
	CE	UV		200–210 nm	
	GC	NPD	GC × GC also used		
	–	Spectrophotometry	Removal of the protein and polyphenols first	274 nm	
	–	NIRS	Without pretreatment		Fast
Phenolics	GC	FID/MS	Derivatization with tetramethylsilane		
	TLC, PC	TLC scanner	Extraction with methanol or water		
	UPC[2]	MS	Extraction with methanol or water		Analysis of heterogeneous polymers
	UHPLC	Q-TOF-MS	Extraction with methanol or water		High resolution and high throughput
	CE	UV	Containing SDS and a phosphate–borate buffer (pH = 7)	200 nm, 10 min	With high separation efficiency
	–	AAS	Reaction with metal ion, such as Cu $(AC)_2$		
	–	NIRS		1000–2500 nm, 7432.3–6155.7 nm, 5484.6–4192.5 nm	
	–	NMR		^1H, ^{13}C	
	–	Spectrophotometry	Ammonium molybdate or ferrous sulfate	280/210 nm, 500–520 nm, 341 nm	
	HPLC	Fluorescence detector			10^{-13} g
		MS or MS–MS	Extraction with methanol or water		High sensitivity
		Chemiluminescence	Extraction with methanol or water		More sensitive than UV
		Electrochemistry	Extraction with methanol or water		High selectivity
		UV and DAD	Hydrolysis of flavonoid glycosides	210 nm, 270–285 nm, 35 min	0.2 ng
Chlorophyll and carotenoids	HPLC	UV/DAD	Extraction with dimethylformamide or acetone, etc.	440 nm	
	–	Spectrophotometry	Extraction with dimethylformamide or acetone, etc.	663 nm, 645 nm, 470 nm, 440 nm	
	HPTLC	TLC scanner	Mineral ether and acetone (7:3)	450 nm	

(*Continued*)

Table 4 (Continued)

Compounds	*Separating technology*	*Detecting technology*	*Pretreatment (extraction, derivatization, etc.)*	*Detecting condition*	*Validity and LOD*
Sugar	–	Spectrophotometry	Anthrone chemical or enzyme	470 nm	0.04 μg ml^{-1}
	HPLC	ELS			2.5 ng–0.20 μg
		MS		ESI	
		Refractive index detector		Zorbax carbohydrate, NH2, or Hypersil NH2 columns	5 mg g^{-1}
		UV	Edaravone, 2-aminopyridine, 2-anthranilic acid	245 nm	pmol
	HPAEC	PAD		0.25 M sodium hydroxide and 1.0 M sodium acetate	
	IEC	PAD			μg l^{-1}
	GPC			μ-Bondagel column, TSK column	Analysis of macromolecular compound
	GC	MS	Alkylation and acetylation		By-products also can hinder separation
	HPCE		2-Aminopyridine, 9-fluorenylmethyl chloroformate, and edaravone	200 nm	nl level
Nutrient elements	ICP-OES or ICP-MS		High-temperature (dry) or concentrated-acid (wet) digestion		
	AAS		High-temperature (dry) or concentrated-acid (wet) digestion		
Volatile constituents	GC	MS/flame ionization detector	Solid-phase extraction, etc.		
Thearubigins and theaflavins	HPLC	DAD/MS		280 nm, C18, Hypesil ODS	0.1–1.0 μg ml^{-1}
	–	Spectrophotometry	Derivatization with AlCl3/flavognost	625 nm/525 nm	
	CE	UV	Acetonitrile, methanol, and acetic acid (71:25:4) and 90 mmol l^{-1} ammonium acetate	380 nm, 10 min	20 μg ml^{-1}
Organic acids	HPLC	UV	Mobile phase requiring strict pH	210 nm	
		AAS	Calcium oxalate		
	GC	TOF-MS	Derivatization required		
	IEC			Anion exchange column	0.48–1.34 mg l^{-1}
	IEC	Conductometric detection/UV		TSK gel OA pack-A, Ion-30 column	
	HPCE			30 kV	

TLC, thin-layer chromatography; GC, gas chromatography; MS, mass spectrometry; UV, ultraviolet detector; UHPLC, ultrahigh-performance liquid chromatography; HPLC, high-performance liquid chromatography; DAD, diode array detector; ICP-OES, inductively coupled plasma optical emission spectrometry; CE, capillary electrophoresis; HAEC, high-performance anion exchange chromatography; HPCEC, high-performance cation exchange chromatography; RP-HPLC, reversed-phase high-performance liquid chromatography; UPC2, ultraperformance convergence chromatography; PC, paper chromatography; HPTLC, high-performance thin-layer chromatogram; HPCE, high-performance capillary electrophoresis; AAS, atomic absorption spectrophotometry; IEC, ion exchange chromatography; NIRS, near-infrared spectroscopy; FLD, fluorescence detector; NMR, nuclear magnetic resonance spectroscopy; PAD, pulsed amperometric detector; FID, flame ionization detector; NPD, nitrogen–phosphorus detection; ELSD, evaporative light-scattering detector; Q-TOF-MS, quadrupole time-of-flight mass spectrometry; GPC, gel permeation chromatography.

structures. There are two categories of methods to determine polysaccharides in teas. One is the so-called direct detection by HPLC, gel chromatography, density gradient centrifugation, and electrophoresis (usually detected by DAD or electrochemical detector after being separated by capillary zone electrophoresis with 50 mmol l^{-1} sodium tetraborate buffer (pH 9.3), alkalescence and precolumn derivatization also being required). Direct measurement is limited because of difficulties in preparing TPSs of high purity. Most commonly, only polysaccharides of homogeneous groups within certain molecular weight ranges can be separated and purified. Another method is the indirect one based on the condensation reaction by monosaccharide such as the anthrone sulfuric acid method or phenol sulfuric acid method after polysaccharides are digested to monosaccharides.

Analysis of Volatile Constituents

The first step in the analysis of volatile compounds in teas is extraction, and there are a number of extraction methods to

collect volatile compounds. The key point in the selecting extraction method is to obtain the extract sufficiently or really represent the original composition in the sample being analyzed. Simultaneous distillation and extraction (SDE) is widely used because it is a one-step isolation–concentration and enhances the yield of extract. The main drawback in SDE is the alteration of some compounds from degradation and hydrolysis or the formation of new products by thermal reactions during the extraction process. To minimize changes in volatile compounds and save time in preparation, solid-phase microextraction (SPME) that involves the use of fused silica fibers coated with different types of polar or nonpolar adsorbents is increasingly used in preparation for analysis of volatile compounds from dry tea samples and tea infusion. Adsorption of target compounds onto the fiber can be done either from the headspace of solid or liquid samples or by directly dipping the fiber into an aqueous solution using a variety of mixing techniques. The effectiveness of SPME extraction is influenced by sampling time, temperature, and sample volume, although it is a fast, effective, and simple method for collecting volatiles. Maintaining consistency in these factors is crucial for obtaining comparable results. In addition, other preparations include microwave-assisted extraction, accelerated solvent extraction, supercritical fluid extraction, subcritical water extraction, full evaporation dynamic headspace, column chromatography extraction, and drop-to-drop solvent microextraction.

GC–MS is the most efficient technique for the separation, identification, and quantification of volatile compounds. Polar or midpolar GC columns are generally used to investigate most tea volatile compounds. When investigating the stereochemistry of volatile compounds, a CHIRAMIX column may be used. Separation of target components from complex mixtures justifies the use of a multidimensional GC × GC–MS. Peaks are identified through comparison with authentic standards, searching the commercial NIST library and the use of retention indices. GC coupled with olfactometry methods is effective to determine the odor-active compounds and their contribution to the aroma quality. Extracts of volatile compounds are stepwise diluted with an organic solvent and injected into GC–olfactometer. Each volatile compound separated by GC is simultaneously evaluated by a panel of experts at the sniffing port. The contribution of a specified component to tea aroma is indicated by its dilution factor.

In recent years, faster volatile analytic systems such as E-nose and transportable zNose have been used. The E-nose consists of a sampling apparatus, a trap tube, a detector unit containing the array of sensors, and a computer system for data recording and analysis. The sensors mimic the human olfactory receptors. E-noses have been successfully used to identify tea grades, to predict tea quality, and to monitor the black tea fermentation process. The zNose is an ultrafast portable GC-based volatile compound analyzer with high sensitivity. The volatile compounds are separated by fast GC and detected by a highly sensitive surface acoustic wave quartz microbalance detector.

Analysis of Chlorophyll and Carotenoids

As with other botanical samples, the principal components of pigment in tea are chlorophyll, xanthophyll, and carotene, a natural pigment. Spectrophotometry is often used for the determination of chlorophyll content because it absorbs different spectra at different wavelengths. And the LC method is applied for analyzing pigment components, with the importance of comparison and selection of solvent extraction. *N*,*N*-Dimethylformamide (DMF) and acetone are commonly used for pigment extraction, while the DAD detector is a good way for identifying the spectral characteristics of chlorophyll and carotenoids.

Determination of Elements in Teas

The total nitrogen is commonly determined by the Kjeldahl method. A more convenient method for nitrogen and additionally carbon, sulfur, and hydrogen is by Dumas combustion on an elemental analyzer. For other elements, dry ashing and wet digestion are the common strategies for sample preparation. At present, closed vessel wet digestions facilitated by the microwave energy are increasingly used. In general, atomic and mass spectrometries are used for the elemental analysis in teas. These include flame-and-graphite furnace atomic absorption spectrometry (F-AAS and GF-AAS), inductively coupled plasma optical emission spectrometry, and inductively coupled plasma mass spectrometry (ICP-MS). The two latter ICP-based techniques are the most effective in the multielement analysis of tea samples. In the case of ICP-MS, information on isotopic distribution is obtained. Hydride generation combined with spectrometric detectors, that is, atomic fluorescence spectrometry, is preferred for the measurements of hydride-forming elements, for example, As, Bi, Se, and Te.

Taste Perception and Analysis of Tea Infusion and Beverage

To bridge the gap between pure structural chemistry and human taste perception, many studies try to establish a reliable analysis system that identifies those tea components responsible of the taste and aroma. The electronic nose, NIRS, aroma sensors, taste sensor system, human psychophysical experiments, and olfactory neural network have been more or less successfully applied.

Taste omission experiments have been performed to narrow the key taste compounds in tea infusion. Based on this, a reduced recombinant containing the bitter-tasting caffeine, nine velvety astringent flavonol-3-glycosides, and the puckering astringent catechin as well as the astringent and bitter-tasting epigallocatechin-3-gallate were prepared. The taste profile of this reduced recombinant did not differ significantly from that of the complete taste recombinant, thus confirming these 12 compounds as the key taste compounds of the tea infusion.

The aqueous taste model was also used to confirm the quantitative results. For example, 15 amino acids, 14 flavonol-glycosides, eight flavan-3-ols, five TFs, five organic acids, three sugars, and caffeine were blended as aqueous solutions in their 'natural' concentrations, and the sensory analyses revealed that the taste profile of this artificial cocktail did not differ significantly from the taste profile of the authentic tea infusion.

Classification of Tea and Discrimination of Geographic Origin

Classification

Due to the distinct fermentation degrees during processing, components in different tea types varied greatly. Common technology (such as HPLC) has been demonstrated to be a useful method to discriminate tea categories (Table 5). For example, based on the content of free amino acids obtained by HPLC and back-propagation in multilayer linear perceptron, five main tea types (green, black, oolong, white, and Pu-erh teas) were successfully classified. Asn, Ala, Leu, Ile, and Glu were the most important discriminating parameters. Compared to HPLC-UV/DAD, UPLC–MS provides larger numbers of differentiating markers. For example, the analysis by nontargeted method utilizing UPLC and high-resolution mass spectrometry showed greater numbers of flavan-3-ols, flavonol, and flavonoid glycoside, which distinguished fermented teas from nonfermented teas. The electronic tongue technique has also been successfully applied in the classification of green and black teas. Based on the different concentrations in phenolic compounds, 43 samples of green and black teas were analyzed by cyclic voltammetry and well separated with the support vector machine (SVM) for pattern recognition method.

Table 5 Examples of classification and geographic tracing in tea products

Classification/ tracing	*Samples*	*Analysis method*	*Data processing*	*Main differentiating markers*
Processing technology	Green, white, black, oolong, and Pu'er teas	HPLC–MS	PCA, k-nearest neighbors, LDA, and artificial neural networks	Polyphenols (catechin, theaflavin, quercetin and kaempferol triglycosides, and quinic acid esters), amino acids (glutamic acid, asparagine, serine, alanine, leucine, and isoleucine), and caffeine
	Green and black teas	Electronic tongue technique	PCA and SVM analysis	–
	Green, oolong, and black commercial tea samples from around the world	UHPLC and high-resolution mass spectrometry	PCA PLS-DA	Caffoyl quinic acid, kaempferol 3-O-rutinoside, kaempferol 3-O-acyl glycosides, gallocatechin, and quercetin-3-O-glucoside
	Oolong tea of five similar varieties	HSPM with GC–MS	HCA, PCA, and stepwise LDA	18 volatiles with the best discriminating capacity selected
Meteorologic and seasonal variations	Spring tea Longjing 43	HPLC and spectroscopy	SVM technology	Tea polyphenol, amino acid, caffeine, and total catechins
	Australia-grown tea	HPLC	Analysis of variance	Epigallocatechin gallate, epicatechin gallate, and epigallocatechin
	Chinese green tea	HPLC	K-nearest neighbor method and Bayesian discriminant method	Free amino acids, catechins, and caffeine
Geographic origin (country of origin)	Teas from various Asian and African countries	ICP-AES and ICP-MS	PCA, CA, LDA, and soft independent modeling of class analogy	Al, Ba, Ca, Co, Cr, Cs, Cu, Fe, Mg, and Mn
	191 green teas from different countries	NMR	PCA and CA	Some minor sugar-containing, theobromine, theogallin, and 2-O-(α-L-arabinopyranosyl)-myoinositol
	15 types of tea from 10 different countries	ICP-AES and ICP-MS	Chemometrics approach	Ca, Sr, Al, Fe, and Mg
	Black tea from nations and different Chinese provinces	FT-NIRS	PLS	Caffeine, water extract, total polyphenols, and free amino acids

HPLC, high-performance liquid chromatography; MS, mass spectrometry; ICP, inductively coupled plasma; AES, atomic emission spectrometry; HSPM, headspace solid-phase microextraction; GC, gas chromatography; NMR, nuclear magnetic resonance spectroscopy; NIRS, near-infrared spectroscopy; UHPLC, ultrahigh-pressure liquid chromatography; FT, Fourier transform; PLS, partial least squares; DA, discriminant analysis; HCA, hierarchical cluster analysis; PCA, principal component analysis; LDA, linear discriminant analysis; CA, cluster analysis; SVM, support vector machine analysis.

Within the same tea category, differences caused by the varieties and processing technologies were relatively small. Consequently, more purposeful methods are needed. For example, 75 oolong tea samples of five similar varieties (Tieguanyin, Benshan, Maoxie, Huangjingui, and Jinguanyin) were analyzed by headspace solid-phase microextraction coupled with GC–MS. The relative content of 26 major volatile compounds varied significantly among the varieties, and 4 discriminant functions enabled simultaneous discrimination of the five oolong varieties with 100% correct rate.

Free amino acid, catechin, and caffeine levels in green tea leaves also show considerable variations among seasons. Such variations are useful information to identify the production seasons of commercial green teas. HPLC-UV and spectroscopy have been used to quantify levels of these quality related compounds (Table 5). By using the SVM technology, the relationships between meteorologic factors and the tea biochemical components have been discovered. The results showed that caffeine and the ratio of tea polyphenols and amino acid of the spring tea Longjing 43 significantly changed according to the daily mean temperature (3–5 days before harvest) and average precipitation (1–19 days before harvest). In addition, for the HPLC method, quantitative data were compared using analysis of variance. EGCG and ECG could be used as quality descriptors for monitoring the seasonal variations of phenols in Australia-grown tea leaves, and the ratio (EGCG + ECG)/EGC has been suggested as a quality index for measuring the differences in flavanol levels in fresh tea shoots across the growing seasons. The K-nearest neighbor (KNN) method in combination with chemical analysis is also recommended for the discrimination of the production seasons of Chinese green tea. The optimal accuracy of the KNN method was <=97.61 and <=94.80% as validated by resubstitution and cross validation tests, respectively, and that of linear discriminant analysis (LDA) was <=95.22 and <=93.54%, respectively.

Geographic Tracing

Geographic origin of teas has been of concern for customers. Recent studies have shown that teas from different locations (countries or provinces of the same country) were well discriminated by analysis of elements and chemical components (Table 5).

Trace element and metal concentrations were always considered to be the main differentiating markers of the geographic origin. ICP-AES/MS coupled with chemometrics analysis can easily identify teas from different countries. With statistical analysis of 17 elements (Al, Ba, Ca, Cd, Co, Cr, Cu, Cs, Mg, Mn, Ni, Pb, Rb, Sr, Ti, V, and Zn), the LDA gave correct assignation percentages of 100.0% and 94.4% for the African and Asian teas, respectively.

NIRS combined with chemometrics tools was utilized as a rapid analysis method to assess quality and to differentiate geographic origins of black teas from different nations (e.g., China, India, Kenya, Sri Lanka, and Burma) and different provinces (e.g., Anhui, Hubei, and Yunnan) in China. The identification accuracy for black tea from different geographic origins reached 94.3%.

Some compounds in connection with quality were also marked as the main difference in compounds of Chinese and non-Chinese teas by nuclear magnetic resonance spectroscopy (^{1}H NMR). With ^{1}H NMR analysis, a total of 191 green teas from different countries, the principal component analysis showed Chinese tea (Longjing) contain higher levels of theanine, gallic acid, caffeine, epigallocatechin gallate, and epicatechin gallate and lower levels of epigallocatechin when compared with other teas.

The appearance and main quality components were similar between the teas from protected or unprotected producing areas, and most studies only provide an identification model without diversity of special compounds. For example, a combination of chromatographic chemical fingerprints with LDA provides a simple and rapid approach to identify Xihu Longjing (highest quality Chinese tea) from other teas (other types of flatten-shaped teas like Longjing and some inauthentic Longjing from other tea-producing areas). High total accuracy rates of 94.8% and 87.6% for the training and test set, respectively, were achieved for distinguishing Xihu Longjing from the other types of tea by stepwise discriminant analysis. The combination of NIRS and statistical model selection also provides an effective and rapid method to discriminate the geographic producing area of Anxi Tieguanyin (a special oolong tea of high quality). A total of 570 representative samples (450 from the original producing area and 120 from unprotected producing areas in China) were measured by NIR. Partial least squares discriminant analysis was performed to develop a classification model and predict the authenticity of unknown objects. As the best model, the sensitivity and specificity reached 0.931 and 1.000, respectively.

Safety Evaluation of Tea Product

The food quality and safety have attracted an ever-increasing attention. Pesticide residues, mycotoxins, and heavy metals are the major contaminants found in teas.

Detection of Pesticide Residues

Pesticide residues are the major potential chemical contaminants in teas for widespread use of pesticides in plantations. Strict regulations have been established for the maximum residue levels in many countries (e.g., in European Community, EC No. 42/2000 and EC No. 1881/2006). Direct determination of pesticide in tea is not easy because of low concentration and matrix complexity. For accurate measurements of pesticide residues, samples must be properly pretreated prior to quantitative determination and a separation/preconcentration step is required. Recently, a number of preparation methods have been developed for extraction, preconcentration, and isolation of pesticides from tea because it is not a well-resolved issue yet. Tea is highly complex, and it has many interference compounds that need to be eliminated prior to determination. GC, HPLC, MS, and immunoassay (ELISA) are usually used in determining pesticide residues. A reliable and highly sensitive determination of multipesticide residues can be achieved by chromatography techniques coupled with MS, tandem MS (MS/MS), triple quadrupole MS, or high-resolution MS (Q-TOF).

Hygiene Tests and Determination of Toxin and Microbe

Unclean process may lead to harmful microorganisms contaminated in tea, especially in Pu'er and dark teas. *E. coli* or mycotoxins can contaminate agricultural products and pose a serious threat to human health. Mycotoxins are toxic metabolites naturally produced by fungi, including the genera *Aspergillus*, *Fusarium*, and *Penicillium* that are the natural fungal flora usually found in the food chain. The major mycotoxins concerned are aflatoxins, deoxynivalenol, zearalenone, ochratoxin, T-2 toxin, and fumonisin. They have been recognized as a serious threat to human health because of their carcinogenic and teratogenic effects. Nevertheless, few reports have been published on the mycotoxin detection in tea samples through HPLC, MS, ELISA, and immunochromatography.

Polycyclic aromatic hydrocarbons (PAHs) also receive increasingly more attention, especially in the smoked black teas. According to the few studies focused on them, GC × GC-TOF-MS can be a good way for the determination of PAHs.

Determination of Fluoride and Heavy Metals in Tea

There has been an urgent desire for detecting heavy metals in tea. Pb, Cd, Hg, and Sn have been considered contaminants by commission regulation of the European Community. Techniques used for heavy metal determination are the same as those used for determining trace elements to establish geographic origin. It is noteworthy that *Camellia sinensis* plants can tolerate and accumulate quite elevated quantities of Al and F. The older leaves contain higher levels of Al and fluoride than young leaves. Dark teas (e.g., brick teas) made with mature leaves are exposed to high fluoride concentrations. Fluoride can be easily determined by the use of fluoride ion-selective electrode or ion chromatography.

Conclusions

The sensory quality and health functions of tea depend on the chemical compositions in tea plant such as flavonoids (or phenolic compounds), theanine, and alkaloids. Recently, with the development and improvement of detection technologies and chemometrics methods, the identification and quantitation of these compounds become more accurate and easily. And these works will fill the gap between the exact chemical components that contribute to the tea flavor and human taste perception. However, more technologies should be developed to evaluate the quality of tea in the specific region or process (e.g., different geographic, ecological environment, and cultural practices, and processing technologies) that produced the inherent distinctive characteristics, which reflect the sensory quality, economic value, and health function. Otherwise, the increasing number of pesticides and other potentially dangerous toxins in tea products also pose special analytic challenges to detection technologies.

Introduction

Tea, produced from the leaves of the plant *Camellia sinensis*, is one of the most widely consumed beverages in the world. It has been used as a daily beverage and crude medicine in China and Japan for thousands of years. The leaves can be manipulated to generate over 300 different kinds of tea. Generally, they are divided into three types: nonfermented green tea, semifermented oolong tea, and fully fermented black tea. To make green tea, fresh tea leaves are steamed or pan-fried, which inactivates the enzymes and prevents the oxidation of tea polyphenols. Black tea manufacture involves crushing the tea leaves to promote enzymatic oxidation and subsequent condensation of tea polyphenols in a process known as fermentation. Oolong tea is semifermented to permit a moderate level of enzymatic oxidation during processing and then dried. About 78% of the tea production worldwide is black tea, whereas green tea and oolong tea constitute about 20% and 2%, respectively. Green tea and oolong tea are more popular in China, Japan, Korea, and some African countries, whereas black tea is preferred in India and the Western countries. The tea plant is considered native to south China and is now cultivated in many other countries. The major tea-producing countries are China, India, Japan, Sri Lanka, Indonesia, and Central African countries.

Epidemiological studies associate the drinking of tea with reduction in the risk of chronic diseases, such as cardiovascular diseases and cancer. There are also laboratory studies suggesting beneficial health effects of tea consumption. These effects are attributed to the polyphenol compounds in tea. Catechins are the most abundant polyphenols in green tea. The main pigments in black tea are theaflavins and thearubigins, which are formed by the oxidation and polymerization of catechins during fermentation. Although thearubigins account for up to 60% of the dry weight of black tea extract, the chemistry of thearubigins is still unclear. In this article, we will discuss the current knowledge on the chemistry of tea and the impact of processing on the profile of tea components.

The Major Components in Tea

Catechins

A typical tea beverage, with 2.5 g tea leaves in 250 ml hot water for a 3 min brew, usually contains 620–880 mg of water-extractable solids. Tea polyphenols, known as catechins, usually account for 30–42% of the dry weight of the solids in brewed green tea. Catechins are members of a more general class of flavonoid, the flavan-3-ols. They are characterized by di- or tri-hydroxyl group substitution of the B ring and the meta-5,7-dihydroxy substitution of the A ring.

The major catechins in tea are (−)-epigallocatechin gallate (EGCG), (−)-epigallocatechin (EGC), (−)-epicatechin gallate (ECG), and (−)-epicatechin (EC) (Figure 1). Gallocatechin gallate (GCG), gallocatechin (GC), catechin gallate (CG), catechin (C), epigallocatechin digallates, epicatechin digallate, 3-*O*-methyl EC, 3-*O*-methyl EGC, and afzelechin are present in smaller quantities. 3″-*O*-methyl-EGCG and 4″-*O*-methyl-EGCG have been identified in different tea samples. EGCG is the most abundant catechin in green, oolong, and black teas. Green and oolong teas typically contain 30–130 mg of EGCG per cup (237 ml), whereas black tea may have up to 70 mg of EGCG per cup.

Flavonols and Flavones

Both flavonols and flavones have been reported from tea. Quercetin, kaempferol, myricetin, and their glycosides (mono-, di-, and tri-) (Figure 2) are the major flavonols present in tea. They make up about 0.5–2.5% wt/wt extract as aglycones in tea infusions. Flavones, such as apigenin, the only flavone identified in tea, and its glycosides, have also been detected in tea but represent a very small fraction of the tea polyphenols. More recently, 19 *O*-glycosylated flavonols, 7 *C*-glycosylated flavones, 28 acylated glycosylated flavonols, and 3 flavonols were identified from green teas and fermented

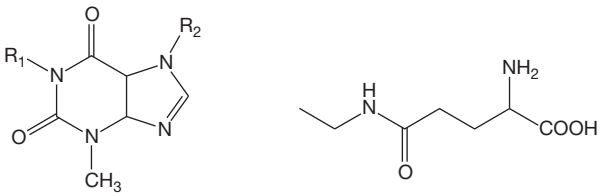
teas using liquid chromatography with diode array and electrospray ionization mass spectrometric detection (LC-DAD-ESI/MS).

Simple Polyphenols

The major simple polyphenols found in tea are gallic acid and its quinic acid ester, theogallin (Figure 3). The amount of gallic acid in black tea is significantly increased due to the de-esterification of the 3-galloyl-substituted catechins by either native esterase or oxidative degallation during fermentation, while the amount of theogallin is decreased during the fermentation process due to the formation of a new theaflavin-type compound, theagallinin, which is the condensation product between EC and theagallin. In addition, cinnamic acid derivatives of quinic acid, the coumaryl and caffeoylquinic acids (Figure 3), have also been identified from tea.

Caffeine and Theanine

The amount of caffeine in tea beverages is determined by the leaf size, the brewing time, and the temperature. It has been reported that there is no difference regarding the caffeine content between green and black teas indicating that caffeine is very stable during the fermentation process. Water-extractable tea solids contain about 2–5% caffeine and much smaller quantities of theobromine and theophylline (Figure 4). Tea contains around 17% nitrogenous materials as protein (~6%)



Caffeine: $R_1 = R_2 = Me$
Theobromine: $R_1 = H$, $R_2 = Me$
Theophylline: $R_1 = Me$, $R_2 = H$

Theanine

Figure 4 Structures of caffeine and its derivatives and theanine.

as well as amino and nucleic acids (~8%). Among the 19 amino acids found in tea, theanine (γ-*N*-ethyl glutamine) (Figure 4) is unique to tea. It is a significant component of both green tea and black tea, comprising about 3% wt/wt of extract solids. Theanine has been associated with improved flavor and antihypertensive effect. It can also be made synthetically on a commercial scale with good yield.

Potassium, calcium, magnesium, and aluminum are the predominant minerals (10–15%) found in the ash of the water-soluble solids of tea. Tea beverage is also a significant source of fluoride at ~1 mg per serving.

Impact of Processing on the Profile of Tea Components

There are two major enzymes involved in the fermentation process in making oolong and black tea. One is polyphenol

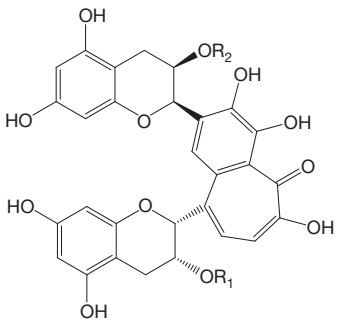
oxidase (PPO), which plays a key role in the oxidation of flavanols to black tea components such as theaflavins and thearubigins. This enzyme is compartmentalized in the leaf microsomes and is released by the rolling and crushing of tea leaves after the withering process, which allows the enzyme to react with the cytoplasmic catechins in tea leaves. It is mainly the action of this enzyme that produces theaflavins. Many studies have been carried out on the PPO-catalyzed formation of black tea oxidation products. Peroxidase (POD) can also catalyze the oxidation of *o*-diphenols to their quinones using peroxide, such as hydrogen peroxide, that were formed by the action of PPO on certain flavanols. In fresh tea leaves, the specific POD activity is more than five times higher than that of PPO and was found to increase during black tea manufacturing. During the firing step of black tea processing, PPO is inhibited thermally, whereas POD remains active to a certain extent. Model oxidation systems have also been used to compare the oxidation products obtained with tea PPO and with horseradish POD. However, the contribution of POD to the formation of black tea pigment in tea fermentation is still not clear. The major polyphenols in black tea are theaflavins and thearubigins, which are formed by the oxidation and polymerization of catechins during fermentation. Theasinensins are the major oxidized catechins found in oolong tea.

Theaflavins

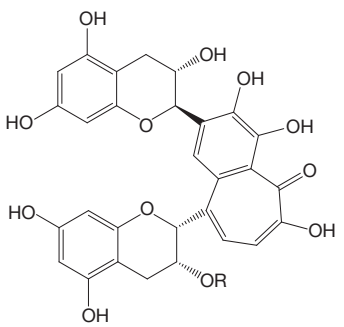
Theaflavins are responsible for the bright red color of black tea and possess a benzotropolone skeleton that is formed from the co-oxidation of selected pairs of catechins, one with a *vic*-trihydroxyphenyl moiety and the other with an *ortho*-dihydroxyphenyl structure. The reaction involves the oxidation of B ring of the catechin molecule to the quinone, which will react with the quinone of a gallocatechin through a Michael addition followed by carbonyl addition across the ring and subsequent decarboxylation to form theaflavins. It is known that theaflavins make important contributions to the properties of black tea, such as color, 'mouthfeel,' and extent of tea cream formation. Their structures are well studied. There are four major theaflavins in black tea, these include theaflavin, theaflavin 3-gallate, theaflavin 3′-gallate, and theaflavin 3,3′-digallate (Figure 5), which are produced by oxidative coupling between EC and EGC, EC and EGCG, ECG and EGC, and ECG and EGCG, respectively. Stereoisomers of theaflavins and a number of theaflavin derivatives, including theaflavic acids and theaflavates, have also been reported from black tea. Our recent study showed that horseradish POD can oxidize tea catechins to form theaflavin-type compounds in the presence of H_2O_2. Eighteen benzotropolone derivatives, which include all the major theaflavins, theaflavates, and theaflavic acids reported in black tea as well as several new benzotropolone derivatives, were synthesized by the reaction of selected pairs of compounds, one with a *vic*-trihydroxyphenyl moiety and the other with an *ortho*-dihydroxyphenyl structure, using horseradish POD in the presence of H_2O_2.

Thearubigins

Thearubigins, the brown pigment in black tea, are heterogeneous polymers of tea catechins. They account for up to 60% of the water-extractable material of black tea by dry weight. Information about their formation, structures, and contribution to black tea quality is still very limited. A partial structure of thearubigins from black tea was elucidated using chemical degradation, which indicated that these compounds were heterogeneous polymers of flavan-3-ols and flavan-3-ol gallates having bonds at C-4, C-6, C-8, C-2′, C-5′, and C-6′ in the flavan-3-ol units. In addition, the possible participation of theaflavins in the formation of thearubigins has been suggested. It was shown that horseradish POD would oxidize theaflavins into thearubigin-like compounds in the presence of H_2O_2. We found that the galloyl ester group of theaflavin 3-gallate is as reactive as the B ring (*vic*-trihydroxy) of EGCG or EGC and the galloyl ester group of ECG and can further react with EC to form the new theaflavin-type tea catechin trimer, theadibenzotropolone A, which was characterized from black tea extract by LC/ESI-MS/MS. Two additional peaks corresponding to the same molecular weight as that of theadibenzotropolone A were also found in black tea extract. To identify these unknown peaks, two new dibenzotropolones, theadibenzotropolones B and C, together with one new tribenzotropolone, theatribenzotropolone A (Figure 6), were synthesized by the reaction of theaflavins



Theaflavin: $R_1 = R_2 = H$
Theaflavin 3-gallate: R_1 = Galloyl, $R_2 = H$
Theaflavin 3′-gallate: $R_1 = H$, R_2 = Galloyl
Theaflavin 3,3′-digallate: $R_1 = R_2$ = Galloyl



NeoTheaflavin: R = H
NeoTheaflavin: 3-gallate: R = Galloyl

Figure 6 Structures of theadibenzotropolones A, B, and C and theatribenzotropolone A.

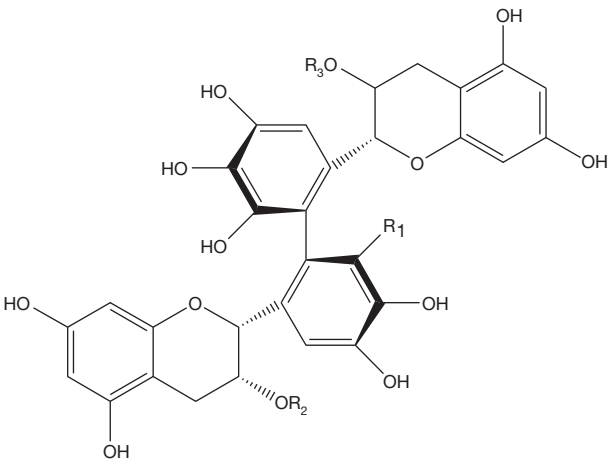
and tea catechins catalyzed by horseradish POD in the presence of H_2O_2. Theaflavin 3-gallate reacts with not only EC to form theadibenzotropolone A but also catechins to form the isomer of theadibenzotropolone A, theadibenzotropolone B, whereas the isomer of theaflavin 3-gallate, neotheaflavin 3-gallate, reacts with EC to form theadibenzotropolone C. Interestingly, theatribenzotropolone A, instead of the two isomers of theadibenzotropolone expected, was obtained through the reaction between theaflavin 3,3′-digallate and EC. We failed to obtain theaflavin 3′-gallate-related theadibenzotropolone derivatives. We further

confirmed the existence of theadibenzotropolone B in the black tea extract prepared from Yunnan black tea using tandem mass spectrometry.

Our results clearly show that theaflavins can further react with tea catechins to form di- or tribenzotropolone-type compounds. The observation that the galloyl ester group of theaflavins can be oxidized to form di- or tribenzotropolone skeletons strongly implies that this type of oxidation is an important pathway to extend the molecular size of thearubigins. Theadibenzotropolones A and B are the first theaflavin-type trimers of catechins discovered in black tea. Using delayed pulsed ion extraction of ions generated via the matrix-assisted laser desorption ionization (MALDI) technique, on line with a linear time-of-flight (TOF) mass spectrometer, we found that theasinensins and/or procyanidins, which are dimers or oligomers of catechins, also react with catechins to generate benzotropolone-type polymers further indicating that this type of oxidation is one of the major pathways for the formation of thearubigins. More recently, Kuhnert and coworkers reported that thearubigins are solely composed from low-molecular-weight compounds with a mass below 2100 g mol^{-1} based on results generated from MALDI-TOF-MS. Whether this conclusion is due to the limitation of current analytic tools to detect larger-molecular-weight components in thearubigins is a topic for further study in order to completely understand the chemistry of thearubigins.

Theasinensins

Theasinensins are compounds formed by the coupling of quinone with catechol or the pyrogallol ring of catechins. Seven theasinensins have been isolated and identified from oolong tea with theasinensins A (EGCG dimer), B (EGCG and EGC dimers), C (EGC dimer), and F (EGCG and ECG dimers) being the most abundant ones (Figure 7). They occur only in very small quantities in black tea probably due to the instability of these compounds during further oxidation and polymerization.



Theasinensin A: R_1 = OH, R_2 = R_3 = Galloyl
Theasinensin B: R_1 = OH, R_2 = Galloyl, R_3 = H
Theasinensin C: R_1 = OH, R_2 = R_3 = H
Theasinensin F: R_1 = H, R_2 = R_3 = Galloyl

Figure 7 Structures of theasinensins A, B, C, and F.

Conclusions

The chemistry of green tea has been well studied. However, information on black tea and oolong tea polyphenols is still lacking. The chemistry and the formation mechanism of thearubigins are almost totally unknown. These large-molecular-weight black tea polyphenols, even though not absorbed, may exert effects in the oral–digestive tract through direct contact or through their microbial metabolites. Further study on the chemistry of thearubigins using advanced analytic techniques is warranted. The formation mechanism of thearubigins under different processing conditions is another topic of future research.

Tea: Health Effects

R Munday, Ruakura Agricultural Research Centre, Hamilton, New Zealand

Types, Sources, and Production of Tea

Tea, prepared by infusion of the dried leaves of *Camellia sinensis*, is a popular beverage in many parts of the world. Archaeological evidence indicates that tea was first consumed during the early Paleolithic era, but the first documented references to tea appeared in China in the third century CE, when it was used as a medicine. Tea was imported into England in 1657, regarded at that time as a medicinal herb, and later grew in popularity as a beverage.

Several types of tea are known, differing in the method of treatment of the leaves after harvesting. The most popular type is black tea, which accounts for some 80% of the market. This is prepared by crushing the leaves, followed by a period of fermentation before drying. The preparation of green tea, which is consumed mainly in Japan and China, involves no crushing or fermentation. Leaves for the preparation of oolong tea, produced mainly in south eastern China, are gently rolled and subjected to a brief period of fermentation.

India is the largest tea producer, followed by China, Sri Lanka, and Kenya. On a per capita basis, the highest consumers of tea are in Qatar, Ireland, the United Kingdom, Iraq, Turkey, and Kuwait.

Dried aqueous or alcoholic extracts of tea leaves are also available on the market, where they are sold as dietary supplements with putative benefits to human health.

Tea Composition

The leaves of *C. sinensis* contain a number of polyphenols, of which (−)-epicatechin (EC), (−)-epigallocatechin (EGC), (−)-epicatechin gallate (ECG), and (−)-epigallocatechin gallate (EGCG) (Figure 1) predominate.

These compounds are preserved in green tea, but the crushing and fermentation processes involved in the manufacture of black tea result in the oxidation of a large proportion of these substances to theaflavins, thearubigins, and other oligomers. The theaflavins (Figure 2) are responsible for the characteristic color and taste of black tea. The degree of oxidation is lower in oolong tea, and this contains a lower proportion of theaflavins than black tea.

As discussed in the succeeding text, these substances are believed to be responsible for the biological effects of tea.

A 200 ml cup of tea contains 150–210 mg of total polyphenols, of which the majority is catechins in green tea and theaflavins and thearubigins in black tea.

Bioavailability of Tea Components

As expected for relatively high molecular weight compounds bearing numerous hydroxyl groups, the absorption of tea polyphenols from the small intestine of animals and of humans is low. Significant amounts pass into the large intestine, where the polyphenols are degraded by gut bacteria to 5-(3′4′,5′-trihydroxyphenyl)-γ-valerolactone, hydroferulic acid, 3,4-dihydroxyphenylacetic acid, and hydrocaffeic acid. In mice, plasma levels of ECGC were only 1.3–1.5 μM even after a very high dose (1.6 g kg^{-1}), and low absorption has also been seen in rats. In these animals, plasma levels of EGCG increased to a maximum after 14 days of continuous administration in drinking water, but then rapidly declined by day 28, possibly reflecting an increased rate of conjugation and excretion. Absorption in dogs appears to be much higher than that in rodents. In fed animals dosed each day with EGCG at 500 mg kg^{-1}, plasma levels were 16.5 and 12.5 μM at day 1 of the experiment in male and female dogs, respectively, and plasma levels were similar after 78 days of feeding. In fasted dogs given the same dose of EGCG, plasma levels were much higher, with

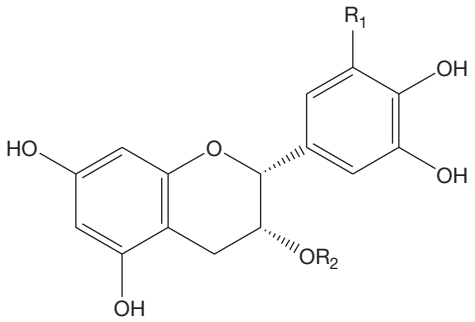

Figure 1 (−)-Epicatechin (EC): $R_1 = R_2 = H$; (−)-epigallocatechin (EGC): $R_1 = OH$, $R_2 = H$; (−)-epicatechin gallate (ECG): $R_1 = H$, $R_2 =$ galloyl; (−)-epigallocatechin gallate (EGCG): $R_1 = OH$, $R_2 =$ galloyl.

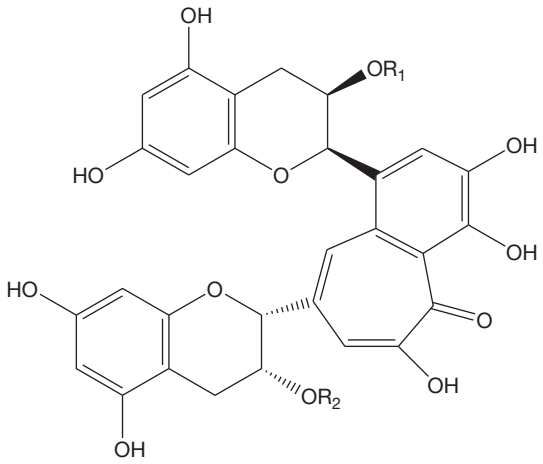

Figure 2 Theaflavin, $R_1 = R_2 = H$; theaflavin-3-gallate, $R_1 = H$, $R_2 =$ galloyl; theaflavin 3′-gallate, $R_1 =$ galloyl, $R_2 = H$; theaflavin-3,3′-digallate, $R_1 = R_2 =$ galloyl.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00686-3

concentrations of 50.9 and 30.9 μM being recorded in male and female animals at day 1 of the experiment and levels increased with prolonged administration, being approximately double the day 1 concentration after 81 days.

In humans, it was estimated that < 0.1% of EGCG is absorbed from green tea, and doses of up to 800 mg of this substance gave plasma levels of 1 μM or less when given with food. As in the case of dogs, absorption of EGCG in fasted individuals was shown to be higher than that in fed, and a plasma level of 8.7 μM was observed after a dose of EGCG of 1200 mg in fasted volunteers. A dose of 700 mg of theaflavins in humans, equivalent to 30 cups of tea, gave a maximum plasma theaflavin concentration of only 1 $\mu g\, l^{-1}$. Most of the absorbed polyphenols from both black tea and green tea is rapidly metabolized in the liver, and the major plasma constituents are the glucuronic acid conjugates and methyl ethers of the polyphenols. These metabolites are excreted in the urine, with only traces of the unchanged polyphenols. The 2′- and 2″-cysteinyl conjugates of EGCG were found in the urine of mice given high doses of this substance. These are derived from the o-quinone of EGCG, indicating that oxidation of EGCG occurs *in vivo*, as it does *in vitro* (see in the succeeding text).

Potential Health Benefits of Tea and Its Components

Antioxidant and Pro-oxidant Effects

Because of the presence of the catechol or pyrogallol moieties in the constituent polyphenols and theaflavins, both green and black teas are strong antioxidants, with similar activity *in vitro*. They have been shown to scavenge many oxidizing species, including superoxide radical, hydrogen peroxide, hydroxyl radical, peroxyl radicals, hypochlorous acid, and peroxynitrous acid. Among the green tea constituents, the order of antioxidant activity is EGCG = ECG > EGC > EC. The antioxidant action of phenols depends upon their ability to form a phenoxyl radical, and the potency of the antioxidant effect is proportional to the stability of this radical. The gallate moiety in green tea polyphenols is particularly effective in stabilizing the phenoxyl radical, which would account for the relatively high antioxidant activity of these compounds.

While there is clear evidence of an antioxidant effect of both black and green polyphenols *in vitro*, there is no convincing evidence of an antioxidant effect of tea or tea polyphenols *in vivo*. This is as expected from the low bioavailability of these substances, since the low plasma levels that are achieved *in vivo* are unlikely to compete with endogenous antioxidants such as ascorbate, tocopherols, and urate. Furthermore, *in vivo* metabolism by methylation and glucuronidation will decrease antioxidant activity. These conjugates are less effective than the parent compounds, due to blocking of the phenolic hydroxyl groups required for antioxidant activity.

Like other antioxidants, tea polyphenols also act as pro-oxidants through their ability to undergo autoxidation, forming superoxide radical, hydrogen peroxide, and hydroxyl radical, collectively known as 'reactive oxygen species' (ROS). Brewed tea contains hydrogen peroxide, resulting from polyphenol oxidation, and urinary levels of hydrogen peroxide are increased after tea consumption.

The autoxidation process of tea polyphenols is initiated by ionization to the phenolate anion (reaction 1), which reacts with molecular oxygen either directly (reaction 2) or through the participation of transition metals, yielding superoxide radical. Superoxide is also formed in the reaction of the semiquinone with molecular oxygen (reaction 3), initiating a superoxide-driven chain reaction (reaction 5). The quinone formed in reaction 3 undergoes comproportionation with the catechol, yielding 2 molar equivalents of the semiquinone (reaction 4). The ultimate products of the autoxidation are the *o*-quinone and hydrogen peroxide. The quinone has been shown to undergo reduction by NADH and thiols, establishing a redox cycle between the quinone and catechol. In the presence of a transition metal, hydroxyl radical is formed from hydrogen peroxide.

Autoxidation of tea polyphenols occurs at neutral pH, although the rate increases with increasing pH, reflecting higher concentrations of the phenolate anion. Tea polyphenols also readily undergo autoxidation in tissue culture media, and ROS production in this situation may be of significance in interpreting the toxic effects of these substances in cancer cells *in vitro*, as discussed in the succeeding text. The rates of autoxidation differ among the various tissue culture media. It is particularly high in Dulbecco's modified Eagle's medium, which contains added iron salts, effective in catalyzing the autoxidation reaction.

The relative rates of autoxidation of green tea polyphenols at neutral pH correlate with their antioxidant activity, with EGCG and EGC being stronger pro-oxidants than ECG and EC. In the gallate derivatives, the reaction proceeds via semiquinone formation on the B ring, with formation of the radical on the central hydroxyl group of the gallyl ring.

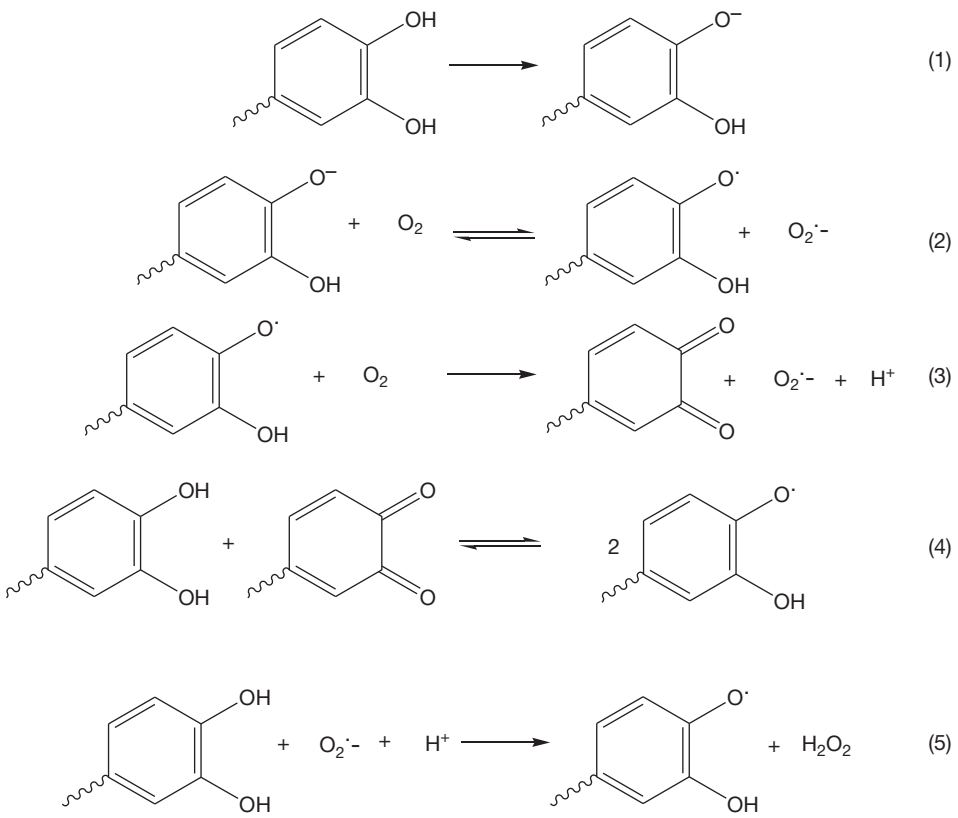
In the presence of salts of copper or iron, tea and tea polyphenols cause DNA cleavage, mediated by ROS. The effect on DNA is inhibited by catalase or by metal chelators.

The antioxidant activity of tea and tea polyphenols has attracted considerable interest, in view of the widely held public perception that ROS generation *in vivo* leads to degenerative diseases and that the initiation or progression of such diseases could be prevented by antioxidants. It was also recognized that the pro-oxidant activity of tea and its components could be valuable, particularly against cancer. Many of the drugs currently used in cancer therapy are pro-oxidants, and the effect of tea polyphenols on cancer cells *in vitro* and on cancer xenografts *in vivo* has been extensively studied. Preliminary experiments on the possible use of tea polyphenols in cancer therapy have also been conducted, as discussed in the succeeding text. The ability of tea constituents to protect against chemically induced cancer has also been extensively studied.

Tea and Cancer

Effect of Tea and Tea Constituents on Cancer Cells *In Vitro*

Green tea and black tea and their constituent polyphenols have been shown to be toxic to many human and animal cell lines *in vitro*, including those derived from the brain, pancreas, prostate, liver, urinary bladder, oral cavity, breast, larynx, colorectum, bone marrow, skin, ovary, tongue, cervix, lung, and miku stomach, to leukemia, sarcoma, and melanoma cells. The toxic changes comprise inhibition of cell growth, cell cycle arrest, and cell death. In most cases, the mechanism of cell death has been identified as apoptosis via the intrinsic



pathway, involving decreased mitochondrial membrane potential, release of cytochrome *c*, and activation of caspase 9 and caspase 3. For the expression of these cytotoxic effects, polyphenol concentrations $>50\,\mu M$ are generally required, and some dose–response studies have shown an increase in cell proliferation at lower concentrations. Comparative studies have shown that normal (nontransformed) cells are relatively resistant to the toxic effects of tea polyphenols.

Among the green tea polyphenols, cytotoxicity to cancer cells has generally been found to decrease in the order EGCG > EGC > ECG > EC. Among the black tea constituents, theaflavin 3,3′-digallate is more cytotoxic than theaflavin 3-gallate, theaflavin 3′-gallate, and theaflavin.

In many cases, ROS have been detected in cells incubated with tea or tea polyphenols, and these substances have been held responsible for the observed toxic effects. Complete or partial protection has been observed by the destruction of extracellular hydrogen peroxide by the addition of catalase to the culture medium. Pyruvate, which similarly detoxifies hydrogen peroxide, has also been shown to protect against the cytotoxic effects.

Addition to the medium of *N*-acetylcysteine, which is known to increase intracellular levels of reduced glutathione and thus potentiate antioxidant defense, has been shown to protect against the cytotoxicity of tea polyphenols, as has superoxide dismutase and metal chelating agents.

While there is good evidence for the involvement of ROS in cytotoxicity *in vitro*, the site of production of these species is uncertain. Tea polyphenols are taken up by cells *in vitro*, where they may undergo autoxidation to form ROS. But, as mentioned previously, the polyphenols readily undergo autoxidation in cell culture media, and hydrogen peroxide formed extracellularly may cross the cell membrane and exert toxic effects within the cells. The inhibitory effect of extracellular catalase is consistent with either intracellular or extracellular generation of hydrogen peroxide, since this substance readily crosses cell membranes, so that intracellularly generated hydrogen peroxide could be detoxified by extracellular catalase. The inhibitory effect of superoxide dismutase, however, definitely indicates extracellular production of ROS, since the superoxide radical does not cross cell membranes, and SOD may protect by decreasing the rate of polyphenol autoxidation in the medium. The effect of metal chelators would also be consistent with extracellular formation of ROS.

Effect of Tea and Tea Constituents on Cancer Xenografts *In Vivo*

The toxic effects of tea polyphenols seen in cancer cells *in vitro* stimulated research on the possible destruction of cancer xenografts in animals. Decreased tumor growth of PC-3, 22Rv1, LNCaP, or LAPC4 prostate cancer cells injected subcutaneously into athymic or severe combined immunodeficient mice was observed with green tea polyphenols. EGCG was more effective than EGC, ECG, or EC. Green tea polyphenols decreased the growth of breast cancer cells 4T1, MCF-7, and MDA-MB-231

implanted in mice, and survival time was increased. EGCG decreased the growth of H1299 lung cancer cells, and apoptosis and oxidative DNA damage, as indicated by increased levels of 8-hydroxydeoxyguanosine, were observed in the cancer cells but not in the host tissue. Evidence for oxidative damage to DNA was also observed in LPPC4 xenografts, along with oxidative damage to proteins. Again, no such effects were seen in normal tissue. Apoptosis in tumor tissue was observed in lung, prostate, and breast cancer xenografts, indicating irreversible damage to the cells. In the experiment with PC-3 cells, however, the tumors were found to undergo rapid growth after the administration of EGCG ceased.

Clinical Trials with Tea Polyphenols

The effects of tea polyphenols on cancer cells *in vitro* and in xenografts *in vivo* stimulated interest in the possible use of these materials as cancer chemotherapeutics, and these substances have been tested in phase I and phase II clinical trials in cancer patients. In a phase I trial, a new treatment is tested in a small group of people in order to determine a safe dosage range and to identify side effects. A phase II trial involves a larger group of people to test efficacy and to further evaluate the safety of the test material.

In two studies without a placebo group, a decrease in plasma markers associated with prostate cancer was observed in men with prostate cancer, but a later double-blind placebo-controlled trial showed no effect, as did a study on hormone-refractory prostate cancer. In a small proof-of-principle study, green tea polyphenols or a placebo was dosed to men with high-grade intraepithelial prostatic neoplasia. After 1 year, only 1 tumor was detected among the 30 treated men, while nine cancers were seen among the 30 men who received the placebo. A follow-up study of available participants after 2 years showed a persistent effect, with only 1 prostate cancer in 13 treated men, compared to 2 out of 9 controls. It is reported that larger trials are under way. No significant effect on markers of cell proliferation was seen in the cancer tissue of women given green tea polyphenols for an average of 35 days before surgery for breast cancer. No clinical benefit was seen in a double-blind placebo-controlled study on cervical intraepithelial neoplasia or in individuals with advanced lung cancer, but a phase II trial with high doses of tea polyphenols in patients with asymptomatic chronic lymphocytic leukemia showed a decline in absolute lymphocyte count and palpable adenopathy in the lymph nodes of 31% of the participants. Liver damage, as indicated by increased plasma levels of alanine aminotransferase and aspartate aminotransferase, was observed in some participants in this trial.

Protection against Chemical Carcinogens by Tea and Tea Constituents in Animals

The possible protective effect of tea and tea polyphenols against a variety of chemical carcinogens, including nitrosamines, heterocyclic amines, polycyclic aromatic hydrocarbons, azoxymethane, 1,2-dimethylhydrazine, and *N*,*N*-dimethylaminoazobenzene, has been investigated in rodents. Various test protocols have been employed, involving the administration of the test materials before, after, or before, during, and after exposure of the animals to the carcinogen. Results have been variable. Some studies have shown a decreased incidence of cancer in the treated animals, although most positive studies have shown no effect on cancer incidence but a decrease in tumor multiplicity and/or tumor size and an increase in latency time to first tumor. Other experiments have shown no effect on cancer incidence or progression, while increases in tumor multiplicity and tumor size have occasionally been reported. In general, green tea has been found to be more effective than black tea, and protection was seen after administration of the test material both before and after the carcinogen, indicating effects on both initiation and progression of cancer.

The effect of tea polyphenols on adenomatous polyposis coli (APC^{min+}) mice has been extensively studied, with most experiments showing a decrease in the spontaneous development of intestinal tumors in these animals. However, EGCG in combination with genistein, which increases the bioavailability of the polyphenol, was surprisingly found to increase the multiplicity of intestinal tumors in APC^{min+} mice. Green tea polyphenols have been shown to inhibit the incidence of prostate cancer in the transgenic adenocarcinoma of mouse prostate mouse model and to decrease spontaneous lung, mammary, and hepatic tumors in certain mouse strains.

Epidemiological Studies on Tea and Cancer

The possible effect of tea consumption on cancer incidence at various sites, including the brain, breast, cervix, colorectum, esophagus, head and neck, kidneys, larynx, lungs, mouth, nasopharynx, ovaries, pancreas, prostate, renal pelvis and ureter, skin, stomach, and urinary bladder, has been investigated. Results are inconclusive, with some studies showing a decrease in cancer incidence in individuals consuming large amounts of black or green tea, others showing no effect, and some indicating an increase in cancer susceptibility. One consistent observation is the increase in esophageal cancer in individuals consuming very hot tea, presumably reflecting repetitive thermal damage to the esophageal epithelium. Similar effects have been recorded in individuals consuming other hot liquids and are likely attributable to the temperature of the liquid rather than its composition.

Tea and Cardiovascular Disease, Stroke, and Diabetes

There is evidence that tea polyphenols decrease fat absorption, as reflected in an increased level of fecal lipids, and green tea has been shown to decrease plasma lipid levels in rats. The effect of tea on blood cholesterol levels has been extensively investigated. Most studies have shown a significant decrease in total cholesterol and LDL cholesterol ('bad cholesterol'), with no significant effect on HDL cholesterol ('good cholesterol'). Other clinical trials with green tea and black tea indicated small, but statistically significant, decreases in systolic and/or diastolic blood pressure.

Several cohort studies have shown an inverse association between tea consumption and risk of cardiovascular disease, although others have indicated no such effect, and one study in Welsh men indicated an increased risk of heart disease with tea consumption. Case control studies gave similar results. Many of the positive studies have been conducted in China and

Japan, where green tea consumption is high. Black tea has shown no effect in several studies, although a European study did show a positive effect in continental Europe, but not in the United Kingdom.

Several epidemiological studies have shown a decreased risk of stroke with tea consumption, while others have shown no effect, and one study suggested an increased risk. An inverse association between consumption of green tea, but not black tea or oolong tea, and risk of type 2 diabetes has been reported.

Induction of Phase 2 Enzymes by Tea and Its Constituents

Increases in the activity of phase 2 enzymes such as glutathione *S*-transferase (GST), NAD(P)H quinone oxidoreductase 1 (NQO1), and uridine 5′-diphosphoglucuronosyltransferase (UDPGT) have been demonstrated in animals and in humans dosed with tea and tea polyphenols. These enzymes detoxify harmful chemicals and facilitate their elimination from the body, and their induction has been shown to protect against many toxic chemicals, including carcinogens. GST was induced in the stomach, small intestine, liver, and lungs of mice; in the mammary gland and liver of rats; and in human lymphocytes. Increased levels of NQO1 were observed in the mammary gland of rats; in the stomach, small intestine, liver, and lungs of mice; and in the liver of hamsters, and UDPGT was increased in the liver and lung of rats. In animals dosed with green tea, black tea, or green tea polyphenols, increased amounts of the detoxification products of aflatoxin B_1 in humans and of 2-amino-3-methylimidazo[4,5-*f*]quinoline in rats have been reported, which may reflect increased activity of phase 2 enzymes.

Toxicity of Tea Constituents to Animals

Single high doses (up to 2000 mg kg^{-1}) of EGCG given by gavage to fasted mice caused severe hepatic necrosis, accompanied by increased malondialdehyde levels in the liver, indicative of oxidative stress. Repeated administration of green tea polyphenols (up to 1000 mg kg^{-1} day^{-1}) by gavage to rats and mice over a period of weeks also induced hepatic necrosis. No evidence of liver damage was observed, however, when similar or higher doses were administered in food or drinking water. Severe toxicity has been observed in fasted dogs given daily doses of EGCG or green tea polyphenols in capsules at relatively low levels (150–200 mg kg^{-1} day^{-1}), including death, centrilobular hepatic necrosis, necrosis of the renal proximal tubules, thymic atrophy, and hemolytic anemia. In contrast, no effect was seen in fed dogs dosed with EGCG at 500 mg kg^{-1} day^{-1}, presumably reflecting the lower degree of absorption of this substance in fed animals.

Toxicity of Tea Constituents to Humans

As noted earlier, evidence of hepatotoxicity was observed in a clinical study with high doses of tea polyphenols. Such compounds are now readily available as 'dietary supplements,' which are marketed primarily as antioxidants and inducers of weight loss. Uncontrolled use of such supplements is not, however, without risk, since liver damage, involving hepatocellular necrosis and cholestasis, has been observed in users of such supplements. While this is an idiosyncratic reaction, seen only in a small minority of consumers, it is a serious problem. In view of such observations, the safety of green tea extracts was reviewed by the US Pharmacopeia Dietary Supplement Information Expert Committee, who classified them in class 2, requiring a warning statement on the product label.

Conclusions

Tea is a popular drink worldwide, with a history of putative beneficial effects on human health. Such history has led to many investigations into the possible beneficial effects of tea and its constituents, with a major focus on green tea and its major constituent EGCG, and on potential effects on cancer. The antioxidant effects of tea have long been discussed, though it is unlikely that tea constituents, or other chemical antioxidants, can compete with the enzymatic antioxidants *in vivo* and thereby augment antioxidant defenses.

There is good evidence for the generation of ROS by tea and tea constituents in isolated cells *in vitro*, and it appears that such species are largely responsible for the cytotoxic effects observed. It is difficult to extrapolate from *in vitro* effects to *in vivo* benefits, however, since much higher concentrations were employed *in vitro* than those that could be achieved *in vivo*. Furthermore, oxygen partial pressure in cell culture media (~150 mmHg) is much higher than that in blood or tissues (<40 mmHg), and the higher oxygen levels will enhance ROS production, and cell systems often do not replicate metabolism *in vivo*. The ability of tea polyphenols to undergo autoxidation, with the generation of ROS, in culture media leads to the conclusion that it is likely that extracellular autoxidation of the tea polyphenols is responsible, at least in part, for the cytotoxic effects of these substances *in vitro*. It is interesting to note that low levels of tea polyphenols have been reported to increase cell proliferation *in vitro* while causing growth inhibition or cell death at high levels. Similar effects have been seen with other ROS producers *in vitro*.

There is comparatively little information on the generation of ROS from tea polyphenols *in vivo*, although some studies have shown evidence of oxidative damage in xenografts after administration of tea polyphenols.

Effects of tea and its constituents on chemically induced cancer are interesting and may be related to the ability of these compounds to increase tissue activities of phase 2 enzymes. Effects on relatively few tissues of rodents have been investigated so far, and a detailed study of organ specificity would be valuable.

Tea constituents have been shown to cause toxic effects in laboratory animals, with fasted animals being more susceptible than fed. It has also been shown that administration via dietary feeding leads to fewer toxic effects than when equivalent amounts are given by bolus delivery, an important point with regard to the relative safety of normal tea consumption compared to the use of tea constituents as therapeutics or dietary supplements.

The bioavailability of tea constituents is low, and efforts have been made to increase bioavailability by use of specific vehicles or by chemical modification. Of particular interest is the work on polyacetylated derivatives, which are well absorbed and are subsequently hydrolyzed to the parent phenols intracellularly. The potential of such compounds in therapy deserves further investigation, although the possibility of toxic effects must be kept in mind.

Reports of potential beneficial effects of tea, particularly green tea, stimulated a market for green tea extracts for use as dietary supplements, and the market is predicted to grow to US $368 million by the year 2020. While clinical trials have generally shown good tolerance in volunteers (although individuals in one experiment given very high doses showed evidence of liver damage), personal use is different from that in a clinical setting in that dosage levels may not be accurately followed. Furthermore, it is possible that individuals using such products for weight loss may be fasting, which will increase the absorption of these substances and thus enhance toxicity. Regulators in the United States have advised that such supplements should be taken with food, not in the fasting state, and that the liver function of users should regularly be checked.

The results of epidemiological studies on tea are presently inconclusive, particularly with regard to cancer incidence. Large prospective cohort studies are required to provide a definitive conclusion with regard to the possible health benefits of tea.

With the green tea polyphenols, there is a correlation between autoxidation rate and pro-oxidant activity, cytotoxicity, and effects on xenografts, suggesting a common role of ROS in all these processes. Similarly, ROS are often involved in the induction of phase 2 enzymes. Other natural products that generate ROS are currently under investigation as cancer preventative agents and therapeutics, and it is possible that given appropriate doses and specific therapeutic targets, some such compounds will in the future prove valuable in the promotion of human health.

Tea: Types, Production, and Trade

X Li and X Zhu, Nanjing Agricultural University, Nanjing, China

© 2016 Elsevier Ltd. All rights reserved.

Tea infusions, which are consumed by a large number of the world's population, are obtained from the leaves of *Camellia sinensis* plant. Tea leaves are primarily manufactured as green, black, or oolong, with black tea representing ~80% of tea products consumed. Regular intake of tea is associated with an improved antioxidant status that may contribute to lowering the risk of heart disease and reduced mutagenicity. Tea possesses significant antioxidative, anti-inflammatory, antimicrobial, anticarcinogenic, antihypertensive, neuroprotective, cholesterol-lowering, and thermogenic properties. Tea has attracted considerable attention for its potential cardioprotective effects, and the primary chemical components of tea are thought to have a beneficial effect by reducing arterial stiffness. Tea polyphenol, caffeine, as well as theanine, are considered as three major bioactive secondary metabolites in *C. sinensis*. The ratio of total polyphenols content to theanine content could be used as a featured parameter for differentiating teas, and theanine in teas could be a reliable quality parameter that is complementary to total polyphenols. In this article, origin, history, types of tea introduced, as well as tea production and consumption are discussed.

Origin and History of Tea

Tea plants are native to East and South Asia and probably originated around the meeting points of the lands of north Burma and southwest China. The tea plant – *C. sinensis* has been cultivated by the Chinese people for more than 2700 years. The Chinese certainly knew of the tea plant and its value to them long ago and had discovered that the infusion of leaves produced a very pleasing drink, if carefully processed. The leaves of tea plant were considered as for medicinal purposes at first, then later as a beverage.

Tea was discovered around 28 BC, the Chinese Shennong time. The Herbal Lection by Shennong quotes: I tasted many herbs and was poisoned, tea healed me. This was the first time that tea had been recorded in history. In Chunqiu times, the person named Ying Xiang Qi Jing Gong (547–490 BC) wrote in his book *Yan Zi Chun Qiu*: Using corn, eggs and tea leaves to prepare dinner. This showed that the tea leaves became a cooking seasoning at that time. It was a common drink during the Qin Dynasty and became widely popular during the Tang Dynasty, when it was spread to Korea, Japan, and Vietnam. In India, it has been used for medicinal purposes for a long period, but apart from the Himalayan region seems not to have been used as a beverage until the British introduced Chinese tea there. Tea was first introduced to Portuguese priests and merchants in China during the sixteenth century, at which time it was termed *chá*. The first European to successfully transplant tea to the Himalayas, Robert Fortune, was sent by the East India Company on a mission to China in 1848 to bring the tea plant back to Great Britain.

As tea is the second most consumed beverage in the world after water, in many cultures it is also consumed at elevated social events, such as afternoon tea and the tea party. Tea ceremonies have arisen in different cultures, such as the Chinese and Japanese tea ceremonies, which employ traditional techniques and sophisticated protocol of brewing and serving tea for enjoyment in a refined setting. One form of Chinese tea ceremony is the *Gongfu tea ceremony*, which typically uses small Yixing clay teapots and black tea.

Types of Tea

In *C. sinensis*, two varieties are found – var. *sinensis* and var. *assamica*. In regard to tea processing suitability, var. *sinensis* has a small leaf and a bush-type habit, which green made in China and Japan is produced from; var. *assamica* has a large leaf and a tree-type habit, which black tea is made from. Tea plants are propagated from seed and cuttings; about 4–12 years are needed for a plant to bear seed and about 3 years before a new plant is ready for harvesting.

Tea is classified into three different varieties or manufacturing types – nonfermented tea, semifermented tea, and completely fermented tea, according to its fermentation level. Green tea, oolong tea, and black tea belong to those three varieties, respectively. Furthermore, there are another three specific tea varieties in China – yellow tea, white tea (lightly fermented tea), and dark tea (postfermented tea), as shown in Figure 1.

The tea fermentation is totally different from the microbial alcoholic fermentations and is defined as the hydrolysis and oxidation of leaf constituents by the endogenous enzymes. As green tea is produced by steaming or pan-firing leaves immediately after plucking, enzyme action is inhibited, and endogenous components in the leaves are retained in the product mainly unchanged; the taste is primarily determined by the choice of clone, time of plucking, shoot maturity, and the cultivation method. In the manufacture of oolong tea, fresh leaves are withered under sunlight for a short period and further indoors for several hours with a gentle rolling. As black tea, the most important physical functions are water removal and particle size determination, whereas the most important chemical aspects occur in withering, fermentation, and drying. The formation of the flavor of black tea is thus initiated during these processes.

'Instant tea,' both hot and cold, is a popular alternative to the brewed products. Similar to freeze-dried instant coffee, but not requiring boiling water, instant tea was developed in the 1930s. The process of instant tea consists of the following operations: selection of raw materials, extraction, aroma stripping, cream processing, concentration, and drying. Every operation will be considered individually. Canned tea is sold prepared and ready to drink. It was introduced in 1981 in

Figure 1 Photographs of six different types of tea products (a, green tea; b, white tea; c, black tea; d, yellow tea; e, oolong tea; f, dark tea).

Japan. In 1983, Swiss-based Bischofszell Food Ltd., was the first company to bottle iced tea on an industrial scale.

Tea Production

In 2003, world tea production was 3.21 million tons annually but by 2010 had reached over 4.52 million tons. The largest producers of tea are the People's Republic of China, India, Kenya, Sri Lanka, and Turkey. Cultivation of the tea plant can be found in more than 60 countries, and tea consumption occurs in more than 160 countries; 2 billion people have the habit of drinking tea in the world. Asia is the main tea-producing area in the world, producing about 80% of the tea. The total tea output of Asian countries reaches 80% in the world. In China, the tea output rose from 676 thousand tons in 2000 to 1552 thousand tons in 2011. The output value rose from 9 billion RMB (Renminbi) in 2000 to 72.8 billion RMB in 2011.

China is the largest producer of tea in the world. A Chinese person discovered the method of plucking tea and tea processing. One-tenth of tea production in China is exported to other district in recent years, and the rest of the tea is for the domestic market. China was not only the largest tea producer, but also the largest exporter of tea in the world in the late nineteenth and early twentieth centuries. The output of tea was 1915 million kg in China in 2012, a leading number for the entire world. Currently 322 million kg of tea is exported, which this year is ranked in second place.

In 2014, China has 41.12 million mu of land for tea plantation area, of which 31.62 million can be plucked. The output of tea was 2092 million kg in China in 2014, and the production of Zhejiang province, Fujian Province, as well as Hunan Province were leading areas.

Sri Lanka is the largest tea exporter in the world. Sri Lanka is an island country in the Indian Ocean (formerly known as Ceylon). The black tea made from Sri Lanka in world market has become more and more popular in recent years. The output of tea was 330 million kg in Sri Lanka in 2012, third in the world after China and India, and 300 million kg of tea were exported, with exports ranked in second place in 2012.

India is one of the largest countries of tea cultivation and export. More than 90% of tea for exporting is black tea in India, whose production is much different from China. A large number of places are suitable for tea plant cultivation, with the area

of Darjeeling and Assam very famous. Approximately 80% tea product is from the Assam area, and the black tea output in the Darjeeling area accounts for 2% of the gross amount.

Japan is a famous area for the cultivation and production of steamed, unshaded green tea (sen-cha). The tea plant was brought from China to Japan by Buddhist monks in the twelfth century, and this led to the production of a steamed brick tea that was used only as a medicine or in upper-class social affairs. The output of tea was 90 million kg in Japan in recent years, and the consumption amount of tea per year according to the number of person is relatively high, reaching 1500 g.

Tea Trade

There have been few changes in three centuries of tea trading. London became the center since drinking tea was first imported to Britain in the seventeenth century. Tea was considered a man's drink to be enjoyed with colleagues at London coffee shops. These were popular meeting places for many walks of life – politicians, lawyers, poets, actors, and writers. By the eighteenth century the ladies of the more affluent classes were going 'Chinese Mad,' using tea as an excuse for displaying their extravagant purchases of Chinese porcelain and Dresden tea sets. A comprehensive tea tray would consist of a teapot and stand, teacups and saucers, a sugar bowl, a milk jug, and a basin. Tea was still expensive and kept in locked tea-caddies. As the nineteenth century progressed, changes in commerce and working hours resulted in the main meal of the day being taken much later in the evening. The prospect of lasting from breakfast until evening did not appeal to the Duchess of Bedford, who was usually credited with being the first to alleviate late-afternoon hunger pangs by introducing a small 4 o'clock meal served with tea.

According to the Food and Agriculture Organization in 2007, the largest importer of tea, by weight, was the Russian Federation, followed by the United Kingdom, Pakistan, and the United States. Kenya, China, India, and Sri Lanka were the largest exporters of tea in 2007 (with exports of 374 229, 292 199, 193 459, and 190 203 tons, respectively). And at that time, the largest exporter of black tea in the world was Kenya, whereas the largest producer (and consumer) of black tea in the world was India.

The tea business, once limited by national borders, has now become more independent than ever. Regional organizations are gaining their own prestige and legal clout. At the global level, the World Trade Organization is now the ultimate authority, with decision-making power that already influences nations tea tariffs, import/export rules, subsidies, and quotas. These regional and global systems are creating new opportunities – and new conflicts – for the entire tea trade. The global process for bringing buyers and sellers more directly together, in this case without auction houses, is termed disintermediation. Disintermediation has already produced cost-effectiveness and shareholder profit for modernized business, with catalog sales of premium tea as a perfect example. Advanced Internet systems, combined with disintermediation, can support a price-stabilizing tea futures market, assuming the market is financially transparent, ethically instituted, and justly enforced.

America entered the tea trade with three American millionaires, T. H. Perkins of Boston, Stephen Girard of Philadelphia, and John Jacob Astor of New York, who all made their fortunes in the China trade. America began direct trade with China soon after the Revolution was over in 1879.

Russian tea tradition included imperial Russia attempting to engage China and Japan in trade at the same time as the East Indian Company. The Russian interest in tea began as early as 1618 when the Chinese embassy in Moscow presented several chests of tea to Czar Alexis.

Tea Consumption

In 1706 the first coffeehouse that offered tea was Tom's Coffee House in London. The House realized that they needed to introduce an added attraction to compete with the many other coffeehouses, and tea was rare, exotic, and extremely expensive. The popularity of tea continued to spread, but it was not until 1839 that the first shipment of Assam India tea was landed in Britain. A healthy trade with India was soon established, and tea clippers were reaching the peak of their sailing days. In 1879 the first limited shipments of Ceylon tea began to arrive, and by 1880 this had been firmly established alongside India and China teas, giving the broad range of teas that are available today.

In recent years, consumers tend to spend proportionally less on tea and more on coffee, as household expenditure on beverages increases. Prices and incomes have a relatively smaller impact on the consumption of tea. Marketing efforts should focus on demographic differences among consumers, increasing accessibility through improved visibility and retailing, and supporting innovative technologies, especially at the consumer level, as demonstrated by the coffee industry.

Most tea consumed outside East Asia is produced on large plantations in the hilly regions of India and Sri Lanka and is destined to be sold to large businesses. Opposite this large-scale industrial production are many small 'gardens,' sometimes minuscule plantations, which produce highly sought-after teas prized by gourmets. These teas are both rare and expensive and can be compared to some of the most expensive wines in this respect.

India is the world's largest tea-drinking nation, although the per capita consumption of tea remains a modest 750 g per person every year. The average tea consumption per person per year was 3157 g in Turkey in 2011, which is the greatest per capita tea consumer all over the world, followed by Ireland (2191 g) and England (1942 g). This data revealed that there is no direct relationship between tea production and tea consumption.

Introduction

Tequila is a Mexican spirit obtained from the distillation of fermented agave juice. In pre-Columbian times, it was called *mezcal*, a drink made from fermenting the juice obtained from the hearts of the agave plant, of which many species occur in Mexico. In colonial times, Pedro Sánchez de Tagle (1530) added distillation to the indigenous technology, developing the tequila known today. The distilled drink is obtained from the fermented juice of the blue agave (*Agave tequilana* Weber var. azul). It is cultivated in the western central region of Mexico, in the state of Jalisco, and some municipalities of the states of Tamaulipas, Nayarit, Michoacán, and Guanajuato.

The elaboration of tequila and its quality are governed by Mexican legislation 'NORMA Oficial Mexicana NOM-006-SCFI-2012, *Bebidas alcohólicas-Tequila-Especificaciones*.' According to this norm, tequila can be classified into two categories: tequila 100% and tequila. The differentiation depends on the percentage of sugar derived from the agave plant used in tequila production.

In tequila 100%, the sugars must come exclusively from *A. tequilana*, grown in the territory specified in the declaration of the denomination of origin. For this reason, this product is labeled '100% agave tequila.' It must also be bottled in a distillery that is located within the territory specified in the declaration of the denomination of origin, and under the supervision of the Consejo Regulador del Tequila.

Tequila refers to a product made with at least 51% agave juice, enriched up to a maximum of 49% of the total reducing sugars, from a source other than the agave juice. This alternative source of sugar must not come from another variety of agave.

In addition, depending on the characteristics acquired in postdistillation, tequila is classified into five subclasses:

White or silver tequila: a transparent, light-colored product obtained from distillation. Dilution with water is used only in appropriate cases to set the required commercial graduation. If matured in oak barrels, this lasts <2 months.

Tequila young or gold: the product of a mixture of rested and aged (or extra-aged) tequila. It can also be called young or gold tequila if additives, allowed by official rules, are incorporated (often, colors or flavors).

Rested tequila (*reposado*): the product has been matured for at least 2 months in oak barrels. It can still be called *reposado* if the *reposado* is blended with aged and extra-aged tequilas.

Tequila *añejo* (aged tequila): this version has been subject to an aging process that is achieved by maturing white tequila for at least 1 year in oak barrels (maximum capacity 600 l). It may also be called *añejo* tequila if it is a blend of aged tequila and extra-aged tequila.

Extra-aged tequila (extra *añejo*): this version has been subjected to maturation for at least 3 years in oak cooperage (maximum capacity 600 l).

Tequila production has evolved into the modern version mainly due to distillation, which modified the ancient *mezcal* produced by Indians before the arrival of Spanish colonizers. However, the basic unit operations have not changed: cultivation and harvest (termed *jima*) of the raw material (derived from the stems of *Agave tequilana* rich in fructooligosaccharides), cooking (to obtain fermentable sugars from the hydrolysis of the agave fructans), juice extraction, fermentation, distillation, filtration and aging, and bottling according to the type of tequila being produced.

Raw Material: *A. tequilana* Weber var. azul

The genus *Agave* (Asparagaceae, formerly Agavaceae) is a monocotyledon, a major subgroup of angiosperms (flowering plants). The genus occurs natively from the southern United States to northern South America, and throughout the Caribbean. Mexico is its most important center of diversity and possesses about 200 recognized species. Since ancient times, many of its species have been of great economic importance in Mexico, used as a source of fibers, medicine, and food, and in the manufacture of alcoholic beverages such as *mezcal* and tequila.

Agaves are rosetteous, perennial, monocarpic plants that live for many years and die after fruiting. The genus is divided into two subgenera: Agave and Littaea. Those in the subgenus Agave have tall inflorescences or scapes (flowering stems arranged in panicles, with the flowers produced in subpanicles). On the other hand, members of the subgenus Littaea have racemose scapes (the flowers being borne in clusters on lateral peduncles).

A. tequilana Weber var. azul is the source of the raw material used for tequila production. It is cultivated in the state of Jalisco, and part of the states of Michoacán, Nayarit, Guanajuato, and Tamaulipas. *A. tequilana* is a species in the Rigidae (a grouping within the Agave subgenus) that possesses rigid lanceolate. It achieves maturity within 7–8 years. Its scape reaches 7–8 m high (Figure 1(a)) and possesses hermaphrodite flowers (Figure 1(b)) that are borne in sub-panicles. The blooming season occurs from May to July, with the fruit and seeds developing from August to September. *A. tequilana* can also reproduce vegetatively by bulbils produced on the subpanicles (Figure 1(c)) and from basal rhizomatous shoots produced around the mother plant. Commercial plantations are started from the rhizomatous shoots (Figure 1(d)) to avoid the high genetic variability inherent in seed produced by cross-pollination.

The part of the plant used as a source of fermentable carbohydrates is the "*piña*". It comprises the true stem and the small basal segment of leaves that remain attached to the stem after harvesting, termed *jima* by agave farmers (Figure 1(e)).

Figure 1 The raw material: *Agave tequilana* Weber var. azul. (a) Mature commercial plantation with some scapes or floral stalks. (b) Hermaphrodite flowers borne in sub-panicles. (c) Vegetative reproduction by means of bulbils produced on sub-panicles. (d) Rhizomatous shoot used to start a new plantation. (e) Plant stems or piñas after harvesting.

These *piñas* take diverse shapes, from ellipsoid to ovoid, depending on environmental conditions and crop management. Finally, the *piñas* are cut in half, or smaller portions, prior to cooking.

Cooking and Carbohydrate Extraction

The ancient process of agave cooking hydrolyzes agave fructans under acidic conditions (pH 3.5–4.5) at temperatures between 80 and 110 °C. This liberates fermentable fructose and glucose molecules. For centuries, brick ovens were used for cooking. However, stainless steel ovens have replaced the former brick ovens to shorten the cooking time and enhance control. Cooking is also an important step because it produces classic sensory notes (e.g., caramel, smoked and wet straw) from compounds such as furans (furfural, 2-acetylfuran, methyl-2-furoate, 5-methylfurfural, 5-hydroxymethylfurfural, and 2-methyl-tetrahydrofuran). Most of the methanol found in tequila is derived from the action of pectolytic enzymes on pectin present in the raw material reacting or via thermal degradation. Methanol formation from pectins has been studied in the production of other spirits, such as *orujo* and the Greek spirits *tsipouro* and *tsikoudia*.

Once cooked, the agave stems are conveyed to steel rolling mills, similar to those used in the sugar cane industry. The mills press the shredded agave. Water is sprayed over the agave bed to leach the sugars from agave fibers. Juice with a solid content of 12–14 g/100 ml is obtained during this step.

Today, equipment called 'diffusers' are also used to extract water-soluble carbohydrates. A diffuser consists of a large steel belt (~2 m wide, and 20–23 m long) that conveys a layer of shredded raw agave across a countercurrent flow of hot water (80 °C). The carbohydrates obtained are hydrolyzed under acidic conditions at temperatures between 80 and 85 °C for 4–6 h. Phosporic acid and hydrochloric acid may be used to achieve the desired pH (1.8–3.0).

Fermentation Process

Fermentation, as in all alcoholic beverages, is a key stage in the elaboration of tequila. During this step, agave sugars are metabolized to ethanol, carbon dioxide, and other flavor-active compounds by the action of different microorganisms, particularly yeasts.

As mentioned earlier, Mexican regulation permits the use of only *A. tequilana* as the main carbon source. This species is characterized by the synthesis and accumulation of a particular reserve carbohydrate, a highly branched fructan that has been dubbed by some authors as *agavina*. In the agave juice, obtained after milling, these polysaccharides are hydrolyzed in order to permit fermentation. Sugars presents in the juice are mainly fructose, with a small percentage of glucose molecules (~10%). In the case of 100% tequila, the only source of the sugars comes from the hydrolyzed fructans obtained in the cooking step. In the case of the product simply designated as tequila, the law authorizes the addition of other sugars, in amounts of up to 49% by weight in the must formulation. Sugars currently employed are cane sugar; *piloncillo* (obtained from the crystallization of whole cane juice); cane molasses; and more recently, hydrolyzed corn syrup.

For the majority of the tequila industry, fermentation is performed using just the agave juice (must). However, some companies still employ a rustic process where the cooked agave is ground in an archaic mill named a *tahona*. In this process, the juice is not extracted and fermentation occurs in the presence of agave fibers. These tend to rise to the surface of the fermentation tanks and cover the fermenting must. Such fermentations are generally longer (several days to more than a week), and the conversion of sugars to ethanol is lower than in the case of liquid must fermentations. Under standard fermentation conditions (without fibers), the initial sugar concentration can range from 4% to 10% w/v (100% tequila), and 8% to 16% w/v (tequila). In some distilleries, in the formulation of

the must, nitrogen or other nutrients are added, such as urea, ammonium sulfate, ammonium phosphate, magnesium sulfate, and in some cases complex commercial nutrients. The amount added depends on the producer.

In general, there are two main types of tequila fermentations: spontaneous and induced (with the addition of selected yeasts). Some companies still prefer spontaneous fermentation as a traditional process because the greater diversity of microorganisms generates diversity of flavor compounds, despite producing less ethanol. For most companies, though, the must is inoculated with a particular strain of *Saccharomyces cerevisiae*. This may come from packaged bakers' yeast, or a commercial dry yeast (normally used for the production of wine, beer, or rum). Another interesting practice is the use of a proprietary, native, isolated yeast strain. Some companies develop their own specific inoculum in tanks on agave juice, using agitation and air incorporation, to produce the desired biomass and suppress ethanol generation. Inoculation of the fermentation tanks is done at 5–10% by volume.

Most producers use stainless steel fermentation tanks, possessing volumes of 2000 to 120 000 l. Some companies still use rustic wooden tanks, with volumes from 2000 to 10 000 l, especially when fermenting in the presence of agave fibers.

A detailed work characterizing the mycobiota has been conducted by a firm that uses traditional spontaneous fermentation. Several yeast species were detected at the beginning. These included *Dekkera bruxellensis*, *Hanseniaspora guillermondii*, *H. vineae*, *Kluyveromyces marxianus*, *Pichia membranifaciens*, *Torulaspora delbrueckii*, and *S. cerevisiae*. During fermentation, the populations of non-*Saccharomyces* yeasts tended to decrease, with *S. cerevisiae* becoming dominant by the end of fermentation. It is important to mention that bacteria were also detected. These could also play an important role in the formation of volatile compounds, or may become a serious contamination problem. Thus, they could affect the conversion of sugar to ethanol.

With must formulated using only juice, a typical inoculated fermentation may be rapid (about 20 h), or up to 3 days in a slower cases. Yeast populations range between 100 and 200 - million cell ml^{-1} by the end of the fermentation. If an inoculum is not added, or fermentation occurs in the presence of fibers, fermentation may take more than 7 days, reaching lower yeast populations in the tank. The temperature reached during fermentation is relatively high, ranging between 30 and 35 °C, and sometimes rising to 40 °C. The rate of fermentation depends on different factors, such as the type of fermentation (with or without fibers), the yeast strain used, medium composition, and operating conditions. At the end of fermentation, the alcohol content ranges between 4% and 9% (v/v), depending mainly on the initial sugar concentration.

Besides ethanol production, fermentation contributes significantly to the generation of other compounds, particularly flavor-active chemicals. Generally, the content of these flavor-active compounds is lower in faster rather than slower fermentations. In a study carried out on different 100% tequila samples, the most important compounds (by concentration), after ethanol, were higher alcohols, methanol, ethyl acetate, and acetaldehyde. The generation of these compounds (except for methanol) occurs during fermentation due to yeast metabolism. Additionally, 24 different esters have been identified, for example, ethyl decanoate, ethyl dodecanoate, ethyl lactate, and ethyl octanoate. In this case, the main yeasts responsible for their production were non-*Saccharomyces* yeasts. *S. cerevisiae* donated few esters. Thus, to obtain these aromatic products, the presence of non-*Saccharomyces* yeasts is desirable. Another interesting function of some non-*Saccharomyces* species is the production of enzymes, such as β-glucosidase, β-cellobiosidase, and β-xylosidase. These are able to hydrolyze complex polysaccharides present in the raw material, generating aromatic compounds such as terpenes.

Distillation

Alembic distillation is an ancient separation process that has been used worldwide by different cultures to obtain spirits. At the beginning of the tequila industry, in the eighteenth century, the only distillation equipment used was the alembic. At the time, it was made out of copper and heated with wood. Without analytical methods, the distillation process was loosely controlled. The distillate was of inconsistent quality and under the empirical control of the distiller. Since the mid-twentieth century, the tequila industry has introduced technological advancements that include steam as the heat source, both for agave cooking and distilling, and the use of stainless steel instead of traditional copper distillation equipment. Recent changes also include the use of continuous leaching processes to extract water-soluble carbohydrates from agave, and continuous distillation columns to derive more distillate.

Traditional tequila distillation consists of two steps. In the first (stripping), fermented must possessing an ethanol content between 4% and 9% V/V is distilled using differential (alembic) distillation. This technique is characterized by the separation of ethanol, together with additional volatiles called congeners. The objective of stripping is to eliminate residual sugars, yeast, minerals, and fibers. This mixture is known as *vinasses*, and the distillate obtained is called *ordinario* (25–30% ethanol volume).

The second step enriches and rectifies the distillate. It involves three fractions: the first (heads), middle (heart), and last (tails). Heads volume usually is around 1% of the batch in the pot of the alembic, and contains mainly ethanol, water, acetaldehyde, isobutyl and isoamyl alcohols, and ethyl acetate. The middle volume, possessing an alcohol content of 55–60%, contains ethanol, esters, terpenes, isobutyl and isoamyl alcohols, organic acids, and other chemical compounds that form the particular and unique sensory profiles of tequila. The size of the heart fraction depends on the ethanol degree in the *ordinario* and contains 80–90% of the ethanol of the initial *ordinario*. The tails fraction contains water, methanol, phenethyl alcohol, furfural, acetic acid, and other larger chain organic acids such as hexanoic and octanoic acids. When continuous columns are used, the obtained distillate usually is blended with alembic distillate to meet regulation dictates and to achieve the desired sensory profile.

To obtain the finished product, the heart fraction is transferred into oak casks in the aging area, or diluted and filtered to obtain silver and gold tequilas. Distillate aging permits the production of tequila *reposado* and tequila *añejo*, with at least 2 months aging for the first, and 1 year for the second. An extra-aged tequila, with at least 3 years in-oak maturation, may also be produced.

Quality of Tequila

The quality of a product for human consumption is defined by the needs and expectations of the consumer. Regarding distilled beverages, a consumer commonly wants and expects a product that is both pleasant to taste and smell, as well as safe. In this regard, tequila quality control is oriented toward understanding, characterizing, and controlling its volatile composition. This involves maintaining methanol and higher alcohols within safe limits and investigating compounds, such as esters and aldehydes (Table 1), and ketones, that donate the bouquet. Quality control analysis also include determining dry matter, ash, alcohol, and furfural.

The identification and quantification of volatile compounds is carried out by gas chromatography, combined with flame ionization or gas chromatography, coupled with mass spectrometry. Solid-phase microextraction is also often used with polydimethylsiloxane or polyethylenglycole as the stationary phase. For general assessment detection, a few microliters of tequila can be directly injected into a gas chromatograph. It permits to know the proportions of the principal functional volatile groups – aldehydes, ketones, esters, and alcohols – and can differentiate among compounds such as isoamyl alcohol, butanol, and methanol. For more detailed analysis, concentration of the volatile compounds before injection allows the identification and quantification of volatiles in microgram quantities. The detailed volatile profile obtained permits correlating tequila's sensory attributes with its chemical origin.

Origin of Tequila's Sensory Attributes

As with other spirits, the distinctive sensory character of tequila is principally provided by the flavor compounds that come from the raw material, cooking, and fermentation. The most abundant components are ethanol and water, with tequila's sensory identity being provided by diverse volatiles in small quantities. Additional volatiles may come from maturation in wood cooperage or occasionally other flavorings. The age of the agave and the region in which it is grown bring diversity to the flavor of tequila. Even though agave must be grown and harvested only in specific appellation of origin regions, microclimates and soil differences within regions bring diversity to the bouquet of tequila.

In fermentation, the use of the local microbial flora will also have an impact on the final character of the product, contributing to distinctive variations among different brands, regions, factories, and spirits. Distillation performed either in copper or stainless steel, and the way it is carried out, affects volatile recovery and restricts the presence of undesirable compounds.

Tequila Flavor Origin

Tequila flavor volatiles have been extensively studied since the last decade of the twentieth century, when this spirit became widely distributed and increasingly popular. About 300 flavor volatiles have been identified. In addition, olfactometry has shown the importance of components such as vanilla, eugenol, esters, and phenyl ethanol. Much of the work has been summarized in a review by Gschaedler. However, as in other foods or beverages, tequila flavor depends on the interaction of multiple volatile compounds, and not solely on components with low thresholds, although they have great impact. Tequila flavor develops progressively, with every step in its production contributing specific sensory attributes to the final product.

Flavor Contribution of Raw Material and Its Elaboration

As mentioned earlier, cooking of the mature agave stem or heart not only releases fermentable sugars, but also promotes the formation of compounds derived by Maillard and caramelizing reactions. The latter provide mainly furanic volatiles. The agave plant is rich in terpenic compounds, and contains both vanillin and syringaldehyde in its juice. The latter two are normally derived from wood cooperage in other spirits. Other compounds with spicy notes, such as eugenol, are also present in the agave.

[a]Valid Official Mexican Standards and Mexican Standards.

[b]Minimum setting may decrease if the producer of Tequila demonstrates to the Conformity Assessment Body, that has a viable method to reduce the content of methanol.

Some agave compounds are transformed during cooking; however, others survive and are present in the final product. There is little published research on the effect of using different juice extraction conditions on volatile composition, especially the use of diffuser technology during cooking. These steps of juice extraction and cooking are very important to tequila's sensory character, as they impact the way volatiles from agave juice are produced, modified, and recovered before fermentation.

Methanol is an important volatile compound produced early in tequila production, coming from the demethylation of the pectin, which occurs abundantly in agave. At high concentrations it is a toxic compound, but at lower concentrations it is a flavor-impact compound (and, as such, a potential authentication marker). In practice, tequila authentication has commonly been directed at the detection of a distinctive agave profile, in particular the presence of terpenes. Authentication has been explored with the use of isotopic ratios, notably the carbon, hydrogen, and oxygen in ethanol and other primary alcohols. This approach appears to be the most accurate.

Ethanol and higher alcohols are mainly produced by yeasts during fermentation. Yeast fermentation also produces esters, aldehydes, and other volatile organics. Moreover, specific yeast strains may enhance ester production, as well as favor the release of terpenes, which provide herbal and floral notes. Yeasts can also affect the presence of vanillin, depending on the conditions, by metabolizing the compound.

Distillation is important in recovering and selectively separating volatile constituents. Nevertheless, chemical transformations of volatiles can also take place, especially when copper is used. A paired comparison test showed significant differences between tequila obtained from stainless steel alembic versus copper pots, the latter being more fruity and flowery.

Including maturation in wood in the production process has a special impact on the spirit's character, but in contrast with some other spirits, such as cask-aged whiskies, unoaked tequila has a pleasant character, especially with 100% tequila. Agave's raw material volatiles blend with those derived from fermentation, after careful distillation. This is illustrated in the sensory profiles obtained for silver tequila (Figure 2).

Rested (*reposado*) tequila remains in wooden barrels for at least 2 months and up to a year. The character of the final product depends on the type of wood used for barrel manufacture, and whether new or reused barrels are used. Wooden barrels provide lignin-derived compounds, such as vanillin, syringaldehyde, coniferaldehyde, and cinnamaldehyde, which are extracted by the spirit, as are oak lactones. Extracted phenolic nonvolatile compounds provide color and induce structural changes in the alcoholic matrix that can modify the volatile release of some compounds. Tequila classified as aged has to be matured in cask for more than 1 year. For this class of tequila, the oaky character is stronger. This results from more compounds having been extracted from the barrels, as well as from phenolic polymerization and longer oxidation. Aged tequila composition may resemble other long-aged, cask-matured spirits, such as whiskies and cognac.

Flavor Attributes of Tequila

Flavor descriptors relate to the raw material, fermentation aromas, and the bouquet obtained during maturation. Cooked agave has odor-flavor notes of browning reactions that are reminiscent of caramel, molasses, or raw brown sugar. They are also similar to cooked pumpkin and overripe or fermented fruits. Agave also can donate spice flavors, due to the presence of eugenol and wood-related compounds (vanillin and syringaldehyde), as well as terpenes with floral and herbal notes. Fermentation provides a vinous character due to the production of higher alcohols, similar to how its generation of esters donates fruity flavors. Terpene transformation and release, carried out by yeasts, also contribute to herbal-floral character. Among impact compounds,

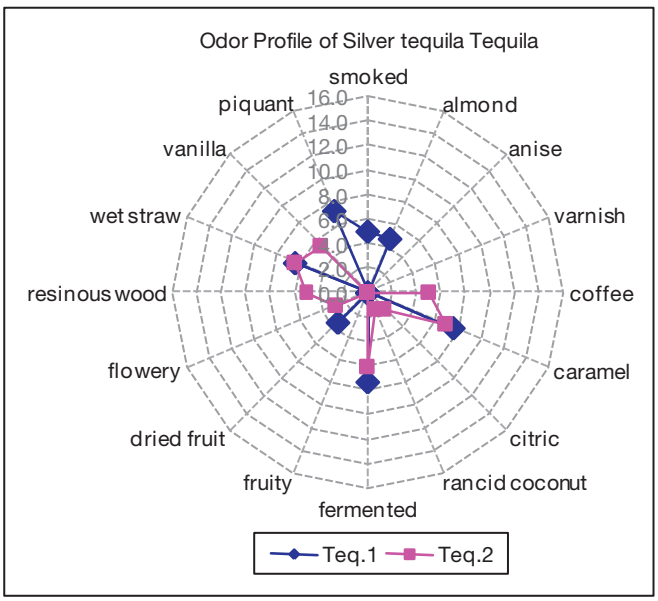

Figure 2 Odor profile of silver tequila from Tequila.

phenylethanol has been reported as odor-active, with a floral odor, with β-damascenone contributing to a fruity-winey smell. Lopez reported these compounds as odor-active components, and indicated that 3-methyl butanol, phenylethyl acetate generate a fermented fruit note. As indicated in the preceding paragraphs, region, growth, and agave cultivation conditions, as well as the fermentation conditions, can impact tequila's sensory profile. Tequila and Los Altos are the traditionally representative regions for tequila production, as shown by the sensory profiles provided by trained judges (Figure 3).

The source material and size of the barrels used in maturation, as well as its duration, generate different volatile profiles in tequila and can offer a variety of sensory nuances suited to different consumers (Figure 4).

Volatile acids can donate sour attributes, whereas vanilla and other woody notes may appear in white/silver tequilas. Nonetheless, the latter are more distinguished by their agave flavor, and the fruitiness and vinous character are provided by fermentation. Oaky, nutty, and spiced flavors, as well as enhanced vanilla and caramel notes, are found in the rested and aged tequilas. With prolonged aging, the woody bouquet may override the agave notes.

Sensory Evaluation

As the tequila industry has grown and the product's popularity has increased, producers have focussed their attention on diversifying tequila's sensory characteristics and improving methods to maintain these attributes. Some large producers now work with expert tasters and have implemented more structured sensory evaluation methodologies. These involve employing trained assessors for quality control, as well as in research and development.

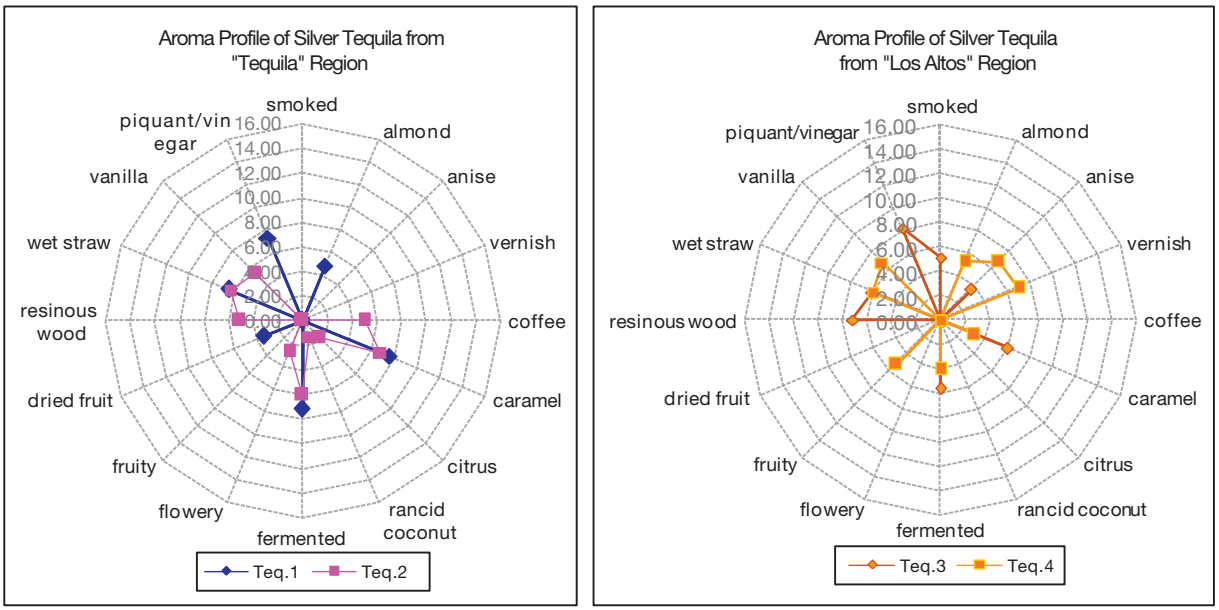

Figure 3 Aroma profile of tequila from Los Altos and tequila from tequila.

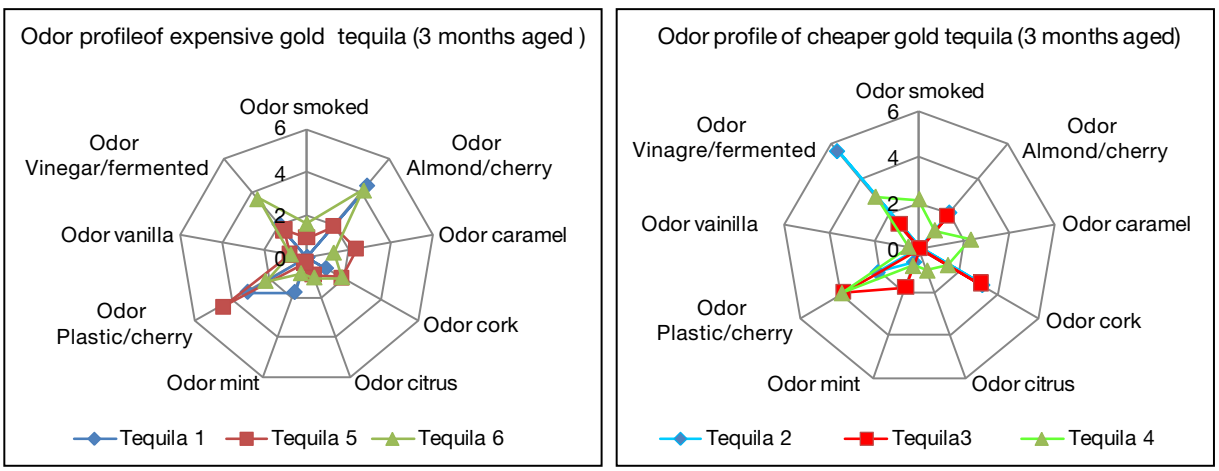

Figure 4 Odor profile of aged tequila.

Other tequila producers have also realized the need for a more structured sensory control protocol. This often follows procedures outlined by the International Standards Organization (ISO). However, few medium or small producers have research and development departments.

Quality Control

Discriminative tests, such as triangle or duo-trio tests, are the most frequently used statistical methods for sensory quality. They are fast and practical, using a typical product as a reference.

Some tequila companies have their own research and development departments. These have facilities for training descriptive assessors who can participate in specific sensory evaluation tests.

Implementing a sensory analysis location on the premises has been important in sensory analysis carried out by research institutions and private consultants.

Background

The discovery of thiamine or vitamin B_1 as an essential nutrient has opened a new area in the field of nutrition research in two respects. First, the nomenclature 'vitamin,' used for the whole class of the later on discovered essential micronutrients of organic origin, was derived from a functional group (NH_2 group) of the molecule. Second, thiamine was the first nutritional factor that could be identified as a curative agent against a deficiency disease in animals.

At the end of the nineteenth century, the Dutch medical officer Ch. Eijkman discovered the beneficial effect of rice bran or unpolished rice, respectively, for the treatment of polyneuritis in chickens resembling beriberi in man, which had been previously induced by feeding polished rice. In 1911, the German-Polish chemist C. Funk isolated a crystalline substance from rice bran and regarded the amino function as the essential principle of the molecule. The exact chemical structure of the thiamine molecule was elucidated by R. Williams and A. Windaus. Because of the sulfur content of the molecule or its thiazole moiety combined with the amine function, the compound was designated as thiamine instead of the former name aneurine. Nevertheless, the classical form of thiamine deficiency, beriberi, mainly affects human beings and has been well known in the rice-eating countries of East Asia for centuries. Even 25 years after the ingenious work of Eijkman, who clarified the cause of this deleterious disease, the mortality rate from beriberi in industrialized countries such as Japan was still more than 25 000 per year.

Physiological Function

Like other water-soluble B vitamins, thiamine is in its primary function coenzymatically active. The thiamine-dependent enzymes are involved in carbohydrate and energy metabolism (Figure 1). Key enzymes in these metabolic pathways are mitochondrial pyruvate dehydrogenase (EC 1.2.4.1) linking glycolysis with the citric acid cycle, α-ketoglutarate dehydrogenase (KDH) (EC 1.2.4.2) within the citric acid cycle, and the cytosolic transketolase (EC 2.2.1.1) in the pentose phosphate shunt. Hence, it follows that the energy turnover of the organism is related to thiamine demand. As dietary carbohydrates are the predominant fuel for the rapid metabolizable energy of the organism, the thiamine requirement is often related merely to the carbohydrates ingested. KDH was identified as the rate-limiting enzyme of the cerebral glucose utilization. A low enzyme activity caused by a reduced intracellular thiamine diphosphate (TDP) concentration results in lactacidosis, cerebral dysfunction of the energy metabolism, and neuronal cell degeneration. Additional thiamine-dependent enzymes are involved in the metabolism of branched-chain amino acids, for example, leucine, isoleucine, and valine. All enzyme reactions are characterized by transfer of an 'active aldehyde' from α-keto acids formed after previous decarboxylation to coenzyme A or an aldopentose.

The coenzymatically active form is TDP, also called thiamine pyrophosphate (TPP) or cocarboxylase, which is formed in the mucosal cell of the intestinal barrier with the aid of thiamine pyrophosphokinase (EC 2.7.6.2) in the presence of ATP. The latter enzyme is also found in mammalian liver and other tissues such as the brain and nerves and in the heart of mammals and birds. Further phosphorylated forms of thiamine, which are found in varying quantities in the tissue, are thiamine monophosphate (TMP) and thiamine triphosphate (TTP). These derivatives are synthesized and metabolized according to the scheme in Figure 2.

Thiamine phosphorylation represents a partitioning process in a deeper compartment. Cell membranes are impermeable for the intracellularly active coenzyme TDP, which is released only after hydrolysis via TMP to thiamine. The total thiamine concentration of the blood cells and of the cerebrospinal fluid (CSF) has a nonlinear relation to the corresponding plasma concentrations. A linear increase in blood cells and CSF has been observed only with thiamine plasma levels above 10 nM (3 $\mu g\,l^{-1}$). Otherwise, with extremely low plasma and CSF concentrations, a disproportionately high TDP content of erythrocytes and TMP content of the CSF are maintained for a longer period. Thus, the intracellular phosphorylation should be seen as a protecting mechanism, inhibiting rapid thiamine depletion by decreasing the membrane permeability.

After TDP, TTP is the next most phosphorylated metabolite, albeit the steady-state concentrations in tissues are rather low. No coenzymatic function has been found for this metabolite. Several investigators have demonstrated in a variety of animals (rats, rabbits, cows, frogs, and pigs) that TTP, together with a distinct part of TDP, is neurophysiologically active in the central and peripheral nervous systems independent of the coenzyme function of the latter. After electrical stimulation of the nerves or treatment with neuroactive drugs, for example, acetylcholine, tetrodotoxin, and lysergic acid diethylamide (LSD), a release of the phosphorylated esters TDP and TTP concomitant with a shift to TMP and free thiamine has been observed. Furthermore, in patients with the deleterious 'subacute necrotizing encephalopathy,' or Leigh's disease, the TTP level in the brain was low and tended toward zero. It has been known for a long time that severe thiamine depletion of the mammalian central nervous system leads to encephalopathies, which are accompanied by regionally selective changes in neurotransmitter function. Though the exact function of TTP is not yet known, it plays an essential role in nerve excitation and transmission, possibly in gating the ion transport. From recent investigations, it has been argued that TDP might also be involved in the inhibition of nonenzymatic glycosylation

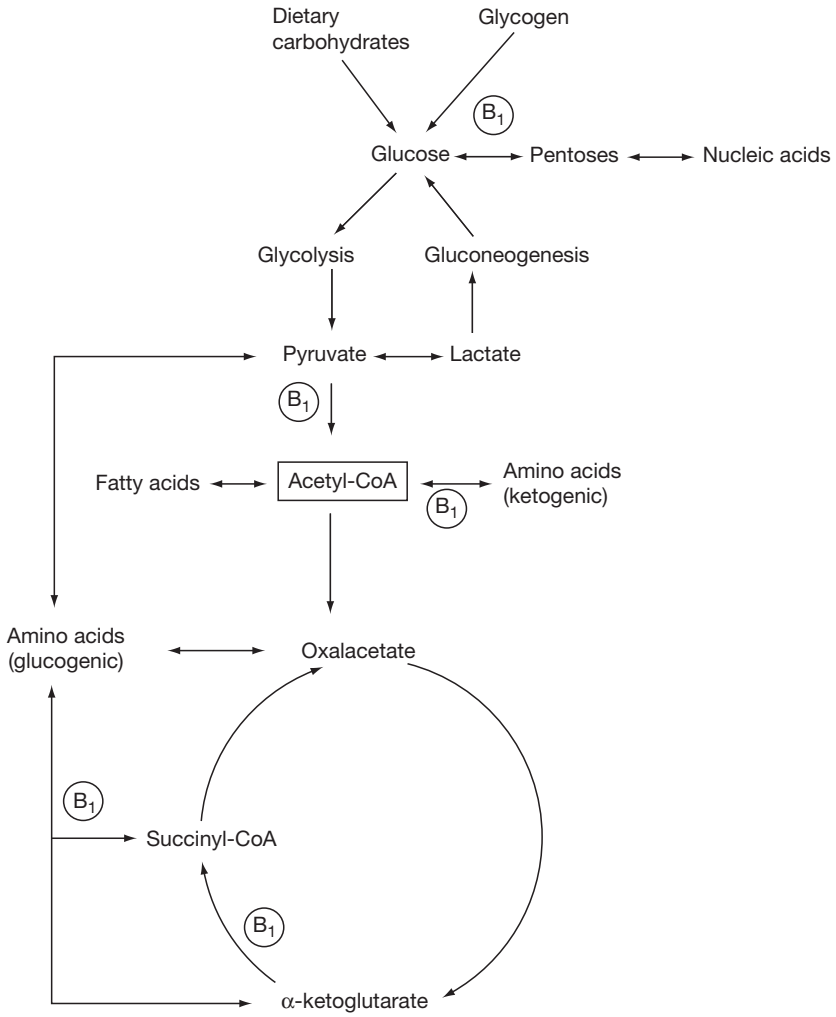

Figure 1 Metabolic pathways involving thiamine.

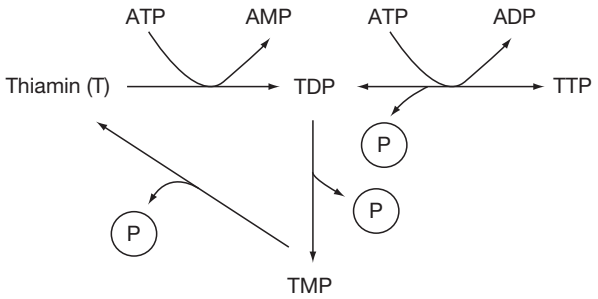

Figure 2 Interconversion of thiamine phosphates (according to Rindi, modified).

processes. It is suggested that the emerging advanced glycosylation end products (AGEs) are the reason for the segmental demyelinization observed in neurodegenerative diseases. Studies on cultivated cells have demonstrated that thiamine and TDP could prevent the AGE formation. In this regard, TDP is more effective than the standard inhibitor aminoguanidine that is normally used.

Absorption, Storage, and Excretion

Thiamine is absorbed from the gastrointestinal tract by a dual system, as has been shown for humans and rats. At low concentrations, it follows an energy-dependent active transport with a saturation kinetics up to a maximal concentration of 2 μM. At higher concentrations, a simple diffusion process is predominant. However, the relative absorption decreases with increasing vitamin doses, so that with gram doses, only about 5% are incorporated.

A close association was assumed between thiamine transport and phosphorylation as well as Na^+ dependency. However, the coupling of thiamine transport with phosphorylation is now doubtful, and there is much evidence of a specific protein carrier being involved in the absorption, but the following intracellular phosphorylation seems to be a rate-limiting step in the active transport of thiamine across the epithelial cells of the intestine. In contrast, in the guinea pig intestine, thiamine seems to cross the brush-border membrane by simple diffusion throughout the concentration range from 0.06 to 10 μM.

The jejunum and ileum have been found to be the main sites of thiamine absorption in rats with a maximal rate in the proximal 22 cm of the small intestine. This specificity seems to resemble that of other animals as well as humans.

After uptake from the intestinal tract, thiamine is distributed rapidly into the organs and tissues according to the requirements. In humans and animals, the heart contains the highest thiamine concentration (3–8 $\mu g\,g^{-1}$ fresh weight), followed by the kidney (2.4–6 $\mu g\,g^{-1}$ fresh weight), liver (2–7.5 $\mu g\,g^{-1}$ fresh weight), and brain (1.4–4.4 $\mu g\,g^{-1}$ fresh weight). Lesser amounts are found in other tissues. Whole blood contains 0.05–0.12 μg of thiamine per milliliter, about 90% of this being found in the corpuscular constituents. The total storage capacity of man is estimated to be 25–30 mg of thiamine, 40% of this being in the muscles. Interestingly, pig muscle has a relatively high thiamine content (8–12 $\mu g\,g^{-1}$) because of feeding conditions, higher than that in muscles of other mammals (1–2 $\mu g\,g^{-1}$) and pig liver (2–4 $\mu g\,g^{-1}$). The thiamine contents of several plant and animal foods are given in Table 1.

As with other water-soluble vitamins, thiamine excretion is dependent on intake. Within the physiological range, most of it is excreted by urine. Besides free thiamine and small amounts of TMP, numerous metabolites can be detected as minor excretion products such as thiazole, pyrimidine, and methylthiazol acetic acid.

After ingestion of therapeutic dosages, the amount of thiamine excreted via bile increases proportionally, as does the unabsorbed part in feces.

Lipid-Soluble Thiamine Derivatives

Under relatively mild conditions (e.g., in the gastrointestinal lumen), thiamine reacts with allicin, the active principle of garlic and onions, to form a lipid-soluble compound, called allithiamine, that is able to penetrate through membranes more easily than the water-soluble salts (Figure 3). Additional *S*-alkyl derivatives have been identified in cruciferous plants, and several lipid-soluble derivatives have been synthesized with a better stability than that of the spontaneously formed allithiamine (*S*-benzoyl- and *S*-tetrahydrofurfuryl analogs being the most important).

Oral administration of these lipid-soluble analogs results in higher thiamine blood levels than with equimolar thiamine doses, because the allithiamines from the gut lumen are preferentially absorbed by passive diffusion and rapidly converted to the active vitamin by reducing SH compounds. These allithiamines are, because of their improved bioavailability, suitable transfer substances with which to establish high thiamine levels in target tissues comparable with drug targeting. The elevated blood level results in an improved vitamin status, as measured by enzymatic criteria.

Table 1 Thiamine content of plant and animal foods (mg per 100 g fresh weight)

Content	*Foods*	
1.0–2.0	Whole wheat and rye	Plant foods
0.9	Para nuts	
0.7–0.8	Soy flour	
0.6–0.7	White bran	
0.3–0.5	Whole cereal products, lentils, oats, unpolished rice, lima beans, whole corn meal, cashew nuts, peanuts, hazelnuts, walnuts, mung beans	
0.1–0.2	Parboiled rice, sorghum, beans and peas cooked, cauliflower, potatoes, fennel, broccoli cooked, asparagus, soy sprouts, mushroom	
<0.1	Fruits, milk products, white flour products	
0.9	Loin pork	Animal foods
0.3–0.5	Liver, kidney (calves, beef, pork), duck	
0.1–0.2	Lean meat (calves, lamb, beef), eel, tuna, salmon, mackerel, plaice and flounder, oysters

Thiamine Antagonists

Synthetic Antivitamins

Like most of the B vitamins, thiamine has a rather high structural specificity, that is, minor modifications of the molecule lead to a decrease or a total loss of physiological activity or even to antagonistic effects. Of the numerous analogs synthesized so far, only the 2-ethyl- and the 2-*n*-propyl homologues in the pyrimidine moiety of the molecule show any biological activity comparable with that of thiamine. For example, when the 4-amino group is replaced by a hydroxyl function, oxythiamine, one of the most potent thiamine antagonists, is obtained. Another prominent antivitamin is pyrithiamine, which contains an ethylene group instead of sulfur in the thiazolium ring. Some thiamine antagonists have been found to exhibit antiprotozoal activity, as in the case of amprolium, which is effective as a prophylactic agent for coccidiosis of fowl. Some of the modified thiamine derivatives are shown in Figure 3.

The use of antagonists results in rapid and severe deficiency symptoms in humans and animals. Amprolium is already known to affect the absorption process already, and this has been suggested as the mechanism for its anticoccidial action in fowls. Other antivitamins appear to function at the coenzyme level, that is, they bind to the apoenzyme but inhibit the following enzymatic reaction. Nevertheless, there are several differences in the action on neurological symptoms. Only pyrithiamine (and not oxythiamine) can block the action potential of a single myelinated nerve fiber. It is also well known that only pyrithiamine produces polyneuritis. In addition, differences in neurophysiological action are caused by the different abilities of both antagonists to cross the blood–brain barrier, which has only been verified in the case of pyrithiamine. However, it can be shown that the amino group of the thiamine molecule is essential for the active transport of the vitamin from the rat small intestine and the formation of TPP.

Thiaminases and Other Antithiamine Factors

Two thiamine-cleaving enzymes have been identified, called thiaminase I and thiaminase II.

	R_1	R_2	R_3	X
Thiaminium ion	Methyl	Amino	Ethanol	Sulfur
Ethylthiamin	Ethyl	Amino	Ethanol	Sulfur
N-propythiamin	*N*-propyl	Amino	Ethanol	Sulfur
Oxythiamin	Methyl	Hydroxy	Ethanol	Sulfur
Pyrithiamin	Methyl	Amino	Ethanol	Ethene
Amprolium	*N*-propyl	Amino	Hydrogen	Ethene
Allithiamin	Methyl	Amino	Ethanol	*S*-alkyl (thiazol oxidatively splitted at C_2)

Figure 3 Thiamin derivatives and antagonists.

Thiaminase I is found in shellfish, clams (but not oysters), some freshwater fish viscera, crustacea, and certain ferns, but very few higher plants. Also, certain species of *Bacillus* and *Clostridium*, which are components of the human and animal intestinal flora, have been found to produce this enzyme. The enzyme catalyzes an exchange reaction, in which the thiazole moiety of the molecule is displaced by another N-containing base or a SH compound. The effect of this compound was first observed when silver foxes were fed with raw fish waste, resulting in a deleterious thiamine deficiency disease called Chastek paralysis. Thiaminase I may also be produced by the rumen microflora of ruminants or by plants and, in the presence of suitable cosubstrates, for example, niacin, and pyridoxine, and certain anthelmintics, seems to be responsible for the ruminant CNS disorder, polioencephalomalacia.

Thiaminase II is of bacterial origin (predominantly *Bacillus*, *Candida*, and *Oospora*) and breaks down the free vitamin, but not the TPP, into pyrimidine and thiazole components. More prevalent are thermostable thiamine-inactivating factors of plant origin, for example, polyphenolic substances such as flavonoids and catechol derivatives in fermented tea, ferns, sweet potatoes, and betel nuts and, in small quantities, in other leaves, fruits, and roots. These can decompose the thiazole component of the vitamin, accelerate the oxidation to the disulfide form, or form unabsorbable adducts with thiamine. Rats fed with food high in polyphenolics have been shown to develop deficiency symptoms as a result of a marked decrease in levels of cerebral thiamine and thiamine-dependent enzymes. Likewise in man, high tea consumption leads to a deficient thiamine status, but ascorbic acid, if present, completely inhibits the thiamine-inactivating processes.

Status Assessment

In terms of biochemical status, urinary vitamin excretion and blood enzymes are suitable criteria. Urinary thiamine excretion is, as with most B vitamins, largely dependent on intake and therefore provides an indication of the recent dietary intake but does not adequately reflect the body stores. At intake levels below 0.5 mg of thiamine per 1000 kcal day^{-1} (0.1 mg MJ^{-1}), thiamine excretion varies only slightly, and the proportion of metabolites in the urine exceeds the vitamin content itself. Because urinary excretion follows a diurnal rhythm, 24 h urine or the creatinine excreted is taken as the basis for status assessment. Occasionally, the status can be interpreted more accurately by a thiamine load test. After administration of a 5 mg dose, vitamin excretion is measured for the following 4 h. A deficient status can be assumed if less than 20 μg is excreted during this period.

Erythrocytic transketolase activity (ETKA), the rate-limiting enzyme in the pentose phosphate pathway, and its activation coefficient (AC) α_{ETK} are often used as an indication of functional status as they give a better idea of body stores than urinary excretion. According to the saturation deficit of the apoenzyme, the transketolase activity can be stimulated *in vitro* by the addition of TDP. The ratio of stimulated to basal activity, which increases with the degree of deficiency, indicated by the AC or α_{ETK}, is commonly taken as a prognostic status index. The AC is better as a comparison of status in groups, because of the large interindividual variation in basal enzyme activity. Moreover, it can be assumed that apoenzyme levels are not affected by the vitamin deficiency. Nevertheless, in alcoholics, either the apoenzyme synthesis or the linkage to the coenzyme TDP seems to be impaired, and the transketolase assay may indicate misleading results about the true status. Furthermore, confounding factors in the enzymatic assay, irrespective of the thiamine status, may include certain cancers, uremic neuropathy, diabetes, and treatment with certain anticancer drugs (fluorouracil and cytoxan) or diuretics, such as furosemide.

Recently, in view of improved high-performance liquid chromatography techniques, the TDP content in erythrocytes has been suggested to be a better indicator of the body stores

Table 2 Reference values of thiamine status parameters

Indicator	Adequate	Deficiency	
		Marginal	Severe
Thiamine excretion in urine (μg per gram of creatinine)	>66	27–66	<27
ETKA–AC	<1.15	1.15–1.25	>1.25
TDP content in erythrocytes (ng per milliliter of sediment)	>38.5	29.5–38.5	<29.5

Source: Finglas, P. M. (1994). Thiamin. *International Journal for Vitamin and Nutrition Research* **63**, 270–274; Frank, T., Bitsch, R., Maiwald, J. and Stein, G. (2000). High thiamine diphosphate concentrations in erythrocytes can be achieved in dialysis patients by oral administration of benfotiame. *European Journal of Clinical Pharmacology* **56**, 251–257.

compared with ETKA and independent of confounding factors. The criteria of the thiamine status indices are listed in Table 2.

Thiamine Requirement

Regarding the essential role of thiamine-dependent enzymes in carbohydrate and energy metabolism, the requirement for this vitamin is usually related to energy intake. Irrespective of the catalytic function of enzymes emerging basically unchanged from a biochemical or metabolic reaction, controlled studies in man have demonstrated that static and functional status criteria (transketolase activity and urinary excretion) deteriorate with increasing energy uptake even when the thiamine supply remains unchanged, thus indicating an increased vitamin turnover. The dependence on energy metabolism seems to be particularly evident in a marginal vitamin status.

Previously, dietary fat was postulated to have a 'sparing effect' on thiamine requirements. This effect is, however, comparatively small, even with major increases in fat in the diet. Furthermore, in a starvation or semistarvation status when the vitamin intake is zero and increasing amounts of fatty acids are metabolized to satisfy the body's energy needs, the tissue stores of thiamine are rapidly depleted.

International committees recommend safe levels of intake amounting to 100–130 μg of thiamine per megajoule, equivalent to 0.4–0.54 mg of B_1 per 1000 kcal. A critical intake point appears to be approximately 0.05 mg of B_1 per megajoule (0.2 mg per 1000 kcal), below which urinary excretion is low, and the first clinical signs of deficiency may appear. A minimum intake of 1 mg day^{-1} is recommended to provide an adequate margin, even for those consuming less than 8 MJ (2000 kcal) daily. The additional values for pregnancy and lactation mostly exceed the calculated additional requirement of pregnant and lactating women. These extra values ensure optimal pre- and postnatal development. In the past, clinical deficiency symptoms of infants were sporadically observed in spite of an inconspicuous appearance of the mother (infantile beriberi; see Table 4).

Owing to the low storage capacity, regular thiamine intake is important. Although, within the margin of physiological requirements, the organism attempts to prevent considerable thiamine losses by partial tubular reabsorption and intracellular fixation as TDP, the biological half-life time of this vitamin is assumed to be 9–18 days. After this period, when thiamine uptake is restricted, early nonspecific deficiency symptoms occur.

Table 3 National recommended daily allowances for vitamins

Country	B_1 (mg day^{-1})
Poland	1.9–2.0
Belgium, Denmark, Finland, France, Hungary, Luxembourg, Portugal, Spain	1.4
Greece, Norway	1.1–1.4
Czech Republic, Sweden	1.2
Austria, Germany, Ireland, Switzerland	1.0–1.3
The Netherlands, the United States	1.0–1.2
Italy, the United Kingdom	0.8–1.2

The recommended daily allowances for several European countries together with the US dietary reference intakes are listed in Table 3.

Deficiency Diseases

In thiamine deficiency, primarily, organs and tissues, such as the central and peripheral nervous system and the heart, are affected showing an increased energy turnover or close carbohydrate dependency. Clinical signs described in most animals refer to lesions in these tissues.

Since Eijkman's observations in fowls, the degeneration of the peripheral nerves was the first pathological symptom of thiamine deficiency noted in animals, leading to spastic pareses and paralysis of the legs. Later on, the role of thiamine in the central nervous system, especially in pyruvate metabolism of the brain, could be demonstrated, too.

Neurological signs are also characteristic of the deficiency state in human beings. The classical manifestation of deficiency can be seen in beriberi. This disease is endemic in several regions of East Asia. Depending on how far the disease has progressed and additional nutrients are involved (e.g., protein deficiency), it is characterized by either polyneuropathies and degenerative muscle wasting (dry or atrophic form) or cardiac arrhythmias and edema (wet or exudative form). The development of exudative beriberi predominates in cases of a high carbohydrate intake and increased physical activity. Protein deficiency is probably involved too. The Wernicke–Korsakoff syndrome, the cerebral form of deficiency, is characterized by mental confusion, memory disturbances, ataxia, ophthalmoplegia, and nystagmus. This syndrome can be interpreted as neuropathy of the central nervous system and is most commonly observed in malnourished alcoholics.

Table 4 Symptoms of clinical thiamine deficiency

Deficiency form	*Neurological signs*	*Cardiovascular signs*	*Other signs*	*Nutrient interactions*
Atrophic beriberi (dry or polyneuritic form)	Degenerative polyneuropathy of the lower extremities, paresthesia, reflex disorders, drop foot, muscle waste, convulsions			Caloric restriction, anorexia
Exudative beriberi (edematous or cardiovascular form)		Sinus tachycardia, cardiac arrhythmias, heart dilatation (beriberi heart), pericardial effusion, cardiac insufficiency	Lung and peripheral edemas, ascites, dyspnea, rarely lactic acidosis without edemas	High carbohydrate intake, protein deficiency, intense physical activity
Wernicke–Korsakoff syndrome (cerebral form)	Nystagmus, ophthalmoplegia, cerebellar ataxia, paralysis of the sixth brain nerve, polyneuropathy (burning feet syndrome), reflex disorders		Psychoses, hallucinations, memory loss, irritability	Alcohol abuse
Infantile beriberi (2–6 months)	Convulsions (increased intracranial pressure)	Tachycardia, cardiac insufficiency	Vomiting, diarrhea, abdominal distension, anorexia, cyanosis, dyspnea

The thiamine-dependent pyruvate dehydrogenase (PDH) and KDH complexes are key enzymes in the metabolic pathways of glucose and other energy-delivery substrates. The activities of both enzymes were found to play a rate-limiting role in mammalian brain mitochondrial preparations. Thus, lactic acid accumulation, as a result of the impaired glucose oxidation and disruption of oxidative phosphorylation utilizing pyruvate, α-ketoglutarate, and succinate as substrates, has been demonstrated in brain mitochondria from deficient rats. There is some evidence that localized lactic acid accumulation may contribute to the brain lesions in the Wernicke–Korsakoff syndrome. Furthermore, it is suggested that neurological symptoms may involve an impairment of the cholinergic neurotransmitter function. Acetylcholine and γ-aminobutyrate are primarily produced through the oxidative metabolism of glucose or via the citric acid cycle with acetyl coenzyme A (acetyl-CoA) and α-ketoglutarate as precursors. Although no change in regional brain acetylcholine levels was found in thiamine-deficient rats, acetylcholine utilization and turnover were reduced, and the central cholinergic mechanisms appear to be depressed in a deficient state. These alterations may be due to a decreased PDH and thereby activity limited acetyl-CoA production.

Infantile beriberi occurring in breast-fed infants between 2 and 6 months has particularly devastating consequences. Symptoms include cyanosis, dyspnea, tachycardia, abdominal distension, and convulsions. Sudden death often occurs as a result of cardiac failure. Nursing mothers, however, often do not show any signs of clinical deficiency. The thiamine deficiency symptoms are summarized in Table 4.

Therapeutic Administration and Toxicity

The importance of thiamine for the metabolism of the central and peripheral nervous systems, as is becoming clear from the deficiency symptoms, implicates its therapeutic application in all neurological system disorders. The recommended doses are 100–300 mg day^{-1}, often combined with pyridoxine and cobalamin. Because of the limited gastrointestinal absorption, the dose should be split up over the day. In progressive polyneuropathy and clinical beriberi, the same dosage may be initially administered i.m. or i.v., for a rapid tissue restoration, followed by oral therapy.

Lipid-soluble allithiamine derivatives can be given in smaller doses, because of the improved absorption. The passage of those derivatives across the blood–brain barrier is alleviated, too, as has been shown in animals. A significant improvement in the neuropathy score by oral application of the lipophilic benfotiamine has been observed in diabetic polyneuropathy patients as well.

As with other water-soluble vitamins, thiamin toxicity is very small when given orally, because of the limited absorption. In rare cases, with parenteral dosages above 100 mg, impaired sensations or even anaphylactic reactions have been observed, but it is not clear as to what extent additional components of the injection solution may interfere.

Thiamine-Dependent Enzymopathies

Thiamine-dependent enzymes are involved in four rare hereditary enzymopathies: leucinosis, Leigh syndrome, congenital lactacidosis, and thiamine-dependent megaloblastic anemia.

In leucinosis or maple syrup disease, the degradation of branched-chain amino acids is inhibited with following the accumulation of ketoanalogs. In the alleviated or intermittent form, this disorder can be improved by an intake of 10–150 mg of B_1 per day under simultaneous protein

Table 5 Congenital thiamine-responsive enzymopathies

Metabolic disorder	*Biochemical defect*	*Clinical symptoms*	*Therapy*
Leucinosis (maple syrup disease)	Keto acid dehydrogenase for the metabolism of branched-chain amino acids	Acidosis, ketosis, cerebral degeneration	Leucine-, isoleucine-, and valine-poor diet, thiamin (orally) 10–150 mg daily
Leigh syndrome (necrotizing encephalomyelopathy)	TTP formation, keto acid dehydrogenase	Lactacidosis, nystagmus, ataxia, convulsions, mental and psychic abnormal development	Thiamine (orally) 2.0 g daily (lipid-soluble derivatives)
Congenital lactacidoses	PDH	Lactacidosis, neurological symptoms, mental retardation	Thiamine lipid-soluble (?)
Thiamine-responsive megaloblastic anemia	Thiamine transport in tissue compartments	Megaloblastic anemia, diabetes, labyrinthine deafness	Thiamine (orally) 20–100 mg daily (lipid-soluble derivatives)

restriction. If untreated, severe neurological complications and physical and mental dysfunctions develop, followed by death.

Leigh syndrome is characterized by a necrotizing encephalomyelopathy and is also observed in ruminants. The exact biochemical defect is poorly understood but is thought to be a hereditary malfunction of TTP transferase, leading to impaired TTP formation, occasionally combined with a decrease in the amount of keto acid dehydrogenase. Neurological symptoms develop, progressing from nystagmus and paralysis of the external eye muscles to convulsions, ataxias, and disorientation resembling the Wernicke disease. Thiamine therapy may be successful, particularly when lipophilic derivatives (fursultiamine) are ingested up to gram dosages. Lactacidosis (which occurs at the same time) can be alleviated by oral intake of hydrogen carbonate combined with a low-carbohydrate diet.

The clinical picture of congenital lactacidosis resembles Leigh syndrome, and it is often impossible to distinguish between the two. The primary cause is a defect of the PDH or of partial enzymes of this complex. Generally, the prognosis is deleterious. The lactacidosis and the concomitant neurological symptoms could only in rare cases be affected by therapeutic thiamine doses.

Thiamine-responsive megaloblastic anemia has until now been very rare. The characteristic symptoms are a very strange combination of anemia, labyrinthine deafness, and insulin-dependent diabetes. The anemia can be improved only by oral doses of 20–100 mg of thiamine. Folate and vitamin B_{12} administration is ineffective. In one case, the diabetes was improved, and insulin therapy was no longer needed.

The primary metabolic defect is unclear. Thiamine-dependent enzymes remain unchanged, and there may be an impairment in thiamine transport in certain tissues. The enzymopathies are summarized in **Table 5**.

Thiamin: Properties and Determination

MV Chandra-Hioe, J Arcot, and MP Bucknall, The University of New South Wales, Sydney, NSW, Australia

Introduction

Thiamine, also known previously as aneurin or antineuritic factor, is a water-soluble B vitamin, designated B_1. Many human biochemical pathways require thiamine, and this has to come from diet, because humans do not synthesize thiamine. Food rich in thiamine can be sourced from legumes, whole grain cereals, vegetables, meat, milk, and dairy produce. The richest sources are yeasts (e.g., dried brewer's and baker's yeasts), liver (especially pork liver), and pork meat. In plant-based foods, thiamine predominantly occurs in the free form, while in animal-based foods, it is bound to proteins.

Chemically, thiamine is composed of a pyrimidine (2-methyl-4-amino-pyrimidine) moiety and a thiazole (5-(2-hydroxyethyl)-4-methylthiazolium) that are linked by a methylene bridge. The pyrimidine ring has an amino group on C_4 and the thiazole ring contains quaternary nitrogen, which confers free thiamine its instability. Cline and Williams first studied the chemical structure of thiamine in 1936, and they subsequently identified the pyrimidine moiety. The structure was eventually confirmed through synthesis of thiamine hydrochloride, thereby also pioneering the large-scale production of thiamine. The chemical structures of thiamine and its phosphorylated vitamers are shown in Figure 1.

Thiamine occurs in the free form and as an array of interconvertible phosphorylated vitamers, such as thiamine monophosphate (TMP), thiamine diphosphate (also called pyrophosphate, TDP), and thiamine triphosphate (TTP). Adults store approximately 30 mg thiamine that is mainly found in the liver, kidneys, brain, heart, and skeletal muscle. The predominant vitamer (80%) is thiamine diphosphate, which is also biologically active.

Thiamine is an enzyme cofactor, involved in the metabolism of carbohydrate and the branched-chain amino acids (leucine, valine, and isoleucine). It also plays an important role in defense mechanisms, and thiamine triphosphate is essential for neural function. According to the dietary reference intake levels set by the US Institute of Medicine, the recommended dietary allowance for thiamine is 1.0 mg day^{-1} for women (19–50 years) and 0.9 mg day^{-1} for men (19–50 years). The recommended daily intake of thiamine in Australia is 1.2 mg day^{-1} for males aged 19 years and over and 1.1 mg day^{-1} for females. Thiamine deficiency, in its early stages, produces nonspecific symptoms that may be overlooked or easily misinterpreted. As it progresses, the deficiency presents as beri-beri, a disease historically prevalent in countries where polished rice is the staple food. Milling yields rice endosperm with low thiamine content, because the thiamine-rich bran is removed. The clinical symptoms of beri-beri include anorexia, apathy, confusion, irritability, muscle weakness, and cardiovascular effects. Edema develops in wet beri-beri, while dry beri-beri is characterized by muscle wasting. In industrialized countries, thiamine deficiency is associated with chronic alcoholism, which affects the central nervous system, collectively presented as the Wernicke–Korsakoff syndrome. Inadequate dietary intake of thiamine has caused governments to implement public nutrition interventions, such as education, dietary supplementation, and food fortification. Upper limits for thiamine intake are not currently specified, because there have been no reports of adverse effects during pharmaceutical trials where thiamine was administered at high doses.

Properties

In food, thiamine is sensitive to pH. The vitamin is stable between pH 2.0 and 4.0, but not stable under alkaline, slightly alkaline, or strongly acidic conditions. The pyrimidine moiety is more inert than the thiazole. According to Bettendorff, at pH <4, the N-1′ of the pyrimidine ring is protonated, but the N-3′ is only protonated in the presence of concentrated sulfuric acid. In alkaline solutions between pH 8 and 10, the hydroxyl group attaches to C-2′ of the thiazole ring and leads to formation of the so-called 'yellow form' degradation product. Consequently, loss of thiamine occurs during commercial cooking of peas or beans, when sodium bicarbonate is added in order to preserve their color. According to Combs, instability due to the presence of sulfites can also occur. Sulfites react with thiamine to cleave the methylene bridge linking the pyrimidine and thiazole ring; this reaction is slow at high pH but is rapid under neutral and acidic conditions. Sodium disulfite ($Na_2S_2O_5$) and sodium bisulfite ($NaHSO_3$) are widely used food preservatives, and these may be responsible for thiamine degradation in aqueous solution during storage, even at low temperature. Free thiamine is easily oxidized to thiamine disulfide and other derivatives including thiochrome (Figure 2), which is fluorescent and thereby useful for detection and quantitative analysis.

Thiamine is also sensitive to high temperature and UV radiation. Loss of thiamine occurs during domestic and commercial food preparation through leaching of the vitamin into water. Prolonged cooking in vigorously boiling water increases the thermal degradation of thiamine as more oxygen is available and stays in contact with the food. Degradation losses of thiamine vary depending on cooking methods; boiling of vegetables causes a 14–66% thiamine loss, pressure cooking 14–35%, and steaming 11–27%. According to Kimura, boiling of pork meat results in 70% thiamine loss, steaming 40%, parching 35%, and frying 30%. Roasted and deep-fried chicken shows a higher thiamine loss in comparison with braising and microwave cooking. Thermal degradation of thiamine also releases sulfur-containing volatiles, such as 4,5-dihydro-2-methyl-3-furanthiol and 5-(2-hydroxyethyl)-4-methylthiazole.

Whole grain cereals are good sources of thiamine. In wheat, the germ contains around 64% of the total thiamine, the bran 33%, and the endosperm 3%. However, the germ and the bran are removed during milling, which yields flour low in thiamine. During bread making, up to 56% of total thiamine is lost due to baking (compared with the wheat flour from which it was

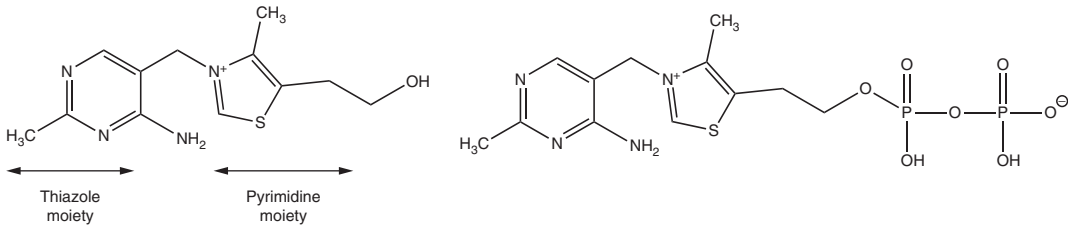

Figure 1 (Left) Free thiamine consists of pyrimidine and thiazole moieties and (right) exists predominantly as thiamine diphosphate.

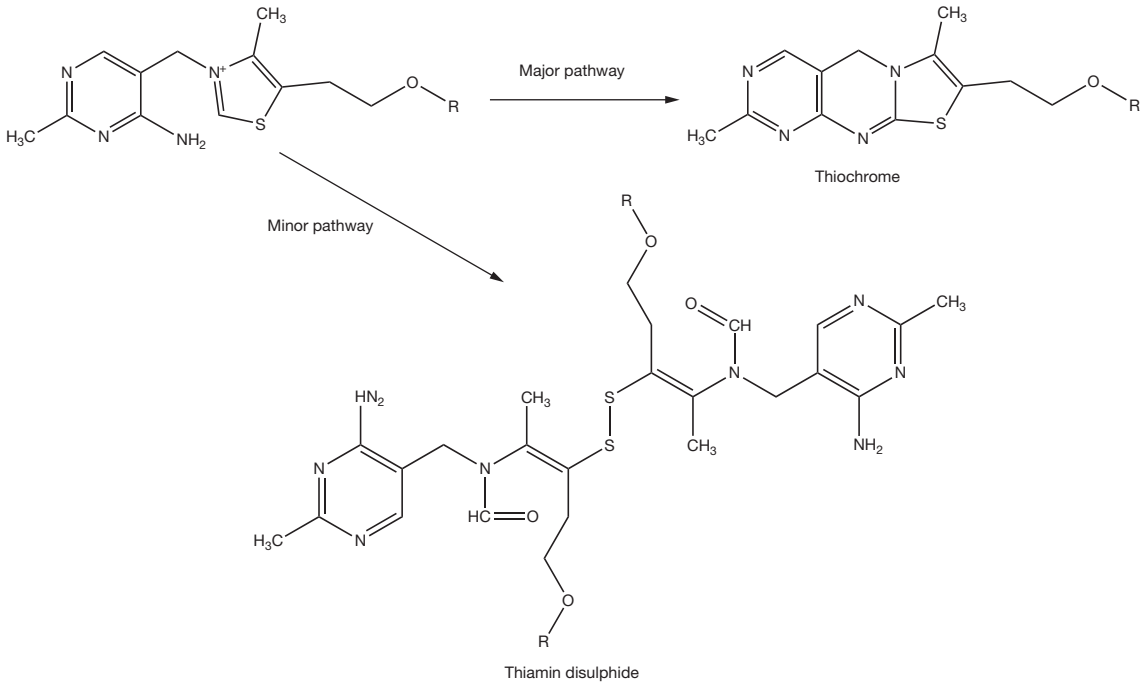

Figure 2 Oxidation of thiamine to fluorescent thiochrome (major pathway) and thiamine disulfide (minor pathway).

made). Extended fermentation during the making of rye sourdough bread also showed a 20–45% thiamine loss.

Anti-thiamine Factors

Several naturally occurring compounds such as o- and p-hydroxy phenols/polyphenols (e.g., caffeic acid, chlorogenic acid, and tannic acid) in ferns, tea, and betel nut behave as thiamine antagonists. Reaction of some phenols/polyphenols with thiamine oxidizes the thiazole ring yielding the non-absorbable (non-fluorescent) thiamine disulfide. Another anti-thiamine factor is the enzyme thiaminase, which is present in microorganisms, ferns, shellfish, and fish. Thiaminase breaks down thiamine by displacing the pyrimidine methylene group with a nitrogenous base or SH compound, thus eliminating the thiazole moiety. Consuming food containing thiaminase, without cooking, consequently leads to thiamine deficiency.

Quantitative Determination of Thiamine Vitamers in Food

To date, several techniques have been used for the identification and quantitative analysis of thiamine vitamers, each with advantages and constraints. High-performance liquid chromatography (HPLC) is the most reported method and is employed for the determination of thiamine and its speciation in various food matrices, dietary supplements, and biological fluids. Advances in mass spectrometry have produced studies, which exploit this technique for thiamine quantitation. Other analytical techniques that have been documented include colorimetric, fluorometric, spectrophotometric, and titrimetric techniques; capillary electrophoresis; microbiological assay; and gas chromatography. The Association of Official Analytical Chemists (AOAC) uses a thiamine assay based on fluorometry that measures thiochrome (AOAC 15th edition 1990, 18th edition 2005), first actioned in 1942. For the purpose of identification and quantitation, thiamine has to be extracted and released from food matrices. This involves sample preparation, which plays an indispensable role in any vitamin analysis.

Extraction of Thiamine

Thiamine in food is bound to protein and occurs naturally in the free form and phosphorylated forms. The initial step prior to any analysis is sample preparation in order to isolate and release thiamine from its binding proteins. Hot acid releases

thiamine from protein and enzymatic treatment(s) may be used to dephosphorylate the vitamers where the objective is measurement of total thiamine rather than speciated quantitation. In plant-based food, acid treatment also hydrolyzes the glycosides. According to the AOAC (Official Method 957.17), thiamine extraction involves hot acid digestion (0.1 M hydrochloric acid) at 95–100 °C for 30 min or autoclaving samples with 0.1 M hydrochloric acid at 121 °C for 30 min. There has been little agreement on the choice of acids; the use of 0.1 M hydrochloric acid, trichloroacetic acid, and sulfuric acid is reported in the literature. Trichloroacetic acid treatment has been suggested to retain the phosphorylated thiamine vitamers, allowing free thiamine to be measured separately from the other vitamers. Digestion of cereal-based food with only 0.1 M hydrochloric acid at 100 °C for 30 min is problematic due to starch gelatinization that prevents the release of thiamine from the food matrix. This potentially leads to inaccurate quantitation of thiamine. Hot acid hydrolysis alone is not sufficient to release protein-bound thiamine from samples of flour, yeast, and pork and needs to be followed by diastase treatment.

Literature has emerged that shows contradictory findings on enzymatic digestion for thiamine extraction. Diastases, such as taka-diastase and clara-diastase, exhibit amylase, protease, and phosphatase activities. Treatment of samples with diastase is performed to measure free thiamine, as its protease function releases thiamine from its binding proteins, amylase hydrolyses starch, and phosphatase digests the phosphate ester. It is suggested that diastase alone is sufficient to extract thiamine from food matrices, and treatment with multiple enzymes (α-amylase, potato acid phosphatase and papain protease) is not necessary. A combination of diastase and acid digestion at 100 °C was shown to be less effective for the extraction of endogenous thiamine, in comparison with treatment with diastase and protease. Extraction of thiamine from yeast, baby food, and cereals shows a high recovery using a combination of taka-diastase and β-amylase after hydrolysis with 0.1 M hydrochloric acid. Digestion with multiple enzymes consisting of papain, amylase, and phosphatase has also been reported for thiamine extraction. The optimized length of enzymatic treatment ranges from 4 to 18 h. Addition of sodium 1-octanesulfonate, during sample processing, produces much cleaner extracts. Sodium 1-octanesulfonate forms an ion pair complex with tetra-ammonium ion and other amino groups found in dried yeast during thiamine extraction, thus minimizing matrix interferences during chromatographic separation. To reduce the incubation time, enzymatic digestion (amylase, papain, and phosphatase) may be performed in an ultrasonic bath for 1 h. Jakobsen compared this approach with taka-diastase digestion at 45 °C for 18 h and found that mean thiamine was not significantly different ($p > 0.05$). The author concluded that varying types of enzymes, pH, and duration of ultrasonication affect the thiamine release causing significant differences in measured thiamine. The AOAC recommends processing of food samples with either taka-diastase or α-amylase treatment (pH 4.0–4.5) at 45–50 °C for 3 h after acid hydrolysis.

Extraction of thiamine from dietary supplements is a simpler and less time-consuming routine due to the high concentrations of synthetic thiamine. Powdered tablets are dissolved in nitric acid (HNO_3) and filtered before oxidation to thiochrome. Milli-Q water is also suitable to dissolve the homogenized powdered tablets followed by centrifugation and filtration. Determination of vitamins in food is often reputed to be lengthy and complex; nonetheless, simple and rapid extractions have been documented. Heat sonication of defatted raw almonds has been reported to simultaneously extract water-soluble vitamins, including thiamine. Non-enzymatic extraction using only 40% methanol (v/v) in 0.1 M aqueous hydrochloric acid was used to measure thiamine in polished rice. The recoveries were 94–101% with incubation at 60 °C for 30 minutes, suggesting that the extraction of thiamine in methanol–hydrochloric acid solution is efficient.

Oxidation of Thiamine

Converting thiamine to thiochrome in the presence of an oxidizing agent is only a prerequisite for fluorometric detection. Oxidation of thiamine in an alkaline solution of potassium ferricyanide (potassium hexacyanoferrate (III) ($K_3Fe(CN)_6$) was first described by Barger et al. in 1935, although the structure was not confirmed (Cline and Williams) until 1936–37. In this study, they found that thiamine hydrochloride was transformed to thiochrome, a pale yellow compound containing sulfur that has an intense blue fluorescence. More recently (2007), hydrogen peroxide derived from horseradish peroxidase was shown to be able to oxidize thiamine to thiochrome and was used prior to fluorometric spectrophotometry.

Solid-Phase Extraction

According to the AOAC method (AOAC 14th edition, 15th edition, 16th edition, 17th edition, and 18th edition), thiochrome is purified using a reusable weak cation exchange column (Bio-Rex 70, Bio-Rad Laboratories) and a weak acidic potassium chloride elution buffer. Afterwards, thiochrome is extracted into isobutanol (2-methyl-1-propanol), prior to fluorometric determination. Solid-phase extraction (SPE) using a Bio-Rex 70 column is an inefficient process in comparison with a reusable reversed-phase C_{18} column. The packing material in a Bio-Rex 70 column needs to be treated and repacked for reuse, unlike the C_{18} column, which can be washed free of sample matrix contaminants. Thiochrome has also been successfully recovered from a C_{18} column, when the elution buffer contains 30% methanol. This suggests that extraction of thiochrome from a potassium chloride elution buffer into isobutanol is no longer essential. The disadvantage of using the reusable cation exchange or the C_{18} column is that the column has to be regenerated and re-equilibrated after each use. In more recent times, disposable SPE columns in the form of cartridges have become commercially available in many different sorbent types. These are usually employed to selectively concentrate thiamine and simultaneously remove sample matrix components from extracts. Ollilainen et al. used radioisotope-labeled (^{14}C) thiamine to assess recovery during sample preparation and found that loss of ^{14}C-labeled thiochrome occurred during oxidation to thiochrome and SPE. The results showed that loading of samples onto SPE columns led to a 14% loss, and using the commercially available C_{18} sorbent,

the extraction efficiency was 85%, which was higher than using phenyl and cyanopropyl sorbents. Surveying the literature reveals little agreement about the merits of performing SPE in the context of thiamine determination. Some researchers perform filtration instead of SPE prior to HPLC analysis.

There are many factors that may influence the extraction of thiamine from food matrices including pH, added amount of enzyme, temperature, and duration of enzymatic incubation. Other considerations, including the length of the thiamine extraction protocol, analysis time, and maximum signal intensities, are also relevant in quantitation. Extraction efficiency is matrix-dependent and needs to be experimentally optimized for each food matrix in order to maintain assay sensitivity across food groups.

Microbiological Assay

In microbiological assay, thiamine is determined based on the growth response of thiamine-dependent microorganisms. Bacteria, such as *Lactobacillus viridescens* or *Lactobacillus fermentum*, are inoculated into the food extracts. After several hours of incubation, the turbidity corresponding to the growth of bacteria is measured using a spectrophotometer at 660 nm. Microbiological assay is useful for measuring total thiamine contents in food, but it has its drawbacks. The composition of thiamine vitamers in food is not ascertainable from bacterial inhibition, because the bacterial growth response does not differentiate between vitamers. Generally, thiamine concentrations determined using microbiological assay are higher than using fluorometry or HPLC.

Fluorometric Assay

Fluorometric spectrophotometry has been the AOAC recommended technique to determine thiamine since 1960. The intensities of thiochrome are proportional to the amount of thiamine present when determined at 365 nm of excitation wavelength and 425 nm of emission wavelength. Thiamine concentrations are then calculated using an external standard calibration to yield measurements of total thiamine.

High-Pressure Liquid Chromatography

HPLC is a separation technique utilizing the differential interaction of analytes with the stationary phase and mobile phase. Chromatographic separation of thiamine vitamers allows free thiamine and individual phosphorylated thiamine forms to be identified and quantified. Using HPLC, it is possible to simultaneously separate all vitamins from the B complex, and this is useful for measuring multivitamins in dietary supplements. Vitamin B complex in various food matrices can also be simultaneously analyzed. Due to varying physicochemical properties and stability of vitamins in food, different extraction protocols have to be performed for some vitamins.

HPLC thiamine analysis is based on ion pair chromatography, a type of reversed-phase chromatography, used for the separation and determination of ionic species. The mobile phase consists of aqueous buffer containing both organic solvent and counterions. As a counter ion combines with thiamine or thiochrome to form a neutral ion pair, this is then retained on a reversed-phase column. Mobile-phase systems suitable for reversed-phased columns include methanol, hexanesulfonate, and/or octanesulfonate. Normal-phase columns, as well as phenyl columns, have also been employed for thiamine analysis, even though they are not widely used.

HPLC can be interfaced with several modes of detection, for example, ultraviolet (UV), UV–Vis (diode array), fluorescence, Fourier transform infrared (FTIR), and electrospray mass spectrometry. Thiamine is detected and identified based on retention time, the wavelength at maximum absorption (UV), UV–Vis spectrum (diode array), and excitation/emission wavelengths (fluorescence). UV detection is useful for measuring high levels of thiamine in fortified food and dietary supplements. Fluorescence detection is suitable for detecting low concentrations of naturally occurring thiamine, as it offers better sensitivity than UV detectors. For fluorometric detection, thiamine is oxidized to fluorescent thiochrome either precolumn or (online) postcolumn.

Pre- and postcolumn oxidation of thiamine

Van de Weerdhof et al. pioneered the use of a fluorescence detector to determine thiochrome after a postcolumn oxidation with potassium hexacyanoferrate [$K_3Fe(CN)_6$]. The composition of the mobile phase was 0.1 M phosphate buffer (pH 6.8) and 10% methanol. Adding methanol as organic modifier in the mobile phase generally increased the formation of thiochrome and produced higher signal intensities. The signal's reproducibility improved with the addition of 12% methanol, while more than 12% methanol led to asymmetrical peaks. A mobile-phase system with pH $>$ 4.0 retained (postcolumn oxidized) thiochrome longer, in contrast to pH between 2.0 and 3.0. A postcolumn oxidation thiamine metabolite, 2-(1-hydroxyethyl)thiamine, was first identified by Ujiie et al., in fish and meat, during 1990. This metabolite is otherwise quantitatively analyzed as thiamine when precolumn oxidation is performed. Animal-based food contains 7–24% 2-(1-hydroxyethyl)thiamine, and in yeast, it makes up 37% of total thiamine. With the widespread use of reversed-phase columns, thiamine oxidation is performed precolumn rather than postcolumn, as it improves the sensitivity. The limitation of precolumn derivatization is that thiochrome has to be analyzed immediately to minimize degradation (due to its inherent instability).

Oxidizing agents for fluorometric detection

Besides potassium hexacyanoferrate ($K_3Fe(CN)_6$), mercuric chloride ($HgCl_2$), copper (II), cyanogen bromide (BrCN), and cobalt (II) have been used as oxidizing agents for fluorometric detection. In fact, thiamine is not stable in the presence of ferrous and cupric salts, thus necessitating the addition of a metal chelation agent to minimize thiamine degradation. Oxidation of thiamine in the presence of potassium hexacyanoferrate yields only 67% thiochrome formation. Fluorescence intensities depend on the pH and the stability of thiochrome. High peak intensities were detected when thiamine was oxidized at pH 7 rather than pH 6, while increasing the pH to 13 reduced the peak intensities. Mercuric chloride ($HgCl_2$) might be an alternative, producing higher fluorescence intensities than potassium hexacyanoferrate; yet, as an oxidizing agent, it is not stable. Oxidation of thiamine leads also to the

formation of non-fluorescent thiamine disulfide as a by-product. The oxidation conditions influence the relative amounts of thiochrome and thiamine disulfide formed. The ratio of thiochrome to thiamine disulfide depends on the pH, type of solvents, and oxidizing agents. Sulfites dissociate the pyrimidine and the thiazole rings causing thiamine degradation, which in turn affects the yield of thiochrome formation.

Liquid Chromatography–Mass Spectrometry

Electrospray (ESI) and atmospheric pressure chemical ionization (APCI) mass spectrometers are often interfaced to liquid chromatographs (HPLC-MS) as 'molecular weight-selective' detectors. In actuality, these systems ionize the compounds eluting from the HPLC by protonation, and the mass-to-charge ratio (m/z) of these 'pseudomolecular ions,' for example, $[M+H]^+$, is measured. It should be noted that these singly charged ions have an m/z ratio that is 1 Da higher than the molecular weight. Quantitation is based on the signal intensity of the individual ion for each analyte. Compounds with chromatographically overlapping peaks are easily distinguished if they have differing molecular weights. They can therefore be independently quantified. Hence, MS detection can offer more specificity than is possible using UV or fluorescence. Ions for all thiamine vitamers entering the MS can be selectively identified and quantified without prior chemical modification. Yamanaka et al. successfully determined thiamine levels in dried yeast using APCI-MS for detection. The thiamine pseudomolecular ion was monitored at m/z 265, along with the structurally related fragment ions (M-CH_2OH) and (M-H_20) at m/z 234 and m/z 247, respectively. APCI is a soft ionization technique that involves the transfer of charges from aerosols within a high electric field. Limited fragmentation of analyte molecules sometimes occurs during the spray ionization process, but the dominant species generated is normally the pseudomolecular ion.

Tandem mass spectrometers (MS/MS) are used as even more specific detectors in HPLC vitamin analysis. MS/MS instruments contain two mass-to-charge ratio analyzers, separated by a collision region where pseudomolecular ions can be deliberately fragmented by energetic interactions with an inert gas. The first analyzer is used as a mass filter to transmit only the selected pseudomolecular ion. This is then fragmented in the collision region, and the second mass analyzer is employed to monitor the fragments generated. When a single pseudomolecular ion and fragment pair are continuously monitored, this is called selected reaction monitoring (SRM). This mode of operation yields the most selective form of detection currently possible, as detected compounds must have a specific molecular weight and form a specific fragment upon dissociation. This selective and highly sensitive technique can be used to quantify trace-level target vitamers in complex matrices, free of interference from co-eluting molecules with similar molecular weights. The most frequently monitored thiamine fragments are m/z 144 (pyrimidine derived) and m/z 122 (thiazole derived), following the cleavage of the methylene bridge during collision-induced dissociation. The sensitivity of tandem MS/MS is also enhanced in SRM mode compared to scanning mode, because the mass analyzers are dedicated to only monitor thiamine-related m/z values and do not spend large parts of their duty cycle scanning m/z values, which are not relevant to thiamine. Positive-ion ESI and SRM mode were used for simultaneous determination of water-soluble vitamin B in pasta and in dietary supplements for regulatory purposes. Riboflavin, niacin, and pyridoxine were extracted from pasta simultaneously with thiamine, while folic acid and pantothenic acid needed to be extracted separately. The accuracy and precision of quantitative analysis using MS/MS are improved by adding known concentrations of stable isotope-labeled internal standards at the start of sample processing. These compounds are 'heavy' thiamine vitamers with molecular weights increased by inclusion of ^{13}C, ^{15}N, or ^{2}H into their structures during synthesis. The exercise then becomes one of relative quantification, dramatically reducing the impact of preparative losses and instrument variables.

Other Analytical Techniques

Thin layer chromatography finds its application for simultaneous separation of thiamine, riboflavin, and niacin. Thiochrome is detected using luminescence, and the method obviates the extraction of thiochrome into isobutanol.

FTIR spectrophotometry interfaced with HPLC was tested for its utility for determination of thiamine, riboflavin, pantothenic acid, and pyridoxine by Li and Brown in 2003. The reproducibility of the method, expressed as a coefficient of variation for thiamine standard solutions, was 6.7% and lower than that obtained using a UV detector.

A method employing capillary zone electrophoresis, coupled with UV detection, was developed and validated for simultaneous determination of thiamine and other water-soluble vitamins in dietary supplements. The separation in this technique is based on the electrophoretic mobility of solvated ions in an electric field. A more recent study showed that the sensitivity of UV detection at 214 nm (default setting) was not sufficient for thiamine quantitation in fortified energy drinks.

Gas chromatography (GC) is a common technique used to separate analytes in the gas phase and requires samples to be volatile. Chemical modification of analytes, to impart volatility prior to analysis, is a common practice for the analysis of biologically relevant molecules with this technique. Partitioning of the analytes occurs as vaporized samples and the inert carrier gas pass through the column. This is a long fused silica capillary tube coated on its inner surface with analyte-retentive polymers. Echols et al. employed a GC equipped with a nitrogen–phosphorus detector for quantitation of thiamine in cereals, meat, and vegetables, because the sensitivity of the more standard flame ionization detector was found to be inadequate for measuring endogenous thiamine in samples. Thiamine could only be detected by GC in the 4-methyl-5-(2-hydroxyethyl)thiazole form, and this approach is therefore of limited utility.

Tocopherols: Physiology and Health Effects

R Järvinen and AT Erkkilä, University of Eastern Finland, Kuopio, Finland

Introduction

Tocopherols and tocotrienols comprise eight structurally related lipid-soluble compounds synthesized by plants and are widely distributed in vegetable oils and foods. They all behave as lipophilic antioxidants and have been associated with other biological functions in the body mainly revealed in cell studies and animal experiments. Importance of tocopherols for animal life was discovered nearly a hundred years ago when scientists Evans and Bishop reported in 1922 that reproductive failure of female rats kept on a diet containing rancid fat could be restored by the administration of fresh green lettuce or ground whole wheat. In sequence to other newly discovered vitamins, this factor was named vitamin E.

The significance of vitamin E as an essential nutrient has been demonstrated widely in different animal species including rodents, cattle, chicken, fish, and primates. Specific deficiency symptoms in different animal species are variable and include encephalopathy in chickens and muscular dystrophy in swine and cows. In humans, deficiency of vitamin E is very rare; typical neurological disorders are discovered only in individuals who suffer from inadequate fat absorption for any reason or who bear a genetic defect in α-tocopherol transport protein.

The term vitamin E used traditionally covered all tocopherols and tocotrienols, and vitamin E activity has been assessed as α-tocopherol equivalents. Besides α-tocopherol, these equivalents include small amounts of vitamin activity estimated to be provided by other tocopherols and tocotrienols. In 2000, the Food and Nutrition Board, Institute of Medicine, in the United States, considered only α-tocopherol an essential nutrient for humans. Nevertheless, the term vitamin E continues to be used as a generic term for different tocopherol homologues. In this article, the name vitamin E is reserved to α-tocopherol.

Of eight tocopherols and tocotrienols that appear naturally in foods, α-tocopherol is nutritionally the most important, and thus far, the majority of studies on their physiology and health effects are about α-tocopherol.

Dietary Sources

Vegetable oils, vegetable oil-based spreads, nuts, and seeds are good sources of tocopherols. Sunflower oil contains high amount of α-tocopherol, followed by corn, rapeseed, olive, and soybean oils. However, γ-tocopherol is the major tocopherol in corn, soybean, and rapeseed oils. Soybean oil provides also moderately δ-tocopherol. Besides α-tocopherol, palm oil contains also tocotrienols. Through use in food preparation, dietary fats affect importantly the tocopherols of mixed dishes and their contribution to the dietary intake of tocopherols. Only small amounts of α-tocopherol are detected in habitually consumed natural foods (cereals, fresh vegetables, and fruits and berries) and in animal products (meat, milk, butter, eggs, and fish), transferred from the feeds of animals. Despite low α-tocopherol concentrations, these foods make a notable contribution to the vitamin E intake due to their consumed amounts. Tiny amounts of other tocopherols and tocotrienols are also detected in several natural foods.

In order to improve nutritive value of foods, α-tocopherol can be added to foods. Synthetic vitamin E habitually used in food fortification and supplements is an equal mixture of eight stereoisomers of α-tocopherol, whereas tocopherols and tocotrienols appearing naturally in foods are free RRR-stereoisomers. In preparations, both synthetic and natural α-tocopherols are esterified in order to increase their stability.

Tocopherol Intake

Data of tocopherol intake are nearly totally limited to vitamin E. Most available nutrient databases do not present values for all tocopherols, and they often report vitamin E as α-tocopherol equivalents (α-TEs). It has been calculated that in diets typical for the United States and Canada, approximately 80% of total α-TEs from foods are contributed by α-tocopherol.

In developed countries, average dietary intakes of vitamin E range between 6 and 16 mg day^{-1}. Marked differences between countries not only are due to the types of oil consumed but also are affected by other dietary habits and may depend on the dietary survey method used and accuracy of food composition tables. In Europe where sunflower, olive, and rapeseed oils are habitually consumed, vitamin E intake is generally higher than in the United States where soybean oil dominates. Among the participants of the NHANES study in 2003–06, mean daily intake of vitamin E from diet of individuals aged 19 years and older was approximately 8 mg in men and 6 mg in women. Variable but somewhat higher intakes of vitamin E are reported in European populations. Mean daily intake of vitamin E from diet in eight European countries ranged from 8 to 16 mg in men and from 7 to 11 mg in women.

Use of vitamin E supplements can increase total vitamin intake greatly. Approximately one-third of men and 40% of women of the NHANES 2003–06 participants reported the use of supplemental vitamin E and their total vitamin intake was 10–20 times that of the supplement nonusers. In Europe, the use of vitamin supplements differs greatly between countries but is generally less common than in the United States. The effect of food fortification on average vitamin E intake is relatively small although certain fortified foods appear high in the ranking of foods by vitamin E content.

No representative dietary intake data of non-α-tocopherols and tocotrienols are available. In the United States, γ-tocopherol is the major tocopherol with estimated intakes exceeding that of α-tocopherol by a factor of 2–4. In Europe, γ-tocopherol intake is clearly lower but variable between countries predicted from the patterns of vegetable oil consumption. Based on few studies

from the United States and Finland, average daily intakes of other tocopherols and tocotrienols are very low ranging from <0.1 to 2–3 mg.

Physiology

Absorption

In foods, tocopherols are associated with lipid structures, and their absorption, transport, and tissue delivery are closely related with overall lipid and lipoprotein metabolism. The presence of bile salts, pancreatic enzymes, and formation of micelles are necessities for their absorption. Esterified forms used in supplements need to be hydrolyzed before absorption. Protein transporters involved in cholesterol absorption also facilitate the intestinal uptake of α-tocopherol. All forms of tocopherols and tocotrienols are taken up by intestinal cells (Table 1), and shortly after intake, they appear in the circulation in concentration reflecting their ingested amounts.

The presence of dietary fat and food matrix appear key factors in α-tocopherol absorption, and vitamin E supplements should be taken at meals. Without fat, approximately 10% of a single dose of naturally labeled α-tocopherol impregnated in fresh apples was absorbed; from a meal with 11 g fat, absorption of α-tocopherol was 33%. Uptake of vitamin E into circulation from supplements taken alone or with a low-fat meal is marginal. However, knowledge of the efficiency of vitamin E absorption is incomplete. The values for α-tocopherol absorption in healthy adults have been greatly variable ranging between 30% and 80% in experiments carried out by various techniques with different doses of α-tocopherol supplied in meals of variable composition. Large individual differences in the absorption of α-tocopherol indicate that there are important, probably genetically determined factors, which affect the uptake of vitamin E in humans.

Transport

Tocopherols and tocotrienols embedded in chylomicrons are transported mainly via lymph to circulation, though they may also be bound to high density lipoprotein (HDL) and excreted directly into portal circulation. In the circulation, chylomicrons are hydrolyzed by the lipoprotein lipase, and tocopherols are transferred to other lipoproteins and peripheral tissues. Chylomicron remnants are taken up by the liver, and at this stage, no discrimination appears between different tocopherols. However, in the liver, α-tocopherol transport protein (α-TTP) preferentially binds α-tocopherol, which controls the intracellular trafficking of α-tocopherol and is necessary for the transport of the vitamin to the plasma membrane before excretion from the liver. When secreted from the liver, α-tocopherol is associated with very low density lipoprotein (VLDL) in plasma, but uptake by HDL is also possible. The transfer through membranes to circulation is assisted by membrane proteins.

In the plasma, vitamin E is transported nonspecifically by all lipoproteins, and there is continuous exchange of α-tocopherol between different lipoprotein fractions assisted by human plasma phospholipid transfer protein. In fasting, plasma α-tocopherol is mainly bound to low density lipoprotein (LDL) and HDL. Delivery from the circulation to tissues can take place by various mechanisms that are available for lipoproteins.

α-TTP has central role in the distribution of α-tocopherol within the body. It regulates the fate of vitamin E and other tocopherols in the liver. Compared to α-tocopherol, the relative affinity of α-TTP for β-, γ-, and δ-tocopherols and α-tocotrienol was *in vitro* 38%, 9%, 2%, and 12%, respectively. α-TTP is also detected in other vital tissues such as the placenta and the brain. The major importance of α-TTP is verified by human vitamin E deficiency disease, which is caused by rare mutations in the α-TTP coding gene. In addition, other α-tocopherol-binding proteins, which may also bind other tocopherols, tocotrienols, and other ligands, have been detected in cells. Several different membrane proteins that are linked with absorption, uptake, and efflux and biliary secretion of vitamin E recognize all tocopherol isoforms similarly.

Metabolism

The metabolism of α-tocopherol is tightly regulated, and unlike other fat-soluble vitamins, there is no toxic accumulation in the liver. α-Tocopherol that is not released into circulation is excreted into the bile via protein transporters or is metabolized and excreted mainly in urine. All tocopherols and tocotrienols are metabolized by ω-hydroxylation and oxidation by cytochrome P450 enzymes followed by side-chain degradation through β-oxidation, while the chromanol ring is left intact. Cytochrome CYP4F2 is engaged in ω-oxidation of tocopherols in humans. This enzyme's catalytic activity for non-α-tocopherols is clearly greater than for α-tocopherol. The final product of α-tocopherol metabolism, α-carboxyethyl hydroxychroman (α-CEHC), is excreted in urine after conjugation. Feces, which contain unabsorbed vitamin, are however the major route for α-tocopherol excretion.

The turnover of α-tocopherol is slow; the depletion of tissues takes decades rather than weeks. In a recent kinetic study with tracer-marked RRR-α-tocopherol in healthy men and women, α-tocopherol half-life in plasma was 44 days and 96 days in red blood cells during 460-day tracking. In further analysis, it was estimated that half-life of the slowest turning over compartment of α-tocopherol, adipose tissue, was on average 184 days.

Non-α-tocopherols and tocotrienols are aggressively metabolized in the liver. Much greater proportion of γ-tocopherol

Table 1 Summary of tocopherol and tocotrienol physiology

	Alpha-tocopherol	*Non-α-tocopherols and tocotrienols*
Intestine	Absorbed similarly	
Circulation	During chylomicron hydrolysis transfer to other lipoproteins and peripheral tissues	
Liver	Chylomicron remnants are taken to the liver, no restriction at this stage	
Liver	Bound by α-tocopherol transport protein (α-TTP), the excess of α-tocopherol is metabolized and excreted	Metabolized and excreted
Circulation	Transport from the liver in VLDL and delivery to other lipoproteins and peripheral tissues	No transport from the liver to circulation?

than α-tocopherol is excreted in urine when consumed in equimolar amounts. Administration of α-tocopherol causes further increase in urinary excretion of non-α-tocopherols and tocotrienols in relation to the size of vitamin E dose.

Tissue Concentration

α-Tocopherol is detected in different tissues all over the body in concentrations that are always higher than those of other tocopherols. The highest concentrations are found in adrenals and adipose and nerve tissues. Adipose tissue is the major reservoir of vitamin E in the body. More than 90% of the total body α-tocopherol is located in fat droplets of adipose tissue cells. However, vitamin E is not easily removed from this store. Brain tissue appears especially resistant to depletion of vitamin E.

In developed countries, average plasma α-tocopherol concentrations range between 20 and 30 μmol l^{-1}, but two to three times higher concentrations are found among vitamin E supplement users. Plasma γ-tocopherol concentrations are always much lower even when γ-tocopherol is the major tocopherol, and use of vitamin E supplements causes further decrease in plasma γ-tocopherol. Among the nonusers of vitamin supplements in NHANES 1999–2000, plasma γ-tocopherol was on average 6 μmol l^{-1} but only 2 μmol l^{-1} among those who used supplements >400 IU day^{-1}. In European countries, mean plasma γ-tocopherol concentrations habitually range from 1 to 2 μmol l^{-1}.

In fasting state, tocotrienols are undetectable in plasma, and after a single dose, they peak in plasma in few hours and disappear within 24 h. However, during long-term supplementation, tocotrienols in different tissues are significantly increased.

Function

Main biochemical function of α-tocopherol is suggested to be its antioxidant activity. As a chain-breaking antioxidant, α-tocopherol prevents propagation of free radical reactions of polyunsaturated fatty acids (PUFAs) in membranes and aids to maintain membrane integrity. However, direct end products of the α-tocopherol oxidation are hardly detected in the tissues, which may depend on the fact that the tocopheryl radical can be reduced back to tocopherol by vitamin C or other reducing agents. Evidence of decreased oxidative stress with α-tocopherol supplementation in humans is inconsistent. Primarily based on *in vitro* studies, α-tocopherol exerts several other important biological functions including modulation of cell signaling and gene expression.

Several enzymes especially those affecting cell proliferation, membrane trafficking, and metabolism of xenobiotics can be modified by α-tocopherol. Genes involved in the metabolism and excretion of vitamin E are regulated by α-tocopherol. Also, the products of vitamin E metabolism are proposed to have biological activities. Several molecular and cellular functions are suggested for water-soluble α-tocopheryl phosphate, which appears in minute amounts in foods and tissues. Yet, the mechanisms causing specific deficiency symptoms of vitamin E such as female infertility of rodents and neurological defects in humans are not known.

Non-α-tocopherols and tocotrienols behave as efficient lipid-soluble antioxidants *in vitro*; however, their biological activity is greatly limited due to discrimination in the liver metabolism. Various nonantioxidant functions that clearly differ from those of α-tocopherol have been associated with non-α-tocopherols and tocotrienols mainly based on cell studies and animal experiments. γ-Tocopherol appears to have stronger antinitrative and anti-inflammatory effects than α-tocopherol. Tocotrienols are suggested to have neuroprotective effects, to inhibit cholesterol synthesis, and to reduce growth of cancer cells.

Recommendations for Vitamin E

Estimates of required amounts of tocopherols concern only vitamin E. In 2000, the Food and Nutrition Board considered only α-tocopherol an essential nutrient. Previously, vitamin E was estimated in α-tocopherol equivalents, which also included small amounts of vitamin activity assumed to be provided by non-α-tocopherols and tocotrienols. Based on rat fertility experiments, biological activities of different tocopherols and tocotrienols were defined as follows: α-tocopherol x1, β-tocopherol x0.5, γ-tocopherol x0.1, δ-tocopherol x0.03, α-tocotrienol x0.03, and β-tocotrienol x0.05; no biological activity was found for γ-tocotrienol and δ-tocotrienol.

In the absence of any specific metabolic function ascribed to vitamin E, it has been demanding to set the basis for the estimation of vitamin E requirement. The Food and Nutrition Board (2000) based their assessment on the intake of α-tocopherol, which was estimated to maintain plasma α-tocopherol at sufficient level to prevent *in vitro* hemolysis of red blood cells taken from humans who participated in vitamin E deficiency experiment. Accordingly, the estimated average requirement of adults was set at 12 mg day^{-1}, and after addition of safety margin, the recommended daily intake was set at 15 mg day^{-1} for men and women.

The recommendation applies to natural RRR-α-tocopherol and 2R-α-tocopherol stereoisomers detected in synthetic α-tocopherol preparations. Synthetic α-tocopherol, all-rac-α-tocopherol or dl-α-tocopherol, is an equal mixture of eight stereoisomers. Due to the low affinity of α-TTP to 2S-vitamers, the relative bioavailability of the synthetic form of α-tocopherol was estimated to be only half of the natural α-tocopherol. This means that only α-tocopherol found naturally in foods and 2R-α-tocopherols in vitamin E preparations contribute to vitamin E activity. Recommended amounts of vitamin E given as milligrams of RRR-α-tocopherol can be transformed into international units (IU) by the following factors: 1 mg of α-tocopherol is equivalent to 1.49 IU of the natural form and 2.22 IU of the synthetic form of the vitamin.

Another approach to estimate vitamin E requirement is based on the relation between the need for vitamin E and the intake of PUFAs. In Europe, the Scientific Committee on Food considered that 0.4 mg of vitamin E per g of total PUFAs is adequate for adults provided that daily vitamin E does not fall below 4 mg for adult men and 3 mg for adult women. Habitual intake of vitamin E among populations without signs of vitamin deficiency has also been used to guide the assessment of the need of vitamin E. Worldwide, there is considerable variation in the national recommendations for vitamin E, and some authorities have considered the scientific basis too vague thus far to set any specific numeric value for vitamin E requirement.

Toxicity of vitamin E is very low. No adverse effects have been described from vitamin E provided by food sources. The Food and Nutrition Board (2000) set the upper intake limit of supplemental α-tocopherol at 1000 mg day^{-1} for adults. This amount covers both synthetic and natural forms of supplemental vitamin E and includes also 2S-α-tocopherol stereoisomers without vitamin activity, but not vitamin E occurring naturally in foods. In Europe, somewhat lower tolerable upper intake level, 300 mg day^{-1} for adults, was proposed by the Scientific Committee on Food in 2003.

Deficiency of Vitamin E

Vitamin E deficiency due to low dietary intake has not been described in normal, healthy individuals. However, deficiency may arise due to prolonged fat malabsorption for any reason, due to genetic defects in lipoprotein transport or genetic defect in hepatic α-TTP. In humans, the peripheral nervous system is most susceptible to vitamin E deficiency. Neurological disturbances associated with low vitamin E status were first described in children who suffered from deficient lipid transport in plasma due to genetic defect in lipoprotein formation.

Primary vitamin E deficiency is caused by genetic defects in α-TTP formation. Symptoms of AVED (Ataxia with Vitamin E Deficiency) include peripheral neuropathy, ataxia, and skeletal myopathy. Retinitis pigmentosa is often associated with vitamin E deficiency. Several different defects have been identified in the gene coding α-TTP, and severity of the symptoms appears to vary depending on the type of genetic defect. Absorption of α-tocopherol is normal in AVED patients, but due to defective α-TTP, tissue vitamin concentrations are not maintained. Progression of deficiency symptoms can be halted by high oral doses of α-tocopherol, and some symptoms may be even reversed if supplementation is started at an early stage.

Although overt deficiency of vitamin E is very rare, risk of marginal deficiency is possible when food intake and fat intake are greatly restricted. There are several intestinal disorders that affect absorption of nutrients such as gastrectomy, celiac disease, Crohn's disease, and short bowel syndrome in addition to hepatobiliary syndromes and cystic fibrosis where the risk of vitamin E deficiency is generally recognized. Medications used to decrease fat absorption also reduce absorption of vitamin E.

In the absence of more specific measurements for the estimation of adequate vitamin E status, determination of plasma α-tocopherol is commonly used. However, since the plasma lipid level influences the α-tocopherol concentration, correction for plasma lipids may be warranted in subjects with high lipid levels. In an experimental vitamin E depletion study, increased hemolytic tendency was discovered in subjects with plasma α-tocopherol concentration below 12 μmol l^{-1}, corresponding to α-tocopherol/total cholesterol ratio of 2.25 μmol l^{-1}. Plasma α-tocopherol concentration above 16.2 μmol l^{-1} has been suggested as an indicator of acceptable vitamin E status.

Vitamin E and Chronic Diseases

Due to its effects on oxidation, immunologic function, and inflammation, vitamin E has been linked to several chronic diseases such as cardiovascular diseases, cancer, and dementia (Table 2). The associations have been studied in humans in observational and interventional settings having either dietary or supplementary intake or serum levels as exposure. Anti-inflammatory and antioxidative functions are also associated with other tocopherols and tocotrienols. Mainly based on nonhuman studies, their efficiency in the prevention of cancer, cardiovascular, and neurodegenerative diseases could be even superior in comparison with α-tocopherol. Thus far, no large-scale human intervention studies of non-α-tocopherols or tocotrienols have been carried out.

Table 2 Disorders or diseases linked to vitamin E

	Dietary intake or plasma levels of vitamin E	*Supplemental vitamin E*
Cardiovascular diseases	Inverse association	No benefit
Cancer	Inconclusive results	No benefit
Type 2 diabetes	Weak inverse association	No benefit
Cognitive decline	Weak inverse association	No effect
Eye disease	Weak inverse association	No effect
Lung function, asthma	Inconclusive results	Insufficient evidence

Cardiovascular Diseases

Atherosclerosis is the central pathway leading to cardiovascular diseases that is thought to be affected by vitamin E. Atherosclerosis is characterized by excessive deposition of cholesterol in the arterial wall and involves LDL oxidation. Most importantly, vitamin E has antioxidant properties and has reduced LDL oxidation especially in *in vitro* and animal studies. In addition, vitamin E could reduce inflammation and affect foam cell formation, plaque stability, and gene expression related to cell signaling.

In observational studies, high vitamin E intake or better status was associated to reduced risk of cardiovascular diseases. The primary prevention trials have not, however, shown significant benefit from the α-tocopherol supplements in relation to different cardiovascular outcomes including myocardial infarctions and strokes. The daily doses have ranged from 30 mg to 300 mg. Accordingly, it has been concluded that there is adequate evidence showing that supplementation with vitamin E in healthy populations without known nutritional deficiencies does not reduce the risk of cardiovascular disease and supplementation is not recommended.

Even though there is no benefit in healthy population, some subgroups experiencing high levels of oxidative stress have been suggested to have benefit. Firstly, it is suggested that diabetic subjects with haptoglobin genotype 2-2 might have benefitted from tocopherol supplementation. The hypothesis is that the diabetic subjects have more LDL cholesterol oxidation and the haptoglobin 2-2 genotype is less efficient in removing oxidative complexes with hemoglobin. Another subpopulation suggested to benefit from tocopherol supplements is hemodialysis patients.

Cancer

Cancers include heterogeneous nature of different types of cancer, and their risk is affected by multiple environmental and genetic influences. Even though risk factors for cancer are considerably more complex than for cardiovascular diseases, the same pathway, that is, the antioxidant properties of vitamin E, is central. Vitamin E could prevent DNA damage and reduce lipid oxidation and activation of carcinogens such as nitrosamines. In addition to acting as a free radical scavenger, vitamin E enhances the body's immune response, which may play a role in cancer prevention.

Several observational studies have analyzed the associations between tocopherols and risk of site-specific cancer incidence. Regarding risk of prostate cancer, observational studies having serum α-tocopherol or dietary vitamin E intake as exposure have been inconclusive. Suggested reduced risk of prostate cancer by 50 mg daily supplementation with synthetic alpha-tocopheryl acetate in the Finnish ATBC (Alpha-Tocopherol, Beta-Carotene Cancer Prevention) study has not been confirmed in other large-scale trials with higher doses of vitamin E; rather, a nonsignificant increased risk of prostate cancer was suggested in SELECT (Selenium and Vitamin E Cancer Prevention Trial) study. Furthermore, the results of SELECT study suggested that in those who have high serum α-tocopherol concentration, selenium supplements can increase prostate cancer risk. Most studies have focused on α-tocopherol; however, it is hypothesized that γ-tocopherol might have beneficial effects instead of α-tocopherol.

Similarly for breast cancer, vitamin E status estimated from intake or plasma concentrations in observational studies or the supplemental intake in clinical trials has not shown significant association or effect. Furthermore, studies on the risk of colon or lung cancer have not provided evidence supporting the role of vitamin E. On the contrary, dietary intake of vitamin E, but not the serum α-tocopherol concentration, was associated with reduced gastric cancer risk in meta-analysis of observational studies.

Meta-analysis of randomized clinical trials has concluded that vitamin E supplementation does not affect cancer incidence or mortality. Dietary supplements are not recommended for cancer prevention.

Type 2 Diabetes

In addition to antioxidant and anti-inflammatory properties, vitamin E is suggested to have an effect on insulin sensitivity through enhanced adiponectin expression. This effect is similar to the thiazolidinediones, which have structural similarities with tocopherols and have been used in type 2 diabetes treatment.

Cohort studies have provided evidence for reduced risk of type 2 diabetes with higher dietary vitamin E intake. However, beneficial effects of vitamin E supplementation in prevention of type 2 diabetes have not been confirmed in large-scale randomized interventions.

Dementia

Dementia and cognitive impairment with increased aging are associated with increased oxidative stress and are thought to be preventable by antioxidants, most of all, by vitamin E. It is hypothesized that the central nervous system with high lipid and iron content is particularly susceptible to oxidative damage by free reactive oxygen species.

Several, but not all, observational prospective studies have pointed to decreased cognitive impairment or reduced Alzheimer disease risk by higher vitamin E intake or higher plasma α-tocopherol concentration. For the prevention of Alzheimer disease, the studies suggest that vitamin E should come from food not from supplements. Cochrane Review in 2012 concluded that there is no convincing evidence that vitamin E is of benefit in the treatment of Alzheimer disease or mild cognitive impairment. A more recent study has, however, suggested slower functional decline and reduced caregiver burden with α-tocopherol supplementation in subjects with mild to moderate Alzheimer disease.

Eye Diseases

Oxidative damage of lens proteins leads to cataract development, and oxidative stress is hypothesized to be one of the pathogenic mechanisms in age-related macular degeneration. Vitamin E is concentrated in lens fibers and membranes and may inhibit cataract by reducing peroxidation of lens lipids and stabilizing lens cell membranes.

A modest borderline protective effect in primary prevention of age-related macular degeneration has been found for vitamin E in an analysis of prospective cohort studies. However, little or no effect for other dietary antioxidants was shown. In intervention studies aimed to prevent or decrease progression of eye diseases, daily supplementation with vitamin E alone or in combinations with other antioxidants or selenium has not reduced cataract risk; neither was it found to be effective against occurrence of age-related macular degeneration.

Respiratory Tract Effects

The role of vitamin E has been suggested in different conditions including common colds, pneumonia, and asthma. Supplementation with α-tocopherol above the recommended levels is suggested to improve immune function, especially in the aged, and thus could affect, for example, the risk of common colds. As asthma is an inflammatory lung condition, a role for vitamin E as an anti-inflammatory agent has been suggested.

Results from few intervention studies on the effect of α-tocopherol on respiratory tract infections have been inconsistent. Even though higher serum α-tocopherol concentration has been associated with better performance in spirometry in cross-sectional analysis and serum levels of α-tocopherol have been lower in subjects with asthma, the role of α-tocopherol in asthma is unclear. It is of note that γ-tocopherol is suggested to elevate allergic inflammation in asthma contrasting the anti-inflammatory effects of α-tocopherol.

Other Health Effects

Preeclampsia is associated with increased oxidative stress. Several randomized controlled trials have been carried out with a combined daily supplementation of 1000 mg of vitamin C and 400 IU of vitamin E. However, the results have been

disappointing, and meta-analysis of nine trials reported no difference in occurrence of preeclampsia between treatment and placebo groups. Combined supplementation of vitamins C and E does not decrease the risk of preeclampsia and should not be offered for pregnant women for prevention of preeclampsia or other pregnancy-induced hypertensive disorders.

Controversially, experimental evidence has suggested that in addition to its antioxidative effect, α-tocopherol could have a possible direct role in bone remodeling, promoting osteoclast fusion, and thus stimulating bone resorption. Two studies have suggested that low serum α-tocopherol concentrations or low dietary intake are associated with increased risk of hip fracture.

Possible Adverse Effects

In general, antioxidant supplements do not seem to prevent cancer, cardiovascular diseases, or death. Contrary to general belief of antioxidant supplements being of no harm, the systematic reviews have concluded that vitamin E supplements may increase mortality. Dietary intakes have not been associated with increased mortality. The following are suggested reasons for the increased mortality: There is interference of the balance between antioxidants and oxidative stress; endogenously derived antioxidants are more important than diet-derived ones; dietary intake in Western countries meets the requirements; and the synthetic forms of vitamin E have different effects than their dietary forms.

In addition, vitamin E is suggested to interfere vitamin K metabolism. High doses of vitamin E could adversely affect vitamin K status and gamma-carboxylation of proteins in the coagulation cascade. The clinical significance of this effect is, however, uncertain, as it could be either beneficial as a mild anticoagulant or adverse by increasing the risk of bleeding especially in users of oral anticoagulants.

Tocopherols: Properties and Determination

NE Craft, Craft Technologies, Inc., Wilson, NC, USA

© 2016 Elsevier Ltd. All rights reserved.

The tocochromanols have absorbance maxima near 220 and 300 nm. They also exhibit fluorescence emission near 325 nm when excited near their absorbance maxima. These characteristics are used to measure the tocochromanols after being isolated from the sample matrix. They are insoluble in water and highly soluble in several organic solvents. Free tocochromanols can be directly extracted but complex samples often require saponification to hydrolyze ester linkages of triglycerides and tocopheryl esters.

Tocochromanols can be measured by gas chromatography (GC) with flame ionization detection (FID) or mass spectrometry (MS) detection. When the correct column and conditions are used, the eight major tocopherols and tocotrienols can be separated with or without derivatization. High-performance liquid chromatography (HPLC) has become the most popular mode of analysis during the past 25 years. In combination with HPLC, tocochromanols can be detected using UV detection, fluorescence detection, electrochemical detection (ECD), evaporative light-scattering detection (ELSD), or MS detection. The eight major tocochromanols frequently are separated using normal-phase HPLC with silica, diol, or amino columns. Until recently, it was not possible to separate the eight tocochromanols by reversed-phase (C18 or C8) HPLC. Now, they have been separated using C30, pentafluorophenyl (PFP), and cyclodextrin columns.

Tocopherols have three chiral centers, which result in eight stereoisomers. All of the stereoisomers have not been separated in a single chromatographic separation. The tocopherol methyl ethers can be separated into five peaks using a CHIRALCEL OD-H column. The addition of GC separation is required to separate the 2S-isomers.

Background

The vitamin E family of compounds is biosynthesized in plants, predominantly in the chloroplasts. They are abundant in the oils of seeds such as corn, soy, rice, wheat, sunflower, and safflower. Unlike plants, animals cannot synthesize vitamin E and must obtain it from their diet. Vitamin E is one of four essential fat-soluble vitamins. It was discovered during the 'Renaissance' of Nutrition in the 1920s and 1930s when many of the vitamins were discovered and isolated. In 1922, Evans and Bishop identified a fat-soluble substance, 'factor X,' which was required for normal reproduction in rats. Observations were confirmed by Sure in 1924 and the name 'vitamin E' was proposed.

α-Tocopherol was isolated from wheat germ in 1936 by Evans' group and synthesized by Karrer et al. in 1938. Evans' group also isolated β- and γ-tocopherols from vegetable oil in 1937. In the 1960s, the tocotrienols were isolated from rice bran oil. Tocotrienols were synthesized in 1976 by Scott et al.

Definitions

'Vitamin E' is a generic descriptor for all tocol and tocotrienol derivatives exhibiting qualitatively the biological activity of α-tocopherol.

'Tocopherol' is the generic description for all mono-, di-, and trimethyltocochromanols, irrespective of biological activity, and is not synonymous with the term 'vitamin E.'

'Tocotrienol' is a trivial name for 2-methyl-2-(4′,8′,12′-trimethyltrideca-3′,7′,11′-trienyl)chroman-6-ol, possessing three double bonds in the phytyl tail.

'Tocol' is the trivial name for 2-methyl-2-(4′,8′,12′-trimethyltridecyl)chroman-6-ol, having no methyl substitutions in the chroman ring.

'Tocochromanols' will be used in this article to refer to all tocopherols, tocomonoenols, tocodienols, and tocotrienols.

Vitamin E: Chemical Properties

There are more than eight naturally occurring tocopherol compounds that have been isolated from plant sources and all have a 6-chromanol ring and a phytyl side chain. The most prominent ones include four tocopherols and four tocotrienols. They differ in the number and position of methyl groups on the phenolic ring (Figure 1). Tocotrienols differ from tocopherols in that they contain three double bonds at the 3′, 7′, and 11′ positions in the phytyl tail.

The tocopherol molecule has three chiral centers at positions 2, 4′, and 8′ in the phytyl tail. As such, there are eight possible stereoisomeric configurations (2^3). All naturally occurring tocopherols (α-, β-, γ-, and δ-) have RRR molecular configuration (2d, 4′d, 8′d, x-tocopherol) in their phytyl groups. Since tocotrienols have only one chiral center at position 2, there are only two possible stereoisomers. The naturally occurring stereoisomer of α-tocopherol, formerly known as D-α-tocopherol, is now designated RRR-α-tocopherol to distinguish it from the synthetic version.

In addition to the natural forms of vitamin E, there are many synthetic forms that are often esterified with different functional groups such as acetate, succinate, and nicotinate. The esterified forms of vitamin E are less susceptible to degradation and thus frequently used as sources of vitamin E in foods and pharmaceuticals. The tocopherol esters must be hydrolyzed to serve as antioxidants.

More recently, additional natural analogs of vitamin E have been identified. These include α-tocomonoenol from palm oil, marine-derived tocopherol from salmon egg, δ-tocomonoenol from kiwi, γ-tocomonoenol from pumpkin seeds, tocotrienols in palm oil, and desmethyl and didesmethyl tocotrienols from rice bran.

Tocopherols are viscous oils at room temperature with a light yellow color; however, they are nearly colorless and

	R_1	R_2	R_3
α	CH_3	CH_3	CH_3
β	CH_3	H	CH_3
δ	H	H	CH_3
γ	H	CH_3	CH_3

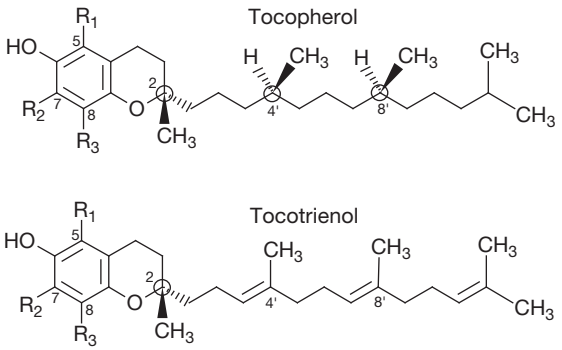

Figure 1 Chemical structures of tocopherol and tocotrienol. α-, β-, δ-, and γ-Homologues exist for both molecules and the R-groups of each are listed in the table. The circles indicate chiral centers, each of which permits stereoisomers. Each tocopherol has eight (2^3) stereoisomers while each tocotrienol has only two.

odorless when highly purified. They are practically insoluble in water but are soluble in oils and organic solvents, such as acetone, alcohols, chloroform, hexane, and tetrahydrofuran (THF). Tocopherols have molecular weights ranging from 396.6 to 439.7 and boil between 200 and 220 °C. They have maximum ultraviolet light absorbance (λ_{max}) at about 220 and 290–300 nm. The absorptivity coefficient ($E^{1\%}_{cm}$) at the higher λ_{max} ranges from 75.8 to 91.4 (Table 1). In addition, tocopherols

exhibit fluorescence emission near 320–325 nm upon UV excitation near the 220 or 290 nm range (Table 1). Vitamin E esters exhibit UV absorbance to a lesser extent and ~6–8 nm hypsochromic to the corresponding tocopherols (286–292 nm). The $E_{cm}^{1\%}$ of the tocopherol esters is about half that of the free tocopherols and the fluorescence is much weaker (Table 1). An example of the UV absorbance spectrum and the fluorescence emission is provided in Figure 2.

Tocopherols can be oxidized by atmospheric oxygen, and the oxidation is accelerated by heat, light, alkali, and metal ions. However, tocopherols are reasonably stable to heat and alkali in the absence of oxygen. The antioxidant property of tocopherols is due to their ability to interrupt free-radical chain reactions by quenching the free radical. The hydrogen from the hydroxyl group in the phenolic ring is donated to the free radical thereby generating a relatively stable radical form of vitamin E, the α-tocopheroxyl radical.

Tocopherols and tocotrienols are effective free-radical chain-breaking antioxidants because they react with peroxyl radicals impairing unsaturated lipid peroxidation.

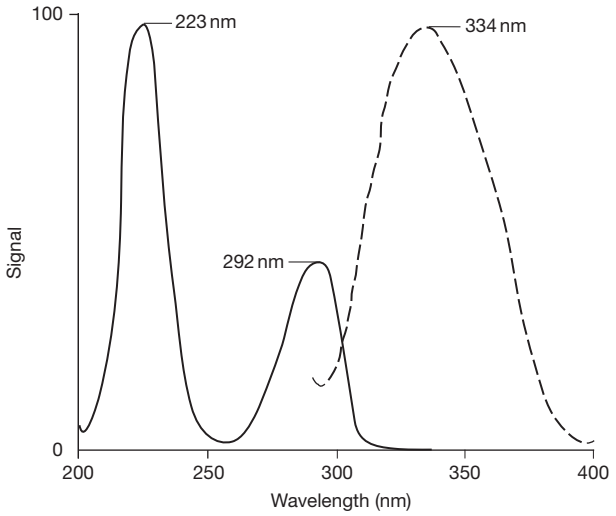

Figure 2 α-Tocopherol UV absorbance spectrum and fluorescence emission spectrum.

Vitamin E: Biological Activity

Biological activity of vitamin E can be expressed in two ways: as α-tocopherol equivalents (α-TEs) and as international units (IUs). According to the National Research Council, one α-TE is equivalent to 1 mg of RRR-α-tocopherol. Historically, biological activities were determined by fetal resorption studies in rats. Other functional indicators have been reported, but recently, the binding of tocochromanols to α-tocopherol transfer protein (α-TTP) has been measured as a potential indicator of biological activity. The biological activity of the various tocochromanols is provided in Table 2.

Tocochromanols are amphipathic molecules consisting of a polar chromanol ring at the head and a lipophilic phytyl tail. These molecules are oriented within biological membranes with the chromanol ring at the polar surface of a membrane and the phytyl tail embedded into the bilayer core. In this manner, they serve as antioxidants to inhibit lipid peroxidation.

Vitamin E is the primary lipid-soluble antioxidant in biological organisms. It is present in membranes throughout the body and transported with lipids in lipoproteins. In biological systems, its role as an antioxidant is the most well-established function. It is likely that ascorbic acid regenerates α-T by reducing the α-tocopheroxyl radical. This recycling cascade is important to spare α-T to provide ongoing protection of membranes (Figure 3).

Table 2 Biological activity of vitamin E

Vitamin E form	*IU (mg)*	*α-TE (mg)*	*α-TPP binding*
Natural (RRR-)			
α-Tocopherol	1.49	1.00	100
β-Tocopherol	0.75	0.50	38
δ-Tocopherol	0.05	0.03	1.5
γ-Tocopherol	0.15	0.10	9
α-Tocotrienol	0.75	0.50	12.5
β-Tocotrienol	0.08	0.05	n.d.

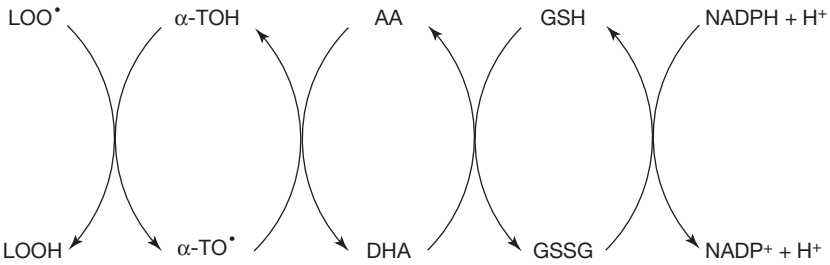

Figure 3 Tocopherol radical recycling.

Due to the presence of a selective α-TTP, α-T is likely to have very specific, non-antioxidant functions. Considerable work is under way to elucidate these functions. It has been reported that α-T regulates gene expression at transcription. Whether these observations are unique, transcriptional functions or indirect responses to oxidative stress and alterations in membrane integrity are still under debate.

Vitamin E: Analysis

The earliest methods to measure vitamin E activity were biological fertility tests. The Emmerie–Engel colorimetric method was the first and long-standing chemical method for the analysis of tocopherols. It is based on the ability of tocopherols to reduce ferric chloride and the colorimetric determination of the ferrous salt with α,α′-dipyridyl or *o*-phenanthroline. In addition, vitamin E has been measured using spectrophotometric and spectrofluorometric assays.

These methods were inaccurate measures of vitamin E activity since they do not separate the various tocochromanols with their differing biological activities. Paper and thin-layer chromatographies soon followed with the necessary selectivity to resolve the various homologues. These early methods have been displaced by GC and (ultra)high-performance liquid chromatography ((U)HPLC). Tocochromanols have been separated using supercritical fluid chromatography, capillary zone electrophoresis, capillary electrochromatography, and micellar electrokinetic chromatography but these techniques are not well suited to lipid-soluble analytes.

Sample Extraction

Tocochromanols are soluble in many organic solvents but insoluble in water. For samples that have relatively high tocol-to-lipid ratios, direct extraction with hexane, petroleum ether, alcohols, THF, chloroform, or ethyl acetate is adequate prior to separation. For many samples that contain high lipid and low tocochromanol content, separation from lipid is necessary prior to chromatography. This may be accomplished by enzymatic or alkaline hydrolysis or solid-phase extraction (SPE).

Tocochromanols are part of the nonsaponifiable fraction of lipids. Saponification is an alkaline hydrolysis that is used often to cleave triglycerides and ester linkages in complex samples. The remaining lipophilic portion of the sample that may be extracted with organic solvents is called the nonsaponifiable fraction. Saponification is used to simplify the sample matrix prior to extracting the tocochromanols. The process typically involves hydroalcohol mixtures of potassium hydroxide or sodium hydroxide. Time, temperature, alkali concentration, presence of antioxidants, and final pH influence the recovery of the various tocochromanols. Saponification may be essential to achieve complete extraction of vitamin E from complex samples, such as grains. There are reports that tocochromanols degrade during saponification. Some methods recommend that vitamin E be hydrolyzed at higher temperatures for shorter times to minimize degradation. For this reason, antioxidants such as ascorbic acid, butylated hydroxytoluene (BHT), and pyrogallol are added to the saponification mix to minimize oxidative losses. BHT and other phenolic antioxidants (butylated hydroxyanisole, hydroquinone, and tert-butylhydroquinone) must be used with caution since they exhibit UV absorbance and fluorescence similar to tocochromanols and may coelute chromatographically. Tocochromanol recovery, particularly the more polar ones, is hampered by alkaline pH during extraction into organic solvents. Tocochromanols will extract efficiently into hexane and similar solvents near neutral pH. The extraction efficiency is affected by the ratio of alcohol and fatty acids relative to hexane. Several good comparisons of extraction/saponification conditions arrive at similar conclusions:

1. Longer solvent exposure with heating and agitation improves extraction.
2. Several organic solvents can successfully solubilize the tocochromanols but the sample matrix will influence which solvent should be used.
3. Many samples require a polar organic solvent to precipitate proteins followed by partitioning into a water-immiscible solvent.
4. It is best to exclude saponification, if possible.
5. Antioxidants should be included and oxygen excluded during saponification.
6. Minimize exposure to alkaline conditions.
7. Alcohol concentration should be diluted to less than ~30% prior to solvent extraction.
8. The addition of saturated saltwater will assist to drive tocochromanols into the organic solvent.

Saponification

An example saponification procedure is described. Samples may be saponified directly or be extracted first and then

saponified. The latter offers greater control over the hydrolysis of oil and vitamin E esters but does not expose the sample matrix to the hydrolysis conditions. For tough samples (seeds), the matrix components may need to be saponified directly to achieve complete extraction of lipids.

Example

Accurately weigh approximately 0.2 g of oil or 2 g of homogenous sample into a 50 ml glass tube with Teflon-lined screw cap. If an internal standard is to be included, it should be added at this time. (Do not use tocopheryl esters as internal standards since they would be converted to free tocopherols.) Mix the sample with 4 ml of ethanol. Add 1 ml of 10% pyrogallol in ethanol. Add 5 ml of 40% KOH in methanol. Displace the air with N_2, cap, and incubate in a shaking water bath at 65 °C for 30 min. Vortex-mix with 10 ml of heptane/10% THF. Add 20 ml of saturated sodium chloride and adjust the pH to ~8 with 1 M HCl. Invert several times and allow phases to separate. Transfer the upper layer to a clean 50 ml tube. Repeat extraction with heptanes/THF two more times. If hexane or petroleum ether alone is used for extraction, it is necessary to dilute the ethanol to less than 30% to obtain efficient extraction of polar tocochromanols. Wash the combined extract with 10 ml of water transferring the lower layer to waste. Repeat until the aqueous layer is no longer hazy. To remove traces of water from the organic extract, add sodium sulfate until crystals do not dissolve. Transfer the organic extract to a clean glass tube and evaporate under a stream N_2 or using a centrifugal evaporator. Dissolve the residue in an appropriate volume of solvent compatible with the chromatographic technique.

Solid-phase extraction

If tocopheryl esters are to be measured, saponification is not applicable. Lipids must be removed via another approach, such as SPE. SPE is a simple, rapid, inexpensive form of chromatography used to isolate a fraction of the sample containing the analytes from other matrix components. It can be performed off-line or on-line to clean up and/or concentrate the sample prior to chromatography. One often uses a packing material (or phase) that is different from the chromatographic column to take advantage of different chemical interactions.

Example

The sample (0.2 g oil or oil from 2 g of solvent-extracted sample) is brought to 10 ml in a volumetric container with hexane. If an internal standard is to be included, it should be added before bringing to volume. A silica SPE cartridge (3 ml volume with 200 mg silica) is conditioned with 3 ml isopropanol followed by 6 ml hexane. A 2 ml aliquot of the diluted oil solution is passed into the column and washed with 6 ml hexane/4% diethyl ether to remove triglycerides. Tocochromanols are eluted into a clean test tube with 3 ml hexane/10% acetone. The hexane/acetone is evaporated under a stream of N_2 or using a centrifugal evaporator. Dissolve the residue in an appropriate volume of solvent compatible with the chromatographic technique.

Chromatographic Separation of Vitamin E

Gas Chromatography

GC has been used to measure α-tocopherol since 1960. Wilson et al. improved the methodology and measured 20 tocochromanols and tocopherol esters using three different columns. Early GC columns packed with stationary phase produced lower resolution and could not separate the β- and γ-homologues. They have been replaced by capillary open-tubular columns with the stationary phase layered on the inner surface of the glass capillary tubing. These longer, narrow columns have the ability to separate all major tocochromanols, typically with increased analysis time. Tocochromanols can be measured underivatized or derivatized using FID or MS. The quantitation limit using capillary GC with FID is ~1 ng but can be reduced to low femtograms using MS detection. The tocochromanols may be derivatized as trimethylsilyl (TMS) ethers or as methyl esters. The derivatized tocochromanols are more stable and volatile and result in better chromatography. The TMS ethers are preferred since they form rapidly at room temperature. Derivatized tocochromanols can be separated using nonpolar, moderately polar, and polar GC stationary phases, for example, DB-1, DB-17, and DB-23, respectively. During GC, cholesterol is a common interference with the α-T and often occurs at much higher concentrations than the tocochromanols.

Until recently, separation of the eight major tocochromanols without derivatization had not been reported, but now, this can be accomplished with or without derivatization. The elution order using GC is influenced by the degree and position of methyl substitutions following the order $\delta < \beta < \gamma < \alpha$.

GC-FID separation of tocochromanols without derivatization

The lipid fraction from samples after SPE or saponification is dissolved appropriately in isooctane. As seen in Figure 4, the eight major tocochromanols and the internal standard, palmityl palmitate, are baseline-resolved during a 12 min chromatogram using the conditions listed in the succeeding text. This method is simple, rapid, and competitive with current LC methods.

Column	Restek Rtx®-20, 30 m, 0.53 mm ID, 0.50 μm
Sample	
Diluent	Isooctane
Conc.	1000 μg ml^{-1} each component
Injection	
Inj. vol.	1 μl split (split ratio 20:1)
Liner	Splitless (4 mm ID)
Inj. temp.	320 °C
Oven	
Oven temp.	270–290 °C at 2 °C min^{-1} to 320 °C at 10 °C min^{-1} (hold 1 min)
Carrier gas	H_2, constant flow
Flow rate	5.2 ml min^{-1}
Detector	FID at 320 °C

(Ultra)High-Performance Liquid Chromatography

Vitamin E was first separated by HPLC in 1971 by Schmidt et al. using a Zipax superficially porous packing. A normal-phase separation of both tocopherols and tocotrienols was reported using Corasil II in 1974. HPLC is the technique of choice to measure tocochromanols since the eight homologues can be separated in short analysis times without laborious sample preparation. The abbreviation 'HPLC' is used to represent both high-pressure liquid chromatography and ultrahigh-pressure liquid chromatography. The principal difference is that instruments used for UHPLC will function above 6000 psi permitting the use of <2 μm particle columns at higher linear velocity. UHPLC columns can be used on conventional HPLC below 6000 psi, but the instruments are not optimized for low flow rates and low dead volume. In recent years, solid-core particle columns have been promoted to achieve performance similar to UHPLC columns using conventional HPLC instruments. Separation examples are provided later in the text.

There are two primary forms of HPLC used for tocochromanol separations: 'normal-phase' liquid chromatography (NPLC) and 'reversed-phase' liquid chromatography (RPLC). NPLC incorporates polar stationary phases and nonpolar mobile phases resulting in longer retention of polar compounds. NPLC separations are well suited for tocochromanol separations due to the solubility of oily fractions in the solvents and the ability to resolve all structural isomers, including β- and γ-homologues. RPLC incorporates nonpolar stationary phases and polar mobile phases resulting in longer retention of hydrophobic compounds. RPLC was developed after NPLC and separates in the reverse order – thus the name 'reversed-phase.' Until more recently, the β- and γ-isomers could not be separated easily by RPLC. However, due to its versatility, ruggedness, and reproducibility, RPLC is more commonly used to separate vitamins.

NPLC separation of tocochromanols

There are several types of NPLC packing materials that have been used to separate tocochromanols. They operate by adsorptive mechanisms (hydrogen-bonding and dipole–dipole) interacting with polar functional groups in the molecules. Two key benefits of NPLC are the solubility of lipids and ability to separate structural isomers. Silica was the first NPLC packing material to be reported for tocopherol separations. Other polar NPLC phases include amino, cyano, and diol. Kamal-Eldin et al. compared the separation of tocochromanols using various NPLC columns and mobile phases. They successfully separated the eight major tocochromanols on 11 columns representing silica, amino, and diol columns. The elution order is the same on the columns, α-T < α-T3, < β-T < γ-T < β-T3 < γ-T3 < δ-T < δ-T3. Bonded NP columns are preferable since they reequilibrate faster and are less sensitive to traces of polar solvents than bare silica. An example separation using a diol column is illustrated in the succeeding text.

Diol HPLC separation of tocopherols and tocotrienols

The lipid fraction from samples after dilution or saponification is dissolved appropriately in hexane. In Figure 5, the eight major tocochromanols and the internal standard, tocol, are baseline-resolved during an 18 min chromatogram using the conditions listed later in the text. Both fluorescence detection and UV detection are displayed. Fluorescence is more specific and sensitive than UV; however, UV has a wider linear range (Figure 5).

Column	Chromegabond diol, 150 × 4 mm, 3 μm
Mobile phase	Hexane/5% dioxane
Flow rate	1 ml min^{-1}
Detection	
Absorbance	296 nm
Fluorescence	Ex 296 nm/Em 340 nm

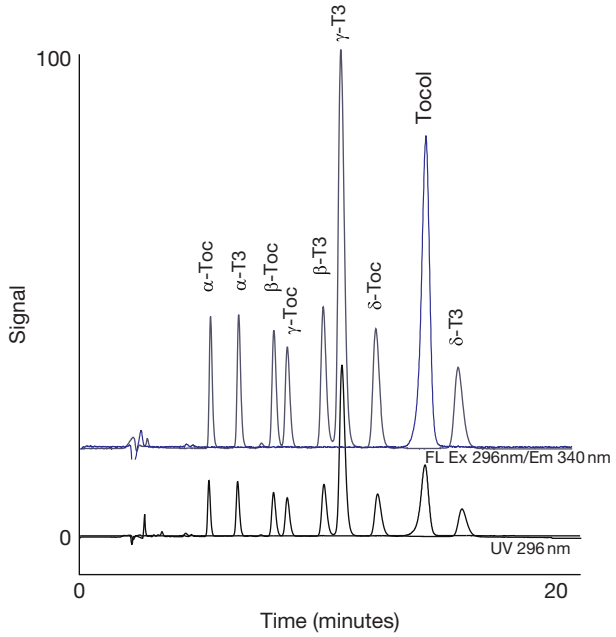

Figure 5 Separation of tocopherols and tocotrienols by NPLC using a diol column.

RPLC separation of tocochromanols

Interestingly, the first published HPLC separation of vitamin E was done using RPLC. There are many types of RPLC packing materials that separate compounds by hydrophobic interactions. These include octyl (C8), octadecyl (C18), triacontyl (C30), phenyl, cyclodextrins, PFP, and polyvinyl alcohol. The strengths of RPLC include ruggedness, rapid gradient equilibration, buffering for pH adjustment, and amenability to electrochemical and MS detection. The weaknesses include poor solubility of lipids, difficulty in separating isomers (β- and γ-homologues), and their poor stability above pH 9–10. α-Tocopherol and its esters are well separated using C18 columns (see Figure 6). Since vitamin E activity is not calculated using the other homologues, C18 separations are the most common. More recently, several RPLC separations have successfully resolved the eight major tocochromanols. Examples of RPLC separations of standard mixtures are illustrated in the succeeding text including UHPLC and core–shell.

C18 HPLC separation of tocopherols and tocotrienols

Column	Thermo Scientific Accucore C18, 150 × 2.1 mm, 2.6 μm (core–shell)
Mobile phase	75 Acetonitrile/15 methanol/10 dioxane
Flow rate	0.3 ml min^{-1}
Detection	Absorbance at 290 nm
Temperature	32 °C

Note the use of conventional HPLC instruments with highly efficient separation and short analysis time (<5 min, **Figure 6**).

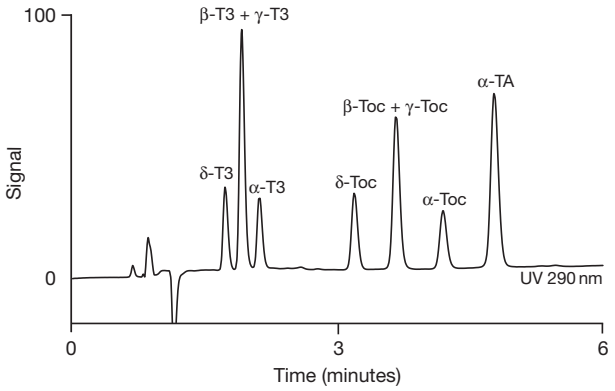

Figure 6 Separation of tocopherols, tocotrienols, and α-tocopheryl acetate using core–shell C18 column.

C30 HPLC separation of tocopherols and tocotrienols

Column	Waters YMC C30, 250 × 4.6 mm, 3 μm
Mobile phase	73 Acetonitrile/19 THF/8 water
Flow rate	1 ml min^{-1}
Detection	Absorbance at 300 nm
Temperature	32 °C

Figure 7 illustrates an RPLC separation of all eight tocochromanols using a C30 column. Analysis time is 22 min but α-TA is still retained. The column is very retentive of hydrophobic compounds so it is necessary to include a gradient at the end of the run to elute strongly retained materials. As of this writing, no <2 μm or core–shell C30 columns with the polymeric synthesis of the YMC C30 column are available. Those currently available do not separate all eight tocochromanols.

PFP HPLC separation of tocochromanols

Column	Thermo Scientific Hypersil Gold PFP, 100 × 2.1 mm, 1.9 μm (UHPLC)
Mobile phase	90 Methanol/10 water
Flow rate	0.25 ml min^{-1}
Detection	Absorbance at 290 nm
Temperature	40 °C

Figure 8 illustrates the RPLC separation of all eight tocochromanols and TA using a PFP column. The elution order for the RPLC columns is δ-T3 < β-T3 < γ-T3 < α-T3 < δ-T < β-T < γ-T < α-T < α-TA. The C30 column is an exception with γ-congeners eluting before β-congeners.

Chiral separation of tocochromanols

There are three chiral carbons in the tocopherols and one chiral carbon in the tocotrienols. Conventional chromatography does not recognize the different stereoisomers unless they are bonded with chiral derivatives. To determine if a product is 2R,4′R,8′R α-tocopherol (the natural form), it is only necessary to demonstrate a single peak using a CHIRALCEL OD-H column that produces two peaks for S- and R-isomers at the position 2. To date, all eight stereoisomers have not been separated using a single chiral chromatographic separation.

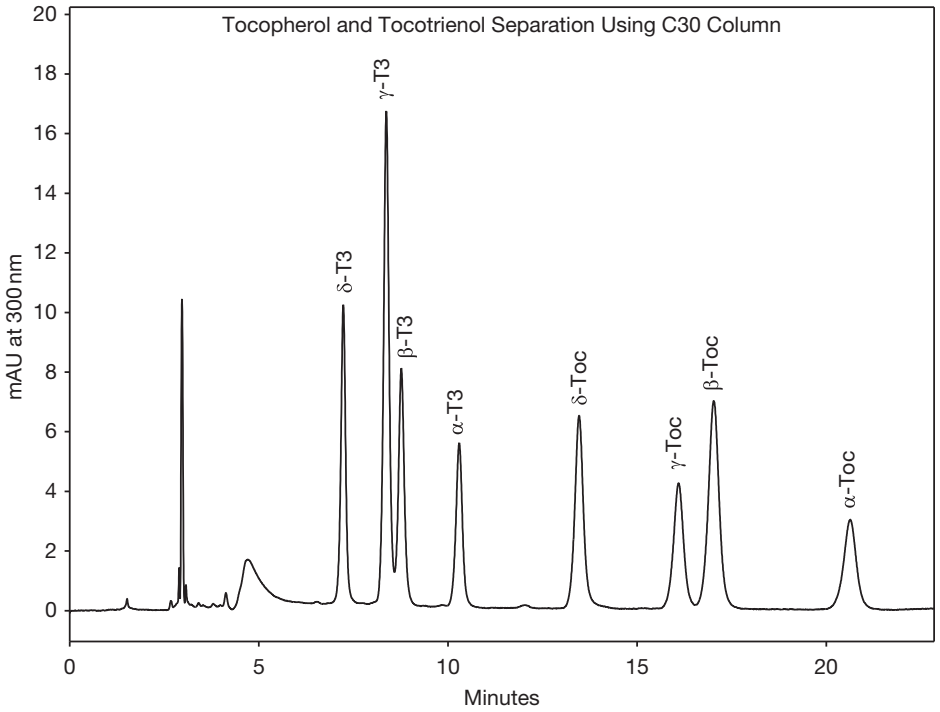

Figure 7 C30 separation of tocopherols and tocotrienols.

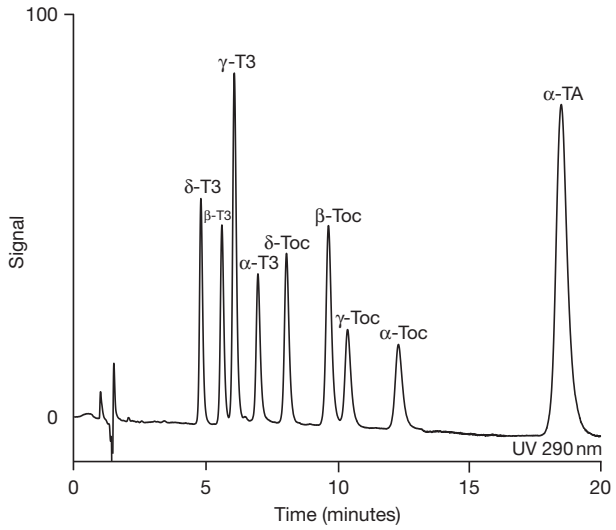

Figure 8 Tocopherols, tocotrienols, and α-tocopheryl acetate using a PFP UHPLC column.

Jensen and Lauridsen resolved five stereoisomeric peaks of the methyl ether derivatives using a CHIRALCEL OD-H column. The isomers elute in the order: peak 1 = four 2S-isomers (SSS-, SSR-, SRR-, and SRS-), peak 2 = RSS-, peak 3 = RRS-, peak 4 = RRR-, and peak 5 = RSR-α-tocopherol.

Quantitative Analysis of Tocochromanols

The most important component of analytic chemistry is standardization. This process was the biggest contributor to methodological error in the Micronutrients Measurement QA Program at NIST. The availability of reliable, high-quality standards and reference materials is limited. For this reason, standards should be qualified before use. Pure tocochromanols are oily materials and problematic to dispense small quantities since they stick to surfaces. It is recommended that a small amount of standard (~10 mg) be transferred to a 10 ml volumetric flask and brought to volume with hexane. The stock standards should be diluted to ~80 ppm in ethanol and scanned spectrophotometrically in a quartz cuvette from 270 to 320 nm. Most $E^{1\%}_{cm}$ for tocochromanols are provided in ethanol. Note that the values in hexane or petroleum ether are about 12% lower than those of ethanol. The absorbance maxima should agree with the values reported in Table 1. Failure to note solvents used in some publications has caused discrepancy regarding λ_{max} and $E^{1\%}_{cm}$. Greater consistency and traceability result from using published values compared to gravimetric standards. The concentration of each standard should be calculated using Beer–Lambert equation and then corrected for its purity measured by HPLC at the λ_{max} of each standard.

Example:

Absorbance at $\lambda_{max}/E^{1\%}_{cm}$ = Concentration g/100 ml
Absorbance at 292 nm α-T/$E^{1\%}_{cm}$ = Concentration α-T g/100 ml × HPLC area purity
=> 0.60 AU/75.8 $E^{1\%}_{cm}$ = 0.007916 g/100 ml × 0.95 purity = 0.007519 g/100 ml
=> 0.007519 g/100 ml × 1000 mg g^{-1} × 1000 μg mg^{-1} = 75.19 μg ml^{-1}

The standards with corrected concentration can be used for method calibrations on any detector type (UV, FL, electrochemical, and MS). If NPLC is being used, several

calibrator solutions from 10 to 200 μg ml^{-1} should be prepared by diluting stock standards in mobile phase. If RPLC is being used, the hexane in the stock standards should be evaporated and then dissolved using mobile phase in the range of 10–200 μg ml^{-1}. Calibrations can be generated at a wavelength slightly away from the λ_{max} but should avoid steep areas of the absorbance spectrum as a slight detector wavelength deviation will cause signal variation. Samples must be measured at the same wavelength and under the same conditions as used for the calibration.

Calibrations can be either external standardization (ESTD) or internal standardization (ISTD).

ESTD is the most common and straightforward form of calibration. Known graduated amounts of the tocochromanols are separated chromatographically and the peak heights or areas are plotted against the standard concentrations, typically creating a linear relationship. When a sample is analyzed, its concentration is estimated by determining where its peak height or area falls on the calibration curve (line). The calculations are easily performed in a spreadsheet or by a data system but the accuracy relies heavily on good laboratory practice, quantitative extraction, and highly reproducible instrumentation. It often involves the use of sample 'spikes' with known amounts of the analytes to determine percentage recovery.

Much of the rigor and uncertainty of ESTD methods can be minimized by incorporating an ISTD. ISTD calibration involves the addition of a known quantity of a compound similar to the analytes at the beginning of the extraction process to adjust for any losses, extraction efficiency, and instrument variability that may occur. The calculations are only slightly modified to make a correction for the 'measured amount of ISTD' relative to the 'added amount of ISTD.' This can be applied to an ESTD calibration as a correction at the end or directly in the ISTD calibration curve by plotting the 'area of analyte'/'area of ISTD' relative to 'concentration analyte'/'concentration of ISTD.' The use of ISTD is preferred over ESTD but the choice of an appropriate ISTD is critical and not always possible. Even with ISTD, one must realize that the ISTD may not be compartmentalized or bound in the same manner as the endogenous tocochromanols and, therefore, not extracted in the same manner.

Internal Standards

Ideally, an ISTD is a chemical that is very similar, physically and chemically, to the analytes of interest. A known amount is added to the sample at the beginning of extraction to correct for any losses that may occur during sample preparation and analysis. As such, it should 'behave' like the compounds being extracted and measured. It is common for a known amount of a homologue of the analytes, not present in the samples, to be added at the beginning of sample processing. The best possible ISTD would be stable isotopes or radiolabeled isotopes of the analytes. This type of ISTD can only be resolved using specific modes of detection, such as MS, and is not universally applicable. For more common methods of analysis, a closely related compound is used, which can be 'seen' by the detector and separated chromatographically. Common ISTDs include tocol, tocopherol acetate, 5,7-dimethyltocol, and tocochromanols not present in most samples, such as δ-tocopherol or γ-tocotrienol. The sample type, mode of separation, mode of detection, and mode of sample preparation all influence the choice of an appropriate ISTD. For example, α-tocopherol acetate would not be a good choice if the sample required saponification or fluorescence detection since α-tocopherol acetate fluoresces poorly and is hydrolyzed to α-tocopherol during saponification. Tocol or 5,7-dimethyltocol would be better choices since they have similar UV absorbance and fluorescence, are not altered by hydrolysis, can be separated chromatographically from the other tocochromanols, and are commercially available (Matreya, LLC).

In GC, ISTDs do not require similar UV or fluorescence properties since FID is the signal response to burning the carbon atoms in a compound. In principal, different molecules produce comparable detector responses so an ISTD needs only exhibit similar retention on the GC column. As such, cholesterol, cholestane, and palmityl palmitate have been used as ISTDs for GC analysis.

Detection of Vitamin E

Ultraviolet detection

Tocopherols and tocotrienols have very similar properties and can be measured using the same types of detection. As noted in Table 1, they have absorbance maxima near 220 and 295 nm. The lower wavelength has approximately fivefold greater absorbance. However, many other compounds exhibit absorbance in the low 200 nm region so it is often less selective and is below the absorbance cutoff for many solvents. Therefore, 290–300 nm is most frequently the region selected for UV detection. UV detection is not highly selective or sensitive (low nanogram) but is very reliable, inexpensive, and the most frequent mode of detection. Photodiode array detection is a form of UV/visible detection that allows the entire UV/visible spectrum to be monitored simultaneously. This offers improved selectivity by verifying that the UV spectrum of sample components matches that of the standards and alternative detection wavelengths should interferences occur.

Fluorescence detection

The tocochromanols fluoresce near 330 nm when excited at 220 or 295 nm. This characteristic produces a selective and sensitive (high pg range) mode of detection. Fluorescence sensitivity is typically 4- to 20-fold greater than UV sensitivity depending on the compound and the HPLC solvents. FL is one of the most common methods to measure tocochromanols, often negating the need to perform saponifications. Note that the tocopherol esters have poor fluorescence and lesser UV absorbance at ~10 nm lower wavelength.

Electrochemical detection

ECD can be used to measure tocochromanols in RPLC when a 'supporting electrolyte' is present in the mobile phase. ECD is the most sensitive mode of detection for tocochromanols due to their low oxidative potential, typically 10- to 20-fold better than FL. The two common forms of ECD are amperometric and coulometric. In amperometric detection, the column eluant passes over a glassy carbon electrode at ~600 mV providing oxidation of ~1% of the sample. In coulometric detection, the column eluant passes through a porous carbon electrode at 350–500 mV providing nearly 100% oxidation of the sample

for sensitivity in the low pg range. The supporting electrolyte is commonly an acetate or perchlorate buffer at 5–50 mM concentration. ECD is a relatively nonselective form of detection, and if other components coelute with the tocochromanols, they could be oxidized simultaneously. However, the tocochromanols are highly electroactive so other components provide minimal interference at the voltage potentials used.

Evaporative light-scattering and corona aerosol detection

ELSD or corona aerosol detection (CAD) are two universal, less-sensitive modes of detection. They may have application when tocochromanols are at higher concentrations. They are amenable to gradient elution in both RPLC and NPLC. In these detectors, the eluant is nebulized and the solvent is evaporated leaving analyte particles to be detected as they are swept through a beam of light. Sensitivity is in the microgram range for ELSD and nanogram range for CAD.

Mass spectrometric detection

MS can be used with either GC or HPLC to measure tocochromanols. It offers high sensitivity (pg range), selectivity, and the ability to identify peaks. Sensitive detection of tocochromanols can be achieved using simpler and inexpensive detectors, such as FL or ECD. It is not a good detector for measuring isomeric compounds (or isobaric) unless they are chromatographically resolved. It has been quite useful when mated with GC since coeluting compounds typically had different masses and fragmentation. The current, common MS interfaces include electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) or atmospheric pressure photoionization (APPI). While the analysis of tocochromanols has been reported using ESI, it is not best suited to measure tocochromanols since they are not readily ionized. APCI or APPI is better suited to lipophilic and poorly ionizing compounds. Szterk et al. recently compared sample preparation conditions and detection sensitivity for the analysis of tocochromanols in meat. The limits of detection of tocochromanols using APCI and APPI were from 0.3 to 2.9 ng ml^{-1}. Other values measured with similar MS methods and ESI are reported in the range of 0.8 ng ml^{-1} to 1 μg ml^{-1}. They concluded that FL was 10- to 1000-fold more sensitive than MS detection.

Tortillas

SO Serna Saldivar and C Chuck-Hernandez, Centro de Biotecnología-FEMSA, Tecnológico de Monterrey, Monterrey, México

© 2016 Elsevier Ltd. All rights reserved.

Introduction

A tortilla can be defined as a flat, round, unfermented bread produced from lime [$Ca(OH)_2$]-cooked maize (*Zea mays L.*) or wheat flour (*Triticum aestivum L.*). The processes and characteristics of maize and flour tortilla differ considerably. Corn tortillas are manufactured from pregelatinized and cohesive doughs, whereas flour tortillas from gluten-developed doughs high in shortening or fat. Both types of tortillas originated in Mexico, where they are considered the national breads and are generally consumed with other fillings such as beans, meats, eggs, and vegetables.

Tortillas currently represent 30% of all baked product sales in the United States and keep being the most popular food in Mexico and many places in Central America. Approximately 120 million tortillas are consumed yearly in the United States, making these the second most popular baked product, after white bread. An average Mexican consumes more than 80 kg of maize tortillas annually. Today, derived products such as flat tostadas and tortilla chips are extensively sold as snacks and for the preparation of fast foods. Taco shells are the American version of tostadas with the only difference that they are usually fried bent (U form) and rarely colored. Regular, low-fat, and fat-free tortilla chips and related products are available in grocery stores in Mexico and the United States.

Tortillas are the main source of energy, protein, calcium, and other important nutrients in Mexico and Central America. Lime cooking considerably increases calcium and the bioavailability of niacin and significantly diminishes the amount of aflatoxins and other mycotoxins originally present in contaminated maize.

Lime-Cooked Maize Products

Matured maize kernels, lime, and water are the three basic ingredients needed for the production of tortillas. Other ingredients, such as preservatives, acidulants, emulsifiers, and hydrocolloids, are used to improve microbial and textural shelf life of table tortillas. Frying oil, salt, and different seasonings are key additional ingredients for the production of fried snacks.

Currently, nixtamalized products are obtained from three distinctive processes: the traditional and laborious method first practiced by indigenous Mesoamericans, the industrial fresh *masa*, and their conversion from dry *masa* flours. In Mexico, 41%, 37%, and 23% of tortillas are produced by these manufacturing processes, respectively. In this country, more than 4.8 million tons of dry *masa* flours is annually manufactured yielding close to 9 million tons of table tortillas. In the United States and other parts of the world, dry *masa* flour is the preferred method to produce related foods. The dry *masa* flour manufacturing process originated in Mexico in the middle of the twentieth century and has rapidly expanded to many countries around the globe. Precooked dry flours for different applications are rapidly growing worldwide because of their convenience and versatility. Flours are convenient because they have a shelf life up to 1 year in storage and require only water to reconstitute the *masa*. The major advantage of using dry flour is product flexibility. *Masa* flours for the production of white and yellow table tortillas, restaurant-style chips, tortilla chips, corn chips, and tamales are available. Additionally, these can be easily blended with other dry additives (e.g., preservatives, gums, and enrichment mixes) before processing.

Three major types of products are industrially manufactured from lime-cooked maize: table or soft tortillas, corn chips, and tortilla chips (Figure 1). Corn and tortilla chips are primarily produced and consumed in developed countries, where they have an important share within the salted snack food market.

The ancient or traditional process to obtain tortillas is still practiced by indigenous people in Mexico and Central America. Traditional maize is lime-cooked in clay pots over a fire, followed by steeping for 8–16 h (generally overnight). The cooking liquor, called *nejayote*, is discarded and then the *nixtamal* is hand-washed. *Nixtamal* is ground into a fine *masa* with a stone grinder called *metate* and then hand-molded, patted, or pressed into disks, which are baked on both sides on a hot griddle. Traditional tortillas are generally produced on a daily basis and are usually thicker and heavier than their industrially produced counterparts.

The modern lime-cooking processes use the same principles as the ancient traditional procedure first devised by Mesoamerican civilizations, but the equipment and procedures have been mechanized to improve production efficiency. The three major operations for tortilla production are lime cooking, stone grinding, and tortilla baking (Figure 1). Lime cooking is considered the most relevant part of the process because it affects functionality and finished product characteristics. Stone grinding also plays a key role because it disrupts swollen starch granules forming *masa* with a given granulation. The degree of cooking and grinding dictates the type of *masa* produced. Fine grinding produces *masa* suitable for table or soft tortillas, while coarse *masa* is preferred for fried snacks. *Masa* is transformed into tortillas after a baking step that forms the typical tortilla structure. This thermal operation inactivates all microbial loads, affects color and sensory properties via browning reactions, and further gelatinizes starch for a structured tortilla. Approximately 146 kg of table tortillas with 44–46% moisture is obtained from 100 kg of cleaned maize.

The industrial production of maize tortillas is labor-intensive and requires considerable equipment. The quality of end products depends on the nature of the raw material and manufacturing practices. The ideal kernel should be sound, free of fissures, uniform, brightly colored, and with intermediate-to-hard endosperm. In addition, the kernels

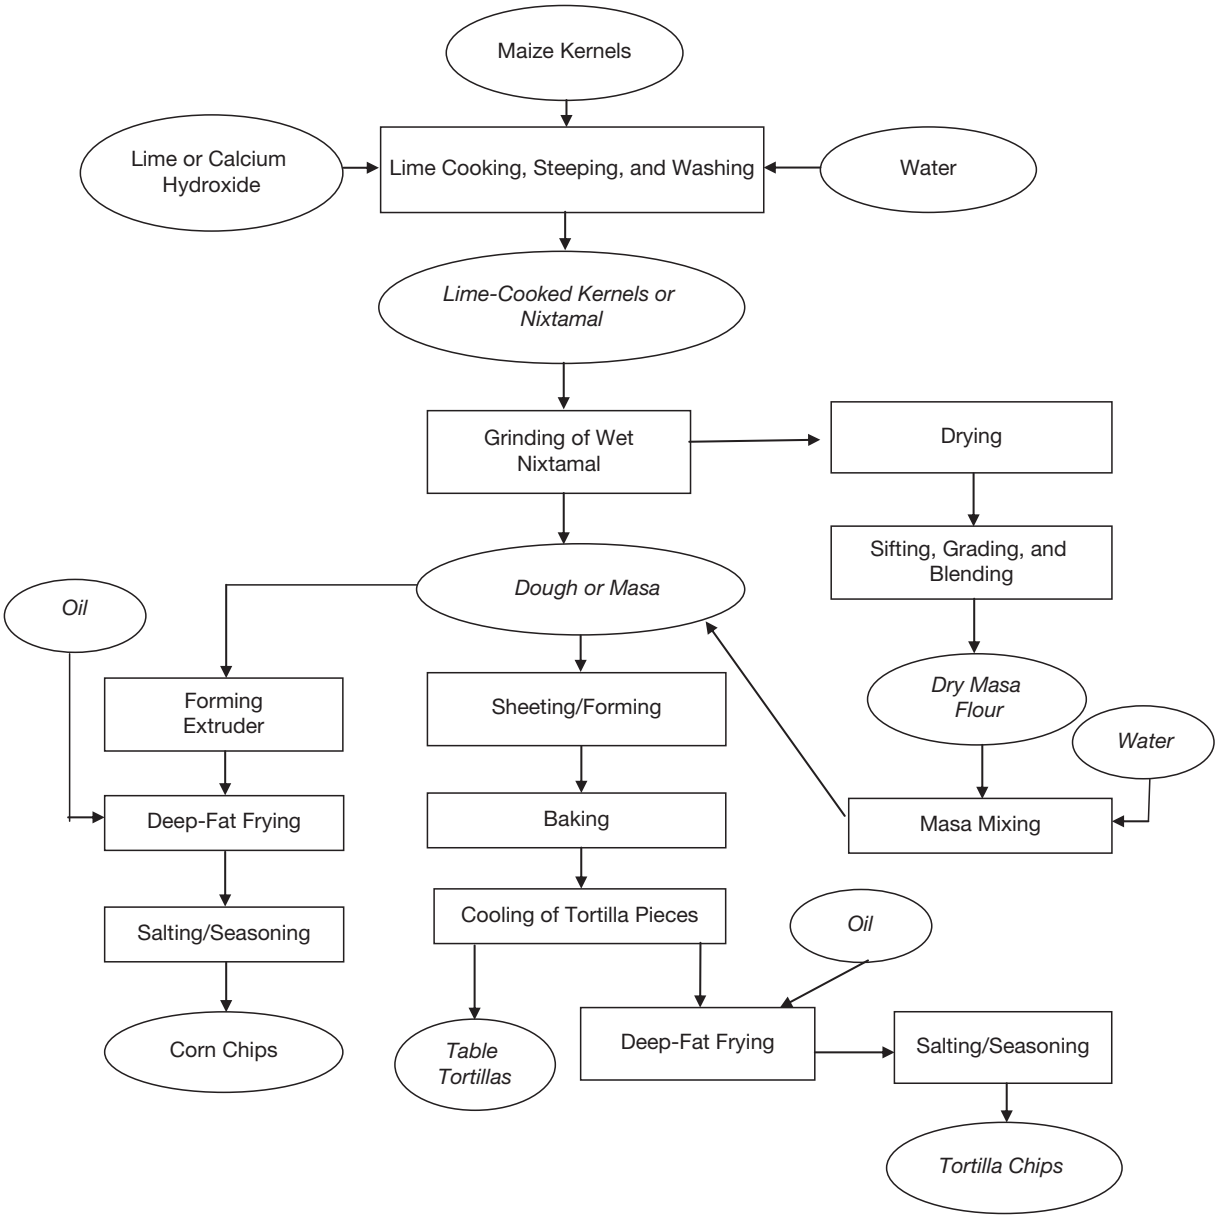

Figure 1 Flowchart of industrial processes for the manufacture of table tortillas, corn chips, tortilla chips, and dry *masa* flour.

should have a rounded crown and a shallow, unwrinkled dent, and the bran or pericarp should be easily removed after lime cooking and steeping. Yellow maize and white maize, or mixtures therefrom, are commercially manufactured into alkaline products. Recently, blue maize and other colored maize have gained market for production of tortillas and related snacks because they are viewed as functional foods.

The industrial tortilla process starts when the cleaned maize is lime-cooked in agitated open baths, vertical cookers, or steam kettles. Kernels are generally mixed with three parts water and 1% lime, based on grain weight, and cooked for 15–45 min at temperatures ranging from 85 to 100 °C. The *nixtamal* is then steeped for 8–16 h in the hot lime solution. After steeping, the lime-cooked grain is pumped with the steep liquor or dropped by gravity to washers. The cooking liquor known as *nejayote* is drained and the resulting *nixtamal* washed with pressurized water. Most of the pericarp and excess lime are removed during this step. Several important changes occur when maize is lime-cooked. Cooking causes partial dissolution of the bran tissue, and the lime penetrates the kernel mainly through the germ and internally transported to the rest of the kernel at a very slow rate. The lime also weakens the endosperm cell walls enhancing the penetration of water and heat that promotes partial swelling and gelatinization of the starch granules.

The cleaned *nixtamal* is discharged into a stone grinder, where *masa* is continuously produced. The grinder consists of two volcanic or synthetic stones carved radially, one stationary

and the other rotating at 500–700 rpm. *Masa* participle size is directly related to the extent of cooking, the gap of pressure between the stones, and the size and depth of the internal grooves. During grinding, the *nixtamal* is disrupted into a plastic and cohesive dough called *masa*. The ground particles are held together by a glue-like mixture of mechanically released partially gelatinized starch granules and sheets of the protein matrix. The attrition during grinding increases the *masa* temperature to near 50 °C and the partially hydrated starch granules are mechanically damaged.

The *masa* is then kneaded by mixers or extruders that feed the forming machine or sheeter rolls. During forming, the *masa* is rolled into a thin sheet (1.5–2 mm thick), which is cut by a rotating cutter positioned underneath the rolls. The formed pieces of *masa* are fed into a three-tier, gas-fired oven for baking. Tortillas are baked at temperatures ranging from 280 to 302 °C for 30–60 s depending on the temperature profile in the different sections of the baking oven. During baking, about 10–12% moisture is lost from the *masa*. This thermal operation also causes further starch gelatinization and protein denaturation, color development due to Maillard browning reactions, and the inactivation of microorganisms. Next, the baked tortillas are cooled on a series of open tiers and packaged when they reach ambient temperature. Tortilla shelf life greatly depends on the effectiveness of cooling. Improper cooling causes microbial problems, sticking of stacked and packaged tortillas, and moisture condensation inside the package.

Tortillas are generally treated with additives such as acidulants, preservatives, emulsifiers, and gums to improve their textural and microbial shelf lives. In fresh *masa* operations, these additives are dosed during grinding or incorporated during the *masa* kneading step before baking.

Fried Products

Frying has stretched the market for nixtamalized foods because the final products have excellent organoleptic properties and a long shelf life. The two most popular snacks, tortilla and corn chips, are usually made from coarsely ground *masa*. Corn chips are produced directly from *masa* and absorb more oil than tortilla chips during frying (Table 2). Tortilla chips are baked similarly to table tortillas before frying. Tortillas chips absorb less oil and have a firmer texture and a stronger flavor compared to corn chips. *Masa* for corn chips is extruded trough a die and cut by rotating knives before frying, whereas *masa* for tortilla chips is formed into triangles, strips, or circles before baking, equilibrating, and frying.

Corn and tortilla chips are often salted and flavored immediately after frying. The hot chips are usually conveyed into an inclined rotating cylinder that delivers onto the product dry seasonings or oil-based slurries. Most popular flavorings include nacho cheese, hot/spicy, barbecue, lemon salt, and jalapeño. Corn and tortilla chips are packaged with aluminized multilayered or plastic bags to prevent texture loss and delay rancidity. A good hot tack and initial seal strength are critical factors to control during packaging of these snacks. Corn and tortilla chips require the typical moisture barrier for most salted snacks.

Dry *Masa* Flour

Production of table tortillas and related snacks from dry *masa* flour has increased significantly during the past 20 years. The major companies that originated in Mexico dominate the industry. The largest company has nearly 30 manufacturing plants in Mexico, the United States, and Central America and keeps constructing new plants in Eastern and Western Europe, Asia, and Australia. Manufacturing tortillas and lime-cooked snacks from dry *masa* flour facilitates the process because processors do not have to concern about selection and storage of the maize kernels, lime cooking, and grinding. Furthermore, the use of dry *masa* flour greatly reduces processing time, labor, capital investment for processing equipment, and wastewater treatment. Additionally, it can be easily blended with other dry ingredients (e.g., preservatives, gums, and enrichment mixes) before processing. Disadvantages include its higher price compared to fresh *masa* and the subtle differences in flavor and texture in favor of fresh *masa* products. The major advantage of using dry *masa* flour is product flexibility. *Masa* flours for the production of white, yellow, and blue table tortillas, restaurant-style chips, tortilla chips, corn chips, and tamales are available.

The industrial process to produce dry *masa* flour is detailed in Figure 1. Dry *masa* producers stress the selection of the best maize hybrids. The ideal white or yellow maize for its production has intermediate endosperm texture, test weight higher than 70 kg hl^{-1}, true density of 1.26 g cm^{-3}, 1000 kernel weight higher than 300 g, and bright colored kernels, which are preferably threshed from white cobs.

In the dry *masa* process, selected maize kernels are heated in a $Ca(OH)_2$ solution and steeped for short periods of time and the resulting *nixtamal* washed with water. Cooking is generally performed in large reactors for 20–30 min at 85–100 °C. The amount of lime usually employed is 1% based on grain weight. The *nixtamal* and cooking solution are separated and the cooked kernels with ~36% moisture are washed with water to remove excess lime and hydrolyzed bran tissue. Then, the nixtamal is ground with a special type of hammer mill into coarse particles in preparation for drying. Drying is commonly performed in drying towers in which warm air flows countercurrent to the pieces of *masa*. The first drying step is flash where *masa* pieces are dehydrated at high temperatures for a short period of time with the aim of removing most free water. Next, particles are dehydrated at lower temperature with the aim of avoiding over gelatinization and attaining the optimum moisture content (around 10%). The particles are then sized or graded in order to formulate different flours for different applications. The coarse particles that do not meet size specifications are reground and then incorporated into final flours. The dry *masa* flour is packaged in 1, 2, or 22.7 kg (50 lb) bags. From 100 kg of cleaned maize kernels, around 93 kg of dry *masa* flour is usually obtained.

At processing plants, dry *masa* flour is simply reconstituted with water to produce *masa*. The correct addition of water and adequate mixing are the most critical steps for obtaining the best *masa* properties. The flour is blended with the water in a slow and gentle manner for 5–10 min. The amount of water commonly required to hydrate flours for table tortillas is 1.2–1.3 l kg^{-1} of flour, whereas for snacks, 1–1.1 kg^{-1} of

flour. Then, the nixtamalized foods are produced similarly as explained before.

Wheat Tortillas

A flour tortilla can be defined as a circular chemically leavened flat bread. Flour tortillas are mainly produced from refined flours although whole wheat and whole grain tortillas are gaining popularity. Generally, tortillas are 2 mm thick and have diameters that vary from 15 to 33 cm. Most wheat tortillas are industrially manufactured by hot-press, die-cut, or hand-stretch procedures (Figure 2). Each operation requires different flour specifications, dough preparation, and baking conditions, which result in various tortilla characteristics.

Wheat flour tortillas are among the fastest-growing baked goods worldwide because they are fundamental in the elaboration of many Mexican dishes widely sold by fast-food and conventional restaurants. In the United States, wheat flour tortillas are considered the fastest-growing market with wholesale sales that surpass 4 billion dollars per year. Tortillas are mainly used as wraps to produce tacos filled with shredded meats, beans, cooked eggs, vegetables, cheeses, and other fillings.

All wheat tortillas contain flour, water, fat, and salt. Table 2 depicts typical formulation for white, whole wheat, and whole grain wheat tortillas. The second major ingredient is shortening that is used to improve dough machinability, flavor, and tortilla texture especially in terms of reheating capacity. In the United States, tortillas contain several other ingredients to improve flavor, softness, rollability, and shelf life. These ingredients include chemical leavening agents, emulsifiers, antimicrobial agents, acidulants, gums or hydrocolloids, and reducing agents.

Wheat flour, the most important ingredient, is preferably enriched and bleached and should have intermediate protein content. Equipment limitations and processing conditions determine the functionality of the flour. Flours for hot-press and hand-stretch tortillas generally require less protein and gluten strength compared to counterparts for die-cut tortillas. Dough mixing time and dough properties are modified by reducing agents (sodium sulfites or cysteine), emulsifiers (lecithin, mono- and diglycerides of fatty acids, and sodium stearoyl-2-lactylate), salt, gums, fat, water content, and dough temperature.

Water (45–55% of flour weight) is needed to form the gluten complex. In some bakeries, water is warmed (35–35 °C) before mixing. Solid or liquid fats (5–15% of flour weight) are added to improve dough properties, retard staling, and produce a softer and more flexible tortilla. Salt (1–2%) is added for taste and to strengthen the gluten complex. Baking powder (1.0–2.5%) gives whiter, less dense, and spongy products. Various natural and modified cellulose gums are added at 0.1–0.5% levels to improve dough machinability and decrease stickiness of baked tortillas. Antimicrobial agents (propionates and sorbates) and acidulants (citric, fumaric, and phosphoric acids) limit fungal growth and extend shelf life.

Wheat tortilla dough is mixed to incorporate the dry ingredients, fat, and water and to form a pliable and viscous dough. The dough is optimally mixed to slightly overmixed and varies in temperature from 26 to 38 °C, depending upon subsequent operations. Then, the dough is divided and rounded into dough balls for hot-press and hand-stretch operations (Figure 2). The dough balls are rested in a warm, moist environment for 5–30 min to relax the gluten complex. Rested dough balls machine easier and form better tortillas. Regardless of the process, the formed tortillas are baked (190–260 °C for 30–50 s) in gas-fired ovens that generally have three tiers. Oven conditions vary depending upon tortilla thickness, type of conveyor (slat or wire), and forming operation. Puffing of tortilla occurs near the end of baking and is more common in hot-press and hand-stretch tortillas. Tortillas are cooled to <32 °C on cooling conveyors before placing into plastic bags for distribution. Improper cooling causes the tortilla to stick together and increase microbial problems. Most processors manufacture both white and different versions of whole wheat flour tortillas.

Hot-press tortillas are slightly off-round, elastic, and resistant to tearing, have a smooth surface texture, and resist moisture absorption from fillings. They are consumed as gourmet table tortillas, *fajitas*, and soft tacos. Die-cut tortillas are perfect circles and have lower moisture content and less resistant to cracking. Most have dusting flour on the surface and are mainly used in *burritos*, frozen Mexican foods, and fried products (e.g., taco salad bowls, taco shells, *chimichangas*, and sweet *buñuelos*). Hand-stretch tortillas are irregular in shape, elastic, and moderately resistant to tearing and usually have leftovers of dusting flour on the surface. Hand-stretch tortillas are consumed as table tortillas, *burritos*, and some fried products.

Hand-stretch operations require more labor, sanitation, and maintenance. The preformed and proofed dough balls are forced to pass through a pair of rolls; the first pair of rolls presses the dough ball into an ellipsoidal tortilla, while the second positioned perpendicularly further compresses into a semiround configuration. The preformed tortillas fall onto a hot surface where operators manually stretch them into round forms. That is the reason this method is named hand-stretch.

In die-cut operations, the dough is shaped into a sheet that is further thinned by a series of cross-rollers on a moving belt. The thin sheet of dough (about 0.5 mm) is cut by a circular die, which forms the shape. The scrap dough is returned to the dough pump and processed. Independent of the process, $\sim$150 kg of wheat flour tortillas with 32% moisture is obtained from 100 kg of flour.

Nutritional Value of Tortillas and Related Snacks

Both maize and wheat tortillas are considered as excellent sources of calories due to their high starch content. Maize tortillas are basically ground maize mixed with small quantities of lime (CaO) that was absorbed during cooking and steeping. Some nutritionists consider maize tortillas as a whole grain item although the alkali treatments break down fiber that is partially lost during the subsequent steps of steeping and *nixtamal* washing. The starch is in practical terms 100% digested and absorbed, and while being digested, glucose is transported to the bloodstream more slowly, thus favoring its value for diabetic people. The consumption of 100 g serving of tortillas (three pieces) with 46% moisture provides about 220 kcal (Table 1). The protein quality of maize and wheat

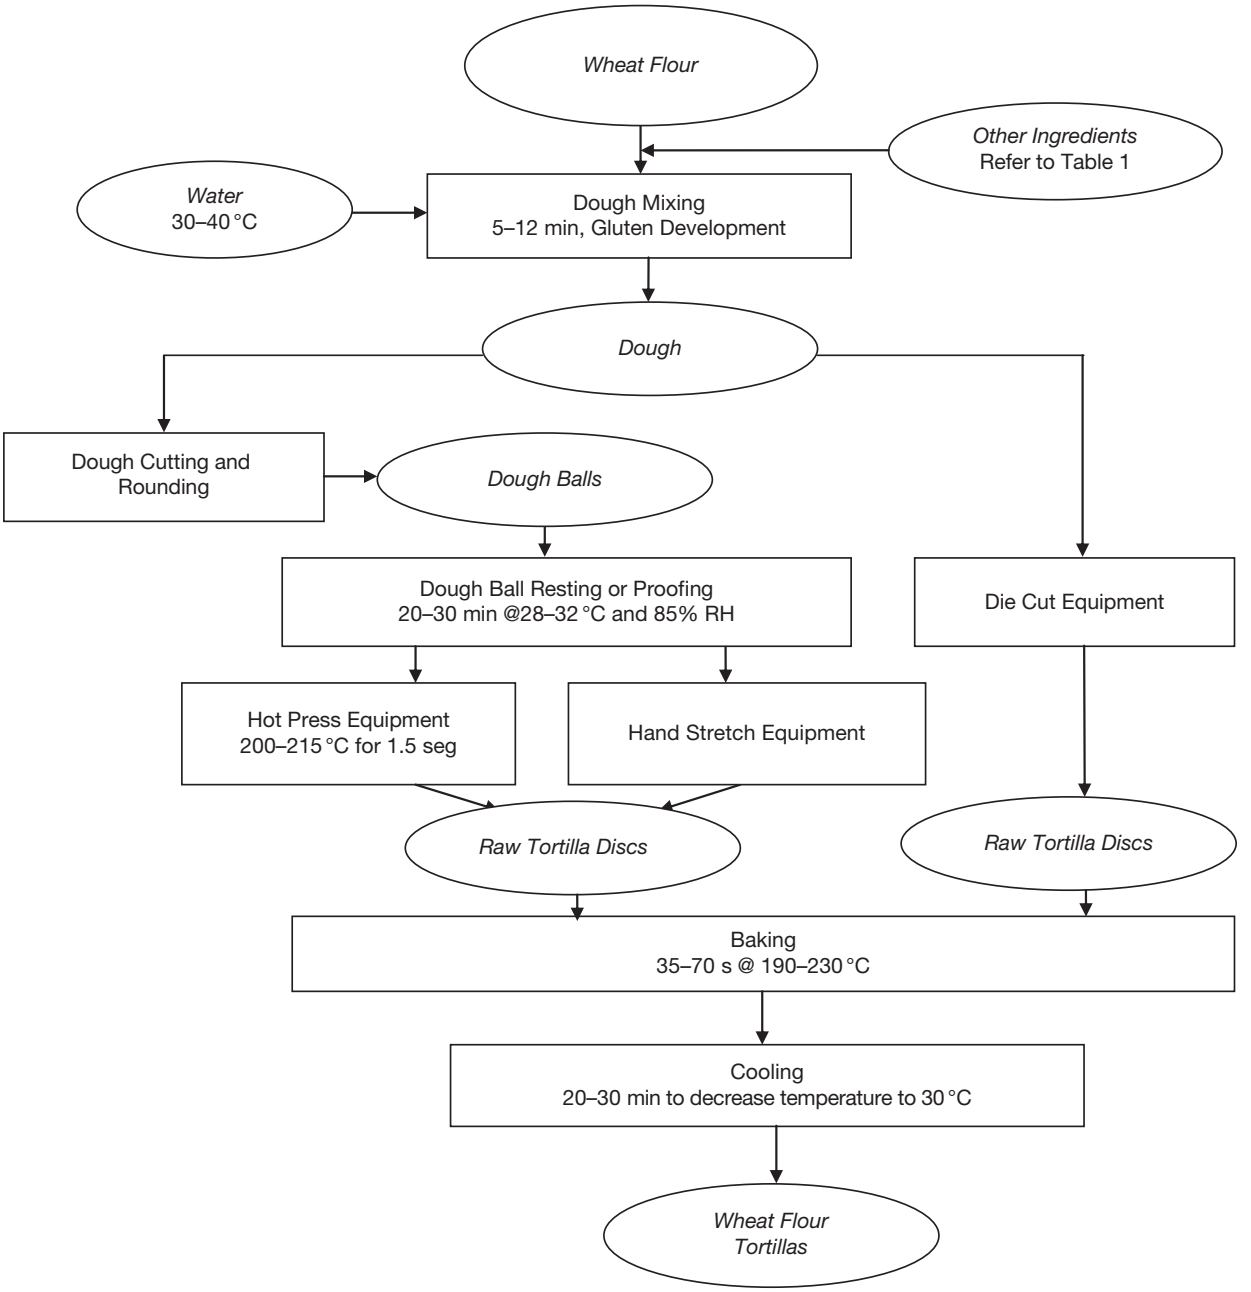

Figure 2 Flowchart of industrial processes for the manufacture of wheat flour tortillas.

tortillas is considered low because these products do not contain enough quantities of lysine to sustain regular growth in infants. This particular amino acid is present in about half of the amount required for optimum growth. Animal and human trials have demonstrated the clear nutritional superiority of opaque-2 and quality protein (QPM) over regular maize tortillas. This is because QPM has higher levels of lysine and tryptophan that result in better nitrogen retention and growth. Lime cooking also increases significantly calcium and most B vitamin levels. The caloric density of corn chips and tortilla chips is more than two times higher compared to table tortillas (Table 2). This is due to oil absorption during frying and their low moisture content. Most snacks are salted or flavored with salt-based flavorings; therefore, these products usually contain large quantities of sodium. This essential electrolyte is considered the single nutrient most abused by modern humans because an average diet usually provides at least ten times of the recommended intake. Hypertension is the main health risk associated with the high intake of this mineral.

Corn and tortilla chips are an important source of energy, protein, dietary fiber, and calcium. Corn chips are higher in calories and oil than tortilla chips. The average oil content of regular corn and tortilla chips is 36% and 24%, respectively (Table 1). Corn and tortilla chips are energy-dense because

Table 1 Nutritional composition of lime-cooked maize products and wheat flour tortillas (per 100 g serving)

	Nixtamalized products			*Wheat flour tortillas*

Emulsifiers[d]	0.1–0.3	0.1–0.3	0.1–0.3
Preservatives[e]	0.2	0.2	0.2
Fumaric acid[f]	0.2	0.2	0.2
Reducing agent[g]	10 ppm	–	–

[a]Generally, all-purpose flours with 10.5% protein are ideally suited for most applications. A higher protein content for whole wheat and whole grain tortillas is recommended. The whole wheat flour may contain different levels of wheat bran, whereas the whole grain wheat flour consists of the whole milled kernel (includes germ, aleurone, and bran at the levels found in the whole grain).

[b]In most instances, the water is warmed to 40–50 °C before dough mixing.

[c]Most common gums are carboxymethyl cellulose or CMC, xanthan, and guar gums sometimes used alone or in combination.

[d]Most common emulsifiers are lecithin, sodium stearoyl-2-lactylate, and monoglycerides used alone or combined.

[e]Most common antimold agents are calcium propionate and potassium sorbate normally used alone or combined.

[f]Quantities vary according to the desired dough pH. Generally, the pH is lowered to 5.2–5.9.

[g]Most common reducing agents are sodium bisulfite and cysteine.

most of the moisture evaporates during the frying process and part of this moisture is substituted by the frying oil. A 100 g serving of regular corn and tortilla chips provides more than 540 and 500 kcal, respectively (Table 1).

Wheat flour tortillas have a nutritional composition similar to table bread although they are slightly more caloric because their formulation contains higher quantities of shortening. In addition, most wheat tortillas are chemically leavened and not fermented. However, wheat flour tortillas contain ~36% more calories compared to maize tortillas due to their lower moisture and higher fat contents. The consumption of 100 g of flour tortillas provides about 320 kcal (Table 1). Nutrient density of whole wheat flour tortillas decreases by about 7% when compared with refined wheat counterparts. Whole wheat flour

tortillas contain 6.9% dietary fiber (3.2% insoluble and 3.7% soluble) instead of 1.8% (0.7% soluble and 1.1% insoluble) of counterparts produced from refined flour. Fat is the second largest nutrient in flour tortillas (4–10% fat), and therefore, they are high in energy from fat and saturated fatty acids especially when hydrogenated shortenings or lard is utilized. Degree of fat saturation or hydrogenation affects contents of saturated and *trans* fatty acids. Wheat flour tortillas have a high rate of protein digestibility (85%) but a relatively low protein quality because gliadins and glutelins have insufficient levels of lysine and threonine. Lysine is present in about half of the amount required for optimum child growth.

Toxins in Food: Naturally Occurring

D-F Hwang and T-Y Chen, National Taiwan Ocean University, Keelung, Taiwan

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The issue of food safety concerns various factors including bacteria, chemicals, and natural toxins. The most important natural toxins in food have been reviewed here, but some naturally occurring toxins in animal that do not cause food poisoning (e.g., snake toxins and cone shell toxins) are not reviewed. Meanwhile, the polluted toxicants such as pesticides, animal drugs, food additives, processed derivatives, and environmental chemicals also are not described here. This description provides useful information of natural toxins in food.

Classification of Toxic Compounds in Mushrooms and Terrestrial Plants

Cyanogenic Glycosides (Cyanogens)

At least 1000 plant species are reported to contain cyanogens. The cyanide in plants is present as a glycoside. At least 20 kinds of glycosides are identified in less than 50 species. Cyanogen is present in the kernels of apples, cherries, peaches, and related genera. Amygdalin is found in the highest amounts in the seeds of the bitter almond, *Prunus amygdalus* var. *amara*. Amygdalin is also a component of some herbal remedies for cancer that have produced unintentional cyanide poisoning. Cassava is a staple food starch from *Manihot esculenta* grown extensively in some parts of Africa as a major food source. The untreated root contains linamarin, a cyanogenic glucoside. Chronic ingestion of linamarin in cassava has been proposed as the cause of epidemics of konzo, a form of tropical myelopathy with sudden onset of spastic paralysis.

Stimulants and Other Psychoactive Compounds

The most widely used food stimulants are xanthic bases (caffeine in coffee, tea, cocoa, and kola nuts; theophyllin in tea; and theobromine in cocoa). Coffee is probably the most popular beverage all over the world. The xanthic bases, especially caffeine, have stimulant effects on nervous and cardiorespiratory systems.

Psychoactive compounds include myristicin, dioscorine, carotatoxin, psilocybin, and psilocin. Myristicin is present in nutmeg, mace, black pepper, parsley, celery, dill, and carrots. Myristicin may play as a weak monoamine oxidase inhibitor. However, nutmeg and mace induce greater narcotic and psychotomimetic activity than an equivalent amount of myristicin or elemicin, also a component of nutmeg.

Dioscorine is found in a few species of yams of the genus *Dioscorea* including *D. dumetorum*, *D. hirsute*, and *D. hispida*. In humans, dioscorine induces a burning sensation in the mouth and throat, abdominal pain, vomiting, diarrhea, speech disturbances, vertigo, salivation, lachrymation, sensation of heat, exophthalmos, deafness, and delirium. In severe cases, death may occur. Carrots and celery contain an acetylenic alcohol, carotatoxin. This compound resembles the powerful central nervous system (CNS) stimulant cicutoxin, a very poisonous substance from the water hemlock (*Cicuta maculata*). Several species of *Strychnos* contain strychnine and brucine (dimethoxystrychnine). Both indoles cause marked CNS stimulation by blocking glycine-gated chloride channels. Cases of unintentional poisoning from seeds of *S. nux-vomica* have been reported. Seeds of *S. ignatii* in the Philippine islands have caused similar toxic effect.

Psilocybin and psilocin are from the mushroom *Psilocybe mexicana*, and muscarline and bufotenine are from *Amanita muscaria* and other mushrooms. Meanwhile, *A. pantherina* contains the excitatory amino acid, ibotenic acid, and its derivative, muscimol. These toxic effects are somewhat variable, including CNS depression, ataxia, hysteria, hallucinations, myoclonic twitching, and seizures.

Several species of the pea family contains several species that produce excitatory amino acids in the seeds. Willardiine, 1-(2-amino-2-carboxyethyl) pyrimidine-2,4-dione, has been isolated from *Acacia willardiana*, *A. lemmoni*, *A. millefolia*, and *Minosa asperata*. Willardiine acts as an agonist on glutamate receptors. Other important excitatory amino acids are present in *Lathyrus sylvestris* (flat pea). Seeds of *L. sativus* (grass pea) are used as food and contain the excitatory amino acid β-L-ODAP (β-*N*-oxalyl-L-α, β-diamino propionic acid).

Cholinesterase Inhibitors

Cholinesterase inhibitors have been detected in several edible fruits and vegetables, including broccoli, Valencia oranges, sugar beets, rutabagas, cabbage, peppers (*Capsicum frutescence*), pumpkins, squash, carrots, strawberries, tomatoes, Jonathan and Stayman apples, lima beans, eggplant, asparagus, turnips, radishes, and several species of potatoes. The most active inhibitor is found in potatoes. The principal acetylcholinesterase inhibitor in potatoes is solanine, a glycoalkaloid formed from aglycone solanidine and glycoside. Solanine is also found in other poisonous Solanaceas, such as the common nightshade (*Solanum nigrum* and *S. americanum*). Greening in potatoes may increase the solanine content. The sprouts may contain lethal amounts of solanine. The symptoms include hyperesthesia, dyspnea, itchiness in the neck, drowsiness, and gastrointestinal effects such as vomiting and diarrhea. The alkaloids chaconine and tomatine have similar toxicities and are also found in potatoes and similar solanaceous foodstuffs.

Cardioactive Glycosides

The plant *Digitalis purpurea* (foxglove) contains the cardioactive glycoside digoxin. In the lily family, squill (*Scilla maritima*) contains scillaren, and lily of the valley (*Convallaria majalis*) contains convallatoxin in the bulbs. Both glycosides have

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00698-X

actions resembling *Digitalis*. Milkweeds (*Asclepias* spp.) are noted for the glycosides in the plants. The cardiac glycoside 6′-O-(E-4-hydroxycinnamoyl) desglucouzarin in *A. asperula*, like *Digitalis*, inhibits Na^+, K^+-ATPase. Other species of *Asclepias* also contain cardenolides. *Nerium oleander* (oleander) contains two major glycosides, oleandrin and nerium. *Thevetia peruviana* (yellow oleander) poisoning has been reported in Australia, Melanesia, Thailand, and India. The seeds are the major source of the cardiac glycosides, the most active of which is thevetin A.

Cardiac Neuroactive and Vasoactive Chemicals

These species of *Veratrum* (*V. album* and *V. californicum*) contain veratrum alkaloids, including protoveratrine, veratramine, and jervine. After ingestion, the alkaloids cause nausea, emesis, hypotension, and bradycardia. The bulbs of the wild camas (*Zigadenus paniculatus* and other species of *Zigadenus*) have been mistaken for wild onions producing severe gastrointestinal toxicity.

Aconitum species (*A. napellus*, *A. carmichaeli*, and *A. kusnezoffii*) have caused accidental poisonings. The concentration of the alkaloids (aconitine, mesaconitine, and hypoaconitine) varies depending on species, place of origin, time of harvest, and processing procedures. Grayanotoxins are reported to induce mad honey poisoning and produced by several genera of Ericaceae (*Rhododendron ponticum*, *Kalmia angustifolia*, and *R. macrophyllum)*. The effect of toxins is marked bradycardia, hypotension, oral parenthesis, weakness, and gastrointestinal upset, resembling aconitine poisoning.

Mistletoes, *Phoradendron flavescens* and *V. album*, are parasitic plants on trees and contain polypeptides phoratoxin and viscotoxins, respectively. Phoratoxin and viscotoxins cause similar effects, including hypotension, bradycardia with negative inotropic actions on heart muscle, and vasoconstriction of the vessels of skin and skeletal muscle. Some fungi (e.g., *Claviceps purpurea*, *Aspergillus fumigatus*, and *Acremonium coenophialum*) are parasitic on grains and/or plants to induce food poisoning. They produce ergot alkaloids, including lysergic acid, lysergic acid amide, ergotamine, ergonovine, and other derivatives. Human lathyrism is a neurological disease associated with the consumption of legumes of the genus *Lathyrus*, particularly *L. sativus*, *L. clymenum*, and *L. cicera*. The toxic compounds include diaminobutyric acid (BA), *N*-γ-oxalyl-α-γ-diaminobutyric acid (ODBA), *N*-β-oxalyl-α-β-diaminopropionic acid (ODPA), and γ-glutamyl-β-diaminopropionitrile (GAPN). Among them, three compounds are neurolathyrogens except for GAPN as an osteolathyrogen.

Hepatoactive Chemicals

Senecio species contain significant concentrations of pyrrolizidine alkaloids (Pas) responsible for liver damage. Four genera *Echium* (bugloss), *Cynoglossum* (hound's tongue), *Heliotropium* (heliotrope), and *Symphytum* (comfrey) also contain Pas. *Lantana camara* also contain lantadene A, which induces hepatotoxicity.

Several species of mushrooms are responsible for most fatal poisoning such as *Amanita*, *Galerina*, and *Lepiota*. *A. phalloides* contains two types of toxins, phalloidin and amatoxins. Phalloidin combines with actin in muscle cells. The α, β, and γ-amanitins are bicyclic peptides. The most toxic α-amanitins bind strongly to RNA polymerase II in hepatocytes, thus inhibiting protein synthesis. Various fungi present in food and produce toxins. Most notable toxins are aflatoxins from *Aspergillus* species, ochratoxin from *Aspergillus* and *Penicillium* molds, and zearalenone from *Fusarium* and *Gibberella* species. Aflatoxin from *A. flavus* and *A. parasiticus* has been associated with primary hepatocellular carcinoma in humans. Fumonisins are *Fusarium moniliforme* and *F. proliferatum* growing on corn.

Some Asian people specially believe that consuming animal bile juice from snake, common carp, grass carp, and other animals can improve their visual ability and liver functions. However, the major component in bile juice of common carp and grass carp is cyprinol sulfate that may induce renal failure. Moreover, bile acids (cholic acid, chenodeoxycholic acid, deoxycholic acid, and lithocholic acid) that are major components in other terrestrial animals may induce serious liver dysfunction and then progressively induce renal failure.

Favic Agents

Consumption of faba beans (*Vicia faba*) or inhalation of its pollen has been associated with the disease known as favism or pollinosis. The symptom is characterized by hemolytic anemia, hemoglobinuria, and shock. The toxic compounds are vicine (glucose + divicine) and convicine (glucose + isouramil). *Poa* and *Festuca* species are major contributors to the allergic response. Pollen from pellitory (*Parietaria* species) is an important cause of pollinosis. Pollen from mugwort, *Artemisia vulgaris*, and ragweed, *Ambrosia artemisiifolia*, also contains allergens causing summer rhinitis. The allergen has been identified as a protein.

Photodynamic Substances

The photodynamic compounds include fagopyrin (in buckwheat *Fagopyrum esculentum*), hypericin (in Klamath weed and St. John's wort, *Hypericium perforatum*), photofagopyrin (in buckwheat), isopimpinelin (in citrus fruits, celery, parsley, and other plants), and pyropheophorbide (from chlorophyll of plants and algae). Specially, abalone poisoning is caused by abalone viscera poison and is unusual in that it causes photosensitization. The toxin, pyropheophorbide, is stable to boiling, freezing, and salting. It is found in Japanese abalone, *Haliotis discus* and *H. sieboldii*. Nori (dried alga products) also caused this pyropheophorbide poisoning in Taiwan.

Toxic Phenolic Substances and Alcohols

There are more than 800 phenolic compounds in plants. These compounds may be divided into two major groups. The first group includes phenolic acids such as caffeic acid, ferulic acid, sinapic acid, gallic acid, flavonoids, lignin, hydrolyzable tannins, ellagic acids, and derivatives of these compounds. Some of these compounds have antinutritive properties and the tannins are carcinogens. The second group includes gossypol (in cotton plant), phlorizin (glycoside with aglycone phloretin in apple), coumarins, myristicin, urushiols (in mango, cashew, pistachio, sumac, oak, ivy, and lac tree), phenolic amines, and catecholamines.

Carcinogens

The Pas from certain *Senecio* plants induced liver tumors. Tannic acid also is hepatocarcinogen. Tannic acid derivatives can be divided into hydrolyzable and condensed tannins. The hydrolyzable tannins are gallic, digallic, and ellagic acid esters of glucose or quinic acid. The condensed tannins are flavolans, which are polymers of flavonoids such as catechins or anthocyanidins. Tannins are widely distributed in plants. Mango fruit contains gallotannins abundant in an unripe fruit. Many tropical fruits are rich in tannins, including dates, persimmons, and sapote fruit.

Cycasin and related azoxyglycosides (neocycasins) are found in the plant Cycadaceae, especially for *Cycas circinalis*, *C. revolute*, *Encephalartos barkeri*, and *Macrozamia spiralis*. Cycasin, neocycasins, and related aglycones resemble the nitrososamine in their biochemical action. A number of alkenyl- and alkylbenzenes with a methylenedioxy substituent in 3,4 position have been already proven to be carcinogenic. These include safrole, isosafrole, and their derivatives. Safrole and isosafrole are 3,4-methylenedioxy-1-allybenzene and 3,4-methylenedioxy-1-propenylbenzene, respectively. Safrole is a hepatocarcinogen and a pulmonary carcinogen. Safrole is present endogenously in sassafras tea (*Sassafras albidum*), *Cinnamomum micranthum*, *C. camphora* var. *glaucescens*, *C. cassia*, *C. zeylanicum*, and *C. loureirii*. Safrole is a trace constituent in cocoa, nutmeg, mace, California bay laurel, black pepper, anise, Japanese star anise, and Japanese wild ginger.

Terpenes and other isoprenoid compounds are cyclic or acyclic hydrocarbons whose derivatives are exact multiples of the isoprene unit. These compounds have been shown to be carcinogenic, cocarcinogenic, or tumor-promoting and are found in oranges, lemons, limes, grapefruits, black pepper, and ginger. Black pepper contains carcinogenic alkaloids piperine, chavicine, and piperettine. Polycyclic aromatic hydrocarbons have also been found in several raw green vegetables, cabbage, leeks, lettuce, tomatoes, and spinach. Dimethylnitrosamine was found in wheat flours, grains, and certain plants. The precursors, secondary amines, and nitrates (easily reduced to nitrites in unfresh vegetables) have been found in many plants. Thiourea, which is a goitrogen and a carcinogen, is produced endogenously in the seeds of *Laburnum* species. Coumarin and lactose are minor constituents of certain edible fruits, for example, strawberries, cherries, and apricots, and a major constituent of tonka beans. Coumarin is present in cassie, woodruff, lavender, lovage, citrus oils, and carrot seed oil. *Petasites japonicus* is used in Japan as a food and herbal remedy. A carcinogen petasitenine, a Pas, has been identified in this plant.

Miscellaneous Endogenous Toxicants

Human lathyrism is a neurological disease associated with the consumption of legumes of the genus *Lathyrus* (*L. sativus*, *L. clymenum*, and *L. cicera*). The corresponding toxic compounds include BA, ODBA, ODPA, and GAPN. BA, ODBA, and ODPA are neurolathyrogens and GAPN is an osteolathyrogen.

The functions of plant estrogens are the same as the animal estrogens. Those phytoestrogens are estrone (in palm kernels, *Elaeis guineensis*), coumestrol (in alfalfa, *Medicago sativa*), several bitter acids (coupulon, lupulon, and adlupulon in hops, *Humulus lupulus*), and isoflavones in soybeans and other sources. Several unusual fatty acids exhibit toxicity. These fatty acids include erucic acid (in rapeseeds and mustard seeds), sterculic acid and malvalic acid (cyclopropene fatty acids in cottonseed and kapok seed), cetoleic acid (in herring oil), and phytanic acid.

In avocado, D-mannoheptulose shows adverse effect on both human and animals. Umbellulone can cause skin irritation, headache, and unconsciousness and is isolated from California bay laurel. Glycyrrhizin is obtained from the root of *Licorice* plant. *Licorice* may pose a considerable hazard in those with heart or kidney disease. The oil of the wormwood plant contains the ketoterpene thujone as a major component. Thujone acts as a convulsant. Onions, garlic, and related species are well known to contain active agents (alliin and allicin). Peppermint oil contains about 40% menthol (a terpene). Cathartic compound, dihydroxyphenylisatin, may be the major agent of prunes. Curcumin is a major component of turmeric and a cholagogue and antioxidant. Carpaine is an alkaloid and is present in papaya. It possesses a powerful cardiac and diuretic action. Several acidified starfruit species in Taiwan contain high amounts of oxalic acid, which may induce renal failure. Meanwhile, Chinese herb nephropathy (CHN) is a new type of subacute interstitial fibrosis of the kidney occurring in females. CHN is not limited to China, but has been reported in France, Spain, the United Kingdom, and Japan. The toxin aristolochic acid is found in these medicinal plants of *Aristolochia* spp.

Classification of Toxic Compounds in Oceanic Plants and Animals

Tetrodotoxin

Tetrodotoxin poisoning is caused by consumption of Japan fugu or puffer. However, the toxin has been reported to be present in newts, frogs, octopus, goby fish, starfish, flatworms, xanthid crabs, and various gastropods. Puffers are found in subtropical and tropical marine waters but can live in fresh, brackish, and marine waters. Tetrodotoxin is distributed in all the tissues, especially in the ovaries, roe, liver, intestines, and skin. Those toxic animals are intoxicated through the food chain. The source of tetrodotoxin comes from bacteria, especially *Vibrio* spp.

Tetrodotoxin is a neurotoxin and is water-soluble and stable to boiling except in an alkaline solution. Toxicity is manifested as a tingling or prickly sensation of the fingers and toes; malaise; dizziness; pallor; numbness of the lips, tongue, and extremities; ataxia; nausea, vomiting, and diarrhea; epigastric pain; dryness of the skin; subcutaneous hemorrhage and desquamation; respiratory distress; muscular twitching, tremor, incoordination, and muscular paralysis; and intense cyanosis. Fatality rates are high.

Ciguateric Toxins

The name ciguatera is derived from the Spanish name 'cigua' for the sea snail *Turbo pica*. The toxins include ciguatoxin, maitotoxin, palytoxin, scaritoxin, and gambiertoxin. Among

these toxins, gambiertoxin is produced by dinoflagellate *Gambierdiscus toxicus*. The notorious fish include moray eels, surgeonfish, red snapper, trunkfish, parrotfish, grouper, and barracuda. These toxic fish accumulate toxins from the food chain. Palytoxin is produced by the soft coral *Palythoa* spp. and dinoflagellate *Ostreopsis siamensis*. The fish, crabs, and polychaete worms living in close association with or eating this mass may become contaminated with palytoxin. Palytoxin has been reported in mackerel, sardine, parrotfish, crabs, and trunkfish. The symptoms include bitter and metallic taste from the meat, nausea, vomiting, diarrhea, myoglobinuria, a burning sensation around the mouth and extremities, muscle spasms, dyspnea, and dysphonia. Death may be caused by the result of myocardial injury. Further, palytoxin is a powerful hemolysin and a predominant inhibitor of ouabain-sensitive Na^+, K^+-ATPase.

Paralytic Shellfish Poisons

Paralytic shellfish poisons (PSPs) contain saxitoxins, gonyautoxins, protogonyautoxins, and related derivatives. Those toxins are found in mussels, cockles, clams, soft shell clams, butter clams, scallops, crabs, gastropods, starfish, puffer, and mackerel. Bivalve mussels are the most common vehicles. Saxitoxin is originally isolated from toxic 'Alaskan butter clams' (*Saxidomus giganteus*) and includes neosaxitoxin and gonyautoxins 1–4. Their action is to bind to the surface of the sodium channels. The toxin produces paresthesia and neuromuscular weakness without hypotension and lacks the emetic and hypothermic action of tetrodotoxin. The toxin is an alkaloid and is relatively heat-stable. The toxin is produced by several planktons (*Alexandrium catenella*, *A. tamarensis*, *A. minutum*, *Pyrodinium* spp., *Ptychodiscus brevis*, *Gymnodinium catenatum*, and others).

Neurotoxic Shellfish Poison

In the coast of Florida, *Gymnodinium breve* forms red tide blooms containing polycyclic ether toxins called brevetoxins. Brevetoxins bind to voltage-dependent sodium channels and the strength of binding varies with the specific affinity of the toxin and thus the relative potency. Symptoms of neurotoxic shellfish poisoning include nausea, tingling and numbness of the oral area, loss of motor control, and severe muscular pain. An additional route of entry in humans may be through the inhalation of aerosolized toxin as a result of the relative case of lysis of unarmored *G. breve* organism during the breaking of waves on the shore. Symptoms are seen as irritation of the throat and upper respiratory tract. Human exposure is primarily via consumption of filter-feeding organisms, which may concentrate the toxin.

Amnesic Shellfish Poison

Amnesic shellfish poison (ASP) is found in mussels harvested from the area of Prince Edward Island in 1987. The poisoning was attributed to domoic acid produced by the diatom *Pseudonitzschia multiseries*. Occurrence of domoic acid has also been reported in California shellfish and produced by *P. pseudodelicatissima* and in anchovies produced by *P. australis*. Domoic acid has been reported in shellfish in other places like Canada, Alaska, Washington, and Oregon and may be as frequent as PSP toxins. Domoic acid has also been reported in red seaweed *Chondria armata*. Domoic acid induces gastrointestinal effects and neurological effects, including dizziness, disorientation, lethargy, seizures, and permanent loss of short-term memory. Domoic acid is an analog of glutamine, a neurotransmitter, and of kainic acid; the toxicity of all three are similar as they are excitatory and act on three types of receptors in the CNS with the hippocampus being the most sensitive. Domoic acid may be a more potent activator of kainic acid receptors than kainic acid itself. The stimulatory action may lead to extensive damage of the hippocampus, but less severe injury to the thalamic and forebrain regions.

Diarrheic Shellfish Poisons

Diarrheic shellfish poisons (DSPs) are produced by dinoflagellates *Dinophysis fortii*, *D. acuminate*, *D. acuta*, *D. norvegica*, *D. mitra*, and *Prorocentrum lima*. The toxins include okadaic acid and its derivatives, dinophysistoxins, pectenotoxins, and yessotoxins. These toxins are polyether compounds and are accumulated by fish and shellfish through the food chain. Okadaic acid was the major toxin in mussel specimens from most of the European countries, while dinophysistoxin-1 was the major toxin in mussel in Japan and in Sogndal, Norway. Scallops in Japan show the most complicated toxin profile. Pectenotoxins were detected only in Japanese shellfish. Victims suffer from diarrhea, nausea, and stomach pain but recover within 3 days without serious aftereffects. Furthermore, okadaic acid analogs possess potent tumor-promoting activity. Pectenotoxins cause acute liver injuries, while dinophysistoxins cause severe injuries on the intestinal mucosa.

Microcystins

The main genera responsible for freshwater toxic blooms are *Microcystis*, *Anabaena*, *Aphanizomenon*, and *Oscillatoria*. Toxins produced include (1) anatoxins, alkaloids, and peptides of *Anabaena*; (2) the peptide microcystin and related peptides of *Microcystis*; and (3) PSPs from *Aphanizomenon*. The properties of *Oscillatoria* toxin suggest they are peptides similar to those of *Microcystis*. Microcystins are peptides that contain three invariant D-amino acids, alanine, erythro-β-methyl aspartic, and glutamic acids, and two variant L-amino acids, *N*-methyl dehydroalanine and a β-amino acid. Individual toxic strains have one or more multiples of this peptide toxin, which is a hepatotoxin and a tumor-promoting factor. Indirect evidence indicates that one or all of these toxins are responsible for certain cases of human gastroenteritis and dermatitis from municipal and recreational water supplies.

Other Marine Toxins

Azaspiracids were observed in mussels (*Mytilus edulis*) in 1995. The symptoms observed were nausea, vomiting, severe diarrhea, and stomach cramps. Until now, azaspiracid poisoning has been reported in Ireland, the Netherlands, the United Kingdom, Italy, France, Norway, and Spain. Shellfish species

involved include mussels (*M. edulis and M. galloprovincialis*), scallops (*Pecten maximus*), and crabs (*Cancer pagurus*).

In 1997, *Pfiesteria piscicida* was reportedly implicated in killing more than 30 000 fish and making ill more than 36 people in Maryland. Victims appeared with symptoms characterized by unique skin lesions, respiratory problems, and neurological complications primarily including short-term memory loss. The *Pfiesteria* toxin was a ligated copper compound. Meanwhile, *Karlodinium veneficum* co-occurs with *Pfiesteria* spp. and produces a unique suite of compounds (karlotoxins) with hemolytic, cytotoxic, and ichthyotoxic properties. The activity of karlotoxins is like those of prymnesin, isolated from another dinoflagellate *Prymnesium parvum*, and amphidinols, a family of hemolytic toxins isolated from the dinoflagellate genus *Amphidinium*.

The Indo-Pacific moray eel (*Lycodotis nudivomer*) possesses a mucous skin secretion with hemolytic, toxic, and hemagglutinating properties. The hemolytic properties can be separated from the hemagglutinating properties. The hemolytic property is lost upon treatment with trypsin and is unstable in the presence of heat or acidic or alkaline media. The skin mucous of other species of eels, European eel (*Anguilla anguilla*), pike eel (*Muraenesox cinereus*), and Japanese eel (*A. japonica*), were found to have proteinaceous toxins.

There is a high content of retinol (vitamin A) in the liver of tuna, shark, grouper, polar bear, seal, and whale. The symptoms of hypervitaminosis A are as follows: headache, nausea, vomiting, fever, vertigo, visual disorientation, and peeling. The muscle of some fish contains a laxative. They can be divided into three types, depending on the major component of the muscular lipid. The fish of the first type contain triglyceride in black cod, *Erilepis zonifer*. The second type contains wax ester in castor oil fish *Ruvettus pretiosus* and the escolar *Lepidocybium flavobrunneum*. The fish of the third type contains diacyl glyceryl ethers. Furthermore, several deep-sea gastropods contain tetramine.

Conclusion

As mentioned earlier, there are a number of natural toxins or toxicants, many of which are not confined to a single species and are therefore most likely to be influenced by the environment. However, some natural toxins are specific to a single species or genus. These natural toxins can induce different types of food poisonings depending on their toxic effects. Those potent neurotoxic toxins, inducing severe symptoms, must be recognized to prevent from mistake.

Trace Minerals and Trace Elements

PA Tsuji, JA Canter, and LE Rosso, Towson University, Towson, MD, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Trace minerals are inorganic substances that, along with vitamins and other micronutrients, belong to those constituents in the human diet that are needed in very small quantities. Some trace minerals are essential components of enzymes and other proteins. Because trace minerals are involved in many tissue-specific cellular functions, severe deficiency of some of these dietary micronutrients may cause debility and disease and may possibly result in death. Whether a mineral is defined as a major mineral, the trace mineral, or even ultratrace mineral, appears to be somewhat arbitrary. Calcium and magnesium are among the major minerals. Iron is treated in separate articles of this encyclopedia. Here, we concern ourselves with a selection of the trace minerals of interest to human nutrition: chromium, copper, manganese, molybdenum, selenium, and zinc, as well as the trace element iodine, which frequently appears in discussion among trace minerals. Arsenic, boron, bromine, cadmium, lead, lithium, nickel, silicon, and vanadium are often labeled as ultratrace elements. Specific sections in this encyclopedia provide further information on arsenic, boron, calcium, cadmium, chromium, lead, lithium, magnesium, and manganese.

The trace mineral-specific recommended dietary allowances (RDA), tolerable upper intake levels (UL), and adequate intake (AI) values, part of the dietary reference intakes (DRI) as used by the Food and Nutrition Board of the Institute of Medicine of the US National Academies, are defined by the average daily intake that meets the basic nutrient requirements of 97.5% of the apparently healthy US population. Slightly different values may be available for European and other populations. The USDA National Nutrient Database for Standard Reference allows convenient calculation of the amounts of trace minerals and other nutrients in our diet.

Chromium

Trivalent chromium, because of its possible involvement in the insulin-regulated metabolism of carbohydrates, lipids, and proteins, is frequently, and more recently controversially, considered an essential mineral for human health. In its hexavalent form, chromium is toxic and even carcinogenic and is not considered a dietary nutrient.

Sources and Production

Chromium is a highly abundant element in the Earth's crust and found in concentrations of 1–300 mg kg^{-1} soil, with the trivalent form, Cr(III), as the dominating species in most cases. Chromium is an important alloying material for steel, and South Africa has maintained the lead in chromium ore production, with ferrochromium and metallic chromium as the two main products of chromium ore refining. Chromates, chromium oxides, and chromium salts have been further used in the pigment and leather tanning industries.

Patterns of Consumption/Human Exposure

In terms of its biological role, considerable controversy exists in terms of chromium's essentiality in human health. Chromium is present in many vegetables (e.g., broccoli, 10 μg/100 g) and fruits and fruit-derived beverages (e.g., grape juice, 28 μg/100 ml, and red wine, 0.7–10 μg/100 ml). Good sources also include beef (55 μg/100 g), poultry, and fish. In the United States, dietary chromium intake ranges from 23–29 μg day^{-1} in women to 39–54 μg day^{-1} in men. Large amounts of trivalent chromium may be consumed through popular dietary supplements, which generally contain 50–200 μg chromium/serving in forms such as chromium chloride, chromium nicotinate, and chromium picolinate, even though the effectiveness of these supplements appears to not have been clinically demonstrated. In the United States, the current dietary guidelines suggest an AI of 25 or 35 μg chromium for adult women and men, respectively. However, in 2014, the European Food Safety Authority (EFSA) published a report stating that the intake of trivalent chromium has no beneficial effect in a healthy population and concluded that no average requirement and no reference intake for chromium could be defined. Subsequently, the EFSA panel suggested that the setting of an AI for chromium was not appropriate, and thus, the AI values that currently exist for the US population have been excluded from Table 1. Excess intake of trivalent chromium from food or dietary supplements has not been observed to result in adverse health effects, and, currently, no UL has been set for dietary trivalent chromium.

Availability, Absorption, and Metabolism

Even though chromium has a fairly low bioavailability, and only 0.4–2.5% of the chromium ingested is absorbed in the intestinal tract, the human body contains about 4–6 mg of this trace mineral. The vast majority of chromium is excreted in the urine and feces, up to 0.4 μg day^{-1}, with increased excretion in those with diets high in simple carbohydrates. Consumption of vitamin C and niacin and intake of insulin and anti-inflammatory drugs appear to increase chromium absorption, whereas intake of antacids and proton pump inhibitors may block chromium absorption or increase excretion.

Health Effects/Physiology

Chromium deficiency is rare, and the recent EFSA report calls into question if a low intake in humans will result in physiological consequences. Those potentially at risk are those that may excrete higher levels of chromium or are unable to absorb chromium from the diet. Although few if any toxic effects of trivalent chromium have been described, exceedingly high quantities of trivalent chromium may inhibit DNA polymerase activity and increase the rate of various mutations in the DNA. Additionally, organ damage, including renal and liver dysfunctions, has been reported in people who have ingested

Note: For all trace minerals listed, the values for infants are AI; ND, not determined.

chromium picolinate supplements containing between 0.6 and 2.4 mg of chromium.

Copper

Copper, like many other trace minerals, is toxic in large amounts, but essential in the human diet at trace levels, and necessary for normal iron metabolism, red blood cell formation, blood coagulation, oxidation–reduction reactions, and scavenging of free radicals. The majority of the body's copper is found as Cu^{2+} species, though it is able to shift between the cuprous (Cu^{1+}) and cupric (Cu^{2+}) valence states.

Sources and Production

Copper occurs naturally in the Earth's crust within rocks, coal, clay, and soil, thus spreading naturally through the environment through dust particles, volcanic eruptions, forest fires, decaying vegetation, and sea spray. Copper is also introduced into our immediate environment through copper mining, manufacturing of copper-containing materials, waste dumps, combustion of fossil fuels, wood production, and phosphate fertilizer production. The concentrations of copper in soil, water, and air are increased in areas polluted by smelting and mining operations and combustion sources. Thus, copper is found throughout the environment from both natural and anthropogenic sources and is widely – but unevenly – distributed in our food supply, including copper-containing dietary supplements. The amount of copper within the soil is not indicative of copper content within the plants growing in the soil, because the mineral binds strongly to the surface layer of the soil and is not in a soluble form.

Patterns of Consumption/Human Exposure

Food sources with high copper content typically include organ meats (e.g., beef liver, ~14 mg/100 g), seafood (e.g., mollusks, 0.7–1.4 mg/100 g), nuts and seeds (1–2 mg/100 g), whole grains, and cocoa products (e.g., semisweet chocolate, 0.7 mg/100 g). Chicken, milk, potatoes, and tea have a lower copper content, but consumption of these foods in the general US population and elsewhere is rather large, leading to a relatively high copper intake. Copper is also present in varying amounts in drinking water due to copper plumbing and brass water fixtures. The median dietary copper intake for men and women in the United States is 1.2–1.6 mg day^{-1} and 1.0–1.1 mg day^{-1}, respectively. Similar ranges have been estimated for adults in different European countries. Regular intake of dietary supplements likely leads to increased copper intakes of 1.3–2.2 mg day^{-1} and 1.0–1.7 mg day^{-1} for men and women, respectively. Pregnant and lactating women require increased copper due to the needs of the fetus or breast-fed infant. To determine the UL of copper consumption, liver damage was used as the critical end point. The adult UL for copper is 10 mg day^{-1} (Table 1).

Availability, Absorption, and Metabolism

Copper is primarily absorbed across the mucosal barrier in the small intestine through a highly effective (55–75% absorption), energy-independent, carrier-mediated diffusion. However, excess uptake of other divalent cations, such as iron and zinc, can inhibit the absorption of copper. Transport of copper through the basolateral membrane into the interstitial fluid and blood is through an energy-dependent, rate-limiting mechanism, before absorbed copper can be transported by albumin to the liver. The primary method of copper excretion is via the gastrointestinal tract, specifically through bile, which has the highest concentration of copper in comparison with other secreted fluids. Copper also can be excreted in low concentrations through urine.

Health Effects/Physiology

General malnutrition or malabsorption can result in copper deficiency, and the condition leading to deficiency can be acquired or inherited. Importantly, copper deficiency can also occur as a result of excessive zinc intake. Copper deficiency, though relatively rare, can cause symptoms of anemia, leucopenia, and neutropenia. Menkes syndrome, a genetic disorder of copper transporter proteins, is characterized by a prominent copper deficiency caused by a reduction in the copper transport. The clinical symptoms of this disease include kinky hair, neurological degeneration, and ineffective temperature regulation and can even result in death at a young age.

Copper toxicity, outside accidental exposures in industrial settings, is rare. Moderately excessive doses can cause acute toxicity symptoms such as nausea, diarrhea, lethargy, and anorexia. Chronic or excessively large doses can result in toxic effects of copper including blood in urine, jaundice due to hepatic necrosis, and little to no urine production due to kidney damage. Copper consumed in quantities of about 1000 times the normal dietary intake level is lethal. Genetic conditions such as Wilson's disease and Indian childhood cirrhosis lead to increased risk of copper toxicity because of the inability to incorporate copper in ceruloplasmin synthesis or to excrete copper in bile, thus causing an adverse hepatic copper buildup.

The primary biochemical role of copper is as a cofactor for specific enzymes and electron transport proteins, fundamental to energy and antioxidant metabolism. Copper is incorporated into several key proteins, including ceruloplasmin (oxidative enzyme and transport protein in the blood), cytochrome oxidase (cellular respiration), superoxide dismutase (catalyzes the removal of oxygen radicals), and metallothionein (copper storage). In the presence of inflammation and cancer, plasma copper and ceruloplasmin concentrations are increased, resulting in increased protection against oxygen radicals. How copper contributes to the development and maintenance of the immune system, demonstrated by an increase in white blood cells in malnourished infants receiving copper supplements, still remains unclear. The role of copper in cardiovascular disease, Alzheimer's disease, Parkinson's disease, and the onset of osteoporosis is currently being investigated with limited conclusive findings.

Iodine/Iodide

The essential trace element iodine is best known for its integral part in the synthesis of the thyroid hormones thyroxine and triiodothyronine, which are required for normal growth,

development, and metabolic processes. Iodine is commonly found as iodide, as well as organically bound forms. In humans, up to 80% of systemic iodine is concentrated in the thyroid gland. Although a nonmetal, iodine is frequently included in the discussion of trace minerals and thus included here.

Sources and Production

Iodine is the elemental form of this trace element; however, it is more commonly found in its inorganic, highly water-soluble, salt form, iodide. Iodide is variable and relatively rare in the terrestrial environment but concentrates in saltwater environments and the plants contained therein. Commercially, iodine is produced from iodine-containing brines, including natural brines and those of gas and oil fields, especially in Chile, Japan, Russia, and the United States. In contrast, large-scale recovery of iodine from seaweed is no longer commercially viable.

Patterns of Consumption/Human Exposure

Common dietary sources of iodine are seaweed (16–2984 $\mu g\, g^{-1}$), seafood such as codfish (117 μg/100 g), yogurt (2.1 mg/100 g), and eggs (50 μg/100 g). Fruits and vegetables also contain iodine; however, this varies widely with the iodine content in the regional soil, anywhere from 10 to 1000 $\mu g\, kg^{-1}$. Iodine fortification is common in agricultural animal feed and table salt, which increases the iodine intake of most individuals to an adequate level. Commercially available dietary iodine supplements are most frequently offered in the form of potassium or sodium iodide. Clinical evaluation of iodine status is difficult, until it is so far advanced that a palpable or visible enlargement of the thyroid gland in the neck (goiter) has emerged; however, common assessment approaches for milder states are urinary excretion over time, serum thyroid-stimulating hormone (TSH) levels, and serum thyroxine levels. Despite worldwide implementation of iodine supplementation programs, inadequate iodine consumption remains a public health problem across the United States and Europe.

Availability, Absorption, and Metabolism

When ingested, iodine in the form of potassium iodide is absorbed to an extent of 96.4%. A vast majority of an individual's iodine taken in through the diet or supplements resides within the thyroid gland, with only 20–30% left to circulate through the blood. After absorption, iodide is converted to iodine in the thyroid gland for the later formation of triiodothyronine and thyroxine. Nonincorporated inorganic forms of iodine are readily excreted by the kidney. The half-life of iodine in a healthy adult's plasma is $\sim$10 h, and up to 90% of total ingested iodine is excreted in the urine within 24–48 h.

Health Effects/Physiology

Iodine deficiency can have serious consequences among both adults and children. Common effects of iodine deficiency are inadequate thyroid hormone activity and birth defects such as mental retardation. When iodine intake is below 100 $\mu g\, day^{-1}$, TSH activity will increase to sequester iodine from the bloodstream. In more serious situations, iodine intake below 10–20 $\mu g\, day^{-1}$ induces hypothyroidism and goiter. If this diminished iodine intake is chronic, thyroid cancer may develop. Groups at increased risk for iodine deficiency include those living in iodine-poor soil regions, pregnant women, and individuals who ingest high levels of goitrogens. Goitrogens, which are organic compounds that inhibit iodine, are found in foods such as soy, cruciferous vegetables, and cassava (also known as manioc or tapioca). These goitrogens are often heat-inactivated during cooking or processing; however, pasteurization of dairy products does not effectively eliminate them. As of 2013, up to 30 countries have been reported as having endemic iodine deficiency.

Iodine toxicity from dietary sources is rare but may occur when highly iodide- or iodophor-contaminated foods or excessive amounts of iodine-containing dietary supplements are consumed. Excessive intake of >1–2 mg day^{-1} may cause thyroid gland irregularities, similarly to what is observed in iodine deficiency. Because the only known function for iodine in humans relates to thyroid hormone synthesis, other symptoms for excessive iodine consumption have not been described.

When iodine status is at an adequate level, it can exhibit beneficial antioxidative and anti-inflammatory effects that can prevent or treat many common ailments. Benefits have been seen in human clinical trials with benign prostatic hyperplasia and benign breast disease. Iodine is an essential component in the human diet, and it is vital to balance food and supplement choices to allow iodine, and other beneficial trace elements, for proper physiological function.

Manganese

Manganese is a constituent of three metalloenzymes, including the principal antioxidative enzyme in the mitochondria, manganese superoxide dismutase, and is known to activate a host of other enzymes. Therefore, though frequently considered an ultratrace element, it is a required mineral of high importance to human health.

Sources and Production

Manganese is widely distributed throughout the Earth's crust and in nodules across the seafloor and thus a relatively abundant metal. It has many important industrial metal alloy uses, especially in steel production, because it improves strength, hardenability, and abrasion resistance. For many years, China has been the world's largest manganese alloy-producing country. Manganese ions are used industrially as pigments and as oxidation chemicals.

Patterns of Consumption/Human Exposure

In contrast to manganese-poor meat and dairy products, plant-based foods, including legumes, dried fruits, nuts (1.8–6.5 mg/100 g), and also tea, are rich sources of manganese. Some fruits, such as pineapple, appear to be a particularly good source of manganese (65 mg/100 g). The manganese content of whole grain products varies, as it largely depends on the plant species and the milling process used. Depending on the

diet, adult intake ranges from 2 to 9 mg day^{-1}, with vegetarians having a higher intake. The daily recommended AI for manganese is 2.3 mg for adult men and 1.8 mg for adult women, as, inexplicably, women may be able to absorb greater amounts than men.

Availability, Absorption, and Metabolism

Manganese is thought to be absorbed in its ion form, Mn^{2+}, throughout the small intestine, likely involving apical transport proteins, such as the divalent mineral transporter. Absorption of this mineral is typically $<5\%$, and homeostatic regulatory control mechanisms keep manganese levels in the desired range. Thus, the efficiency of manganese absorption appears to be inversely correlated with dietary intake. However, relatively little is known regarding factors affecting manganese absorption. Upon entering the circulation, manganese is rapidly removed from the blood and transported into cells. The half-life of manganese in blood appears to be about 10–42 days, and it is subsequently excreted, primarily through the bile in feces.

Health Effects/Physiology

Albeit having been described for various animal species, a diet-dependent manganese deficiency is unlikely in humans. Deliberate elimination of manganese from the diet over the course of several weeks has been reported to result in decreased serum manganese levels and occurrence of symptoms such as nausea, dermatitis, and altered metabolism. The UL for manganese has been set at 11 mg day^{-1} for adults. Manganese toxicity due to organ accumulation has been described in individuals with liver failure. Neonates that may be exposed to high levels of manganese through parenteral nutrition also may possibly show signs of manganese toxicity. Furthermore, increased chronic exposure to airborne manganese dust, an environmental or occupational inhalation health hazard in welders and smelters, may cause symptoms such as coughing, reduced lung function, and multiple neurological problems, because inhaled manganese appears to be transported directly to the brain.

Molybdenum

The trace mineral molybdenum is widespread in the human diet and depends on the molybdenum content of soils, which varies geographically. This element has strong redox properties and plays an important role as cofactor for four metalloenzymes.

Sources and Production

Molybdenum is mined and processed worldwide, with major operations in China, the United States, and Chile. Even though molybdenum is contained in various minerals, only molybdenite appears to be suitable for the industrial production of marketable molybdenum products, primarily for metallurgical applications including high-strength alloys. Other commercial applications include its use in fertilizer and in the semiconductor industries. Excessive, long-term exposure to soluble molybdenum compounds can potentially be found in industrial settings, where molybdenum dusts and fumes can be generated by mining or metalworking. Even though this type of exposure can be toxic, it is also relatively rare.

Patterns of Consumption/Human Exposure

Dietary intakes of molybdenum have been reported to vary widely, about 40–460 μg day^{-1}. Legumes (up to 184 μg/100 g) and grains grown in molybdenum-rich soils are good sources of dietary molybdenum. Nuts and vegetables other than legumes usually contain fewer than 50 μg/100 g, whereas meats (beef, pork, poultry, and fish) may provide up to 130 μg/100 g. The mean dietary intake of molybdenum has been estimated to range from 76 to 109 μg day^{-1} in women and men. Molybdenum intake is increased in those consuming nutritional supplements that frequently contain sodium molybdate or ammonium molybdate.

Availability, Absorption, and Metabolism

Molybdenum, usually in the form of the dietary molybdate, is readily absorbed in the small intestine, most of which appears to occur through passive diffusion. Absorption of molybdenum ranges from 50% from foods to over 90% when ingested as a dietary supplement in the form of ammonium molybdate. Ingestion of large quantities of sulfates may inhibit molybdenum absorption. Retention of dietary molybdenum is well regulated, and most of the excess molybdenum is excreted in the urine.

Health Effects/Physiology

In terms of the biological role, molybdenum is frequently found as a metal heteroatom at the active site of at least four known enzymes, which are important oxidoreductases. Even though severe molybdenum deficiency may result in amino acid intolerance, disorientation, and eventually coma, this appears to have only been encountered in a single reported patient maintained on total intravenous nutrition for 18 months. Dietary molybdenum deficiency in healthy populations has not been observed thus far, though very rare inborn metabolic disorders affecting the molybdenum cofactor affect the activity of molybdenum-containing metalloenzymes. Much like dietary molybdenum deficiency, toxicity due to excess molybdenum intake is rare. Accordingly, the UL for molybdenum is set at 2 mg. Of greater concern is the potential interference of high levels of molybdenum with the absorption of copper, potentially resulting in a copper deficiency.

Selenium

Selenium is a mineral that occurs in inorganic (elemental selenium, selenide, selenate, and selenite) and organic (including methylated selenium compounds and selenoamino acids) chemical species. It is toxic in large amounts but essential in the diet at trace levels. Most of its effects in human health are due to its incorporation through selenocysteine, the 21st amino acid, into selenium-containing proteins (selenoproteins).

Sources and Production

Selenium is fairly ubiquitous in the environment, though the amounts in which it is found vary geographically. Except in those areas where the burning of fossil fuels and industrial waste from steel plants contributes significantly, the contribution of aerosolized selenium is considered to be insignificant to human health. The primary bioavailable forms of selenium in water are inorganic selenate and selenite ions, and federal standards allow up to 50 $\mu g\,l^{-1}$ in drinking water, as regulated by the US Environmental Protection Agency (EPA) under the Safe Drinking Water Act. At typical levels, the selenium content in drinking water contributes only slightly to the daily intake, except in instances where selenium levels are elevated, as in areas of the Midwestern United States. In that part of the country, locations are known for their infamously high soil selenium content, and values from 50 to 330 $\mu g\,l^{-1}$ in wells have been reported. In the terrestrial environment, the weathering of phosphatic rocks, coal, and other organic-rich deposits is a major source of selenium, and seleniferous soils are widespread in parts of China, Russia and in parts of North and South America. However, selenium-poor soils are also found within the same regions, indicating strong geographic variation. Overall, the contribution of exposure to inorganic forms in water and soil to human selenium status is generally very minor. More important for the health of the general population are dietary exposures to mainly organic selenium forms in plants and animals. The largest use of selenium, and thus exposure for humans, is pharmaceutical and agricultural supplement use for human and farm animal diets. The addition of sodium selenite to fertilizer and/or animal feed for cattle, hogs, and chickens in areas where the soil is selenium-poor, including areas such as southwestern Oregon, is a common practice.

Patterns of Consumption/Human Exposure

Based on extrapolations from animal studies and repletion studies in selenium-deficient regions of China, the DRI for selenium in the United States was established in 1989, with an RDA of 70 μg for men and 55 μg for women, and then further adjusted in 2000 to 55 $\mu g\,day^{-1}$ for both men and women (Table 1). This amount, which is slightly lower than allowances for many European countries, but substantially higher than the recommendation in countries such as Japan, was found to achieve maximal activity of plasma glutathione peroxidase; at the same time, it is well below the adult UL of 200 μg. It should be noted that the third National Health and Nutrition Examination Survey (NHANES III), which assessed plasma selenium in over 17 000 participants, provided very compelling evidence that over 99% of the participants were selenium-replete and that routine supplementation with selenium does not appear warranted in the United States to meet current RDA requirements.

Our primary source of selenium intake is through food. Animal and human studies have shown that the bioavailability of selenium compounds varies depending on the source and form of selenium. In the United States, wheat products are highly popular and thus are one of the primary sources of dietary selenomethionine, the major available form of selenium found in grains. On average, wheat-based breakfast cereals contain below 3 μg/100 g (e.g., cooked cream of wheat) to over 100 μg/100 g (e.g., puffed wheat). However, highly variable selenium levels in about 50% of all food items exist, and the total selenium content in wheat can vary as much as 500-fold due to geographic differences and fertilization techniques. Fruits and vegetables typically contain only small amounts of selenium, unless grown under selenium-enriched conditions, which can increase their selenium content greater than 50-fold. Other plants that can accumulate selenium include various species of algae, multiple *Brassica* species, garlic, and, notably, Brazil nuts, which have a reported average selenium content of 1500–1900 μg/100 g. Fungi, such as mushrooms and yeast, are also capable of accumulating substantial amounts of organic and inorganic forms of selenium. In the United States, meat, especially organ meats, and fish are other important sources of dietary selenium. Domestic beef, chicken, lamb, and pork have an average selenium content of 10–40 μg selenium/100 g tissue, whereas dairy products contribute 3–15 μg/100 g. The selenium content in fish ranges from about 12 μg/100 g (freshwater catfish) to over 70 μg/100 g (canned tuna). The content of selenium in commercially available dietary supplements (including multimineral supplements) may include any of the organic and inorganic forms of selenium or selenium-enriched yeasts. The supplemented daily dose varies dramatically, and may be 10–200 μg, at the upper end reaching nearly four times the RDA for adults and 50% of the UL.

Availability, Absorption, and Metabolism

Absorption of the various chemical forms of dietary selenium is efficient and occurs primarily in the small intestine. Initial absorption is estimated to be around 80% but depends on the presence or absence of other trace elements and proteins. The transport mechanism of dietary selenium across the intestinal epithelium remains to be elucidated. For extracellular transport, two selenoproteins, selenoprotein P and glutathione peroxidase 3, are known to distribute selenium through the plasma. Subsequent utilization and metabolism of organic and inorganic selenocompounds, and therefore bioavailability and retention of absorbed selenium, appear to depend on the selenium species profile in the diet. The overall bioavailability has been reported to be around 14% of the original selenium content in the food, and 2–20 mg selenium can be retained in an adult human body. Metabolism of dietary selenium depends on the form ingested. Selenium levels are detectable not only in the red blood cells, liver, spleen, and heart but also in nails and hair. Excretion of selenium can occur via the kidneys in urine, the gastrointestinal tract in feces, and the lungs through expired air.

The basic human selenium requirements needed for survival and the amounts sufficient to maintain near-optimal functions of the molecular mechanisms in which selenium is involved are in a delicate balance. There appears to be a U-shaped profile for predicting the risk–benefit consequences of supplementation with dietary selenium, especially considering the differential responses to selenium supplementation due to human gene polymorphisms in selenoprotein genes. Thus, the established level of suggested selenium intake for the general population is still highly controversial. Like with many other

dietary micronutrients, the individual biological response may depend on factors, such as gender, ethnicity, selenium status, and background health.

Health Effects/Physiology

Selenium plays an important role in human development and boosting the immune function. At least two diseases have been linked with severe selenium deficiency, which are generally restricted to children of selenium-poor geographic areas in China, Central Africa, and southeast Siberia, requiring prophylactic oral selenium administration. Keshan disease, which results in congestive cardiomyopathy (heart failure and pulmonary edema), and Kashin–Beck disease, which results in osteoarthropathy and joint necrosis, both respond to dietary selenium supplementation. Myxedematous endemic cretinism, which results in mental retardation, appears to be associated with a combined iodine and selenium deficiency.

Selenium toxicity, or selenosis, is defined by blood selenium levels $>100\ \mu g\ dl^{-1}$ and is rare outside accidental industrial exposures or manufacturing errors of dietary supplements. Selenosis can result in gastrointestinal upsets, hair loss, white blotchy nails, garlic breath odor, fatigue, irritability, and mild nerve damage.

Rather than small-molecular-weight selenocompounds, more attention in recent years has been given to selenoproteins being the primary responsible agents in the health benefits of selenium. The one health benefit that has received the most attention is selenium's role as a cancer-preventive agent, primarily mediated through the action of specific selenoproteins (e.g., thioredoxin reductase 1). However, the evidence is very inconsistent, with at least one human clinical cancer prevention trial using selenium supplementation having shown a decreased incidence in prostate, colon, and lung cancers, whereas other trials, including the recent study SELECT in a selenium-replete population, found no positive health benefits. Considering the negative outcomes of this last major clinical trial, and the recent evidence that certain selenoproteins may not only prevent but also promote cancer, the American Institute for Cancer Research and the National Institutes of Health do not recommend selenium supplementation in cancer prevention.

Zinc

Zinc is an essential dietary trace element found in many natural and synthetic sources and is a constituent in over 150 essential mammalian enzymes. Many of these enzymes are involved in major metabolic processes, including DNA and insulin syntheses.

Sources and Production

Although zinc is ubiquitous in our environment, the levels of zinc vary geographically with soil type and are also influenced by proximity to industrial-based institutions that increase the metal content of soils. Plants and microorganisms take up the zinc that presents in water-soluble forms, and it thus enters our food supply. Commercially, zinc is obtained through zinc ore mining and hydrometallurgical or pyrometallurgical extraction from zinc blende. Because of the industrial processes involved, in some areas of the world, current production and/or previously established zinc dumps increase the environmental concentration of zinc in soil and thus plants.

Patterns of Consumption/Human Exposure

Seafood, red meats, and poultry are major sources of dietary zinc with examples such as cooked oysters (89 mg/100 g), beef (7.9 mg/100 g), and Alaskan king crabs (7.5 mg/100 g). Chicken, pork, or meats with high fat content have moderate zinc contents (between 1 and 2.5 mg/100 g). Other adequate sources of dietary zinc are beans, nuts, dairy products, and fortified breakfast cereals, whereas green leafy vegetables and fruits are only modest sources of zinc (<1 mg/100 g). Dietary supplements are another main source of zinc, mainly in the forms of zinc gluconate, zinc acetate, or zinc sulfate, only 23% of which is elemental zinc. Zinc lozenges and denture creams are also sources contributing to zinc status. The median zinc intake values in adult males and females are only 14 mg day^{-1} and 9 mg day^{-1}, respectively. Accordingly, clinical studies have showed that between 35% and 45% of adults over the age of 60 years fail to meet the RDA (Table 1). In contrast, excessive intake of zinc can also be detrimental. Above 150–450 mg day^{-1}, chronic effects such as immune function reduction, low levels of high-density lipoproteins, and impaired iron and copper statuses occur.

Availability, Absorption, and Metabolism

Although zinc is found in many parts of a standard diet, the zinc bioavailability from these dietary sources is not equal. Zinc is more bioavailable from animal-based foods than plant- or grain-based products, exacerbated by the fact that phytates, which are found in whole grains and legumes, bind to zinc and inhibit its absorption from dietary sources. Individuals sustaining a vegetarian diet may require up to 50% more dietary zinc than nonvegetarians due to the large amount of dietary phytates consumed.

The cellular transport of zinc is predominantly accomplished through two major solute-linked carrier gene families, the zinc transporter families, which promote cellular zinc efflux, and ZIP, which supply zinc to metalloproteins. Zinc is distributed in many tissues throughout the body, and only 10–20% of total zinc is found within the blood plasma. Upon consumption, zinc is absorbed primarily in the duodenum for later transport to the liver for binding to albumin. Extraneous zinc is secreted by the kidneys, pores in the skin, or male ejaculate fluid.

Health Effects/Physiology

Zinc deficiency can be a serious health concern. However, assessing this deficiency is not easily achieved. Plasma zinc concentration is a common method to assess zinc status; however, this is susceptible to diurnal variability. Minor symptoms of zinc deficiency are nonspecific and include loss of appetite, impaired immune function, and growth retardation. More severe symptoms include hair loss, diarrhea, impotence,

delayed sexual maturity, skin or eye lesions, impaired wound healing, hypogonadism, and lethargy. Individuals at higher risk for zinc deficiency are those whose physiological well-being is already compromised, such as the elderly, those suffering from gastrointestinal diseases, pregnant or lactating women, sickle-cell anemia patients, and alcoholics. Instances of low zinc levels in human milk impairing infant zinc status have been reported.

Zinc toxicity can present different pathologies depending upon the form of zinc consumed. Acute and chronic high intake of salts, such as zinc sulfate, can induce gastrointestinal symptoms such as pain, cramping, diarrhea, nausea, and vomiting. Elemental metallic zinc, however, can induce quite different symptoms such as light-headedness, lethargy, and other neurologically based difficulties.

Zinc has been implicated in the successful therapeutic treatment for multiple common ailments, including severe diarrhea in children, which can cause damage to the intestinal mucosa and affect the absorption of other dietary nutrients. The World Health Organization has suggested 10 mg day^{-1} zinc supplementation for children under 6 months of age upon onset of diarrhea or 20 mg zinc for children above 6 months. China has implemented such a regimen with an ~26% reduction in risk of severe diarrhea in children under 5 years of age.

There has been some evidence in the utilization of zinc supplementation in the treatment of common cold symptoms. Virus-induced common cold cases are commonplace worldwide, and these viral infections induce oxidative stress in the body. This stress elicits the activation of immune cells, such as macrophages, and inflammation. Zinc supplement lozenges, when taken within 24 h of symptom onset, may decrease the severity and length of a viral common cold infection; the suggested mechanisms are zinc's antioxidant properties and the ability to block viral binding sites to host cells. Zinc deficiency also hampers the development of T cells in the body, therefore making a response to infectious disease less effective. Another disease influenced by zinc is age-related macular degeneration. This condition can be worsened by inflammatory damage and oxidative stress, both of which can be alleviated by zinc and other antioxidative nutrients. Various skin conditions, such as dandruff, rosacea, acne, eczema, and warts, have also been treated successfully with zinc-based products.

Although zinc has many physiological benefits, deleterious interactions between dietary zinc and several common prescription medications occur. Antibiotics, such as tetracyclines and quinolones, may interact with zinc and cause diminished activity of the drugs and reduce zinc availability, itself. Similarly, thiazide diuretics can increase the urinary excretion of zinc leading to a zinc deficiency.

Traditional Foods

LF D'Antuono, Università di Bologna, Cesena, Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The semantic meaning of 'traditional food' should be clear: a food in which broad-sense knowledge (ingredients, way of preparation, role, etc.) is transmitted from generation to generation. Although not encompassing explicit reference to the way the knowledge is transmitted, common interpretations of this definition are the following:

- 'Traditional' knowledge is the complex of information and skills belonging to communities, as a result of the interaction with the environment in which they live and the available resources.
- The transmission of 'traditional' knowledge generally occurs through informal means, often orally.

Recent debates indicate that people have no difficulty to independently interpret tradition, in connection to food, attaching personal facets to this term, such as old-fashioned, consumed often in daily life, linked to special events, folkloric, belonging to a specific place, homemade, not elaborated, tasty, and natural.

For sure, 'traditional' is not a technical term and does not indicate precisely defined attributes; it is rather routinely used as a broadly agreed concept, with a not surprising share of subjective interpretation. The term 'traditional food' encompasses a series of different, overlapping, sometimes contrasting attributes, with relation to the sociocultural and economic context.

Nevertheless, reaching a so-called objective definition of traditional foods has been central in contemporary discussions, even since traditional foods recently attracted the interest of both industry and consumers, for different and, also in this case, partially contrasting reasons.

These aspects will be shortly treated in this presentation.

What 'Traditional' Foods Really Are

The Intimate Nature of 'Traditional' Foods

The intimate nature of 'traditional' foods cannot be disjointed from the context in which they originate.

The two attributes of 'being known in the local expertise' and 'transmitted through generations' are intrinsic in the term 'traditional.' This situation is typical of the so-called indigenous communities, in which individual foods do not represent merely a recipe, but the final step of food systems, a complex of knowledge and skills through which the available resources are produced or collected and processed into foods. Besides an intrinsic variability, due to geographic and seasonal constraints, some other traits characterize true-sense 'traditional' food systems of local communities:

- Raw materials and ingredients are mostly supplied on-place, from either farming or wild harvesting or a mix of the two. Of course, even in the more remote societies, external inputs to food systems have always occurred (e.g., sugar, salt, spices, and other ingredients exchanged), not affecting, however, the main pattern of supply.
- Food preparation is mostly done in-house, with intrinsic variability due to personal interpretations, likes, and supply constraints.
- In these situations, the knowledge for raw materials production, food preparation, and storage is embedded in local culture.
- Food value is directly perceived by individuals, without the need for third-party mediation.

As a result, in such societies, the concept of a 'traditional food' is substantially ill-defined, since tradition and customs largely coincide. Raw material producers, food processors, and consumers very often coincide in the same subjects. 'Traditional foods' are substantially everyday's food that can be accessed locally.

Contemporary Facts About Traditional Food Nature

Contemporary urban societies are characterized by a complex network of social relations, by the specialization of roles and lifestyles, simply making not possible the adoption of food habits similar to local rural communities:

- When food is prepared at home, the ingredients are almost entirely purchased.
- Food preparation very often is not done in-house: a relevant share of prepared foods is bought from the market.
- The knowledge and skills (and possibility) for raw materials production are almost completely lost; a similar trend is sometimes occurring for food preparation skills.
- The perception of food values increasingly occurs through the communication from third parties.

Very rarely, consumers are also producers of the food they eat. 'Tradition' is not a part of everyday's ways of life and therefore also tends to become a communicable credence character. Food is mainly 'market food' and traditional foods tend to become a market category. Recent opinions convincingly stated that 'tradition' is therefore a product of modernity, rather than an intrinsic attribute of localized food systems.

The current debate for a 'traditional food' definition developed in this context, with the aim of fixing the characterizing traits of this category.

The Trend Toward Traditional Food Definitions

Formal Definitions

The effort to attain a 'traditional food' definition is mainly, and rather typically, west European, for the following reasons:

- In west Europe, a prevailing centralized regulatory approach in setting quality standards, including foods, is adopted.

- West Europeans largely attained a quantitatively satisfactory food intake and the population growth rate is low. Food consumption is therefore not expected to significantly increase in the medium term. In this situation, food processors try to find occasions of expansion with product differentiation. Traditional foods became a tassel of this strategy, generally positively perceived by consumers, but needing some kind of categorization in order to set proprietary standards.

A road toward definitions already started during the setting up of procedures for denominations of origin legislation. Recently, two EU-funded network projects independently attained a definition, adopting different approaches.

The EuroFIR definition is based on a critical re-elaboration of previous approaches, definitions, and regulations, with special focus on the need to (a) agree upon a definition to be used in the research environment and (b) attain a 'standardization of traditional food concept,' in view of their registration, within the EU regulatory systems.

The EuroFIR definition is articulated and deals with three levels of the food production chain:

- Traditional ingredient (raw material or primary product). "Raw material (species and/or varieties) or primary product either alone or as an ingredient, that has been used in identifiable geographical areas and remains in use today (taking into account cases where use was abandoned for a time and then reinstated) and its characteristics are in accordance with current specifications of national and EU legislation."
- Traditional composition. "The uniquely identifiable composition (in terms of ingredients) that was first established prior to the Second World War and passed down through generations by oral or other means (taking into account cases where composition was abandoned for a time and then reinstated) and when necessary is differentiated from the composition defined by the generally recognized characteristics of the wider food group to which the product belongs."
- Traditional type of production and/or processing. "The production and/or processing of a food that: (a) has been transmitted from generation to generation through oral tradition or other means, and (b) has been applied prior to the Second World War and remains in use (taking into account cases where application was abandoned for a time and then reinstated) despite its adjustment to binding rules from national or EU food hygiene regulations or the incorporation of technological progress, under the condition that production and/or processing remains in line with methods used originally and that the food's intrinsic features such as its physical, chemical, microbiological, or organoleptic features are maintained."

The following points of this detailed definition may be the subject of further discussion:

- Setting a time reference to World War II as a divide between traditional and industrial ways of food preparation may fit to some urban areas of Europe, but cannot be generalized, since it tends to exclude all the still alive knowledge in rural areas, even in Europe, and in most parts of the so-called developing world. With respect to time reference, other definitions set different, more flexible time limits, such as 25 or 50 years or 'one generation.'
- The idea of fixing standards may fit to a regulatory or proprietary claim context but is in contrast with what happens in local societies, where recipes are continuously fitted to the available resources and constraints and to the availability of new ingredients and tools.

The EuroFIR definition was therefore substantially mainly aimed at the use in a scientific and regulatory context.

The TRUEFOOD definition was generated by quantitative surveys aimed at investigating consumers' perceptions of the traditional food concept, with special respect to the relations to technological innovation and the potential for industrial exploitation. The definition is

- A product frequently consumed or associated with specific celebrations and/or seasons, normally transmitted from one generation to another, made accurately in a specific way according to the gastronomic heritage, with little or no processing/manipulation, distinguished and known because of its sensory properties and associated with a certain local area, region, or country.

It is clear that, together with some consistent statements, as the association with a certain region, or the reference to reduced manipulations, this definition contains a combination of the different facets that consumers perceive. As an example, the two aspects of being 'frequently consumed' or 'associated to specific events' represent two rather opposite aspects of tradition: the first being part of everyday's life and direct perception and the latter being communicated through religious or other kinds of beliefs.

The Categories in the European Regulatory Context

The steps for food registration at EU level are the following:

- Setting up a pool of promoters (generally associated growers or processors)
- Defining a disciplinary of production, containing all the necessary details
- Submitting the application to the EU, through the competent national authorities and having it approved
- Committing the control and certification to an authorized external body
- Finally, bringing the system to a steady state of functioning

The use of the registered food name, labels, and deposited logo is reserved to the consortium associates who, in turn, must comply with the agreed and certified rules.

Apart from wines, for which specific designations are in force, the European categories of specific foodstuff registration (and protection) are the following:

PDO and PGI: Council Regulation (EC) No. 510/2006 of 20 March 2006

TSG: Council Regulation (EC) No. 509/2006 of 20 March 2006

- Protected designation of origin (PDO). "Designation of origin is linked to the name of a region, a specific place or, in exceptional cases, a country, used to describe an agricultural product or a foodstuff:

  - originating in that region, specific place or country, and
  - the quality or characteristics of which are essentially or exclusively due to a particular geographical environment with its inherent natural and human factors, and
  - the production, processing and preparation of which take place in the defined geographical area."
- Protected geographical indication (PGI). "Geographical Indication is linked to the name of a region, a specific place or, in exceptional cases, a country, used to describe an agricultural product or a foodstuff:
  - originating in that region, specific place or country, and
  - which possesses a specific quality, reputation or other characteristics attributable to that geographical origin, and
  - the production and/or processing and/or preparation of which take place in the defined geographical area."
- Traditional specialty guaranteed (TSG). "Traditional specialty guaranteed designation does not refer to an origin, but highlights the traditional composition or means of production of the product."

Not all the presently registered products belong to traditional foodstuffs (e.g., mineral waters are clearly a different case), but the registration of most of them started from an approach aimed at promoting the values connected to the native local food chain systems.

It is rather evident that a strong relation between the need for standardization and description, on one side, and registration, on the other, does exist. It is also clear that all the effort of registration is addressed at commercial production of the registered foodstuffs, but it often has only a vague connection to the 'protection' of traditional foods in their original contexts and little to do with the food values as locally perceived, which do not need third-party mediation.

Together with official EU categories, many others do exist at national or local levels, in different countries. An interesting example is represented by the Slow Food approach. Although being a private label and a successful market operation, this system embeds the concepts of food as a component of social networks and local production systems.

Some Characteristics of Traditional Foods in On-Site Food Systems

A relatively high amount of research in local tribal communities contributed to a clear vision of their food systems. Recently, investigations have also been carried out to document local food systems in industrialized countries, revealing typical and lesser known aspects, somewhat in line with the food concepts of indigenous communities and contrasting with the contemporary traditional food stereotype. Some traits are hereafter illustrated, with special reference to rural south and east Europe, in which the dietary basis is largely represented by starchy materials.

Food Strategies

Although largely modified by present-day styles of life, the basic strategy of traditional food supply in local contexts is still well present, not only in the memory of the elderly.

The prevailing strategy was that of one-course meal, generally from the combination of an energetic staple (cereal or potatoes) with other ingredients of various nature. The concept of multiple courses within a meal was almost absent, particularly with respect to that of a 'dessert.'

Cereals were primarily used as flour or grits to prepare gruels or porridges, easier and faster to prepare than products requiring the kneading of dough. Porridges can easily be combined with an array of ingredients, allowing the more effective exploitation of what is available: animal fats or meat, eggs, dairy products, vegetables, or all kinds of fruits. Among foods from dough, the unleavened types are more typical of precarious rural situations.

The fats used were those locally available, of either plant or animal origin.

Typical foodstuffs were generated by the need of preservation of perishable materials, from classical drying of meat, to drying or reducing water content of fruits and vegetables, to fermentation. All these preservation methods gave rise to some presently renowned 'typical products' and to many others, still well rooted in local or regional food systems, although not yet well known by the public.

Variability

Variability of composition is a consistent trait of local foods, mainly depending on

- the need of preparing a palatable and nutritional meal using the available ingredients, subject to seasonal and other supply constraints;
- the personal interpretation and likes of each household manager;
- the need of using the more expensive materials, like wheat, as cash crops, replacing them in domestic life with other materials, like corn and potatoes; this motivation does not hold anymore at present times, but generated a series of foods that are still known nowadays.

Because of these reasons, an almost continuous variation of both the kind and amounts of some food ingredients was in many cases generated. Perfect examples are again represented by cereal gruels with greens, in which composition may include any available green, either wild or cultivated, and in which texture may range from a thick porridge to a soup, according to the ratio between the cereal components, water, and the other ingredients. Similar situations do exist for filled pastries or other baked products. Among the latter, another illuminating example is the 'bustrengo,' a typical product of the Romagna and Marche regions (Italy) that is made of a cereal component and dried fruits; originally, it was prepared from leftover bread basis, with the addition of corn flour, mixed with the available dried fruits (apples, pears, figs, cornelian cherries, etc.); it was used as a main course, not as a dessert. During subsequent time and space steps, the cereal basis changed to rice or wheat flour; chocolate or coffee were added, as well as candied fruits and other ingredients. As a result, nowadays, asking for the 'true bustrengo recipe' is simply a nonsense. And this fact would certainly create relevant difficulties and debate in the case that whatever of the currently

prepared samples should be chosen as a reference specimen for a registration proposal as the 'true bustrengo.'

The final message is that the definition of a standard recipe, representing the reference specimen, seems to be more a matter of choice, convenience, and preference, often a mere artifact, than a real possibility for most traditional foods.

Convergence of Ingredients and Preparation

In many cases, similar ingredient utilization strategies, available raw materials, and local conditions determined the occurrence of striking cases of morphological and compositional convergence, also in remote and not communicating regions. The examples are innumerable. The cereal flour and condensed fruit syrup (mainly grape) puddings called 'sughi' in Italy and 'pelamushi' in Georgia are exactly the same. The range of variation of half-moon-shaped pastries filled with seasoned greens is perhaps higher within-type than between an average Italian (Romagna region) 'crescione' and Armenian (Nagorno-Karabakh Republic) 'zhynghial.'

Almost all these convergent foods are, however, perceived as very typical in their origin areas.

Traditional Food Evolutions and Trends

Ingredient Migration, Adoption, and Substitution

Native crops and animals have been always migrating with people. New crops and animals have always been exploited by explorers and colonizers. As a consequence, a progressive trend to the inclusion of new ingredients in local food systems occurred. Migrations are either historical or contemporary, the only difference being in the perception of the moment in which a new ingredient became 'traditional.' The examples are, again, innumerable, the better known of which are perhaps represented by the diffusion of American crops, like tomatoes, potatoes, corn, and chili pepper, to Europe first and worldwide later. And nobody would doubt to consider tomato as a characterizing ingredient of some old world traditional foods, like the Italian pizza or sweet pepper as a staple for Balkan sauces like the 'lyutenitza' or 'ajvar.'

After its introduction to Europe, corn substituted a range of previously used cereals in gruel preparation, because of yield advantages and socioeconomic reasons. Corn was also used to replace the more priced wheat flour in baked foods, losing popularity again when average economic conditions improved but, at the same time, giving rise to a series of products that are nowadays considered as 'traditional.'

Overall, new crops and animals are regularly adopted in local systems, when they do represent an advantage, whatever its nature, provided it is easily and directly perceived in the local economic culture.

Availability of New Tools and Technologies

New 'soft' technologies, compatible with the local skills, enterprise size, and financial resources, in the case of commercial productions, are readily adopted in local food systems.

Sometimes, the availability of new technologies determined substantial shifts in the kind of products and also in the overall resource exploitation strategies. As an example, the availability of refrigeration and freezing technologies tended to bring out of use the practice of fruit and, in some cases, herb drying, although to variable extent in different geographic areas.

In many cases, the availability of new technologies allowed the manufacturing of 'new' foods from native ingredients, as it is the case of the many kinds of puffed grain cakes from a range of local cereals. It is interesting to note that these new products are still perceived as connected to local dimension, provided the main ingredient is clearly individuated as local.

Standardization

As already stressed, variation and diversity are intrinsic and functional attributes of local food systems. However, in a world increasingly characterized by intensive flows of materials, information, and finances, purely local, closed systems are quite rare. A move toward standardization of ingredients and procedures can be connected to (a) convenience of the players in the food chain; (b) safety, hygiene rules, and private standards; and (c) origin or other certification schemes (e.g., organic).

Standardization by convenience of stakeholders

Raw materials. High raw material variability is acceptable for home productions, in which most operations are done manually, or when it does not substantially hamper cultural practices. When production is scaled up to commercial level, even at small scale, a degree for raw material standardization allows attaining consistent flow charts in time and buffering lags in the production flow. The standardization of raw materials may be attained either by means of selection within local plant and animal populations, when feasible and economically sustainable, or by substituting traditional ingredients with more easily available ones (e.g., wild greens with spinach), or by purchasing ingredients on the market.

Processes and products. Despite variability being a characterizing trait of traditional foods, also small-scale processors feel the need of a degree of recipe standardization in order to

- calibrate flow charts and keep them as constants as possible;
- offer a constant product in time to customers;
- be able to attach consistent nutritional information;
- differentiate from competitors.

This latter point is very important: although within-firm standardization is often sought for, the homogenization with potential competitors is mostly avoided. Local-scale processors produce their own variants, with small, but sometimes significant differences in ingredient types and balance and overall sensorial characteristics. With this respect, however, it has been pointed out that a weakness of local food manufacturers is their failure to offer a sufficient amount of product with constant characteristics, to be permanently known and available on the market.

Rules (hygiene, safety, and private standards)

Rather strict national or supernational food safety rules are applied in the Western world, with special respect to Europe, often requiring relevant financial exposure to comply with, often representing an objective barrier for small-scale processors.

In addition, private standards proliferate in Western food distribution systems. It has also been pointed out that private standards may impact small growers and processors, from limited and often contingent integration in global systems to exclusion.

Registration and certification

As explained, designations of origin and other certification forms, like TSG, are a typical European tool of traditional food promotion. In official documents, it is stated that registration can help the promotion of rural economies of the more remote and less favored areas.

Until now, the registered products belong to quite different categories, characterized by extremely different production size: from the worldwide renowned Parmigiano–Reggiano cheese to very small and local products, hardly known outside their native areas.

Some implicit facts of the registration scheme are conflicting with the real nature of traditional food:

- Registration needs the codification of standard procedures, which are hardly applied in traditional food systems management.
- Registration implies the certification of procedures by a third-party body; this is contrast with the fact that in local contexts, knowledge belongs to the community and is internally shared.
- Registration implies that the communication to consumers is also mediated by third parties. This may be unavoidable in present urban societies, characterized by a high level of specialization and low awareness of food origin, but is anyway contrasting with the fact that in local systems, pure consumers, intended as mere buyers of food manufactured by third parties, do not exist, since most people maintain high capability of producing food, and the share of food produced and manufactured at individual or community level is generally high.

While registration can be an effective tool for commercial protection of the better-known registered foods, there is little evidence that this had significant effects for the promotion of very local minor foodstuffs. In general, it seems that the chances of success for a registered product are higher if registration is pursued as a means for the consolidation of already existing agreements among producers and production and processing schemes and if the definition of the area and procedures is as inclusive as possible.

Among the facts connected to registration, the appropriation of a collective, locally consolidated food name by only the registered producers is often perceived as little acceptable.

Finally, there is often a basic skepticism about the efficacy of a centralized approach for the characterization of local products. Small-scale growers and processors are often seeking for different, more flexible, trust-based, self-certified ways of 'branding from below' that, however, lack a clear legislative background.

Trend to Work in Chain

Raw materials processed in local food systems almost never are market-purchased commodities. Small-scale, market-oriented enterprises tend to promote the use of local raw materials, although suppliers and processors do not necessarily coincide in the same persons. Moreover, local raw materials themselves (the so-called typical crops) often represent the starting point for the establishment of small-scale food systems.

The initiative for traditional food production can be generated by growers who also become processors or, in other cases, from processors who establish raw material supply agreements with individual or associated growers. In all cases, the establishment of local production chains may generate overall benefits for the economy of the location. All these examples do not correspond to the concept of a closed, traditional market system, but rather represent the answer of local stakeholders to the challenges of revalorization of small-scale, differentiated agro-food productions that recover knowledge of places, in a well-defined niche or regional-scale market perspective.

Relations of Traditional Foods to Other Specific Categories

- *Local foods*. Localized productions can coincide or not with a traditional food concept. Cases of present-day supply chains, like on-farm marketing, are often based on non-traditional products and ways of production.
- *Street foods*. Street foods are defined as foods sold on the street and for which some steps of final preparation are also carried out on the street. At almost world level, a relevant share of street foods is generated from some kind of traditional foods.
- *Ethnic foods*. Ethnic foods are typical of well-defined communities. Most ethnic foods in reality are traditional foods, outside their original contexts. Therefore, they substantially belong to the traditional food panorama, although lacking the requisite of being processed within their native systems.
- *Fusion foods*. Fusion foods are foods mixing the experiences of different cultures, in terms of ingredients or ways of preparation. Although intrinsically variable, fusion foods often retain multiple links to the concepts of ethnicity and tradition. Some fusion foods, well before the term was invented, became traditional: an example is represented of corn gruels ('polenta') in Italy, generated by the combination of the pre-Roman concept of a cereal gruel with the availability of corn, as a new ingredient.

Concluding Remarks

Despite the apparent semantic straightforwardness, the term 'traditional food' encompasses articulated facets, including tensions between new and traditional, small- or large-scale, and local and global.

Two characterizing points of local food systems are being still governed by substantial local knowledge and dominated by the perception of experience characters. Both conditions cannot be applied to urban societies, where a constant communication pressure, including the traditional food message, is exerted on consumers by third-party players.

The move toward standardization, although clear in its aims and potential economic impact, is again not matching the intrinsic nature of traditional foods. Basically, the main drawback of the current academic ad regulatory approach to traditional food definitions is to consider them as a mere recipe. Traditional foods are, in reality, the final product of a

system, in which variable and evolving conditions determine an almost continuous variation of their composition. The present debate about defining a standard traditional food is therefore rather redundant. A standard recipe of a traditional food, with consistent compositional and sensory properties over time, may represent an excellent and successful achievement, a sample of tradition-type family of foods, but could hardly be considered the 'true' specimen of something that is intrinsically variable.

Contrary to common belief, traditional foods are far from static, and local foods systems are prone to evolution, provided it is compatible with the local management structure and finances.

In the transect from almost closed tribal rural communities to globalized urbanized societies, a continuous range of situations is still present, also within industrialized countries, supporting often viable local economies. The best perspective for its preservation is perhaps represented by avoiding making too narrow categories, enhancing consumers' awareness and capability of self-appreciation of food quality, and accepting and stimulating the coexistence of exploitation schemes at different scales.

Introduction

A triglyceride (TG) – also called triacylglycerol (TAG) or triacylglyceride – is a molecule in which all the three –OH positions of glycerol are esterified by fatty acids (FAs) (see Figure 1): since the three fatty acyl moieties R1, R2, and R3 may in general be different, a high number of triglyceridic species are present in food products.

Indeed, TAGs are the main constituents of vegetable oils (where unsaturated FAs are mainly linked to the glycerol backbone) and animal fats (in which saturated FAs are usually predominant). The number of TGs in a given natural oil or fat is a function of the number of FAs present and the specificity of the enzyme systems involved in the particular fat synthesis reactions. Many plant seed fats have the potential to provide 125–1000 different TGs, animal fats contain potentially 1000–64 000 TG species, and butterfat could generate 2 863 288 TGs from 142 different FAs. In general, the chain lengths of the FAs in naturally occurring TGs vary, but most of those that can be found in oils or fats contain an even number of carbon atoms (as a consequence of their biosynthetic pathway, which passes through acetyl-CoA) in the range between 14 and 20. On the other hand, triglycerides containing FAs with an odd number of carbon atoms may be found in the fat of some animals, in particular ruminants, due to the action of specific bacteria that are able to synthesize odd- and branched-chain FAs.

TGs play a key role in both human life and activities. They represent the predominant way of storing energy in plants and animals and, for humans, are both a source of fat for consumption and a raw material for industrial processes.

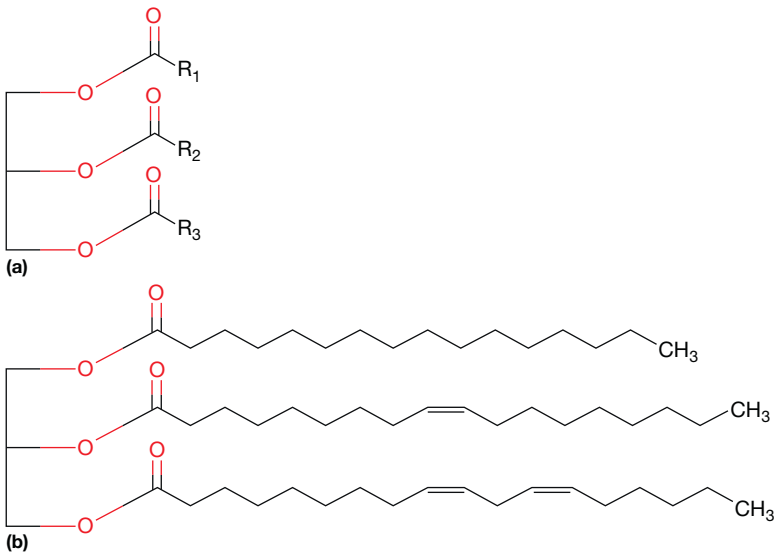

Figure 1 (a) Chemical structure of a generic triacylglycerol. (b) Chemical structure of a specific triglyceride in which R1 is palmitic acid ($C_{16:0}$, P); R2, oleic acid ($C_{18:1}$, O); and R3, linoleic acid ($C_{18:2}$, L). Using the conventional abbreviations for largely occurring fatty acids, such triglyceride would also be indicated as POL.

In this context, the chemical analysis of TAGs and, in particular, the possibility of characterizing and quantifying the individual molecular species play a determinant role in both the biochemical and technological fields and for food quality control. Indeed, the analytical chemistry of TGs allows not only to understand the biosynthetic, metabolic, and technological processes involving these molecules but also to authenticate the genuineness of a particular oil or fat product or assess its nutritional value.

For instance, the determination of serum TG levels is a standard analytic procedure in clinical practice, but it carries very little information on the metabolic status of the individual. On the other hand, specific metabolic disorders may be evidenced through the screening of the distribution of TG molecular species in a lipidomic platform. In the technological field, the possibility of predicting, controlling, or designing the consistency characteristics is very important to the properties of margarines, shortening, and specialty fats. This datum has been often related to the FA composition or with the liquid/solid ratios at various temperatures, but it is mainly related to the crystal structure of TGs, which may exist in different polymorphic forms. Since the predominance of one of these forms within a particular temperature range is related to the distribution of the unsaturations among the three positions of the TG, if not even to the chemical nature of the individual molecular species, chemical profiling of the TAG fraction might allow to define the consistency characteristics of commercial fats and oils in terms of their particular TG distribution.

TG analysis plays an important role also for the investigation of the biosynthetic metabolism of these molecules. Indeed, many studies have reported how the patterns by which nature assembles glycerol and FAs into complex mixtures of TGs should follow only two or three pathways in living organisms. Accordingly, the possibility of relating the total FA composition to the complete triglyceridic profile represents a valid supporting tool for the formulation and validation of biochemical hypotheses. A direct consequence of this is that the distribution of the various TG molecular species reflects the botanical or animal origin of oils and fats. This observation, in turn, means that TG analysis may be used to detect frauds and adulterations in the framework of the quality control of oil and fat products (e.g., fraudulent addition of seed oil to extra virgin olive oil).

From an analytic standpoint, two factors make the analytical chemistry of natural fat TGs particularly difficult: the extremely large number of possible molecular species and the very similar chemical and physical properties of most of these molecules. These two issues result in the fact that chromatography, often hyphenated with mass spectrometry (MS), is almost always used for such purpose. In the remainder of the article, the main approaches for the characterization and quantification of TG molecular species will be presented.

Chemical Analysis of TAGs: General Considerations

TAGs, as many of the existing classes of lipids, occur in nature as a very complex mixture of individual constituents that are often very similar to one another. Indeed, all the members of the family differ only in the kind of FAs that is esterifying the three available hydroxyls of the glycerol moiety. Accordingly, for a complete structural analysis of the triglycerols, it is necessary to separate them into individual molecular species, that is, into single molecules having a specific combination of acyl residues linked to the glycerol backbone. In this respect, considering the high similarity among the FA residues, which are usually found in natural triglycerides, the task can be highly challenging, if not almost impossible, when the separation of enantiomeric forms of the same species is concerned.

Moreover, the aim of the analyst is usually to try to separate these lipids into their individual species in their native form, for example, without any preliminary hydrolysis or similar reaction that may break the molecules into constituent parts: in this way, it is possible to characterize each species in terms of its metabolic function or biosynthesis or, again, physical and chemical properties.

From an analytic standpoint, chromatography, both used alone or in combination with mass spectrometric detection, is the technique of election for the characterization of TAGs. In this respect, the choice of which specific approach to use depends on the kind of information that is sought. Indeed, for instance, reversed-phase liquid chromatography provides a separation of the triglyceridic species, which is based on the total number of carbon atoms in moiety corrected by the number of unsaturations. On the other hand, in silver ion chromatography, the separation along the column is mainly driven by the degree of unsaturation of the acyl moieties. If some of the TAGs contain a polar substituent, such as – OH or NH_2 groups, then absorption chromatography could be used to separate those polar species from the standard ones, which are less polar. In general, none of the methods available are able to produce a complete fractionation of the TGs into their constituent species (even if either gas chromatography or high-performance liquid chromatography coupled to mass spectrometry (XC-MS) techniques is very promising in this respect), so that it is often customary to achieve a better separation by coupling two or more approaches in series.

Chromatographic Techniques

As anticipated, chromatography plays a fundamental role in the characterization and quantification of triglyceridic species, as the large majority of the methods proposed for this purpose involve one or more chromatographic steps. In the succeeding text, the role of the different chromatographic techniques proposed so far for TG profiling will be discussed together with their advantages and disadvantages.

Absorption Chromatography

Absorption chromatography on silica, both in thin-layer chromatography (TLC) and in column, may be successfully used to separate groups of TGs having large differences in polarity, allowing, for instance, the resolution of molecules containing short chains or oxygenated FAs (keto, hydroxy, or epoxy derivatives). As a general principle, smaller molecules (having a lower molecular weight/containing a lower number of carbon atoms) are more retained by the stationary phase than the larger ones, which travel faster. Literature studies report on

the use of such approach for the fractionation of 'acetin fats' (TGs containing both long-chain FAs and acetic acid) according to acetate content or for the characterization of beluga whale TGs, which are characterized by the presence of isovaleric acid and consequently can be separated according to isovalerate content.

Even if polarity and molecular weight are the main driving forces determining the elution order in absorption chromatography of TAGs on silica, the degree of unsaturation can provide a further modulation of the retention properties. Indeed, given the total same number of carbon atoms, the affinity for the stationary phase increases with the degree of unsaturation, so that the more unsaturated species are more retained and elute later than the less unsaturated ones. However, it should be stressed that this characteristic does not lead to a complete separation of the differentially unsaturated species having the same number of carbon atoms, which still remain partly overlapped with one another. On the other hand, absorption chromatography offers rather scarce possibilities of identifying positional isomers (such as ABA or AAB, A and B being two different FAs) unless the acyl moieties have very different chain lengths.

This technique is instead very useful and effective in fractionating oxygenated TAGs, that is, those molecular species containing hydroxy, ketone, aldehyde, ester, epoxy, or ozonide groups on their FA moieties. Since the presence of these groups may significantly alter the polarity of the species, it is possible to use absorption chromatography to separate the TGs on the basis of the number of oxygenated FAs per molecule.

Silver Ion Chromatography

Introduced in the 1960s by de Vries and Morris, silver ion chromatography proved immediately to be one of the most useful techniques for the separation of TGs. It is based on the weak interactions that may form between the Ag^+ ion and the π-electrons of double and triple bonds. Indeed, the nature of these interactions is such that the binding energy of the Ag^+/unsaturated FA complex is low enough to allow that it may be easily formed and dissociated during the time involved in the chromatographic process. Since the exposure to Ag^+ ions does not induce any chemical modification in the TG structure, the separated fractions may be recovered unaltered for further analysis, for example, by reversed-phase high-performance liquid chromatography (RP-HPLC). Moreover, silver ion chromatography can be accomplished both in TLC systems and using HPLC apparatuses, allowing a greater versatility of implementation.

Thin-layer chromatography

Silver ion TLC is usually implemented by impregnating the layer of absorbent with a silver salt (in general, $AgNO_3$), even if some authors employed an alternative approach involving the addition of the silver salt to the mobile phase in conjunction with reversed-phase TLC separation. In order to impregnate the layer, the Ag^+ salt is dissolved in a suitable solvent (water, methanol, ethanol, ammonia, or acetonitrile). For the development, the mobile phase is constituted mainly of two-component systems, the best combination seeming to be chloroform/methanol followed by hexane/diethyl ether or toluene/diethyl ether.

In silver ion chromatography, the fractionation of the TGs occurs mainly according to the total number of unsaturations in the molecule, but the way the double bonds are distributed among the FA moieties plays also an important role: given the total number of unsaturations, a molecule in which all of those are concentrated on an individual FA will be retained more firmly by the stationary phase. Accordingly, by considering TGs made up of FAs, which may contain zero to three double bonds, the following elution order may be expected for the different species:

SSS – SSM – SMM – SSD – MMM – SMD – MMD – SDD – SST – MDD – SMT – MMT – DDD – SDT – MDT – DDT – STT – MTT – DTT – TTT

where S, M, D, and T indicate saturated, monounsaturated, diunsaturated, and triunsaturated fatty acyl moieties, respectively. In the literature, there have been also attempts to resolve TG mixtures containing more highly unsaturated species, but the extent of separation has not been satisfactory.

In general, to improve the resolution of the separation, to repeat the development of the plates more than once has been proposed, changing the polarity of the solvent: in particular, it is suggested to start with the most polar mobile phase for the first development and, successively, proceed with other phases of decreasing polarity.

Another key characteristic of silver ion chromatography is that it is able to distinguish between species that contain isomeric FAs: *trans* olefins form weaker π-complexes with silver ions than do *cis* olefins; hence, molecules containing *trans* isomers are less retained than those with *cis* double bonds.

Additionally, it has been shown that this technique allows also the resolution of positional isomers of TAGs. For instance, it has been shown that when only one of the three fatty acyl moieties contains unsaturation, the symmetric species SUS (S and U indicating saturated and unsaturated FAs, respectively), where the olefin esterifies position 2 of the glycerol molecule, are less retained by the stationary phase, probably because of the lower availability of the central unsaturated acid to the Ag^+ ions.

High-performance liquid chromatography

HPLC (especially in its reversed-phase configuration; see also section '**Reversed-Phase High-Performance Liquid Chromatography**') is by far the most widely used technique for the separation of lipids, so, it has been natural, once suitable universal detectors for these class of substances (such as those based on refractive index or evaporative light scattering) have become available, to try to implement silver ion chromatography through the use of such an instrumentation.

Silver ion HPLC may employ two different kinds of packed columns: those containing silica gel impregnated with silver nitrite and the ones who involve the use of silver ions attached to a cation exchanger. The former kind has more disadvantages as there may be leaching of silver ions, plugging of the column, or precipitation of silver nitrite, all phenomena that can significantly limit its working life. Indeed, columns of the second type are the ones that are most often used now, due to their commercial availability (or to the fact that they may be easily

prepared from a commercial ion exchange HPLC column). In this respect, different studies in the literature report cation exchange columns containing benzenesulfonic acid chemically bonded to silica gel to be the most promising stationary phase. As far as the mobile phase is concerned, it is suggested to employ gradients of acetone and acetonitrile or mixtures of the two into chlorinated solvents (usually a dichloromethane/dichloroethane 1:1 mixture).

The use of reversed-phase configurations with mobile phases containing Ag^+ ions has also been reported, but it has not been demonstrated to give significant improvements over the standard RP-HPLC fractionation.

Analogously to what was already discussed, the elution order of the species reflects the degree of unsaturation of the molecules, even if there are slight differences with respect to the one for TLC, and some TGs may coelute. Indeed, the order that is normally observed is (the abbreviations having the same meaning as in section '**Thin-layer chromatography**')

SSS – SSM – SMM – SSD – MMM – SMD – MMD – SDD = SST – SMT = MDD – MMT – SDT = DDD – MDT – STT – DDT – MTT – DTT – TTT

Also in this case, it is possible to achieve further fractionation of geometric and positional isomers, by opportunely tuning the experimental conditions.

Reversed-Phase High-Performance Liquid Chromatography

Reversed-phase liquid chromatography is the most widely used method for the analysis of the TG mixtures. Due to the nature of the used phases, the retention process is influenced by a combination of the total length of the acyl chains (total number of carbon atoms) and of the overall degree of unsaturation. Indeed, to understand and rationalize the elution order of the different TGs in a mixture when RP-HPLC is used, a quantity called 'equivalent carbon number' (ECN) or 'partition number' (PN) has been introduced: it has been defined as the total number of carbon atoms (CN) in the fatty acyl moieties (i.e., without counting the glycerol backbone) reduced by twice the number of double bonds in the molecule (n), according to the formula:

$$\mathrm{ECN} = \mathrm{CN} - 2n$$

Chromatographic elution will therefore follow the order of increasing ECN, the lighter and more unsaturated species having lower retention times than the larger and more saturated ones. At the same time, TGs with the same value of ECN will tend to be partially or completely coeluted. This is what can be expected, for instance, when considering $C_{14:0}$–$C_{16:0}$–$C_{18:0}$, $C_{16:0}$–$C_{16:0}$–$C_{18:1}$, $C_{14:0}$–$C_{18:0}$–$C_{18:1}$, $C_{18:0}$–$C_{18:1}$–$C_{18:2}$, $C_{16:0}$–$C_{18:0}$–$C_{16:1}$, and so on. However, it must be stressed that the resolving power of actual instruments is such that complete coelution never occurs, as the factor for each double bond may not be considered to be constant and equal to 2.0, but its value may become slightly lower and depend on the position of the unsaturations (for instance, accounting for minimum differences between a single diene and two monoenes). A typical RP-HPLC chromatogram of a vegetable oil is shown in **Figure 2**.

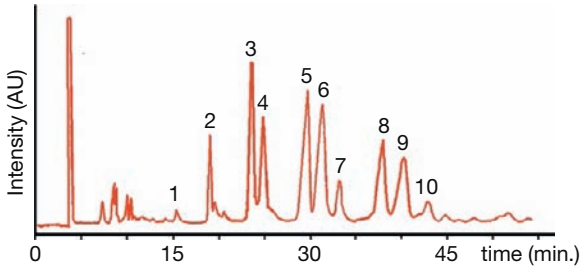

Figure 2 Example of an RP-HPLC chromatogram of a rice bran oil sample showing the elution order of the TG molecular species. Chromatographic conditions: isocratic elution with acetone/acetonitrile (55:45 v/v) on an LC-18 column (250 mm length, 4.6 mm i.d., and 5 μm particle size); differential refractometric detection. Legend: 1, LLLn; 2, LLL; 3, LLO + LnOO; 4, PLL; 5, LOO + SLL; 6, PLO; 7, PPL; 8, OOO; 9, POO + LOS; and 10, PPO (meaning of the abbreviations is described in the list at the beginning of the article).

Although aqueous mobile phases were generally used with alkyl-bonded phase columns, due to the lipophilicity of TGs, water could not be used in the mobile phase for this particular application; therefore, the mobile phases generally employed consisted of mixtures of weak and strong nonaqueous solvents, the former being almost always acetonitrile while the latter being usually chosen among chloroform, dichloromethane, isopropanol, or acetone. Among those, the combination acetone/acetonitrile is by far the mobile phase that is used most often, both because it guarantees a very good partition for almost all the TG species and because it does not interfere with most of the detectors employed (the only exception being ultraviolet spectroscopy (UV) as the cutoff for acetone is significantly higher than the absorption wavelengths of the analytes). The major difficulty in the HPLC of TAGs is that of detection, as many of the available universal detectors possess a poor sensitivity and may suffer from major drawbacks. As already mentioned, one possibility can be the use of UV absorbance as detecting system; in particular, the chromophores that are present in TGs are the ester carbonyl group, and isolated double bonds, which result in a UV absorbance at low wavelengths (190–237 nm). Such a wavelength interval is the limiting factor in the choice of the solvent system to be adopted (it was already stated earlier that acetone cannot be used with such detector and alternative strong solvents, e.g., dichloromethane, should be employed). Moreover, significant baseline drift may be observed when operating in gradient. Another widely used alternative is represented by the measure of the refractive index; however, differential refractometry is much less sensitive to TGs than is UV detection, and it is incompatible with the use of gradient elution. On the other hand, the complexity of natural TG mixtures would require gradient elution to fully utilize the resolution power of liquid–liquid chromatographic systems. These drawbacks have been mostly overcome by the introduction of the commercially available mass detector, which allowed the expansion of the possible conditions for TG separations, including that of gradient elution. The mass detector system, which possesses the characteristics of showing very narrow and symmetrical peaks in the separation of many TG mixtures regardless of their carbon number distribution, is the evaporative light scattering detector (ELSD). ELSD is universal and may be used with almost any solvent, also in gradient,

provided that they are volatile enough to evaporate in the heating chamber, without showing any drift in the baseline.

MS using either atmospheric pressure chemical ionization (APCI) or electrospray (ESI) is for sure an invaluable tool for both identifying and quantifying molecular species of TAGs. This topic will be covered in detail in section '**Hyphenated Techniques (XC-MS)**.'

High-Temperature Gas Chromatography

Due to its desirable characteristics in terms of repeatability, relative inexpensiveness, robustness, and wide range of linearity, many researchers investigated the possibility of using gas chromatography (GC) coupled with flame ionization detection for the analysis of the molecular species of TAGs. However, considering the high molecular weight of the species involved, from an experimental standpoint, the use of GC in the analysis of TGs presents several difficulties. First of all, in order to elute these family of lipids, high temperatures are needed, which are close to the limits of thermal stability both for the stationary phase and for the analytes themselves. This issue reflects in the need of paying great attention to the sample injection device and to select very carefully the nature of the stationary phase. In this respect, there has been a considerable improvement in the temperature stability of GC stationary phases, by the introduction of chemical bonding to the support and cross-linking of polymers. In particular, low-polarity phases (of the methyl silicone kind) are most stable to high temperatures but only permit separation by chain length (even if both the degree of unsaturation and the different chain lengths of the fatty acyl moieties may still provide a partial resolution). On the other hand, higher-polarity or polarizable phases (usually consisting of phenyl methyl silicones) provide an improved separation by both chain length and degree of unsaturation, but they are least stable to high temperatures. Accordingly, it is nowadays more and more customary to shift toward the use of medium-polarity phases, as a compromise, which provides an adequate degree of separation by degree of unsaturation for many practical purposes with acceptable temperature stability.

In general, if the instrumental conditions (flow rate, temperature ramp, and choice of the injection technique) are controlled and set to values that ensure that artifacts are not present and that the sample is not lost selectively during injection or through degradation on the column, high-temperature gas chromatography (HT-GC) analysis of TGs provides accurate recoveries and may attain a high precision.

Hyphenated Techniques (XC-MS)

MS is a powerful analytic tool, as it allows obtaining both structural (qualitative) information about the species and quantitative data relating to mass. Under optimum conditions, it can provide the molecular weight, the empirical formula, and often the complete structure of an unknown compound in addition to giving a measure of the amount present. It is therefore not surprising that in more and more applications, the RP-HPLC and HT-GC approaches described in sections '**Reversed-Phase High-Performance Liquid Chromatography**' and '**High-Temperature Gas Chromatography**' are coupled to mass spectrometric detection, in order to improve the performances of the methods.

In GC-MS, many applications involved the use of electron impact ionization, even if – more recently – both chemical ionization (for instance, using NH_3 as the reagent gas) and ESI have been gaining more and more relevance. In the latter case, it is suggested that the inspection of the fragments at m/z $[M-RCOO]^+$, $[RCO+128]^+$, $[RCOO+74]^+$, or $[RCO]^+$ can be used to identify the molecular species (M being the molecular ion). On the other hand, when chemical ionization is used, limited fragmentation is observed – the base peak being either the quasimolecular ion or the $[MH\text{-}RCOOH]^+$ one, depending on the nature of the reagent gas.

A similar consideration may be done as regards HPLC-MS. In this case, ionization is carried out by means of one of the atmospheric pressure ionization (API) interfaces, most commonly either APCI or ESI. These API sources share the same common characteristics of providing a 'soft' ionization of molecules and resulting usually in a protonated molecule or molecular adduct ion and only a few large fragments. However, as already briefly discussed in the preceding text, in the case of GC-MS, ESI and chemical ionization carry a diverse and often complementary information, as they result in spectra in which the relative proportions of the intact protonated molecule and adduct ions versus the fragments are different.

ESI almost always produces an intact molecule ion $[M+H]^+$ or adduct ion $[M+X]^+$ (X = Li, Na, NH_4, etc.) and only small abundances of fragments, unless tandem MS is applied. However, in order for TAGs to be amenable to be analyzed by ESI-MS, the addition of an electrolyte to produce adduct ions (e.g., ammonium formate or ammonium acetate to form $[M+NH_4]^+$) is often necessary. In this context, the possibility of using lithium adducts $[M+Li]^+$ for the analysis of TAGs by ESI-MS appears as a valid option, as it allows the identification of regioisomers and the localization of double bonds in a relatively easy fashion.

On the other hand, APCI results in a high quantity of diacylglycerol-like fragment ions $[M-RCOO]^+$, while the amount of protonated molecule formed is determined by the degree of unsaturation in the molecule. Indeed, in the case of polyunsaturated TAGs, the molecule ion $[M+H]^+$ represents the base peak, while it is almost absent in the case of saturated TAGs. Moreover, APCI-MS allows also the characterization of the regioisomeric composition of TGs, as the ratio of the $[M-RCOO]^+$ fragments produced is related to such an information.

Triacylglycerols: Structures and Properties

Introduction

Lipids are a large and diverse group of naturally occurring substances that are characterized for being mostly soluble in nonpolar organic solvents such as hydrocarbons, chloroform, benzene, ethers, and alcohols and usually insoluble in water. This group of substances includes fatty acids, glycerolipids, glycerophospholipids, sphingolipids, sterol lipids, prenol lipids, saccharolipids, and polyketides. Triacylglycerols belong to the glycerolipid class. This class comprises all compounds containing fatty acids esterified to the glycerol with the exception of glycerophospholipids. These last compounds are considered a separate class because of their abundance.

Most of all commercially important fats and oils of animal and plant origins are composed almost exclusively of triacylglycerols. They can be solid or liquid at room temperature depending on the nature of the fatty acid composition. They also represent the majority of dietary lipids, playing a major role in nutrition. This article will be dedicated to describing their structure and properties. The following article will describe their characterization and determination.

Triacylglycerol Structure

Triacylglycerols are composed of a glycerol molecule that has been esterified with three molecules of fatty acids (Figure 1). If the glycerol is only esterified with two molecules of fatty acids, the resulting glycerolipid is named diacylglycerol. Analogously, when the molecule of glycerol is esterified with one molecule of fatty acid, the resulting glycerolipid is named monoacylglycerol. Triacylglycerols can be converted into di- and monoacylglycerols by the action of lipases, and these hydrolyzed glycerolipids can also be further esterified into triacylglycerols.

Because more than one thousand fatty acids have been described and they can be distributed among the three positions of the glycerol skeleton, the number of possible combinations is very high. However, the number of common triacylglycerols is much reduced.

Although glycerol is not a chiral molecule, when substituents at positions 1 and 3 are different, a chiral carbon is created at carbon 2 of the glycerol backbone and each triacylglycerol can exist in two enantiomeric forms. To avoid confusions between the two terminal carbons of the glycerol molecule, the 'stereospecific numbering' (*sn*) system is employed.

In a Fischer projection, as the one shown in Figure 1, the secondary hydroxyl group is on the left of the carbon 2 of glycerol. Using this projection, the carbon atom above C-2 is numbered as C-1, and the carbon atom below C-2 is numbered as C-3. The triacylglycerol is termed as triacyl-*sn*-glycerol when stereochemistry is considered. When the detailed stereochemistry is not specified, the terminal carbons of glycerol are termed as α- and α′-positions, and the central carbon as the β-position. This nomenclature is also employed for mono- and diacyl-*sn*-glycerols (Figure 1). Thus, three isomers exist for each diacylglycerol (1,2-, 2,3-, and 1,3-diacyl-*sn*-glycerol) and for each monoacylglycerol (1-, 2-, and 3-monoacyl-*sn*-glycerol). When the detailed stereochemistry is not specified, only two diacylglycerols (1,2- and 1,3-diacylglycerol) and two monoacylglycerols (1- and 2-monoacylglycerol) are considered.

As an abbreviated nomenclature, triacylglycerols are commonly described by a combination of three letters representing the composing fatty acids. Thus, for example, the tripalmitin or tripalmitoylglycerol is represented as PPP, and POS would represent a triacylglycerol composed of palmitic, oleic, and stearic acids.

In general, triacylglycerols are a heterogeneous mixture of fatty acid combinations that will depend on the fatty acid composition of the source. However, fatty acids are not usually distributed at random among the carbons of the glycerol molecule. Thus, for example, in vegetable oils, saturated fatty acids are predominantly esterified at positions *sn*-1 and *sn*-3 of the glycerol, and there is not too much difference between both positions. Polyunsaturated fatty acids (mainly linoleic and linolenic acids) are esterified primarily at position *sn*-2. Monoenoic acids are relatively evenly distributed. However, less-common fatty acids tend to be concentrated at position *sn*-3.

For most species, in animal depot fats, saturated fatty acids are found predominantly at position *sn*-1; position *sn*-2 tends to contain mainly unsaturated fatty acids, although shorter-chain fatty acids can also accumulate at this position in some cases, and longer-chain fatty acids exhibit some preference for accumulating at position *sn*-3. On the other hand, pig and related species accumulate palmitic acid at position *sn*-2, stearic acid is at position *sn*-1, and position *sn*-3 is preferred by oleic and linoleic acids.

Triacylglycerol compositions of milk fat are different for each species and depend on both the diet and the nature of the fatty acids synthesized in the mammary gland. Among them, triacylglycerols of cows' milk are especially asymmetrical containing all the butyric acid and most of the hexanoic acid at position *sn*-3.

In fish oils, myristic, palmitic, and palmitoleic acids are mainly esterified at positions *sn*-1 and *sn*-3; oleic acid and long-chain monoenoic acids are mainly located at positions *sn*-1 and *sn*-3 with a higher proportion at position *sn*-3 when the chain length increases; polyunsaturated fatty acids are concentrated at position *sn*-2 and there are also substantial amounts at position *sn*-3.

Triacylglycerols are also fairly extended in eukaryotic organisms such as yeasts, molds, and fungi. Among prokaryotic organisms, only species from the actinomycetes group accumulate triacylglycerols to a significant extent.

Triacylglycerol Properties

Triacylglycerols are hydrophobic molecules that are the result of the triple esterification of the hydroxyl groups of glycerol by fatty acids. This structure is going to play a major role in their physical

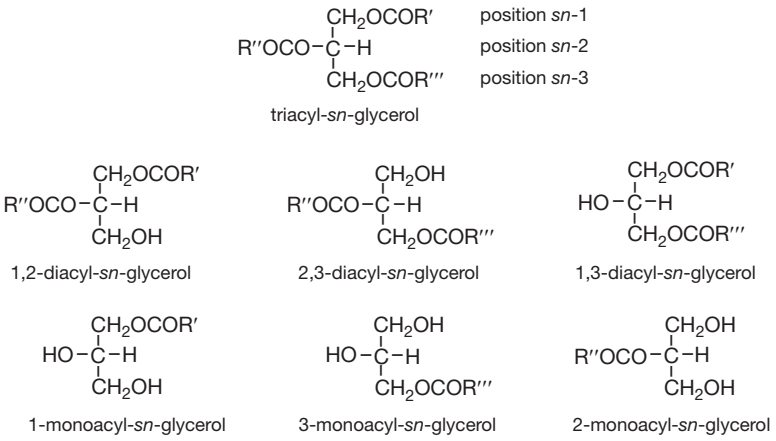

Figure 1 Chemical structures and numbering for triacyl-*sn*-glycerols, diacyl-*sn*-glycerols, and monoacyl-*sn*-glycerols.

properties, which will be determined by the organization of the hydrocarbon chains of the present fatty acids; their chemical properties, in which both the ester groups and other functional groups of the fatty acyl chains will be the groups susceptible to be modified; and their biological properties, because of the importance of essential fatty acids in the daily diet.

Physical Properties

The physical properties of triacylglycerols are of great practical importance because many of their technical applications, including their uses in edible products, depend on the oiliness, surface activity, solubility, melting behavior, or other properties peculiar to long-chain compounds.

Crystallization and polymorphism

Triacylglycerols exhibit a monotropic polymorphism. This means that each triacylglycerol has several crystalline varieties, which can be converted from one variety to other. All these varieties can be obtained from the liquid-state and solid-state transitions are very rare. Usually, the most stable form of triacylglycerols has a triclinic subcell with parallel hydrocarbon chain planes, which is noted as β. A second common subcell is hexagonal with no specific chain plane conformation, which is noted as α. Other varieties are noted as β′. For pure triacylglycerols, the most stable variety is generally β, but for mixtures of triacylglycerols, it is most frequently β′. Some triacylglycerols exhibit several β′ and/or β varieties. In such cases, the notation of the different varieties is done by ascending order starting from the most stable to the least stable. Thus, for example, β_1 is more stable than β_2. Therefore, the stability of the different polymorphic varieties in pure triacylglycerols increases in the order $\alpha < \beta'_2 < \beta'_1 < \beta_2 < \beta_1$. The melting points increase in the same order.

Among the different fats, the polymorphic behavior of cocoa butter is especially complex and five different polymorphs (or six according to other authors) are recognized (γ, α, β′, β_2, and β_1). The desirable physical properties of cocoa butter and chocolate – snap, gloss, melting in the mouth, and flavor release – depend on the formation of the polymorph β_2, which has to be obtained under controlled temperature conditions. Unfavorable storage conditions can produce the change of polymorph β_2 to the most stable polymorph β_1, which can make the product unsuitable for consumption.

Melting

Each individual triacylglycerol has a specific melting point for each polymorphic variety. It depends on the average chain length of the fatty acids, the position of the fatty acids on the glycerol molecule, the relative proportion of saturated to unsaturated fatty acids, and the processing techniques employed. However, fats are mixtures of mixed triacylglycerols that crystallize in several crystal forms, and all these forms have specific melting points. Therefore, fats do not have sharp melting points, but do have a melting range. If the melting range is $< 5\,^{\circ}C$, the fat is considered to be nonplastic. If the melting range is large (sometimes it may exceed $40\,^{\circ}C$), the fat is called plastic.

Plasticity

Plasticity is a consequence of the semisolid state of fats at room temperature, in which a certain proportion of triacylglycerols are solids and others are liquids. Within this temperature range, fats can be molded and they will maintain the produced deformation after the removal of the stress. One of the most important properties of fats is their solid fat content. Fats may retain their solid character with solid fat contents as low as 12–15%. The relationship between hardness and solid fat content indicates that there is a range of solids in which fats are plastics (this is the plastic range). Shortening is an example of a fat with an extended plastic range.

Viscosity

Triacylglycerols are more viscous than water as a consequence of the attractions among their long fatty acyl chains. This is one of the reasons why oils have the ability to form oily or lubricating films. Viscosity of triacylglycerols increases with oxidation and polymerization. For this reason, viscosity has been used to determine the condition of a fat employed in deep frying.

Vapor pressure

Triacylglycerols of long-chain fatty acids have very low vapor pressure. For this reason, they can only be distilled by molecular or short-path distillation.

Refractive index

Each triacylglycerol has a specific refractive index that depends on triacylglycerol structure, temperature, and density. Refractive index normally increases with hydrocarbon chain length, with the number of double bonds, and with conjugation and decreases when temperature increases.

Ultraviolet spectroscopy

Triacylglycerols containing saturated, monounsaturated, or methylene-interrupted polyunsaturated fatty acyl chains absorb ultraviolet light at wavelengths too low for convenient study. On the other hand, ultraviolet spectroscopy is a valuable tool for detecting triacylglycerols containing fatty acyl chains with conjugated double bonds.

Infrared spectroscopy

The most frequent use of infrared spectroscopy is in the recognition of *trans* isomers. The *trans* double bond of a fatty acid chain produces a characteristic absorption at 968 cm^{-1} that does not change for additional double bonds unless these are conjugated. In addition, triacylglycerols have a strong absorption band around 1740 cm^{-1} that may be of diagnostic value.

Nuclear magnetic resonance spectroscopy

Low-resolution instruments are employed to determine the proportion of solid and liquid in a fat (or mixtures of triacylglycerols) and the content of oil in a seed. High-resolution instruments provide a great amount of information about triacylglycerol structure.

Chemical Properties

Reactions of fatty acyl chains at double bonds, at allylic carbons, or at carboxylic groups of triacylglycerols are important both in biology and for industry. Thus, oxidation reactions can produce food spoilage and can cause problems within living tissues. In contrast, chemical reactions on fatty acyl residues are widely employed to develop products for industry (from cosmetics to detergents).

Oxidation

Oxidation of triacylglycerols is responsible for their deterioration. When present in foods, oxygen causes rancidity accompanied by odors that make foods difficult to accept. On the other hand, triacylglycerol oxidation products can be desirable for certain foods or processes such as some deep-fried flavors. These reactions also play a major role in tissues, although oxidation usually takes place enzymatically after hydrolysis of the triacylglycerol.

Triacylglycerol oxidation is a consequence of the existence of unsaturated or polyunsaturated fatty acyl chains. Thus, oleic acid is generally more susceptible to lipid oxidation than any saturated fatty acid because of the lower bond energy of hydrogen atoms adjacent to a double bond (allylic protons) that allows an easier abstraction. Furthermore, hydrogen atoms in the center of the 1,4-pentadiene system of polyunsaturated fatty acyl chains (doubly allylic protons) are around 20 times easier to remove than allylic protons of oleic acid. Moreover, the higher the number of 1,4-pentadiene units, the higher its susceptibility to oxidation. Therefore, saturated triacylglycerols should be expected to be relatively stable to oxidation, but triacylglycerols containing highly polyunsaturated fatty acids are easily oxidized unless lipid oxidation is inhibited in some way.

The mechanism of autoxidation of unsaturated triacylglycerols is a catalytic process that proceeds via free radicals and involves the reaction of oxygen with the unsaturated fatty acyl moieties of triacylglycerols according to Figure 2. It includes three general steps: initiation, propagation, and termination.

The formation of a radical (TAG•) from an unsaturated fatty acyl chain is the key event in the initiation step. This can occur by thermal or photochemical cleavage of the allylic CH bond or by hydrogen atom abstraction by a free radical initiator.

The first step of propagation normally begins with the addition of molecular oxygen to the TAG• to form a peroxyl radical (TAGOO•). This step is produced easily. However, the rate-limiting step of the reaction is the abstraction of a hydrogen atom from a second molecule of triacylglycerol (TAG) to produce a radical in this new molecule of triacylglycerol to continue the radical chain. Radical scavengers can also produce the hydroperoxide at the same time that they break the free radical propagation.

Once formed, the hydroperoxide can suffer a homolytic cleavage to produce alkoxyl and hydroxyl radicals. Termination reactions are those reactions that produce nonradical products from the radicals derived from triacylglycerols. This includes monomeric compounds with molecular weights similar to the initial triacylglycerols but containing oxygenated groups such as hydroxyl, hydroperoxy, keto, or epoxy; polymeric compounds that can also contain oxygenated groups; and volatile products, including hydrocarbons, aldehydes, and ketones, among others. Alkoxyl radicals can also be neutralized by radical scavengers.

Hydrolysis and saponification

Triacylglycerols can be hydrolyzed in basic, acidic, and even neutral media. The reaction is irreversible in basic medium (saponification) and is reversible under acidic or neutral conditions. It produces fatty acids (or their salts) and glycerol, and it is the best procedure to obtain the fatty acids required by the industry. Additionally, this reaction is also produced in the presence of lipases.

Interesterification

Interesterification is employed to change fatty acid composition or fatty acid distribution in the triacylglycerol molecule (Figure 3). It can be carried out in a single triacylglycerol or between several triacylglycerols. If it is carried out within a single triacylglycerol, fatty acids are moved to the different positions of the triacylglycerol. As a consequence, the triacylglycerol is randomized and changes in the physical properties of the triacylglycerol are produced. If it is carried out between two triacylglycerols, fatty acid chains are interchanged among the three positions of both triacylglycerols. This reaction can be

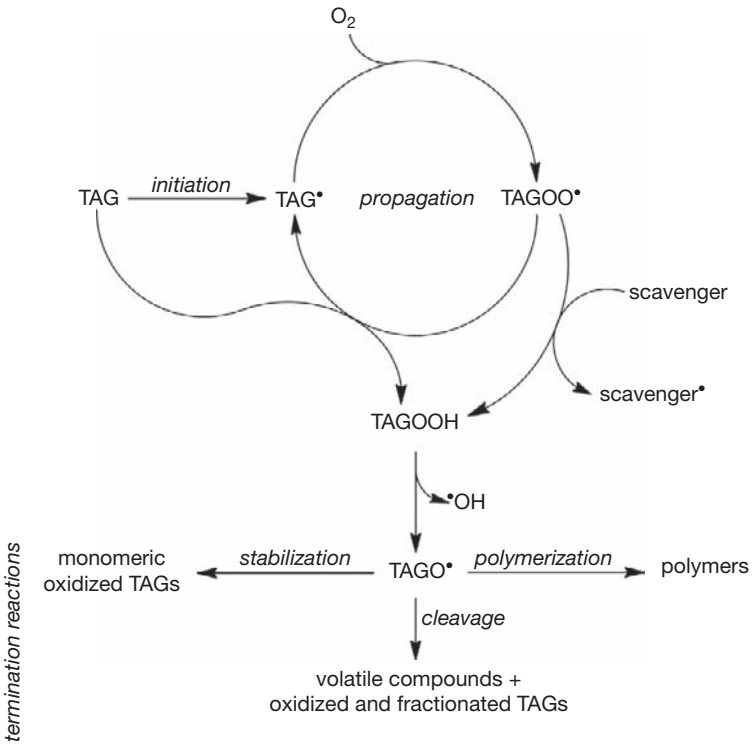

Figure 2 Triacylglycerol oxidation. Abbreviations: TAG, triacylglycerol; TAG•, triacylglycerol radical; TAGO•, alkoxyl radical from triacylglycerol; TAGOO•, peroxyl radical from triacylglycerol; TAGOOH, hydroperoxide from triacylglycerol.

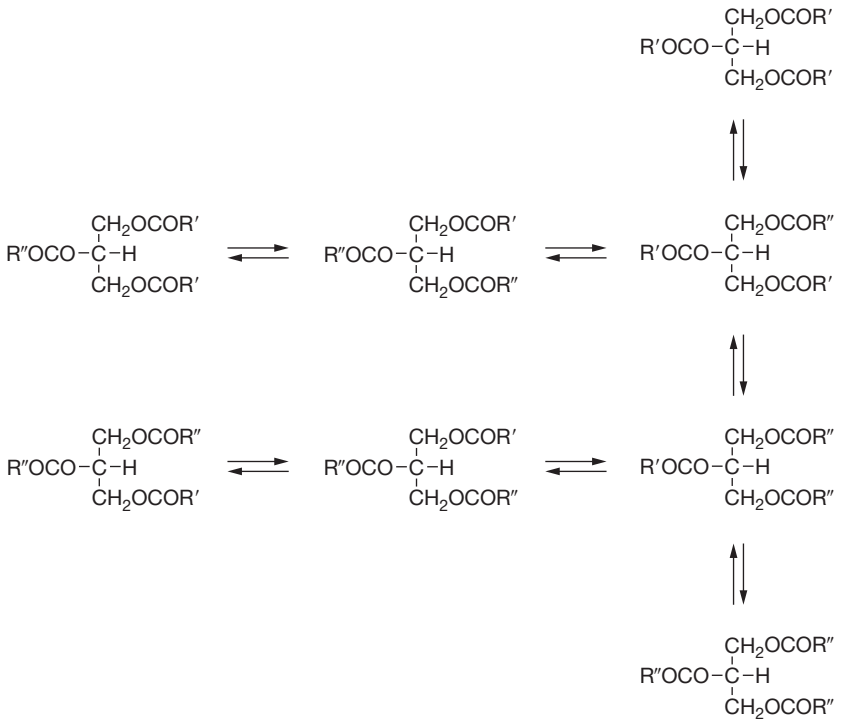

Figure 3 Interesterification reaction of triacylglycerols.

carried out either chemically or enzymatically. Enzymatic interesterification has the advantage that it can be directed to certain positions, which avoids randomization.

Alcoholysis

Alcoholysis is the esterification reaction between a triacylglycerol and an alcohol in the presence of sodium methoxide or lipases. If the reaction is carried out with glycerol, the products are mono- and diacylglycerols, which are widely employed as emulsifiers. This last reaction is usually performed using nonspecific lipases. If reaction is carried out below the temperature of crystallization of monoacylglycerols, the equilibrium of the reaction is shifted to the production of monoacylglycerols.

Hydrogenation

Hydrogenation of triacylglycerols is carried out either to increase its melting point (transform a liquid triacylglycerol into a solid or semisolid one) or to increase its oxidative stability during storage. Reactions are carried out at relatively high temperatures in the presence of catalyzers. Isomerizations can be produced, including the formation of *trans* double bonds.

Formation of polyols

The triacylglycerol containing ricinoleic acid at the three positions of the glycerol molecule is a natural polyol that is widely employed in making a variety of polyurethane products ranging from coatings to foams. Unsaturated triacylglycerols can also be converted into polyols by cleavage of ethylenic chains, which can be carried out by ozonolysis. This reaction is produced by addition of ozone to a carbon–carbon double bond with the formation of an ozonide, which later breaks down to produce aldehydes, carboxylic acids, or – under reductive conditions – alcohols. Under these last conditions, the produced compounds are polyols with terminal primary hydroxyl groups. Additionally, formation of secondary hydroxyl groups in fatty acyl chains can be achieved by epoxidation and ring opening.

Functional Properties

Triacylglycerol properties are very important in food design. Triacylglycerols are incorporated into processed foods for a variety of reasons, including their action as lubricants, enhancers of eating properties, moisture barriers, heat conductors, and nutrition providers, among others. The functional ability of triacylglycerols depends on their structure and a mixture of triacylglycerols is usually employed. In this way, plasticity and melting can be adapted to the specific food product. Thus, for example, a shortening will make tender biscuits only if the employed mixture of triacylglycerols has the proper ratio of solids to liquids because solids provide structure and creaming and the liquid oil provides lubricity.

Nutritional Properties

Triacylglycerols are a major source of storage energy and are important precursors both in the body's metabolic processes and in the essential components of cell membranes and other biological structures. Triacylglycerols also play an important role in the absorption of fat-soluble nutrients, including fat-soluble vitamins and other dietary and medical supplements.

Triacylglycerol metabolism

Triacylglycerols cannot be absorbed as such by the intestine. In addition, they are not soluble in water. To absorb these molecules, the dispersion of triacylglycerols into small particles with sufficiently exposed surface area for rapid attack by digestive enzymes is needed. This is achieved by detergent action (bile salts, fatty acid soaps, and monoacylglycerols) and mechanical mixing. Once triacylglycerols are emulsified, they are hydrolyzed by enzymes excreted by the pancreas, being pancreatic lipase the most important enzyme. This enzyme is specific for primary ester linkages, which results in the formation of free fatty acids and 2-monoacylglycerols. These compounds are absorbed from the lumen by intestinal mucosal cells where triacylglycerols are resynthesized, packaged into chylomicrons, and directed to the lymphatic vessels of the abdominal region and finally enter the circulation via the thoracic duct.

Fatty acids can be liberated from triacylglycerols in chylomicrons with lipoprotein lipase. Adipose tissue is especially active for secreting this enzyme into the surrounding blood vessels. This enzyme rapidly hydrolyzes the triacylglycerols at the cell surface, releasing free fatty acids, which are absorbed into the adjacent adipocytes and reutilized for triacylglycerol synthesis within the cell. Triacylglycerols are stored as cytoplasmic lipid droplets enclosed by a monolayer of phospholipids and hydrophobic proteins. Chylomicron remnants reach the liver, where the remaining lipids are hydrolyzed and absorbed. The fatty acids within the liver can be utilized for a variety of purposes, including their conversion into triacylglycerols and their storage as lipid droplets within the cytoplasm of the cells. Most of these newly synthesized triacylglycerols are exported into the plasma in the form of very-low-density lipoproteins (VLDL). These particles are transported to the peripheral tissues, where they are hydrolyzed and the fatty acids absorbed.

Triacylglycerols and health

Triacylglycerols are present in plasma in the form of multiple triacylglycerol-rich lipoproteins, predominantly intestinally synthesized chylomicrons in the postprandial state and hepatically synthesized VLDL in the fasted state. If triacylglycerols are not correctly removed and their concentration increases, hypertriglyceridemia is produced. Patients with hypertriglyceridemia may experience diverse complications (including diabetes, hypertension, and obesity) that confer an increased risk of cardiovascular events. In fact, epidemiological evidence indicates that plasma triacylglycerol concentration is a strong independent risk factor for cardiovascular disease, suggesting that prolonged residence of plasma triacylglycerol-rich lipoproteins, especially in the postprandial state, may contribute to cardiovascular disease susceptibility. For that reason, dietary factors that contribute to raised postprandial triacylglycerols have become a focus of concern. On the other hand, dietary factors that reduce triacylglycerol concentrations can be good for the heart. To this respect, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have shown to reduce cardiovascular mortality at a dose of $\sim$1 g d^{-1} without significant reductions in triacylglycerols, but plasma triacylglycerol reduction can be achieved with higher EPA + DHA doses.

Severe hypertriglyceridemia is also a cause of acute pancreatitis. Although the pathophysiology of hypertriglyceridemic pancreatitis is not well established, it is hypothesized that pancreatic lipase hydrolyzes excess of triacylglycerols into free fatty acids, which are toxic to the acinar cells and the vascular endothelium. Additionally, chylomicrons increase the viscosity of blood and impair blood flow in the pancreas causing ischemia within this organ.

Triacylglycerols are also the main compounds responsible for fatty acid intake in common diet. The metabolic functions of fatty acids depend on the length of the carbon chain, degree of saturation, the stereochemistry and position of the double bonds, and their position in the triacylglycerol molecule. These functions will be discussed in other articles.

Vegetable Oils: Composition and Analysis

AJ Dijkstra

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Edible oils and fats have been produced for centuries, so it is not surprising that their analysis has a long history. The French chemist Michel Eugène Chevreul, who can be regarded as the first lipid chemist, had a book published in 1823 in which he coined names like stearic acid, oleic acid, and butyric acid, all compounds he discovered and described. He also reported melting points, which he used to assess the purity of compounds obtained by recrystallization – a method he developed – and to define the titer of fats.

One of the fatty substances that Chevreul investigated was cholesterol, which he obtained from human gallstones. He noted that it differed fundamentally from oils and fats in that he could not saponify the cholesterol. Oils and fats were used extensively in soap works and left some 'unsaponifiables.' Accordingly, oils and fats also became characterized by their unsaponifiable content.

Subsequent quantitative analysis made use of what methods were available at the time. Early on, a number of titrimetric methods were developed, the results of which were reported as 'values': acid value, iodine value (IV), etc. Fatty acid compositions started to be determined, but as explained by Gunstone, this determination took a long time (http://lipidlibrary.aocs.org/history/beforechrom/index.htm). This became much easier with the advent of gas–liquid chromatography (GLC), first with packed columns and later with capillary columns. The latter enabled separations between isomers, first *cis–trans* and later also with respect to positional isomers of unsaturated fatty acids. GLC was combined with mass spectrometry; HPLC was used for analysis of the triglyceride composition with silver-ion HPLC providing a means to separate triglycerides according to their degree of unsaturation. Liquid chromatography was combined with mass spectrometry, and more sophisticated analytic techniques were developed for a research environment.

Perhaps, the most useful method to characterize a fat is by its solid fat content (SFC). Its determination makes use of a 'time-domain NMR' technique that is also referred to as 'pulse NMR.' In fact, the equipment used for this determination was specifically developed for fat characterization and replaced the laborious dilatometric method. The same equipment can also be used to determine the oil content of oilseeds.

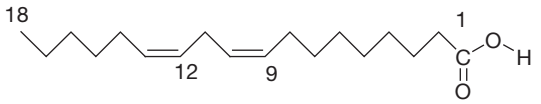
Composition of Vegetable Oils

Saponifiable Fraction

The saponifiable fraction of vegetable oils, usually at least 98% of the oil, is characterized in that it forms soaps (salts of fatty acids), when the oil is treated with an alkali such as sodium hydroxide. The fraction contains several different classes of compounds that will be discussed later. The main constituent of the saponifiable fraction is triglyceride oil, but some of this oil has been hydrolyzed so that this fraction also contains partial glycerides and free fatty acids (FFAs).

Fatty acids

Nearly all naturally occurring fatty acids are carboxylic acids with a straight chain and an even number of carbon atoms. If they contain double bonds, these are mostly in the *cis*-configuration, and in polyunsaturated fatty acids, the double bonds tend to be methylene-interrupted. This is illustrated by the molecular structure of linoleic acid shown below:



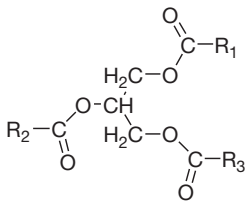
In this molecule, the carbon atom of the carboxyl group has number 1. The first double bond starts at carbon atom number 9 and the second one at number 12. The systematic name of this fatty acid is therefore (9*Z*,12*Z*)-octadeca-9,12-dienoic acid. Because this is rather a mouthful, scientific literature often uses a shorthand notation: 9c12c-18:2. This notation starts with the location and configuration of the double bonds. Then, the number of carbon atoms of the fatty acid chain is given, which is followed by the number of unsaturated bonds. This shorthand notation is explained in http://lipidlibrary.aocs.org/education/names/FAnames1.htm.

When a fatty acid is synthesized in plants, it is elongated at its carboxyl end. Consequently, the position of a double bond does not change with respect to the other, methyl end. So, there are families of fatty acids according to the distance of the last double bond to the methyl end. This distance can be indicated with the prefix *n* or ω. The linoleic acid shown in the preceding text is part of the *n*-6 or ω-6 family of fatty acids.

Table 1 lists some fatty acids that kept their trivial names, their shorthand notations, and sources.

Triglycerides

The official name of a triglyceride molecule is 'triacylglycerol,' indicating that it consists of a glycerol backbone that is esterified by three fatty acids as shown below:



The fatty acid chains R_1, R_2, and R_3 can be the same but seldom are. Only oils with a very high content of a single fatty acid such as oleic acid in 'high-oleic sunflower seed oil' will contain a triglyceride with three identical fatty acids, in this case trioleate. Normally, the fatty acids are different so that a triglyceride oil contains very many different molecular species.

In vegetable oils, the distribution of the fatty acids over the glycerol backbone is not fully random but 1,3-random, 2-random. This is illustrated by the soybean oil data in Table 2. The saturated fatty acids 16:0 and 18:0 predominantly occupy the outer or 1,3-positions in equal amounts: 18:2 mainly occupies the 2-position and 18:1 fills the empty positions. An example of the fatty acid distributions for a few oils is given in Table 2.

Table 1 Trivial names, shorthand notations, and occurrence of several fatty acids

Trivial name	*Notation*	*Source*
Butyric acid	4:0	Butter
Caproic acid	6:0	Butter
Caprylic acid	8:0	Coconut oil, palm kernel oil
Capric acid	10:0	Coconut oil, palm kernel oil
Lauric acid	12:0	Coconut oil, palm kernel oil
Myristic acid	14:0	Coconut oil, palm kernel oil
Palmitic acid	16:0	Palm oil
Stearic acid	18:0	Cocoa butter, shea butter
Oleic acid	18:1(*n*-9)	All vegetable oils
Linoleic acid	18:2(*n*-6)	All vegetable oils
α-Linolenic acid	18:3(*n*-3)	Linseed oil, soybean oil, Canola®
γ-Linolenic acid	18:3(*n*-6)	Evening primrose oil, blackcurrant, seed oil, borage oil
Arachidic acid	20:0	Groundnut oil
Gondoic acid	20:1(*n*-9)	High-erucic acid rapeseed (HEAR) oil
Behenic acid	22:0	
Erucic acid	22:1(*n*-9)	HEAR

Partial glycerides

The hydrolysis of triglycerides leads to the formation of FFAs and di- and monoglycerides: diacylglycerol and acylglycerol. Often, this hydrolysis is catalyzed by a lipase enzyme present in the raw material. This is the reason that palm fruit bunches are sterilized before the oil is extracted from the fruitlets and that rice bran profits from being heated in an expander/extruder as soon as possible. Both partial glycerides have two positional isomers: 1,2- and 1,3-diglyceride and 1- and 2-monoglyceride. The compounds with the fatty acids at the outer position are thermodynamically more stable. So, whereas statistically, the 2-monoglyceride fraction is 1/3, at equilibrium, it is only 10%.

Monoglycerides are so volatile that most will be removed from the oil during vacuum stripping. They can be synthesized by glycerolysis of triglycerides and then concentrated by molecular distillation. They are used as food grade emulsifiers and serve as starting material for various other emulsifiers and oleochemicals. Diglycerides remain in the oil during processing. They do not act as emulsifier but can be used in food as a kind of fat substitute for obese and diabetic patients.

Vegetable waxes

Oils containing waxes comprise sunflower seed oil, rice bran oil, corn germ oil, safflower seed oil, and grape-seed oil. Vegetable waxes are esters of fatty acids and fatty alcohols. Fatty alcohols are monohydric long-chain alcohols. If both the fatty acid and the fatty alcohol are saturated, the resulting wax will have a high (>70 °C) melting point as a result of which oils containing such waxes will throw an unsightly deposit when cooled. When the alcohol is unsaturated, the melting point of the wax is much lower and the wax will remain dissolved when the oil is cooled.

Wax compositions published in the literature are rather contradictory. They also depend on whether they refer to the crystalline wax fraction or the total wax content of the oil. However, there seems to be some kind of consensus that the main fatty acids in the crystalline waxes are 20:0, 22:0, and 24:0 and that the main alcohols are 24:0, 26:0, and 22:0. This

Table 2 Positional distribution of fatty acids in vegetable oils

Oil	*Position*	*8:0*	*10:0*	*12:0*	*14:0*	*16:0*	*18:0*	*18:1*	*18:2*	*18:3*
Coconut[a]	1,3	11.4	9.1	32.7	22.2	13.2	4.0	5.6	1.1	
	2	2.9	1.1	78.2	10.2			5.9	2.0

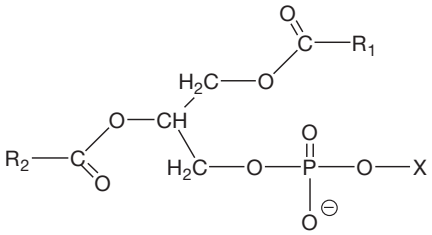
is to some extent confirmed by the carbon number composition of the waxes themselves that shows a range of 38–52 for the crystalline waxes and a somewhat lower range for the waxes that also contain unsaturated waxes and peaks of around 44. According to some authors, waxes also contain odd-numbered fatty acid and/or fatty alcohol chain lengths.

Phosphatides

Phosphatides are diglycerides that have been esterified with a phosphate group at the *sn*-3 position that itself can again be esterified with the hydroxyl group of compounds indicated as X: choline, ethanolamine, or inositol. The resulting phosphatides are called phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylinositol (PI). The structure in which R_1 and R_2 represent fatty acid chains is given in the succeeding text:



The phosphate group has a free hydroxyl group left that is quite acidic (p*Ka* < 3.5). In crude oil, it may have a metal counterion (potassium, calcium, or magnesium) or hydrogen. This hydrogen is titrated when the acidity of the oil is measured. When the group X is a hydrogen atom, the phosphatide is called phosphatidic acid (PA). It is formed during the drying, conditioning, and extraction of the oilseeds. If PA is present as a free acid or potassium salt, it will be removed from the oil by hydration on water degumming. If PA is present as a calcium or magnesium salt, this salt will remain in the oil on water degumming as a so-called nonhydratable phosphatide.

Besides PC, PE, PI, and PA, there are some minor phosphatides such as phosphatidylserine in which the phosphate group has been esterified with the amino acid serine. There are the lysocompounds in which one of the fatty acids moieties has been eliminated. There is the acetylphosphatidylethanolamine in which the amino group has been acetylated. There is the phosphatidylglycerol in which the phosphate group has been esterified with a glycerol moiety.

Unsaponifiable Fraction

The unsaponifiable fraction of vegetable oils can be isolated by extracting the soaps that result from oil saponification with an organic solvent (diethyl ether).

Tocopherols and tocotrienols

The general structural formula of the tocopherols is given below:

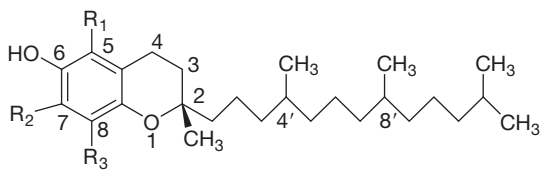


Table 3 Molecular structures of tocopherols and tocotrienols

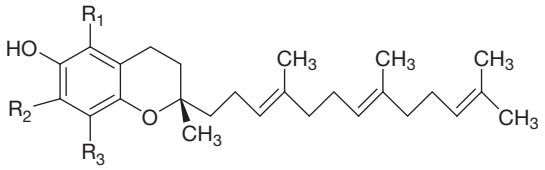
Type	R_1	R_2	R_3
α	CH_3	CH_3	CH_3
β	CH_3	H	CH_3
γ	H	CH_3	CH_3
δ	H	H	CH_3

The benzene ring on the left has three substituents named R_1, R_2, and R_3. The extent to which these substituents are methyl groups determines the type in accordance with Table 3.

Accordingly, α-tocopherol, which has the highest vitamin E activity, carries three methyl substituents on its benzene ring and δ-tocopherol only one. The same nomenclature is valid for the tocotrienols illustrated below:



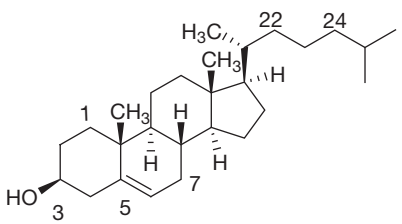
In addition to one or more methyl groups, the benzene ring also carries a hydroxyl group. This group can be esterified, but in vegetable oils, only the free tocopherols are present. Accordingly, they act as antioxidants according to the same mechanism as the synthetic antioxidants butylated hydroxytoluene (BHT) and butylated hydroxyanisole (BHA), which also have a stereochemically hindered phenol group.

Vegetable oils vary widely in their tocopherol and tocotrienol contents as illustrated by Table 4.

Given their molecular weight of about 400 Da, which is not that different from that of monoglycerides, it is only to be expected that some tocopherols will be removed from the oil during vacuum steam stripping. The amounts depend of course on the initial concentration of the tocopherol and the stripping process conditions (relative amount of stripping medium, system pressure, and oil temperature). By using a two-stage condensing system, a condensate that is rich in tocopherols can be isolated. It can be used to enrich oils that are poor in tocopherols and thus increase their oxidative stability.

Phytosterols

Phytosterols are the sterols that occur in plants. Their molecular structure is similar to that of cholesterol, the main sterol in animals. Its structure has been represented in the succeeding text together with the position numbers that refer to the double bonds and substituents:



How these various phytosterols differ from cholesterol has been indicated in Table 5.

Table 4 Tocopherol and tocotrienol contents of various vegetable oils

	Tocopherols (mg/100 g)					*Tocotrienols (mg/100 g)*				
Oil	*α*	*β*	*γ*		*Total*	*α*	*β*	*γ*	*δ*	*Total*
Palm	26		32	7	65	14	3	29	7	53
Soybean	10		59	26	96					0
Canola	17		35	1	53					0
Sunflower	49		5	1	55					0
Coconut	0.5		0.6		1	0.5		2	0.6	3
Corn germ	11	5	60	2	78					0
Wheat germ	121	65	24	25	235	2	17			19
Olive	20	1	1		22					0
Rice bran	12	4	5		21	18	2	57		77

Source: Table 2.48 in Gunstone, F. D., Harwood, J. L. and Dijkstra, A. J. (eds) (2007). *The lipid handbook* (3rd ed.), Boca Raton, FL: CRC Press.

Table 5 Molecular structures of various phytosterols

Phytosterol	*Position of additional methyl group*	*Position of double bond in ring system*	*Position of double bond in side chain*	*Substituent in side chain*
Cholesterol	–	5	–	–
Brassicasterol	–	5	22	24-Methyl
Campesterol	–	5	–	24-Methyl
Stigmasterol	–	5	22	24-Ethyl
β-Sitosterol	–	5	–	24-Ethyl
Δ5-Avenasterol	–	5	–	24-Ethylidene
Δ7-Avenasterol	–	7	–	24-Ethylidene
Δ7-Stigmasterol or spinasterol	–	7	22	24-Ethyl
Citrostadienol	4	7	–	24-Ethylidene

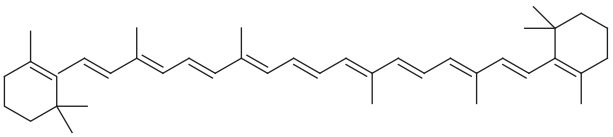
All phytosterols have a hydroxyl group at the 3-position. In vegetable oils, this group can be esterified with a fatty acid but if it is not, it is referred to as a free sterol. Like tocopherols, free phytosterols will also be partially removed from the oil during vacuum stripping; esterified sterols are insufficiently volatile and remain in the oil.

When the double bond in the sterol is saturated, the resulting compound is called a stanol. Cholesterol yields cholestanol on hydrogenation. Phytostanols are used in dietary fat products like margarine because they reduce the cholesterol absorption from food and thus lead to a somewhat reduced blood serum cholesterol content, which some people consider to be desirable.

Coloring compounds

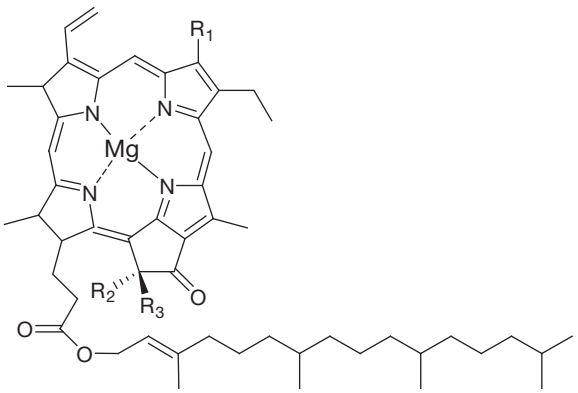
Vegetable oils contain two kinds of coloring compounds: carotenes and chlorophyll. The carotenes give the oils an orange–red color that is very pronounced in crude palm oil. The chlorophylls and their derivatives are responsible for the green color in crude oils.

The structural formula of β, β-carotene is shown below:



Its molecular formula ($C_{40}H_{56}$) and conjugated polyene structure show that it is a polyisoprene-based molecule. The structural formula given above relates to the synthetic, all-*trans* isomer. Crude vegetable oils may also contain isomers with one or more *cis* double bonds. β, β-Carotene is a precursor of vitamin A. In addition to this, vegetable oils can also contain hydroxyl-substituted compounds such as lutein, violaxanthin, and neoxanthin. All of them are thermally unstable. So, when oil containing these compounds is heated, they decompose in the so-called heat bleaching process.

Chlorophyll is an ester of a chlorophyllic acid and a phytol alcohol. Its structure is given in the next column:



The chlorophyllic acid moiety on the left contains a magnesium ion. If this has been replaced by two hydrogen ions,

Table 6 Molecular structures of various chlorophyll-related compounds

Derivative	*Type*	R_1	R_2	R_3
Chlorophyll	α	CH_3	CO_2CH_3	H
	α′	CH_3	H	CO_2CH_3
	β	CHO	CO_2CH_3	H

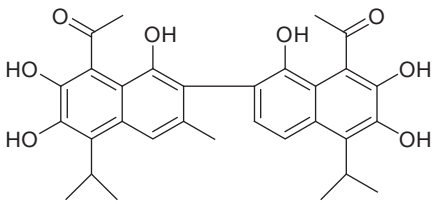
the resulting compound is called pheophytin. The structure contains several groups indicated by R_1, R_2, and R_3. Their nature determines the chlorophyll derivative in accordance with Table 6.

In this table, the α- and β-types differ with respect to the R_1 substituent. In the α-type, this is a methyl group, whereas in the β-type, this is a formaldehyde group. The difference between the types without and with prime is stereochemical with respect to the dimethyl ether group.

Miscellaneous unsaponifiable compounds

The presence of unsaponifiable compounds necessarily precedes their molecular identification, but they could have been given a name when isolated. So shea butter, 'beurre de karité' in French, was found to contain a substantial unsaponifiable fraction that did not dissolve in acetone. It was given the name 'karitene,' but this name does not stand for a compound in true chemical sense; it is the name given to a fraction that is highly unsaturated and probably consists of a mixture of different polyisoprenes.

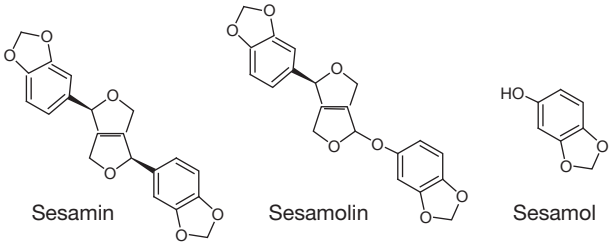
An unsaponifiable compound that is specific for cottonseed oil is gossypol; its molecular structure is shown below:



The systematic name of this compound is 1.1′,6,6′7,7′-hexahydroxy-3,3′-dimethyl-5,5′-bis(1-methylethyl)-[2,2′bi-naphthalene]-8,8′-dicarboxaldehyde. Most of the gossypol remains in the meal, but the (±)-form in cottonseed is toxic to non-ruminants. It is removed from the oil during the neutralization process since the many phenolic hydroxyl groups react with the alkali.

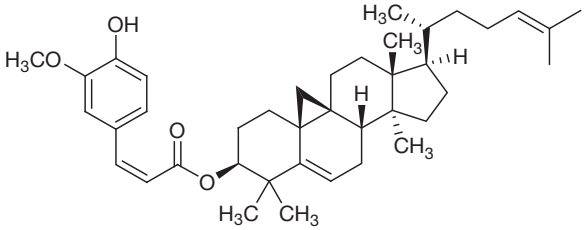
Cottonseed oil also contains some fatty acids (sterculic acid and malvalic acid) that contain a cyclopropene ring. This feature is used for the detection of cottonseed oil by the so-called Halphen test. Kapok seed oil also contains these cyclopropenoid acids and also gives a positive Halphen test.

Sesame oil contains two unsaponifiable compounds that are typical for this oil: sesamin (0.5–1.1%) and sesamolin (0.3–0.6%). The latter compound can release sesamol during oil processing. The molecular structures of these compounds are given in the succeeding text:

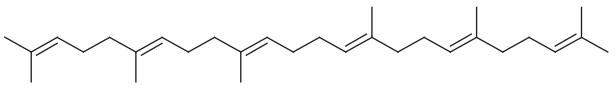


The presence of sesamol can be detected by the reaction of Baudouin in which the oil is treated with hydrochloric acid and an ethanolic solution of furfural; a red color results. For a long time, Belgian margarine had to contain 2% of sesame oil by law to enable the adulteration of butter with margarine to be detected.

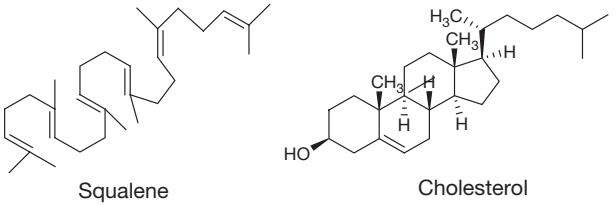
Rice bran oil also contains unsaponifiable compounds that are particular to this oil: oryzanols. They are esters of ferulic acid (4-hydroxy-3-methoxycinnamic acid) and cycloartenol (oryzanol A) or 24-methylenecycloartanol (oryzanol B). The structure of oryzanol A is given in the succeeding text:



Hydrocarbons cannot be saponified. Vegetable oils can contain various hydrocarbons not all of which have been identified. A hydrocarbon of which the structure has been determined is squalene:



Its systematic name is (6*E*,10*E*,14*E*,18*E*)-2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene. Squalene is found in several vegetable oils in variable amounts. Olive oil contains 700–1200 ppm of squalene, which is about half the total unsaponifiable. Squalene is the precursor of phytosterols, which becomes clear when the molecular structure is represented in a different manner next to cholesterol, as shown below:



Analysis of Vegetable Oils

Because oils and fats are traded and often have to meet specifications, it is necessary to use standard analytic methods for these

specification parameters. Consequently, what is now the American Oil Chemists' Society (AOCS) started as the Cotton Products Analysts. The AOCS therefore publishes 'AOCS Official Methods and Recommended Practices' after having tested proposed methods or changes, by having them evaluated by several laboratories; other national societies like the DGF (Deutsche Gesellschaft für Fettforschung) and countries also publish their own methods.

Points and Values

When early analytic methods became established, their results were expressed as 'points' or 'values.' Points refer to temperatures and values have other units.

Slip melting point

Oils and fats are mixtures of a large number of different triglycerides. Therefore, they do not have a sharp melting point but a melting range. Fats are also polymorphic, and different polymorphs have different melting points. Consequently, the temperature at which the fat is completely molten depends on how this melting point is determined. The agreed method to determine the 'slip melting point' measures the temperature at which a column of fat of specified length starts to rise in an open capillary tube under the influence of a hydrostatic pressure by placing the capillary in a water bath that is heated.

Cloud point

The cloud point of an oil is the temperature at which the oil becomes hazy when it is cooled down. This temperature is especially important for oils that could solidify during transport, and it is also used when estimating the wax content of oil to be winterized. Strict adherence to the method is essential for attaining a reasonable repeatability.

Smoke point

The smoke point is the temperature at which smoking is first detected when the oil is heated in a special cabinet with special illumination. The smoke point decreases from normal values $>200^{\circ}C$ when the FFA content of the oil increases as during deep fat frying.

Acid value

The acid value of an oil is determined by titrating a solution of the oil in diethyl ether with an alcoholic solution of sodium or potassium hydroxide. It is expressed as the amount of KOH (in mg) to neutralize 1 g of oil.

Often, the acid value is converted to an FFA content by multiplying the acid value with a factor that equals the molecular weight of the fatty acid concerned (usually oleic acid, MW = 282.4) divided by ten times the molecular weight of the potassium hydroxide (56.1). This factor ten stems from the fact that the acid value is expressed as mg/g, whereas the FFA content is expressed as a percentage. When the FFA content is expressed as 'wt% oleic acid,' this factor therefore equals 0.50.

Saponification value

Whereas the acid value only takes FFAs into account, the saponification value (SV) refers to the FFA plus any ester bonds present in the sample. It is determined by saponifying a known amount of sample with a known amount of ethanolic potassium hydroxide and titrating the excess of potassium hydroxide with hydrochloric acid. Like the acid value, the SV is also expressed as mg KOH per gram of oil.

The SV is an indication of the average molecular weight of the oil. HEAR with relatively few ester bonds per unit of weight has therefore a low SV of 174–176. Oils with predominantly fatty acids with 18 carbon atoms like sunflower seed oil or soybean oil have an SV of 191–194, whereas lauric oils like coconut oil and palm kernel oil have SVs of 255–270 mg KOH per gram of oil. Because of these differences, it is quite understandable that the SV determination has been an essential tool in vegetable oil characterization.

Ester value

The ester value of an oil is not determined directly. It is calculated as the difference between the SV and the acid value. It is not much used.

Hydroxyl value

The hydroxyl value (HV) of an oil is an indication of its hydroxyl group content. The hydroxyl groups can be part of fatty acid moieties such as ricinoleic acid (9*Z*,12*R*)-12-hydroxyoctadecenoic acid, but they can also be part of the glycerol moiety when this is not esterified as in partial glycerides. So, in oils without fatty acids with hydroxyl groups, the HV is an indication of the partial glyceride content.

The HV is determined by acetylating the free hydroxyl groups with an excess of acetic acid anhydride, hydrolyzing the excess, and determining the acetic acid content of the final reaction mixture. As usual in this kind of determination, a blank is used to avoid systematic errors. The HV is also expressed as mg KOH per gram of oil.

Iodine value

The IV is perhaps the most often quoted value of an oil. It is a measure of the degree of unsaturation. It is determined by weighing an amount of sample, the mass of which depends on the expected IV. When this value is low (0–5 g I_2/100 g oil), a sample mass of about 3 g is appropriate, whereas when the IV > 130, a smaller amount of 0.10 g suffices. The sample is dissolved in 25 ml tetrachloromethane, and then, 25 ml of Wijs solution is added. This solution of iodine monochloride (ICl) in glacial acetic acid is commercially available as such. After mixing, the reaction mixture is allowed to stand in the dark for 1 or 2 h for the addition of the ICl to the double bonds to take place.

After standing, an amount of 20 ml of an aqueous 10% potassium iodide solution is added with some (150 ml) additional water after which the iodine content of the mixture is determined by titration with sodium thiosulfate. By carrying out a blank determination with the same amounts of reagents, the amount of iodine added to the double bonds in the sample can be calculated by difference.

The IV is actively used in the hydrogenation of vegetable oils. Its value describes the extent to which an oil has been hydrogenated. Fully hydrogenated oils specify an IV of <1. The

IV is also used to characterize an oil so as to have an idea about its likely stability.

Peroxide value

When oil is stored, it can deteriorate by oxidation. Since one of the early oxidation products is a peroxide, the peroxide value (PV) of an oil provides information how fresh the oil is. It is determined by allowing the peroxides in the oil to liberate molecular iodine from a saturated solution of potassium iodide. The liberated iodine is then titrated with sodium thiosulfate. The PV is expressed as mmol of active oxygen per 2 kg of oil (Wheeler method) and of per 1 kg of oil (Sully method).

Anisidine value

When primary oxidation products decompose, they can form aldehydes and ketones. The former, especially 2,4-dienals and 2-alkenals, can be determined by allowing them to react with *p*-anisidine. The reaction product is yellow, so its amount is determined by measuring its absorbance at 350 nm against a blank in the reference cell (E_b). The absorbance of the oil itself is also measured against pure isooctane in the reference cell (E_a). The anisidine value is then calculated according to

$$p\text{-AV} = \frac{25 \times (1.2 \times E_b - E_a)}{W}$$

wherein W stands for the mass of the sample in grams. To distinguish the anisidine value from the acid value, the former is often written as *p*-AV so that the AV refers to the acid value.

Totox value

The Totox value is defined as the sum of the anisidine value and two times the PV (p-AV + 2 PV). It is an arbitrary value to indicate the oxidative load an oil has had to suffer.

Miscellaneous values

When it was not yet possible to determine a fatty acid composition by GLC, other methods were used to get an idea about this composition. The Reichert–Meissl value indicates the number of ml 0.1 N lye that is required to neutralize the water-soluble fatty acids that have been volatilized with water vapor from a 5 g fat sample. The Polenske value is similar in that it also indicates how many ml 0.1 N lye are required to neutralize certain fatty acids from a 5 g sample, but the difference is that the Reichert–Meissl value is concerned with the water-soluble fatty acids (butyric acid and caproic acid), whereas the Polenske value titrates the volatile fatty acids that do not dissolve in water (caprylic acid and capric acid).

The determinations of these values are difficult to repeat, and the outcomes are not an accurate representation of the fatty acids concerned. In fact, these values are well and truly obsolete, but in the past, they have been useful to establish the adulteration of butter with margarine.

The Crismer value measures the solubility of an oil in a standard solvent mixture of *t*-amyl alcohol, ethanol, and water (5:5:0.27 by volume). Values are characteristic for each oil since this solubility depends on degree of unsaturation and fatty acid chain length. It was used in international trade, mostly in Europe.

Instrumental Analytic Methods

Some instrumental analytic methods have been used for a long time. The refractive index of an oil can be measured with the Abbe refractometer to indicate the degree of unsaturation of a vegetable oil. The higher its IV, the higher the index. It can be used to follow the progress of a hydrogenation batch.

When UV spectrophotometers became available, they started to be used in the determination of the fatty acid composition. Conjugated dienes and trienes absorb at 232 and 268 nm, respectively. So, after conjugation of the polyunsaturated fatty acids, their content could be quantified. The spectrophotometric method can also be used to assess oil deterioration.

Chromatographic Methods

The advent of GLC greatly facilitated lipid analysis. It is fast, reproducible, and quantitative. In the early days of GLC, packed columns were used and their performance only allowed a fatty acid analysis. Consequently, research in many field focused on the fatty acid composition of lipids rather than on their triglyceride composition. The hydrogenation process is a typical example of this focusing. This focus on fatty acids rather than on triglycerides also affected nutritional studies in which insufficient attention was given to the fact that in the body, fatty acids on the outer position of a triglyceride are digested through a different mechanism as those on the middle position.

Later, with capillary columns, GLC could also tackle triglyceride analysis and distinguish between fatty acid isomers and *trans* fatty acids. Progress was made in the analysis of triglycerides by GLC for the determination of the carbon number composition, and this complemented the analysis HPLC determination of the partition number composition. These and other chromatographic methods are available from *The Lipid Library* (http://lipidlibrary.aocs.org/analysis.html).

Nuclear Magnetic Resonance

Two routine measurements make use of nuclear magnetic resonance methods. One is the low-resolution pulse NMR method to determine the SFC of a mixture of solid, crystalline fat, and liquid oil. It is used intensively to follow the partial hydrogenation of vegetable oils and for specifying fat blends to be used in margarines and shortenings, and it also plays a vital role in confectionery fats.

The method involves melting the fat sample at 80 °C in a special glass tube that fits the NMR spectrometer, tempering the sample at 60 °C for at least 5 min, cooling it for a set period of 60 min at 0 °C, and transferring it to the measuring temperature and keeping it there for 30–35 min before transferring it to the NMR instrument. This sounds very labor-intensive, but the transfers of the glass tubes to the various thermostatic baths and the measuring instrument can be fully automated by laboratory robotics.

For cocoa butter and other fats like cocoa butter equivalent having a high content of symmetrical monounsaturated triglycerides, the thermal treatment of the sample is slightly

different in that it also comprises a tempering stage. After having been placed in the 0 °C bath for 90 min, the samples are tempered at 26 °C for 40 h. Then, they are cooled again at 0 °C for another 90 min before being brought to the measuring temperature where they are kept for 60 min before being transferred to the NMR instrument.

Another NMR method used in lipid chemistry uses the ^{31}P NMR spectrometer for the determination of phosphatide compositions. It uses triphenyl phosphate as internal standard and thus arrives at absolute values for the contents of the various phosphatides. Often, these contents do not account for the total phosphorus content of the sample as determined by inductively coupled plasma emission spectroscopy (ICP-ES) (see later). The reason for this discrepancy is not known, but the presence of phytates has been suggested and after all, you do not need much phytates to introduce a lot of phosphorus.

Inductively Coupled Plasma Emission Spectrometry

Originally, the analytic method using ICP was used to determine the trace element contents of aqueous samples, for instance, effluents. In 1982, the use of this ICP equipment to measure the concentration of these elements in oils was published, and now, the method has become a standard tool for the control of the degumming process, and it has been incorporated in AOCS compendium of analytic methods that can be used when specifying oil in trading contracts.

Oil Stability Index

The oil stability index (OSI) of an oil is determined with a piece of equipment called Rancimat®. In the equipment, samples of oil are kept at a set temperature, and air is bubbled through the sample at a set rate. The air leaving the sample is bubbled through distilled water, the conductivity of which is monitored. In the early stages of the measurement, this conductivity hardly changes, but after a certain period, called the 'induction period,' it increases because the air has stripped volatile acids like formic acid from the oil sample. The conductivity curve shows an inflection and the point in time where this extrapolated inflection commences is called the 'OSI'; it is expressed in hours, and the temperature at which the experiment was carried out should be mentioned as well.

The OSI has been found to be determined by the fatty acid composition of the sample and its antioxidant content. Experiments have been carried out in which oil was stored under different conditions and its OSI was measured at set intervals. Sometimes, the OSI did not alter from one interval to the other. This allows the conclusion to be drawn that the OSI does not predict shelf life. All it can do is reveal batches that deviate from normal.

Vegetable Oils: Dietary Importance

SC Savva, Research and Education Institute of Child Health, Cyprus

Introduction

Vegetable oils are obtained from plants, such as seeds, nuts, fruits, and vegetables, and are the major source of monounsaturated fatty acid (MUFA) and polyunsaturated fatty acid (PUFA) in the diet. Three of them are rich sources of saturated fatty acids: coconut oil, cocoa oil, and palm oil. Cocoa oil is the first ingredient in ice cream produced by the industry, and palm oil is the usual oil in fast-food preparation. They are also a dietary source of fat-soluble vitamins and antioxidants. Oils made from walnuts, almonds, olives, sesame seeds, and flax seeds have been used for 5000–6000 years for several purposes. Olive oil is known as the oldest vegetable oil as this is concluded from residues of olive oil found in huge clay pots in the Minoan palaces in Crete and from excavations in Tunis.

The worldwide per capita total supply of vegetable oils and certain specific ones during the past 50 years is shown in Figure 1. This figure clearly shows that the worldwide supply of vegetable oils (kcal capita^{-1} day^{-1}) has more than doubled during this period, and this is mainly due to the increased supply of sunflower oil, soybean oil, palm oil, and rape and mustard oil. On the contrary, the per capita consumption of olive oil has remained relatively stable at the international level over this period. Figure 2 presents the food supply (kcal capita^{-1} day^{-1}) of the five most commonly used vegetable oils in 2011 in different parts of the world, expressed as percentage of total per capita daily supply of vegetable oils. Obviously, the supply of vegetable oils varies substantially in different parts of the world; the supply of soybean oil predominates in the Americas, in Northern and Southern Africa, and in Eastern Asia. The supply of sunflower oil predominates in Southern Africa, Central and Western Asia, and Eastern Europe. Rape and mustard oil is mainly used in Northern Europe and Oceania. Palm oil is mainly used in Eastern, Central, and Western Africa and Southeastern Asia. Olive oil remains the most widely used vegetable oil in Southern Europe, whereas it is also supplied in Northern Africa and Western Asia in lower amounts.

Vegetable oils are extracted from oilseeds by pressing using an expeller or cold press, centrifugation, or solvent extraction. Some oils, such as virgin olive oil, are extracted and used with mechanical pressure under controlled temperatures without any further treatment. Most vegetable oils, however, are refined to some extent in order to remove undesirable contents such as free acids and oxidized materials and alter their properties such as color and odor. Refinement enables the production of edible oils improved in terms of taste, smell, appearance, and stability enabling a longer shelf life. Refinement, however, alters the fatty acid composition of vegetable oils. Cold-pressed olive oil and other vegetable oils such as sunflower have been reported to have a lower linoleic acid (LA)/alpha-linolenic acid ratio (ALA) as compared with refined vegetable oils and a higher amount of oleic acid. Similarly, β-carotene was present in cold-pressed vegetable oils but is absent in the refined ones.

Hydrogenation of vegetable oils is a process used in order to produce semisolid or solid fats from vegetable oils. During the process of partial hydrogenation, *trans*-fatty acids (TFAs) are produced that have adverse health effects, and therefore, alternative methods of converting vegetable oils to solid fats have been introduced. Interesterification, that is, rearrangement of fatty acids within a triacylglycerol, is a process now widely used, although there are conflicting data regarding possible adverse health effects on lipoprotein and serum glucose metabolism and hemostasis parameters. More recently, concerns have been raised, as it has been shown that the substitution of interesterified fat for partially hydrogenated fat in the maternal diet of mice poses an increased risk for offspring in adult life. There is also evidence that interesterification may affect obese and nonobese adults' metabolic state in a different way.

Vegetable oils should be stored in dark, cool, and dry places since they are sensitive to heat, light, and exposure to oxygen. Vitamin E is particularly sensitive to sunlight. Storing edible oils in refrigerator may cause them to thicken or become cloudy, although this is reversed when left in room temperature.

One important property of vegetable oils is the smoke point, that is, the temperature that a given oil begins to smoke. In general, olive oil – similarly to butter and lard – has a lower smoke point. The smoke point of vegetable oils is affected by the degree of refinement; more refined vegetable oils have a higher smoke point. On the other hand, the longer a vegetable oil has been exposed to heat, the lower its smoke point, and therefore, the use of the same vegetable oil repeatedly should be avoided in cooking.

Nutrient Composition of Vegetable Oils

Vegetable oils are mainly composed of triacylglycerols, that is, esters of fatty acids with glycerol, but they also contain free fatty acids, monoacylglycerols, diacylglycerols, and nonglyceridic nutrients. The fatty acid composition of vegetable oils varies, and most edible oils are high in MUFA or PUFA, whereas three of them are high in SFA. Nevertheless, the rapid increase in vegetable oils consumption observed during the past 100–150 years represents the most important factor that contributed to the elevation of dietary omega-6-to-omega-3 ratio to its current value of 20–30 compared with a ratio of 2 in the hunter-gatherer diets.

The composition of vegetable oils in fatty acids varies depending on several factors including climate, soil, fruit, seed or plant maturity, genetic variation of the plant, and degree of refinement. It should also be stressed that processed vegetable oils, particularly the partially hydrogenated ones,

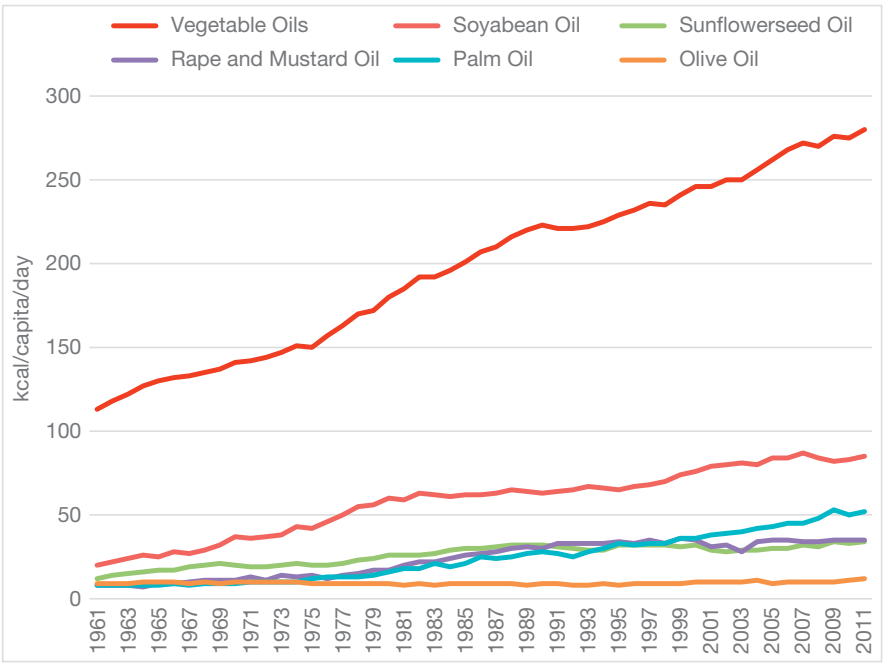

Figure 1 Food supply (kcal capita^{-1} day^{-1}) of vegetable oils in the world between the years 1961 and 2011. Food and Agriculture Organization of the United Nations. Statistics Division (FAOSTAT). http://faostat3.fao.org/home/E. Accessed on 20/12/2014.

also contain considerable amounts of TFA. In Table 1, the composition of certain vegetable oils in total saturated fatty acids (SFAs), PUFA and MUFA, and the essential LA and ALA is presented. The USDA National Nutrient Database for Standard Reference was used as a reference for this table. Blends of vegetable oils and those processed for industrial use were not included in this table. It is obvious from Table 1 that SFAs are the predominant fatty acids in certain vegetable oils (coconut, palm, babassu, and cupu assu) ranging from 49–86%, which is higher than the SFAs in lard (pork fat) and beef tallow. Olive oil, avocado oil, and hazelnut oil are richer in MUFA along with the high-oleic sunflower and safflower oils. The composition of vegetable oils in PUFA varies considerably, but the more favorable ones in terms of LA/ALA ratio are cold-pressed flaxseed oil (LA/ALA ratio of 0.3, with ALA content of 53.4 g/100 g), canola oil (LA/ALA ratio of 2.1), and mustard oil (LA/ALA ratio of 2.6).

Other minor constituents present in vegetable oils include pigments, flavor compounds, hydrocarbons, sterols, phenols, and vitamins. Some of these constituents are present in crude oils, whereas in refined ones, constituents such as phenols may be removed. Table 2 presents the nonglyceridic nutrients most consistently present in the selected vegetable oils derived from the USDA National Nutrient Database for Standard Reference. It should be underlined that minor differences exist between both the glyceridic and nonglyceridic nutrients presented here from USDA database and other locally produced vegetable oils.

Nutritional Value of Vegetable Oils

Dietary fat contributes to the texture, flavor, and aroma of a wide variety of foods. Foods high in fat content are considered the most palatable ones. Dietary fat has a direct impact on taste perception activating a large network of brain areas including the somatosensory cortices and thalamus that control taste.

Although most fatty acids may be synthesized in the body, two are unable to synthesize and are thus called essential fatty acids, which are the omega-6 LA and the omega-3 ALA polyunsaturated fatty acids. A balanced diet is necessary in order to achieve sufficient intake of energy and nutrients for optimal growth, health, and well-being. Fatty acids are important nutrients because they represent a major source of energy; after absorption, fatty acids are converted to energy via β-oxidation or are stored in adipose tissue for later use. Fats and oils enable food digestion and facilitate the absorption of vitamins and phenols.

Fatty acids are important structural molecules in cell membranes, and neural tissues such as the brain are particularly rich in long-chain PUFA (LCPUFA). LCPUFA are also precursors of eicosanoids, that is, inflammatory mediators, mediating platelet aggregation, leukocyte migration, vasoconstriction, vasodilation, blood pressure, bronchial constriction, apoptosis, and oxidative damage. Fatty acids play an important role in cholesterol metabolism, even from an early age, and thus may be associated with cardiovascular disease later in life. Certain fatty acids and drugs affecting lipid metabolism activate peroxisome proliferator-activated receptors (PPARs), which in turn control the expression of genes implicated in intra- and extracellular lipid metabolism, implicating, thus, a role of these fatty acids in the regulation of energy partitioning, insulin sensitivity, adipocyte development, and neural function throughout the life span.

It is now widely accepted that dietary SFAs increase serum LDL-cholesterol levels and thus increase the risk for CHD. Controlled trials and observational studies provide robust

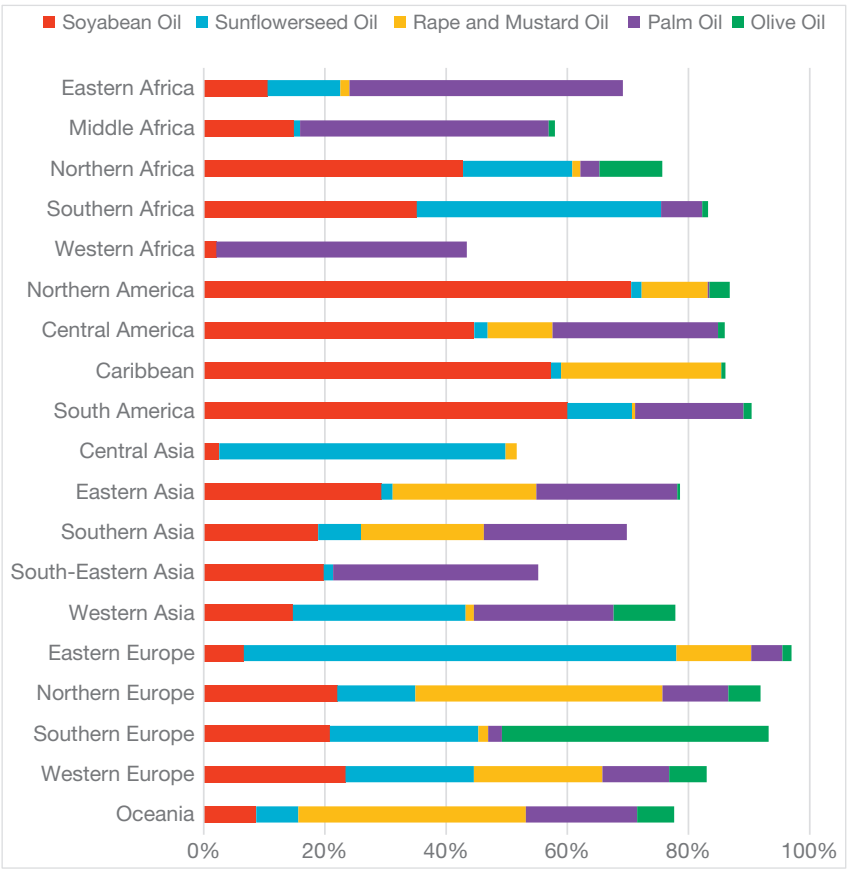

Figure 2 Food supply (kcal capita^{-1} day^{-1}) of five most commonly used vegetable oils expressed as percentage of total daily supply of vegetable oils in different parts of the world in 2011. Food and Agriculture Organization of the United Nations. Statistics Division (FAOSTAT). http://faostat3.fao.org/home/E. Accessed on 20/12/2014.

evidence that consumption of TFA from partially hydrogenated oils adversely affects cardiovascular disease risk factors and increases the risk for cardiovascular disease, perhaps because TFAs act as proinflammatory mediators and induce endothelial dysfunction. A substantial body of evidence suggests that the consumption of diets rich in the long-chain omega-3 PUFA (eicosapentaenoic acid or EPA and docosahexaenoic acid or DHA) or supplements containing these fatty acids is beneficial in inflammatory diseases, cardiovascular disease, and autoimmune diseases. A recent meta-analysis has shown an inverse association between marine omega-3 LCPUFA intake and risk for breast cancer. Particular attention is given upon the intake of LA and the ratio of LA/ALA. It has been shown that sunflower oil rich in LA and high in LA/ALA ratio may predispose to metabolic syndrome. Substantial debate exists in relation to LA intake and cardiovascular disease risk. Nevertheless, it appears that the benefit of LA intake is with substituting LA for SFA in the diet in significantly reducing the risk for CVD. Experimentally, it has been shown that in Wistar rats, a diet supplemented with garden cress oil and its blended oils enriched with ALA significantly modulated fatty acid profile in various tissues increasing content in EPA, DHA, and ALA and decreasing LA and arachidonic acid (AA). At the same time, this diet significantly decreased serum total cholesterol, LDL cholesterol, and triglycerides. However, other studies in humans failed to show any association of the LA/ALA ratio in predicting cardiovascular disease morbidity and mortality.

Sterols comprise an important fraction of the nonglyceridic part of vegetable oils, and they are essential components of cell membranes. When present in foods, sterols efficiently reduce the absorption of dietary and biliary cholesterol, thus enabling reducing serum LDL-cholesterol levels by up to 10%. It should be noted, however, that oil refinement may substantially result in sterol loss by 10–70% depending on the oil and refinement method. Interestingly, beta-sitosterol is thought to have some anticarcinogenic properties, an issue that is still unclear.

Vegetable oils are also a rich source of vitamin E, with known antioxidant properties. The human diet contains eight different vitamin E-related molecules synthesized by plants, but vitamin E is usually expressed as alpha-tocopherol, which is the most active form. Again, processing of vegetable oils, particularly heat-treated oils, results in reduction of tocopherol content. Alpha-tocopherol serves as a peroxyl radical scavenger that protects polyunsaturated fatty acids in membranes and lipoproteins.

Phenols are important natural antioxidants, which are mainly present in olive oil. They bind free radicals, forming phenol radicals, thus preventing lipid tissues from oxidation. More specifically, phenols prevent LDL-cholesterol oxidation and thus prevent atherosclerotic plaque formation. Thus,

Table 1 Fatty acid composition of vegetable oils (g/100 g of vegetable oils)

Oil	*Total SFA*	*Total MUFA*	*Total PUFA*	*LA*	*ALA*
Grams/100 g					
Almond oil	8.2	69.9	17.4	17.4	0.0
Apricot kernel oil	6.3	60.0	29.3	29.3	0.0
Avocado oil	11.6	70.6	13.5	12.5	1.0

Note: Blends of vegetable oils and those processed for industrial use were not included in this table.

US Department of Agriculture, Agricultural Research Service, Nutrient Data Laboratory. USDA National Nutrient Database for Standard Reference, Release 27. Version Current: August 2014. (Available from http://www.ars.usda.gov/Services/docs.htm?docid=24912.)

phenols have been acknowledged for their benefits in cardiovascular health and aging and their anti-inflammatory and anticancer activities. Vitamin K, an important component of four coagulation factors, is present in some vegetable oils in varying amounts.

The Role of Selected Edible Vegetable Oils in the Prevention of Chronic Diseases

Olive Oil

Olive oil as already mentioned is the oldest known edible oil. Extra virgin olive oil has been routinely used in the traditional Mediterranean diet and is mainly produced and used in Mediterranean countries of Europe and Northern Africa, although recently, it is increasingly used in Northern Europe and North America. It is mainly used as a salad dressing and in cooking. The pioneer Seven Countries Study concluded that populations consuming this traditional Mediterranean diet experienced low coronary heart disease (CHD) and cancer mortality compared with populations consuming a "Western diet." The Mediterranean diet has been shown to reduce the secondary complications, recurrence, and even death after first myocardial infection. The typical Mediterranean diet was rich in fruits, vegetables, legumes, whole-wheat bread, nuts, fish, and extra virgin olive oil as the main source of dietary fat. The consumption of olive oil in the traditional diet of the island of Crete was over 90 g per person per day, which was around one-third of the total daily energy intake.

The fatty acid composition of olive oil depends on several factors such as latitude of production, climate, variety, and maturity of the fruit. It has been shown, for instance, that olive oil from Tunisia has a lower content in MUFA and higher content in palmitic acid compared with olive oil from Mediterranean countries of Europe. The fatty acid composition of olive oil is SFA 14 g/100 g, MUFA 73 g/100 g, and PUFA 11 g/100 g mainly as LA. Olive oil has also important nonglyceridic content. Olive oil is the only edible oil with squalene, which is the precursor of sterols. It also contains sterols, tocopherols, and carotenoids. It should be noted that processing of olive oil may reduce tocopherol content. The high concentration of oleic acid in olive oil renders it resistant to lipid peroxidation. Moreover, the high content of alpha-tocopherol along with the low PUFA content preserves oxidation of olive oil.

The unique composition of olive oil, which is rich in MUFA and antioxidants, leads to a reduction of serum LDL cholesterol and the preservation or even increase of HDL-cholesterol levels. A recent meta-analysis documented the beneficial health effect of MUFA and particularly oleic acid on health status. This meta-analysis showed an overall risk reduction of all-cause mortality (11%), cardiovascular mortality (12%), cardiovascular events (9%), and stroke (17%) in the highest compared with the lowest third in MUFA, oleic acid, and olive oil consumption.

Minor constituents of olive oil are also suggested to play an important role in cardiovascular disease prevention independent of olive oil's fatty acid content. It has been shown that phenolic-enriched virgin olive oil helps to decrease LDL cholesterol and, moreover, olive oil phenolic compounds appear to protect LDL against peroxyl radical-dependent and metal-induced oxidation *in vitro*, an effect that is more pronounced in virgin olive oil than refined olive oil. The higher phenolic content of extra virgin oil appears to reduce postprandial inflammatory markers such as TXB(2) and LTB(4) 2 and 6 h after the meal compared with refined olive oil.

It is argued that a substantial proportion of cancers such as colorectal, breast, pancreas, prostate, and endometrial cancers may be prevented with the adoption the Mediterranean diet. A relatively recent meta-analysis of 19 case–control studies concluded that higher intake of olive oil is associated with lower odds of having any type of cancer irrespective of the country of origin. On the other hand, an older meta-analysis examining the association of breast cancer risk with biomarkers of fatty acids intake showed a positive association of breast cancer risk with oleic acid in cohort studies but failed to show any association in case–control studies although a protective role of ALA for breast cancer risk was identified. It should be stressed that the latter meta-analysis was based on

Table 2 Nonglyceridic composition of vegetable oils

Oil	*Choline, total (mg/100 g)*	*Phytosterols (mg/100 g)*	*Vitamin E (alpha-tocopherol) (mg/100 g)*	*Vitamin K (phylloquinone) (μg/100 g)*

US Department of Agriculture, Agricultural Research Service, Nutrient Data Laboratory. USDA National Nutrient Database for Standard Reference, Release 27. Version Current: August 2014. (Available from http://www.ars.usda.gov/Services/docs.htm?docid=24912.)

biomarkers of fatty acids intake and, therefore, dietary sources of MUFA other than olive oil may account for this association. These data raise the question of whether olive oil's monounsaturated fatty acid content or its antioxidant components are responsible for its beneficial effects. Many studies have shown that vitamin E protects against a number of cancers, which may be a result of its antioxidant action, stimulation of the immune system, and other actions.

Canola Oil/Rapeseed Oil

Canola oil is produced from rapeseed using plant breeding techniques. These techniques introduced in the early 1970s assured the production of canola oil safe for human consumption because it made it possible to reduce erucic acid to less than 5% from previously 50%, which is potentially harmful for health. The breeding techniques also meant that levels of glucosinolates were also reduced.

Canola oil has lower contents of SFA (7.4 g/100 g), whereas it is high in MUFA content (63.3 g/100 g) and has a balanced ratio of LA/ALA (19.0/9.1 g/100 g). Among the nonglyceridic content, canola oil contains vitamin E (as alpha- and gamma-tocopherol), vitamin K, and beta-sitosterol.

Canola oil is currently thought of as one of the healthiest edible vegetable oils. A recent review has concluded that canola oil decreases serum total cholesterol and LDL cholesterol and, thus, the risk for CHD, although the modulation of HDL cholesterol and triacylglycerols remains controversial. There was also evidence that canola oil-based diets have a positive effect in glucose homeostasis compared with SFA-based diets. This review, also, concluded that canola oil may offer some anticancer activity for some forms of cancer.

Flaxseed Oil

Flaxseed (or linseed) oil is produced from flaxseed and is now increasingly used in nutrition. It contains 9.0 g SFA/100 g, 18.4 g MUFA/100 g, and 67.8 g PUFA/100 g of which 53.4 g is ALA. This unusually high content of ALA makes this oil oxidize rapidly, and therefore, this oil is not supplied as a pure oil, but it is supplied with a suitable antioxidant preparation. Flaxseed oil is also rich in alpha- and gamma-tocopherol, vitamin K, and phytosterols.

The presumed health benefits associated with omega-3 PUFA has made flaxseed oil a good dietary source of achieving the nutritional adequacy in ALA. This is supported by a recent review that collectively shows that increased ALA consumption

is associated with a lower risk for coronary heart disease morbidity and mortality, lower odds for carotid plaques, and thinner segment-specific carotid intimal/media thickness, whereas increased phospholipid ALA content is associated with a lower risk for stroke. Although most studies have reported modest effects of flaxseed oil on blood total cholesterol, LDL cholesterol, and HDL cholesterol, ALA from flaxseed oil tends to increase the concentrations of the large, less atherogenic LDL-cholesterol subfractions. The modulation of serum triglyceride levels by ALA and flaxseed oil consumption remains obscure. Evidence also suggests that dietary ALA is associated with lower blood pressure, but the association of flaxseed oil intake with blood pressure levels is inconclusive. Ingestion of flaxseed oil or ALA may help in preventing or treating a variety of diabetic complications and modulates coagulation in diabetic patients but not in healthy individuals.

Sunflower Oil

Sunflower oil is used in cooking, salad dressings, and manufacture of fat spreads. Plant breeding produced varieties with improved fatty acid profile, such as the high-oleic sunflower oil, and at the same time resistant to insects. The traditional sunflower oil is high in PUFA content (mainly LA) and low in SFA. Currently, however, there are varieties with high oleic and mid oleic content. Sunflower has also nonglyceridic content, consisting of tocopherols and plant sterols.

The demand for the sunflower oil has declined since 2000, and most research regarding health effects was done much earlier. Studies had shown that substituting sunflower oil for SFA in the diet may result in decreasing total cholesterol and LDL cholesterol, which is thought to be favorable with respect to decreasing risk of cardiovascular disease. However, those studies raised concerns because of a parallel decrease in HDL cholesterol. A more recent study comparing intake of mid-oleic sunflower oil with the typical American diet has shown a decrease in both total cholesterol and LDL cholesterol with no effect of the experimental diets on triglyceride levels, rate of oxidation, or lipid hydroperoxides. A newer study, however, has shown that sunflower oil rich in LA and high in LA/ALA ratio may predispose to metabolic syndrome.

Corn Oil

Corn oil is mainly produced and consumed in the United States where it is mainly traded in blends of vegetable oils and also in China and Brazil. Most corn plants in the United States are genetically modified to yield more hardy crops. In the United States, it has been shown that corn oil is mainly used in fast-food restaurants, whereas meat used in fast foods, such as beef and chicken, is from animals fed with corn. It should be noted that US corn agriculture has been criticized as environmentally unsustainable. Refined corn oil is composed of PUFA 59%, MUFA 24%, and SFA 13% with a ratio of LA/ALA of 83. Corn oil contains also gamma- and alpha-tocopherols and beta-sitosterol.

There is only scarce research in the last two decades regarding consumption of corn oil and health. A study that examined the effect of high-fat diet rich in PUFA and low in SFA or TFA compared with a diet high in SFA or TFA leads to improvements in lipid profiles including serum total cholesterol and LDL cholesterol and triglyceride levels, thus reducing cardiovascular disease risk. A diet prepared with corn oil (or palm olein) reduces not only total cholesterol and LDL cholesterol but also HDL cholesterol compared with a diet prepared with coconut oil. The corn oil diet also reduced the serum triglyceride levels.

Soybean Oil

Soybean is mainly used for cooking, but it is also used in margarine and spread production and mayonnaise. According to the Food and Agriculture Organization of the United Nations (FAOSTAT), soybean oil is the most widely used vegetable oil worldwide, which experienced a more than fourfold increase in food supply between 1961 and 2011. Most of the soybeans used today in producing vegetable oils are genetically modified crops, which have been used to modify the fatty acid composition.

The composition of soybean oil is mainly of PUFA (LA 51.0 g/100 g and ALA 6.8 g/100 g), with MUFAs at 22.8 g/100 g and SFA 15.7 g/100 g. Soybean oil is the richest vegetable oil in vitamin K and contains tocopherols (mainly gamma and delta and less alpha). Soybean oil essentially lacks phytosterols but has a considerable amount of beta-sitosterol.

Palm Oil

Palm oil is an edible oil derived from the flesh of the fruit of the palm tree, which should be distinguished from palm kernel oil obtained from the kernel of the fruit, which has limited food interest. Palm oil is separated into liquid (olein) and solid (stearin) fractions, from which several types of palm oil are produced for use as a cooking oil, for manufacture of margarines and shortenings, and for bakery use such as the production of biscuits, cookies, and ice creams. Palm oil is the least expensive among the most common edible oils, and the low price justifies the wider use of palm oil in less developed parts of the world (see **Figure 2**). Equally important, the oxidative stability of the oil because of its fatty acid composition enables its use in high temperatures and ensures a prolonged shelf life of products made of palm oil, thus making it a popular edible oil.

Palm oil has a balanced fatty acid composition between SFAs (approximately 50%) and unsaturated fatty acids (MUFA 39% and PUFA 10% mostly as LA). The major fraction of SFA consists of palmitic acid (44%). Palm oil contains nonglyceridic contents including carotenes, tocopherols, tocotrienols, sterols, and squalene, which diminish after refinement.

Most of the studies on health effects of palm oil focussed on its effects on serum lipid levels. Despite the relatively high SFA content of the oil, its structure is thought to account for the beneficial effects described in numerous nutritional studies; oleic acid is predominantly attached at the sn-2 position in triacylglycerols, whereas SFAs are attached on the sn-1 and sn-3 positions. Dietary palm oil was found to reduce serum total cholesterol and LDL cholesterol and triglycerides and increases HDL cholesterol. Improved lipoprotein(a) and apo-A1 levels were also demonstrated from palm oil diets. Virgin palm oil also provides carotenes apart from tocotrienols and

tocopherols that have been shown to be powerful antioxidants and potential mediators of cellular functions. These compounds can be antithrombotic, cause an increase of the prostacyclin/thromboxane ratio, reduce restenosis, and inhibit HMG-CoA reductase (thus reducing cholesterol biosynthesis).

Coconut Oil

Coconut oil is extracted from the kernel of matured coconuts harvested from the coconut palm and is high in saturated fats. Coconut oil is a common edible oil in certain countries, and there is a controversy regarding its effects on lipid profiles and cardiovascular disease risk. The high content of SFA raised concerns that it could lead to more artherogenic lipid profiles, and thus, health professionals in the 1980s recommended that coconut oil should not be used. This has changed however, as it was noted that countries with high intake of tropical oils had some of the lowest rates of cardiovascular heart disease, and recently, the use of coconut oil has become more popular because of the potential cardiovascular benefits.

SFAs in coconut oil increase serum HDL cholesterol more than LDL cholesterol to give a more favorable lipid profile relative to dietary carbohydrates. Recently, it has been shown that replacing high-PUFA vegetable oils by 75% with coconut oil in the diet of broilers is associated with a reduced fat deposition and increases lipoprotein lipase, hepatic lipase, and total lipase activities, thus affecting favorably lipid profile. In pigs, replacement of standard diet with coconut oil modulates the adipose tissue gene expression and fatty acid composition, with minimal effect on serum lipid profile. Interestingly, in mice with stress-induced injury, coconut oil was recently shown to improve lipid profile and restore oxidative stress.

Other potential outcomes have also been described with use of coconut oil. In breast cancer patients, virgin coconut oil consumption during chemotherapy helped improve the quality of life and reduced symptoms related to side effects of chemotherapy.

Conclusions and Recommendations

The balance of fatty acids in humans' diet is one much debated issue. Research has mainly focussed on certain components of the vegetable oils rather than employing supplementation of whole oil to the diet and estimate a number of specific end points. Moreover, there is mostly a lack of studies comparing health end points between diets consisting of different vegetable oils. Therefore, studies have concluded that many individual vegetable oils may be part of a balanced diet, but we are able to recommend the use of virgin olive oil as the only edible oil with ideal fatty acid composition and many micronutrients with antioxidant properties reducing the risk for all chronic diseases.

Current dietary recommendations propose that SFAs should be lowered to less than 10% of total energy intake. A relatively recent meta-analysis showed that substituting PUFA for SFA helps to reduce CHD events. An interesting study showed that in diabetic patients, a healthy diet, rich in vegetables and a vegetable oil with a considerable amount of PUFA and antioxidants, replacing SFA for 8 weeks, decreases DNA oxidation expressed as DNA strand breaks.

Current dietary recommendations suggest replacing SFA in the diet with MUFA or PUFA. For example, solid fats in home-prepared food such as butter and lard could be replaced with vegetable oils that are rich in MUFA and PUFA. All vegetable oils, however, are more than 99% fat, and therefore, the consumption of vegetable oils or products prepared from vegetable oils should be used in moderation. Thus, modern dietary recommendations suggest the use of a small amount of vegetable oils – 30–45 ml each day – in cooking, salad dressings, margarine, and mayonnaise. PREDIMED study has recently demonstrated that the daily use of 45 g of olive oil resulted in a 30% reduction in the risk of major cardiovascular events among high-risk persons.

The nutritional value of edible oils is based not only on the fatty acid composition but also on the minor components with antioxidant activity. Processing and storage of edible oils may alter the composition of oils in nonglyceridic contents; refinement and exposure to sunlight may destroy the vitamin E and other nonglyceridic contents in vegetable oils. Partial hydrogenation of edible oils, which may be responsible for TFA formation, is now less commonly used, and other methods are utilized in order to provide edible oils with functional and desired organoleptic properties. Interesterification is now one of the methods used. The use of interesterified fat produced from vegetable oils needs further research to determine if its use is safe to human health. As further research is still warranted in order to evaluate currently used vegetable oils, it is likely that a wider variety of edible oils will be available through conventional plant breeding techniques or plant breeding using genetically modified technology. It is therefore safer to use only olive oil, which has been used for thousands of years mainly by the Mediterranean populations having health-promoting effects and disease prevention.

The lack of studies comparing health effects of different vegetable oils is further complicated by the fact that in most societies, a different combination of vegetable oils is currently consumed. Before the introduction of most vegetable oils in modern diets, olive oil was the main vegetable oil used in nutrition for many millennia. Olive oil has been an important constituent of the Mediterranean diet, which proved beneficial in preventing disease and prolonging life expectancy. The Mediterranean diet has been even proved as cost-effective compared to a prudent Western diet in patients with previous CHD. Therefore, the use of olive oil as an unsaturated edible oil should be encouraged when and where possible. However, the current international epidemic of obesity in both children and adults should lead to a restriction of fat and oil intakes specifically for those who are overweight or obese. Oils are high-energy dense foods providing 9 kcal g^{-1} as compared to carbohydrates and proteins providing 4 kcal g^{-1}. A balanced diet, selecting appropriate portions from all five food groups, and daily moderate to vigorous physical activity almost daily are internationally accepted recommendations.

Vegetable Oils: Oil Production and Processing

AJ Dijkstra and G van Duijn

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Oils and fats are mixtures of different organic molecules called lipids. Triglycerides are by far the most common component of oils and fats; these biological molecules are water-insoluble. Oils and fats can be extracted from plant or animal sources. The difference between a fat and an oil is that a fat is solid or semisolid at normal room temperature (20 °C in Europe and the United States), while an oil remains liquid.

Early vegetable oil production in Europe was mainly concerned with olive oil. For climatic reasons, it was limited to the Mediterranean; more northern countries used lard or butter as the fat source in their diet. This distinction still exists. Countries used to olive oil now use vegetable oil for cooking, the shortage of butter led to the invention of margarine, and lard has been replaced by vegetable shortening in countries that traditionally used lard.

Oil production has evolved from the early process comprising a grinding step to open the cells in the oleaginous raw material and an expelling step in which the oil is squeezed out of the ground fruit or seed paste to a process that may also comprise a solvent extraction step.

Oils and fats have been used since ancient times for food preparation and in nonfood applications like lamp oil, lubricant, soap manufacturing, and skin care. This article will only deal with the production of oils and fats for use in food preparation or as a food ingredient. Oils and fats in food provide functional and nutritional benefits. They serve as a heat transfer medium at elevated temperatures (frying), provide lubrication (spreads), improve taste (dressings), and give texture to a wide range of foodstuffs. On top of this, they supply a concentrated source of energy, deliver critical building blocks for the body, and act as a carrier for essential minor components like vitamins A and D. A balanced intake of oils and fats is essential for human health.

The Oil and Fat Supply Chains

The supply chains of vegetable oils and fats consist of the following:

- The growing and harvesting of the oil crop.
- Oil extraction to recover the oil; the by-product meal is mostly used as animal feed.
- Purification to reduce the level of unwanted minor components.
- Modification of the melting characteristics as required for particular products.
- All transport and storage from grower to end user.

The main origins of supply for the world vegetable oil and fat market fall into three main categories (more details will be given in other articles):

1. Annually planted oilseed crops like soybean, rapeseed, and sunflower seed
2. Fruit oils like palm and olive oil
3. Kernel oils like palm kernel oil, coconut, and other nut oils

Oilseed crops are generally not grown in the regions where the oils are consumed. Oilseeds are transported and stored as seeds, and the separation into oil and meal is mostly performed close to the consumer markets. Under controlled conditions, oilseeds can easily be stored for a long time, at least until the next harvest arrives. Overseas shipping is mainly in the form of seeds.

Like other fruits, fruit oils have a short shelf life. After a few days, they start to deteriorate, resulting in a poor oil quality. The extraction of oil from fruits is done close to the crop growing area, and the extracted oil is then stored and transported to the consumer markets. Overseas shipping is only as oil.

In contrast, kernels can be stored after drying and transported over long distances, although extraction is generally performed where the fruits are grown. Overseas shipping is mainly as oil.

Vegetable Oil Extraction

Olive Oil

The annual world production of olive oil varies around 2.8 million tonnes. Spain is the main producer with an average annual production of 1.2 million tonnes, followed by Italy and Greece. After harvesting, the olives are first of all cleaned and washed with water. Then, they are crushed in a hammer mill from where the resulting paste is fed to a malaxer in which the paste is slowly agitated to allow the dispersed oil droplets to coalesce. Talc and/or enzymes can be added to improve the oil yield.

In old olive oil mills, the paste is then spread onto circular filter cloths that are stacked inside a hydraulic press. Modern mills use a decanter to separate the oil from the waste. If a two-phase decanter is used, this will separate the paste into some 80 wt.% wet pomace and 20 wt.% turbid oil. This oil is then washed with 10–20% water to yield clear oil and not too dirty washing water. The amount of water used affects the residual polyphenol content of the oil and is therefore quite critical.

When a three-phase decanter is used, only 50 wt.% dry solids (pomace) are produced, but the addition of further washing water leads to a large effluent stream (black water) that has to be treated before it can be discharged. When the pomace is extracted with, for example, hexane, the oil thus obtained can no longer be called 'virgin.' It has to be refined to yield a bland olive oil called 'pomace oil.'

Oils from Seeds with a High Oil Content

Although the production of oil from seeds with a high oil content (around 40%) also leads to the meal by-product, the

value of this by-product is low in comparison with the oil. These seeds are therefore grown for their oil. Unlike fruit oils, seeds can be stored so that an oil mill processing oilseeds can operate the whole year round. After harvesting, the seeds are dried to a water content of less than 16% of the dry, oil-free matter to prevent microbial spoilage during storage.

At the oil mill, the seeds are first cleaned to remove any stones and other extraneous matter that might damage the flaking rolls. Then, they are conditioned to a temperature of 60–70 °C to soften the cell so that the subsequent flaking requires less electrical energy. In the flaking process, two perfectly cylindrical rolls flatten the seeds so that cells within the seed are opened and oil can be squeezed out of the flakes without having to pass through a cell wall.

The flakes are passed to a screw press that is fitted with a decreasing-volume Archimedean screw that builds up pressure along its shaft. This shaft rotates inside a slotted barrel that allows the oil to pass through. This oil contains many meal particles that have to be removed. In a first clarification process, the oil is screened or allowed to settle, and then further clarification is realized by filtration or the use of a decanter centrifuge. The solids removed contain a substantial amount of oil and are therefore returned to the screw press.

The press cake leaving the screw press is too hot to enter the solvent extraction plant. It therefore has to be cooled and broken into pieces to permit proper percolation during solvent extraction. A very effective way of treating the press cake is by pelletizing, since this treatment also ruptures cells that survived the flaking and pressing processes. When the cake has reached a temperature of no more than 60 °C, it is ready for solvent extraction, which will be discussed in the next section.

Because the hull of a sunflower seed accounts for up to 30% of its weight, it can be advantageous to dehull the seeds prior to the expelling step. This increases the capacity of the screw presses and the extraction plant; it lowers the wax content of the oil and increases the protein content of the meal. The dehulling process comprises the opening of the seeds by impact and a separation by winnowing. Some hulls have to be included in the feed of the screw press to give it some body. The hulls are usually used on-site as a boiler fuel.

Oils from Seeds with a Low Oil Content

The prime example of an oilseed with a low oil content is the soybean that contains around 18–21% oil. Soybeans are primarily grown for the protein content of the meal that is used in the animal feed industry on a large scale; the oil can be regarded as a by-product. Because its use in poultry farming requires a high (>48%) protein content and a low (<3.5%) fiber content, the beans are often dehulled before being extracted.

In the classical dehulling process, the beans are dried and held for tempering. This makes the beans shrink away from the hulls so that after cracking, the hulls can be separated from the cracked cotyledons by aspiration. In the so-called 'hot dehulling' process, the beans are conditioned to a temperature of 65–70 °C in a tower in which tubes, which are heated with low-pressure steam, heat the beans quite quickly. This and the subsequent superficial heating in a fluid bed dryer cause the hull to shrink away from the cotyledon. Cracking leads to a mixture of separate hull fragments and cracked cotyledons that are separated in cascade aspirators.

For the cracking process, two or three sets of superimposed corrugated rolls are used wherein opposing rolls run at different speeds to grip the beans. Cracking should aim at breaking the bean into four to six smaller pieces and avoiding fines and mashed beans. Subsequently, the cracked cotyledons are flattened into flakes of some 0.25–0.30 mm thickness in between flaking rolls that are similar to those used for high oil content seeds.

Processing the flakes in an expander is optional. The expander is a kind of extruder in which the flakes are compressed until on leaving the die, the compacted mass expands causing further cell rupture. The resulting collets have the advantage that they have a higher bulk density than the flakes, so expanders are often used to increase the capacity of an existing oil mill. Collets also have the advantage of a reduced liquid holdup, which saves energy in the desolventizer.

The extraction solvent used is invariably hexane. Industrial hexane is a mixture of alkanes with a boiling range of 66–69 °C comprising *n*-hexane (~62%), methylpentanes (~23%), and methylcyclopentane. It is highly inflammable and its explosive range in air is 1–8% by volume. Consequently, extractors are operated at a slightly subatmospheric pressure to prevent the hexane from escaping.

Solvent extractors operate countercurrently to minimize the oil content of the extraction residue leaving the extractor and maximize the oil content of the miscella. Two types of extractor are in industrial use: percolation and immersion. In the immersion type, the screen under the material being extracted has so little open area that it constitutes the greatest flow restriction. Immersion extractors provide more contact time between solvent and seed material but require more draining time than percolation-type extractors. Both types ensure a miscella strength of around 30% oil and a residual oil content in the meal of < 1 wt.%.

The solvent–wet extraction residue or 'marc' leaving the extractor is then treated to remove the solvent, first by indirect heating and then by heating with live steam. This raises the temperature of the meal to 105–100 °C in the toasting section where antinutritional enzymes are denatured. Since the live steam causes the moisture content of the meal to increase, it has to be dried. Air is used to dry the meal to a residual water content of 13–14 wt.% and cool it down at the same time.

The hexane-laden vapors leaving the desolventizer are at atmospheric pressure. Using their latent heat to evaporate the hexane from the miscella requires the latter to be under a reduced pressure; in industrial practice, this pressure is about 500 hPa absolute. The latent heat content of the vapors leaving the desolventizer suffices to evaporate < 90% of the hexane present in the miscella so that the composition of the liquid leaving the first evaporator is around 80 wt.% oil. It is further concentrated using steam and finally treated in a steam stripper operated at 200–400 hPa absolute.

If the oil has to be shipped, it must be degummed with water to prevent a deposit being formed during transport and storage. In this water degumming process, an amount of water that is about the same as the gum content of the oil is mixed with the hot oil, allowed to hydrate the mucilaginous matter. and then separated by a centrifuge. Drying these gums yields lecithin.

Vegetable Oil Refining

Process Sequence

The vegetable oil refining process was introduced at the start of the twentieth century to produce good-quality oils and fats for use in margarine production and as frying oil. Before 1900, oils were cleaned by removing water and solids by decanting. The refining process has been optimized to reduce the natural taste and color and to remove most of the free fatty acids present in the extracted oil. Later, it was discovered that the process also removes many of the contaminants present in the extracted oils, like solvent residues, metals, polyaromatic hydrocarbons, and pesticide residues, bringing these contaminants below the legal limits.

The refining process is a combination of the following process steps; more details are given in the following sections:

- Degumming: A pretreatment process mainly applied to seed oils to reduce their phospholipid contents.
- Neutralization: The purpose of neutralization is to reduce the concentration of free fatty acids by reaction with a diluted alkali solution, typically sodium hydroxide. The reaction product (soap) is removed by decanting or by centrifugation.
- Bleaching: The main purpose is to remove residual soap, color pigments, and oxidized components. In this process, bleaching earth (natural or activated clay and/or silica) is added to the oil as an adsorbent. The earth and adsorbed impurities are subsequently removed by filtration.
- Dewaxing: Removal of natural waxes present in some vegetable oils by cooling and filtration.
- Deodorization: Under high vacuum, the oil is heated to 180–270 °C, while steam is blown through the oil. The objective is to remove volatile components and to create an odorless oil with a bland taste and increased storage stability.

The process sequence of combined degumming/neutralization followed by bleaching and deodorization is called chemical refining, referring to the reduction of free fatty acids by a chemical reaction. The process sequence of degumming followed by bleaching and deodorization is called physical refining, referring to the reduction of free fatty acids by the physical process of vacuum stripping. An overview of the possible process sequences is given in Figure 1.

Degumming Processes

As indicated in the refining process flow sheet (Figure 1), many different routes lead from crude oil to fully refined oil, and the number of steps can differ.

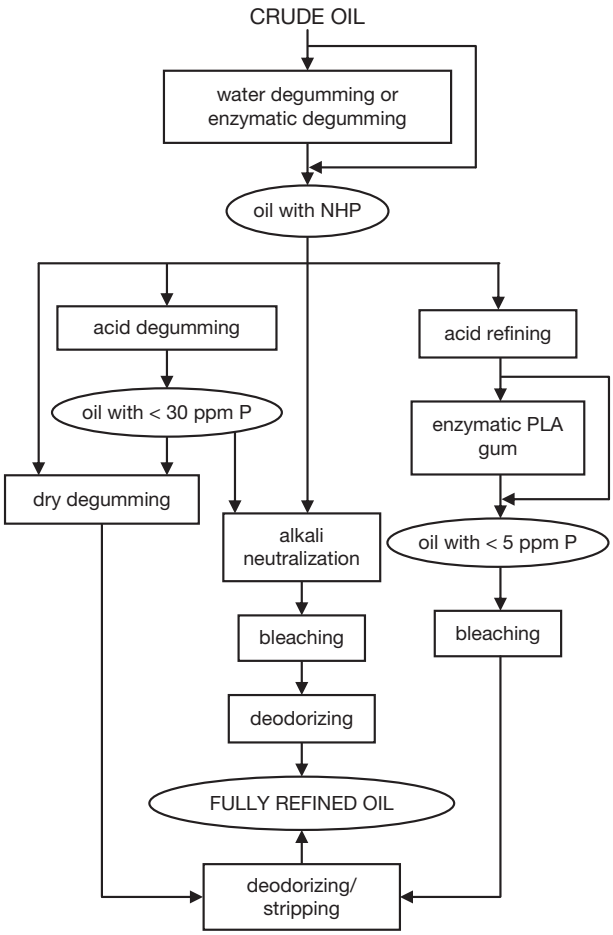

Figure 1 A block diagram of possible vegetable oil refining process routes.

The route with only two steps consists of the dry degumming process, followed by physical refining. In the dry degumming process, some phosphoric acid is mixed into the oil and allowed to react with the phosphatides. Then, bleaching earth is added, and this adsorbs the phosphatides, the excess phosphoric acid, and also the coloring matter present in the oil. This bleaching earth is removed by filtration, and the bleached oil is ready for physical or steam refining. Since the bleaching earth requirement in the dry degumming process is proportional to the phosphatide content of the crude oil, this two-step route is only economical for oils and fats with a low phosphatide content. Examples are palm oil, lauric oils, lard, and tallow.

In the acid degumming step, the crude or water-degummed oil is treated with a strong acid that is subsequently diluted with water to form a gum phase that is removed by centrifuge. However, this dilution raises the pH insufficiently to pull all the gums into the gum phase. Consequently, the acid-degummed oil requires a further degumming treatment before the oil can be physically refined.

In the acid refining process, the crude or water-degummed oil is also treated with a strong acid, but instead of diluting the acid with water, it is neutralized with caustic soda. This raises the pH to a value where still no soaps are formed but where all the phosphatidic acid that has been liberated by the acid treatment is dissociated. It therefore moves completely into the aqueous phase and can be separated from the oil as sodium phosphatidate. The acid refining process produces an oil that can be physically refined after it has been bleached.

The water degumming process and the acid refining process produce a gum phase as by-product. This gum phase also contains oil, and if the gums are disposed of by mixing with the meal, the oil is sold at meal value that is less than if it were to be sold as oil. To recover at least some of this oil, enzymatic gum treatment processes using a phospholipase have been developed. As shown in Figure 1, phospholipase C (PLC) can be used in the water degumming step or on the gums obtained by water degumming. This enzyme catalyzes the hydrolysis of the bond between the phosphate moiety and the glycerol moiety in phosphatides as indicated in Figure 2. This hydrolysis generates diglycerides that move into the oil phase and thus contribute to oil yield. It also produces phosphate esters of choline, which are water-soluble and do not retain any oil.

Another phospholipase that can be used to treat the gums and thereby increase the oil yield is phospholipase A (PLA). Figure 2 shows that there are two enzymes that catalyze the hydrolysis of a fatty acid ester bond: PLA_1 and PLA_2. Both enzymes are commercially available. They form lysophosphatides that retain less triglyceride oil and free fatty acids that are removed during a subsequent neutralization process. They can be added to oil that has already been acid-refined or to the gums resulting from the acid refining treatment. Because the oil savings resulting from the various enzyme treatments are proportional to the amount of gums, these treatments only make sense when applied to oils with a high phosphatide content.

Neutralization Processes

In the neutralization process, oil containing FFAs is treated with lye, a solution of sodium hydroxide or caustic soda in water. This reacts with the FFA to form sodium soaps that are insoluble in the oil and therefore form a separate soap phase. This soap phase also contains phosphatides, when present in the crude oil, and triglyceride oil. After this soap phase has been separated from the oil, it is called soap stock. Formerly, it was used in a soap works adjacent to the refinery. It can be used as an animal feed ingredient, but in Europe, it is more common to react the soap stock with sulfuric acid at elevated temperatures and recuperate its fatty matter as 'acid oils,' a mixture of fatty acids and triglyceride oil. This process also generates an acid-aqueous effluent stream that contains phosphates and sulfates and has a high BOD. It has to be neutralized, its phosphate may have to be removed by a lime treatment, the resulting precipitate will then have to be separated, and then what is left has to be treated in an effluent plant to lower the BOD. All this makes soap stock splitting a cumbersome process that is preferably avoided. It has been a powerful driving force for the shift towards physical refining.

In alkali refining, there are two routes. The oldest route that has been developed and is still in use in the United States is the

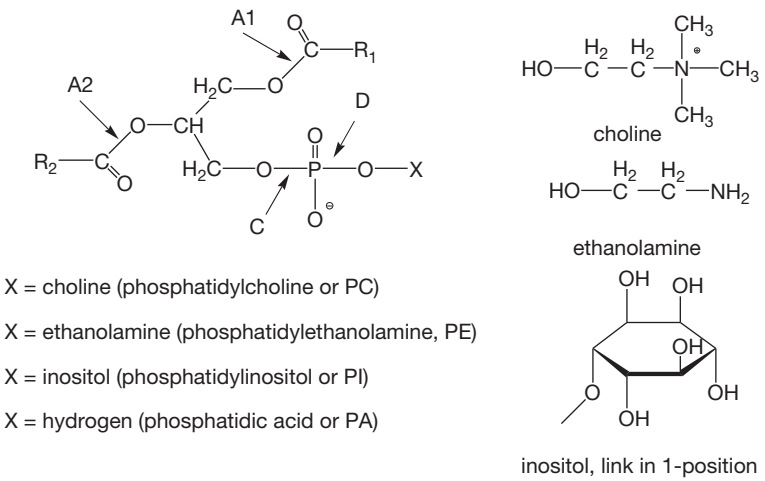

Figure 2 Chemical structure of phosphatides and indications which phospholipase enzyme catalyzes the hydrolysis of which bond.

so-called 'long mix' process. Dilute lye (14–18°Bé or 130–180 g NaOH/L of water) is added and mixed into cold oil, and then the oil is heated until a clear separation between oil and soap stock is obtained. The soap stock is removed by centrifugal separator, and to lower the residual soap content, the oil is either washed with water or treated with silica hydrogel. In Europe, the 'short mix' process is almost universally used. In this process, a degumming acid (phosphoric acid) is finely dispersed in the hot (90–100 °C) oil, it is allowed to react in a holding vessel, and then less dilute lye (20–28 °Bé or 145–215 g NaOH per liter of water) is dispersed in the oil. Separation between oil and soap stock is almost instantaneous, allowing the mixture to be sent to the centrifuge without much holding time. Again, the oil phase can be washed or treated with silica hydrogel, but in Europe, water washing is more common.

Bleaching of Vegetable Oils

Crude and degummed/neutralized vegetable oils differ widely in color. Palm oil is deep red, rapeseed oil is greenish, and sunflower seed oil has not much color. These colors are caused by two groups of compounds. The red color stems from carotenes, with β-carotene being the most common, and the green color originates from chlorophyll. Carotenes are thermally unstable so they break down when the oil is deodorized or physically refined. Because palm oil also contains the thermally more stable chlorophyll, which is removed by bleaching earth, palm oil has to be treated with this adsorbent to yield an almost colorless fully refined oil.

The bleaching process itself is quite simple. Depending on the color of the oil, an amount of 0.5–4.0 wt.% of bleaching earth is mixed into hot (80–110 °C) oil, the suspension is given some time to approach the adsorption equilibrium, and the earth is then removed by filtration. The filters used for this step are invariably pressure leaf filters that are precoated by circulating oil with bleaching earth over the filters. Filter aids like diatomaceous earth can also be used.

Bleaching earth is a pretty universal adsorbent, but it insufficiently adsorbs certain compounds that are considered to be undesirable. Among these compounds are the polyaromatic hydrocarbons (PAHs). Low-molecular-weight polyaromatic hydrocarbons are sufficiently volatile to be removed by vacuum stripping, but high-molecular-weight polyaromatic hydrocarbons require another means of removal. This means is provided by treating the oil with activated carbon, a highly effective adsorbent for this kind of compounds. Bleaching clay and activated carbon can be used simultaneously.

Dewaxing of Vegetable Oils

Some vegetable oils like sunflower seed oil, rice bran oil, and corn germ oil contain waxes. These waxes are esters of fatty acids and fatty alcohols. When both of them are saturated, the wax has a melting point > 70 °C, which causes the waxes to crystallize at refrigeration temperatures and form an unsightly deposit. To prevent this from happening, the oil has to be dewaxed. In the dewaxing process, the oil is cooled down to cause the waxes to crystallize. They can then be removed by filtration with a pressure leaf filter and filter aid. Since the amount of filter aid is proportional to the wax content and oil is also retained in the filter cake, filtration becomes quite expensive when the oil has a high wax content.

Then, it is more economical to remove the bulk of the waxes in a wet dewaxing process using a centrifugal separator and remove residual waxes by filtration. This wet dewaxing process employs water with a detergent, which can be soap, to concentrate the wax crystals in the aqueous phase. It can therefore be combined with the neutralization step.

The ideal cooling profile comprises a slow cooling from above the cloud point of the oil to below this cloud point to limit the number of crystal nuclei. Cooling from below this cloud point can be fast and maturation is not necessary.

Deodorization

The deodorization process is carried out at a high temperature (180–270 °C). Because of this high temperature, residual peroxides and carotenes will decompose, and when the temperature is too high, *trans* isomers can be formed. The more double bonds a fatty acid contains, the more prone it is to this kind of isomerization. This is the reason why refined oil specifications contain an upper limit of 1.5 wt.% for oils containing linolenic acid (soybean oil and canola oil) and an upper limit of 1.0 wt.% for sunflower seed oil and corn oil, which do not contain this fatty acid.

Apart from these chemical reactions, vacuum stripping is a physical process that can be described by the laws of Raoult and Dalton. The reduction of volatiles in the oil depends on the stripping steam flow, the vacuum pressure, the oil temperature, the oil volume, the vapor pressures of the volatiles, and the equipment design.

The deodorization process can be carried out in batch, continuous, or semicontinuous installations. Batch deodorizers have one single compartment in which the process steps of deaeration, heating, stripping, and cooling are sequential in time. In continuous deodorizers, the process steps are simultaneous in different compartments (trays) of the deodorizer, and both input and output are constant over time. In semicontinuous deodorizers, the process steps are simultaneous in the different trays, but tray filling and emptying is discontinuous. Filling stops after a certain level has been reached in the first tray. After allowing sufficient time to perform the process step for that tray, the bottom valve is opened and the content drops into the next tray for the next process step. Figure 3 shows a basic layout of a semicontinuous deodorizer. Oil can also be fed to the top of a packed column and trickled down through this column, while the stripping flows countercurrently. This type of column has a lower stripping steam usage than the crossflow system to reach the same final concentration of volatiles.

Obtaining stable oil is more than just getting rid of the volatiles present in the oil to be deodorized or physically refined. When triglyceride oils are heated for prolonged periods, strong off-flavors are developed. Deep fat frying in coconut oil smells different from frying in sunflower oil, let alone tallow. The chemical nature of these smells is not known, and since they are not released by freshly deodorized oil, they must be formed during deep fat frying from flavor precursors. Accordingly, the deodorization process should

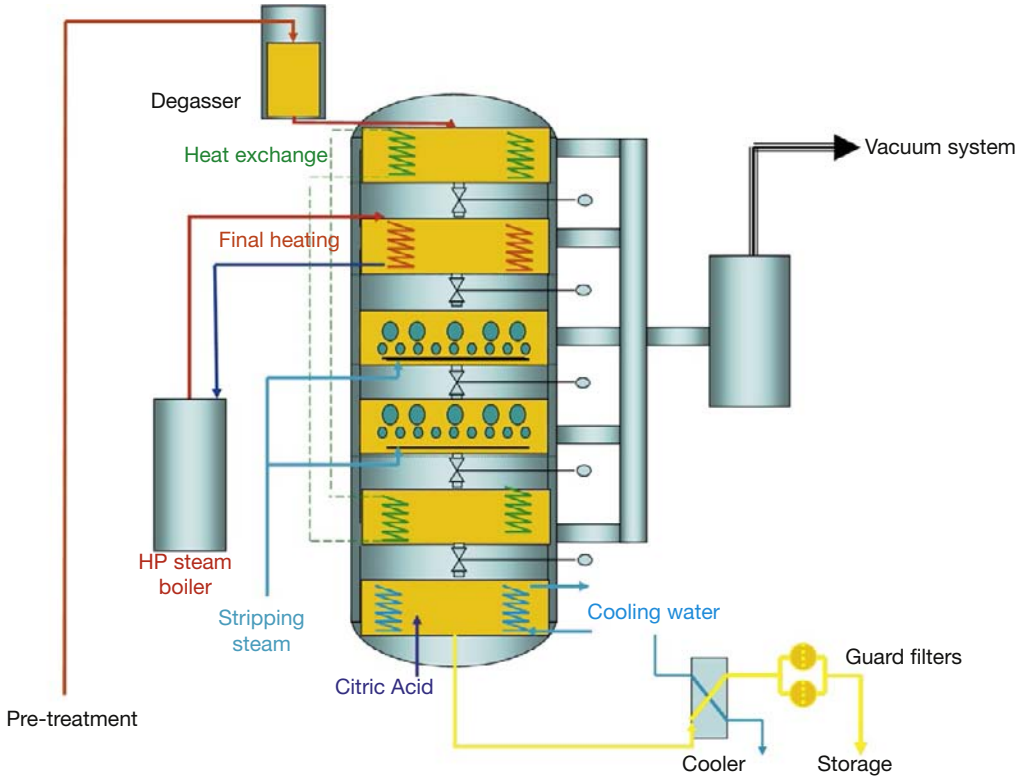

Figure 3 The layout of a semicontinuous deodorizer. From G. van Duijn, lecture material.

provide some holding time at a high temperature to enable the thermal breakdown of these flavor precursors.

There are two reasons why the deodorization process is the most energy-intensive step of the refining process. Firstly, it is carried out at temperatures of up to 270 °C, and secondly, it is carried out under a vacuum of 2–10 hPa, which has traditionally been maintained by steam ejectors. Accordingly, heat exchange between ingoing and outgoing material either directly in a plate heat exchanger or indirectly by using one or even two thermosiphons has led to energy savings. The use of a mechanical vacuum pump in combination with a surface condenser for the distillate has limited the steam usage to the stripping steam but increased the consumption of electrical energy.

Vegetable Oil Modification Processes

The Purpose of Oil Modification

When Mège-Mouriès invented margarine in 1869, he used tallow olein as the fat phase, but when more and more margarine was produced, a shortage of solid fat emerged. Accordingly, the invention of the hydrogenation process in 1903 led to an almost immediate industrialization despite the fact that this also involved building plants for elemental hydrogen. Mège-Mouriès also described a dry fractionation process to obtain his tallow olein, but that process only began to be applied on a large scale with the increased production of palm oil in the last quarter of the twentieth century.

Networks of solid fat crystals play an important role in many food products. For example, margarines consist of an emulsion of small droplets of an aqueous phase dispersed in liquid oil stabilized by a structure of solid fat crystals. The fat crystals supply structure and texture to the product, they prevent the oil from leaking out of the product, and they avoid coalescence of the dispersed aqueous phase droplets. Solid fat crystal networks have similar functions in whipped cream and ice cream, where they stabilize a foam of air bubbles dispersed in an emulsion of fat droplets in water; they also play an important role in bakery products. Most of the seed oils are too low in solids at the temperature at which the product is used (generally ambient temperature) to fulfill this role. Tropical oils, such as palm oil, palm kernel oil, and coconut oil, have a higher solid fat content, but for many applications, they are still too soft. Modification of the melting performance of naturally occurring oils and fats is required to produce fats with optimal properties for the aforementioned applications. The modification technologies that can be applied are the following:

1. Hydrogenation
2. Interesterification
3. Fractionation

Hydrogenation

Hydrogenation of oils and fats has been applied on a large scale since the start of the past century to produce hard fats from a wide variety of oils and fats (mainly liquid oils and fish oil). Hydrogenation involves the addition of two hydrogen atoms to unsaturated double bonds (C═C) in the fatty acid moieties of the triglycerides. The more saturated fat resulting

from this reaction has a higher melting point than the starting material.

In the hydrogenation process, hydrogen gas reacts with liquid oil at elevated temperatures and pressures in the presence of a solid catalyst. The hydrogenation of edible oils is always carried out as a batch process. Oil is preheated by the previous batch, the catalyst (nickel on an inert support) is added, and hydrogen gas is dispersed in the oil. Hydrogenation is an exothermic reaction so the temperature of the batch starts to rise and has to be controlled by cooling. The reaction is continued until the product properties aimed for have been reached (partial hydrogenation). The catalyst is removed by filtration and residual nickel is removed in a post-bleaching step.

As well as saturation, the isomerization of double bonds also takes place during the hydrogenation reaction. Two types of isomerization reaction will occur: geometric isomerization (*cis*–*trans*) and positional isomerization (shift of double bond along the fatty acid chain). The complete reaction mechanism is quite complicated because of the many steps involved, and it is still not yet fully understood and kinetically quantified.

In response to the findings of adverse effects of *trans* fatty acids on blood lipids, the food industry has practically eliminated components containing *trans* fatty acids from their fat phase compositions. This has drastically reduced the application of partial hydrogenation as a method of producing solid fats. Full hydrogenation of almost all double bonds reduces the *trans* isomer content to an acceptable level but results in a product with a very high melting temperature. Such a product can only be used after interesterification with a liquid oil.

Interesterification

Interesterification involves a rearrangement or reshuffling of the fatty acids on the glycerol backbone of the triglyceride molecule. Interesterification is catalyzed by an alkaline catalyst or by a lipase enzyme. The most commonly used alkaline catalysts are sodium methanolate and sodium ethanolate. The early interesterification process was used to extend the plastic range of lard used as shortening. Later blends of different raw materials were used to change their physical properties so that they could be used as hard fat in margarine and as shortening.

For a long time, the interesterification reaction has been assumed to proceed with a glycerolate anion as the catalytic intermediate. This anion would then attack the slightly positive carbon atom of a carboxyl group. If this group left as a hydroxyl anion, ester interchange would have been the overall result. An alternative reaction mechanism has been proposed recently that assumes that the initial catalyst (sodium methanolate) abstracts an α-hydrogen from a fatty acid moiety, thereby forming an enolate anion. This enolate anion then acts as the catalytic intermediate. When it reacts with water, it will form a free fatty acid, the formation of which could not be explained by the glycerolate mechanism.

The alkali (sodium methanolate or ethanolate)-catalyzed reaction takes place in prerefined oil (low in water and in free fatty acids) at elevated temperatures (100–110 °C). The reaction is very fast; full randomization results within a few minutes even in factory-scale vessels (10–40 t oil content). After the reaction, the catalyst is inactivated by the addition of water. This addition of water leads to the formation of free fatty acids and sodium hydroxide that will combine to form soaps. The reaction of sodium methanolate with a fatty acid moiety leads to the formation of methanol, and when this reacts with an enolate anion, methyl esters will be formed. The soap is removed by water washing and decanting. Methyl esters are more volatile than triglyceride molecules and are removed during high-temperature deodorization. Both soap and esters constitute a yield loss.

In addition to the basic catalysts used, lipase enzymes have also been introduced for the interesterification process. Interest in the use of lipase originates from the attempts to produce cocoa butter equivalents (CBEs), symmetrical monounsaturated triglycerides that are compatible with cocoa butter. This isomeric requirement ties in with the *sn*-1,3 specificity of the lipase enzyme. Interesterifying a triglyceride that consists almost entirely of trioleate (high-oleic sunflower seed oil, for instance) with stearic acid or methyl stearate should generate a CBE.

Lipase enzymes are also used in a nonstereospecific interesterification process. To overcome the fundamental problem that enzymes need water to be active but use this water to hydrolyze fats, this process uses a large amount of rather dry, immobilized enzymes. It is a continuous process, using four reactors that are filled with enzymes. The first of these, which is filled with an enzyme that has lost most of its activity, acts as a kind of guard for downstream reactors. It is emptied when the product leaving the last reactor is insufficiently randomized, filled with fresh enzymes, and relocated as the last reactor. What impurities in the oil cause the enzyme to lose its activity is still not quite clear, so as a precaution, the oil fed to the first reactor has been neutralized, bleached, and deodorized. The enzymatically interesterified oil needs to be deodorized before it can be used in food products.

Fractionation

Fractionation is the controlled crystallization of the more saturated and/or longer-chain triglycerides, followed by separation of the solid phase (stearin) and liquid phase (olein). By far, the most important oil, fractionated worldwide, is palm oil, the main reason being the demand for clear liquid oil (palm olein). More recently, there has been a growing interest in the solid product of palm oil fractionation (palm stearin) for the production of cocoa butter equivalents, cocoa butter replacers, and margarine hard stocks. Besides palm oil, palm kernel oil, partly hydrogenated liquid oils, cottonseed oil, and milk fat are also fractionated.

Processes for Producing Virtually *Trans*-Free Hard Stocks

The combination of full hydrogenation, interesterification, and fractionation and the availability of a variety of different oils and fats can be used to produce virtually *trans*-free hard stocks with various melting ranges.

Liquid seed oils, low in solid fats, are first fully hydrogenated to generate solids combined with a very low *trans* level (<1.25%). These fully hydrogenated oils may subsequently be interesterified with nonhydrogenated liquid oil to reduce the solid fat content at high temperature (>40 °C). This solid fat content can be further reduced by fractionation (see **Figure 4**).

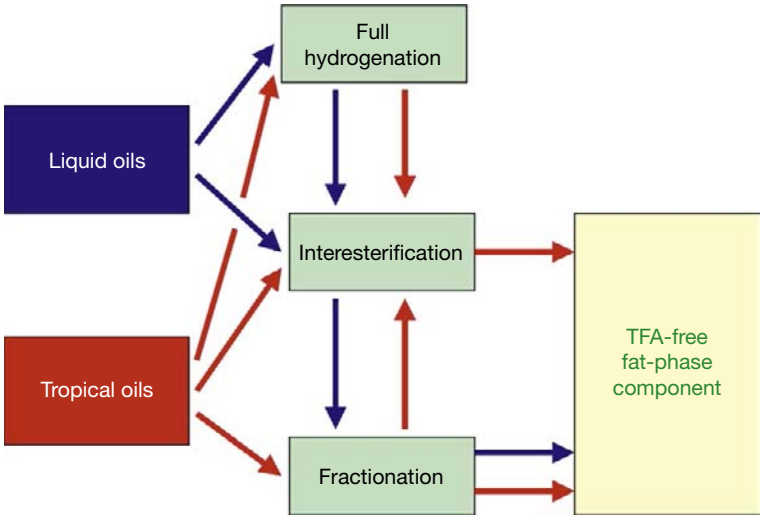

Figure 4 Process routes to produce *trans*-free hard fat components.

The presence of relatively high solid contents in tropical oils creates more flexibility in oil modification routes. Fractionation alone will produce a relatively soft stearin, which is not optimal for structuring margarine. Fractionation followed by interesterification with other (fractionated) components is used to produce 'nonhydrogenated' hard fats. Full hydrogenation followed by interesterification is an alternative way to obtain a hard fat high in solids with a steep melting line without fractionation (see **Figure 4**).

Vegetable Oils: Types and Properties

AJ Dijkstra

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Vegetable oils can be classified in different ways. One way would be according to the amount of produced oil. Then the list of oils should start with palm oil followed by soybean oil, then rapeseed oil, sunflower seed oil, and so forth. However, this way has the disadvantage that the order may change like in 2006, when for the first time, more palm oil was produced than soybean oil. Another way could be according to the most important fatty acids. Then, the lauric acid oils like coconut oil, palm kernel oil, and babassu oil would be grouped together. This has the disadvantage that it is not clear what determines the importance of a fatty acid. Is it the concentration of the acid or its uniqueness? Should borage seed oil, which contains 23% γ-linolenic acid (GLA), be grouped with other oils that contain this dietary important acid like evening primrose oil and black currant seed oil? Or should it be grouped with oils like soybean oil and corn oil because these oils have in common that linoleic acid is their major acid?

In an encyclopedia, it would be logical to list the vegetable oils in alphabetical order but this also has disadvantages. It would lead to undesirable duplication because the health effects of GLA would have to be repeated for each subsequent oil that also contains this acid. Another aspect to be considered is that several vegetable oils have an entry of their own.

Again, undesirable duplication should be avoided. Therefore, oils not having an entry of their own will be grouped together according to a specific trait, for instance, GLA content. The names of the groups will be in alphabetical order, and within a group, the oils will be listed alphabetically.

What properties to list? Handbooks like the *Physical and Chemical Characteristics of Oils, Fats, and Waxes* list properties such as specific gravity, refractive index, iodine and saponification value, titer, and fatty acid, tocopherol, tocotrienol, sterol, and triglyceride composition. However, many fats have not been analyzed in such detail. Often, only the fatty acid composition has been determined, and after the other properties, nothing has been filled in. So *The Lipid Handbook* does not mention the properties for which no data are available but limits itself to what is known. In addition, it provides some production figures and also some data on international trade.

Confectionery Fats

Because the production of milk chocolate requires additional cocoa butter and the demand for cocoa powder in chocolate-flavored drinks and confectionery is less than amount corresponding to the additional cocoa butter requirement, there is a structural shortage of cocoa butter. This is reflected in the relative prices of cocoa powder and butter. Accordingly, cocoa butter equivalents (CBEs) have been developed. These are vegetable fats that are compatible with cocoa butter; which means that when they are blended with cocoa butter, the blend has the same physical and especially crystallization properties as pure cocoa butter.

This can only be achieved when these CBEs are chemically almost the same as cocoa butter, that is, they have a similarly high content of monounsaturated triglycerides in which the oleic acid is esterified to the middle hydroxyl group (the 2-position) in the glycerol. Because of this positional requirement, 1,3-specific lipase enzymes have been used to develop these CBEs. By using a starting material with a high oleic acid content at the middle position and allowing this to react with stearic acid or its methyl or ethyl ester by the presence of this specific lipase, oleic acid moieties at the outer positions were replaced by stearic acid moieties. Suitable starting materials are high oleic oils such as a sunflower seed variety bred for deep-fat-frying applications and olein fractions resulting from the production of CBEs, such as shea olein.

However, the interesterification reaction is an equilibrium reaction so a large excess of stearic acid moieties is required to ensure that both outer positions are occupied by stearic acid. Lipase enzymes also have the drawback that they need some water to be active and that this water leads to hydrolysis that causes free fatty acids and partial glycerides to be formed. These partial glycerides isomerize, which causes a lack of 1,3-specificity. Consequently, the reaction product of the enzymatic interesterification contains triglycerides with stearic acid on the middle position and also triglycerides that still have an oleic acid at one of the outer positions. Consequently, this reaction product requires extensive purification before a CBE with acceptable quality results.

Moreover, Directive 2000/36/EC of the European Parliament and of the Council of 23 June 2000 relating to cocoa and chocolate products intended for human consumption allows 5% vegetable fat in chocolate and specifies that they are obtained only by the processes of refining and/or fractionation, which excludes enzymatic modification of the triglyceride structure. The vegetable fats allowed in the EU as raw material for producing CBEs are Borneo tallow (illipe butter), palm oil, sal fat, shea butter, kokum gurgi, and mango kernel fat. Table 1 lists some properties of these and similar fats.

In Table 1, the major fatty acids of the butters (16:0, palmitic acid (P); 18:0, stearic acid (St); 18:1, oleic acid (O)) have been listed as well as the contents of the monounsaturated triglycerides. When the butters themselves had to be processed, their stearin fractions have been listed as well.

Allanblackia (*Allanblackia floribunda*)

Allanblackia nuts are grown in West Africa (Ghana). The butter contains > 50% stearic acid (St = 18:0) and > 40% oleic acid (O = 18:1). Consequently, it has a high StOSt content and can be used as a raw material for cocoa butter equivalents. The butter has not been listed among the vegetable fats that can be used in the EU in chocolate.

Table 1 Fatty acid and triglyceride compositions of some raw materials for confectionery fats

Butter/oil	*16:0*	*18:0*	*18:1*	*POP*	*POSt*	*StOSt*	*Total*	*IV*
Cocoa butter	25	35	34	15	39	27	81

*Borneo tallow (*Shorea stenoptera*)*

Borneo tallow is also called illipe butter. It is obtained from a tropical tree 6–15 m high with 5 cm nuts. The kernels are enclosed in a thin, brittle case set in an acorn-like cup with winglike attachments that enable the nut to fall clear of the parent tree. The nuts are collected from the ground and dried in the sun until the shells are sufficiently brittle to be separated from the kernels by pounding in rice mortars. The seed is usually solvent-extracted. Similar meals are made from other Shorea species. Illipe butter is one of the fats that are allowed in chocolate in the EU as cocoa butter equivalent.

The triglyceride composition of illipe butter makes it eminently suitable as a cocoa butter equivalent. Its major triglycerides are POP (9%), POSt (29%), and StOSt (42%). It has therefore a higher stearic acid content than cocoa butter itself and thus also a higher StOSt content, which can be used to 'offset' the high POP (P = 16:0) content of the much cheaper palm oil midfraction that is also allowed in chocolate.

*Chinese tallow tree (*Sapium sebiferum*)*

The Chinese tallow tree produces fruits that contain two kinds of oil/fat. The kernel contains a highly unsaturated oil that contains hydroxy acids that may be esterified with a fourth fatty acid. This oil is not for food purposes but can be used in varnishes. The wax on the outer shell is the tallow listed in the table. It contains about 20–25% tripalmitin that has to be removed by fractionation if a fat with a high monounsaturated triglyceride content is to be produced.

*Kokum gurgi (*Garcinia indica*)*

The kokum gurgi tree grows along the western coast of India. Its seeds contain 23–26% fat that after refining can be used as CBE without having to be fractionated. Its use is permitted in chocolate in the EU.

*Mango kernel fat (*Mangifera indica*)*

The annual production of mango fruits approaches 30 million tonnes with about half of this in India. Because of mango juice production and mango fruit canning, the mango kernels are available as a waste product. They contain 7–12% fat. The stearin fraction of this fat has a high StOSt content so it can be combined with the cheaper POP palm oil midfraction to form a CBE. The ratio can be varied to compensate variations in the cocoa butter properties.

*Mowrah butter (*Madhuca latifolia*)*

The mowrah or mahua tree grows in Central India, both wild and cultivated. Mowrah seeds are about 2 cm long and contain some 50% fat, which contains 16% linoleic acid. Fractionating the fat to get rid of triglycerides with linoleic acid is difficult. These triglycerides will be concentrated in the olein, and since the filter cake will also contain some olein, the stearin will contain some of them. Accordingly, mowrah butter is not an ideal raw material for CBEs, but it can be used for filling fats in blends with palm oil midfraction.

*Phulwara butter (*Madhuca butyracea*)*

The phulwara tree is native to Nepal. Its fruits contain three seeds that make up 20% of the fruits. The seeds contain 42–47% oil and the kernels some 60–66%. This oil has a very high palmitic acid content implying that it also contains tripalmitin. When this is removed in a first fractionation step, the first olein can be refractionated to yield a midfraction that will have a high content of monounsaturated triglycerides. It will be similar to palm oil midfraction.

*Sal fat (*Shorea robusta*)*

The sal tree is native to the Indian subcontinent ranging from Myanmar in the east to Nepal and northern and Central India. The kernel content of the seed is about 50% and the oil content of the kernel is some 30%. Besides the palmitic, stearic, and oleic acids listed in the table, sal fat also contains 6–11% arachidic acid (20:0). Its use in chocolate is allowed in the EU, but to increase the monounsaturated triglyceride content of the fat, it has to be fractionated. It is the stearin that is used as CBE.

Shea butter (Vitellaria paradoxa)

The shea tree was formerly also denoted as *Butyrospermum parkii* but this name is superseded. The tree grows across Africa from Cameroon to Uganda, but in the east, the subspecies is mainly *Vitellaria nilotica* and in Cameroon, Mali, and Burkina Faso, it is *Vitellaria paradoxa*. These subspecies differ in that the subspecies *V. nilotica* contains less unsaponifiable and shows a higher oleic acid content than the fruits grown in the west, which show a wide range of fatty acid compositions. The composition given in the table is representative of the shea butter used for CBE.

In many African countries, the women collect the nuts of the wild-growing shea tree, shell them, and boil the kernels with water from which they scoop the butter after it has solidified. The butter can also be produced by screw pressing. Refining involves the removal of the polyterpene constituent of the unsaponifiable. Subsequent fractionation leads to a stearin fraction that is permitted as CBE in chocolate in the EU.

GLA-Containing Oils

From a health point of view, GLA-containing oils are quite interesting since GLA or (6*Z*,9*Z*,12*Z*)-octadeca-6,9,12-trienoic acid is an ω-6 polyunsaturated acid that has been formed by dehydrogenation of linoleic acid. For some people, that can be a slow process so they may therefore benefit from ingesting GLA instead. Once ingested, the acid can be converted into dihomo-γ-linolenic acid (20:3ω-6) by chain elongation, in which the acid can be converted by dehydrogenation into arachidonic acid (20:4ω-6), an essential hormone (prostaglandins, thromboxane, and leukotriene) precursor.

Table 2 shows the fatty acid compositions of a number of oils that contain GLA.

Table 2 shows that the genetically modified rapeseed oil has the highest content of GLA. Moreover, rapeseed is a fully domesticated crop with a low production cost. It is therefore by far the cheapest source of GLA, but purely emotional fear is likely to prevent it from being utilized, at least in Europe. Soybeans have also been genetically modified to increase their stearidonic acid content and that may suffer a similar fate.

Table 2 Fatty acid compositions of various oils containing GLA

Oil	*16:0*	*18:0*	*18:1*	*18:2*	*γ-18:3*	*18-4*	*Other*

Source: *The lipid handbook*, 3rd ed., Gunstone FD, Harwood JL, Dijkstra AJ (eds) (2007). Boca Raton, CRC Press.

Black currant seed oil (Ribes niger)

Since black currants are used industrially to make fruit juice and jellies and there are no seeds in these products, the processing plant will have the seeds as by-product, making it relatively easy to use them for oil production. Their oil content is only 16% so the oil has to be produced by solvent extraction. The extracted oil is preferably refined.

The oil also contains some stearidonic acid (18:4). This is an ω-3 acid with the systematic name (6*Z*,9*Z*,12*Z*,15*Z*)-octadeca-6,9,12,15-tetraenoic acid. This acid is the first metabolite in the conversion of α-linolenic acid to the longer-chain ω-3 fatty acid eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).

Borage seed oil (Borago officinalis)

Like black currant seed oil, borage seed oil has an appreciable content of GLA (18:3 23%), and the seed also contains more oil than black currant seeds: 26–38% against 16% for black currant seeds. Borage is cultivated on a small scale for its seed and seed oil in Europe. Borage seed oil also contains 38% linoleic acid (18:2), 16% oleic acid (18:1), and palmitic and stearic acids.

Evening primrose oil (Oenothera biennis)

Evening primrose is grown commercially for its seeds in at least 15 countries, and in 1988, the United States and Canada produced 300–400 t of seed. A cultivar was developed in which GLA content has been increased to a range of 10.4 to 12.1% while total oil content increased to a range of 16.4–26.7%.

Echium *seed oil* (Echium plantagineum)

A common name for *Echium plantagineum* is Paterson's curse, since the plant is toxic to nonruminants like horses because of a high concentration of pyrrolizidine alkaloids. Its seeds contain 27% oil. The plant is native to southern Europe, but it has been introduced in Australia, South Africa, and the United States.

Gourmet Oils

In this section, a number of oils will be grouped that are sold at high prices because of their taste or other presumed, often cosmetic benefits. To maintain their taste, they have in all likelihood not been refined, resulting in quite short shelf life. Some of these gourmet oils have a long history like the local pumpkin seed oil in Styria, one of the federal states in southeast Austria, or walnut oil in southwest France; others are just fashionable, often for short times.

The prime example of gourmet oils is olive oil, but this oil will not be discussed here because it has an entry of its own (502). Accordingly, the discussion will be limited to well-established food oils with a history of their own, whereas the mentioning of other gourmet oils will be limited to their fatty acid composition in the table later in the text. In Table 3 whose data have been assembled from various sources, the totals may not add up to 100% as a result of rounding

Table 3 Fatty acid compositions of various gourmet oils

Oil	*16:0*	*18:0*	*18:1*	*18:2*	*18:3*	*Others*

off literature data or because some minor fatty acids have not been included in the table.

*Avocado oil (*Persea americana *and* Persea gratissima*)*

Avocado oil is a fruit oil. The avocado tree is grown in frost-free areas and in particular in the United States (FL and CA), New Zealand, Israel, and South Africa. Most of the oil is in the flesh of the fruit; the seed in the fruit contains only 2% oil. The edible flesh of the fruit represents 50–80% of the fruit weight and its oil content increases with maturity while the fruit remains on the tree. It can reach some 30% late in the season. The oil can be produced by cold pressing but the use of a decanter after the flesh has been homogenized and given some malaxation time is more efficient.

Avocado oil has an IV of 85–90 because it has a high (up to 74%) oleic acid (18:1) content and a low (10–15%) linoleic acid (18:2) content. In fact, its fatty acid composition is quite similar to that of olive oil. Avocado oil is an expensive oil that is used in cosmetics rather than food.

*Grapeseed oil (*Vitis vinifera*)*

The annual world production of grapes is almost 70 million tonnes. Most of these grapes are used for wines, some for jellies and jams, and some are eaten as such. Vintners press the grapes to release the juice and filter off the skins and the pips. Wine filtration depends on the type of wine. For white wine, they filter early, but for red wine, they allow the wine to extract color from the skins so they filter later. This means that the liquid retained in the filter cake contains alcohol so they may distill the filter cake to obtain a liquor (grappa) and thereby char the pips. This is reflected in the quality of the ensuing oil that may be difficult to bleach.

Like jelly manufacturers, wineries collect the pips that can serve as raw material for grapeseed oil. The filter cake must be dried to avoid mold formation. The oil content of the pips is only 6–13% so the oil can only be produced by solvent extraction. Hexane is the most convenient solvent. Grapeseed oil contains waxes so its refining process should comprise a dewaxing step. Well-refined grapeseed oil is almost colorless and has a bland taste. In Belgium, it is sold especially for fondue, which, given its high linoleic acid content, is rather surprising.

*Hempseed oil (*Cannabis sativa*)*

Global hempseed oil production is around 10 000 tonnes *per annum*. Most seed is grown in China and Canada In the US, the cultivation of industrial hemp crops was indiscriminately lumped into the same legal category as drug - *Cannabis* but nowadays, more and more states allow hemp and cannabis to be grown for industrial, medicinal, and recreational purposes. The oil content of the seed is about 35%.

When discussing hempseed oil processing, Callaway and Pate stressed the necessity to maintain an inert atmosphere throughout the processing, and when discussing hempseed oil stability, they ascribed the poor stability of hempseed oil to its high content of polyunsaturated fatty acids. However, when listing typical nutritional values for vitamins and minerals in hempseed, they mentioned an iron content of 14 mg per 100 g or 140 ppm and a copper content of 2 mg per 100 g or 20 ppm. Even if a small fraction of these metals ended up in the oil, for instance, as phosphatidate, that would already explain the poor shelf life of the oil. The statement that 'defatted meal resulting from solvent extraction is not suitable for human food because residual solvents (typically hexanes) contaminate the final product' will most certainly be disputed by those skilled in the art.

Nut oils

Table 3 lists several nut oils: almonds, Brazil nuts, cashew nuts, hazelnuts, macadamia nuts, pine nuts, pecan nuts, pistachios, and walnuts. Nuts have a woody shell that can constitute an important mass fraction in comparison with the kernel inside the nut. Since the residual oil content of a screw press cake is lost when this cake is not extracted with a solvent, it usually pays to shell the nuts before the pressing step and only feed the screw press with the kernels. This is especially true when shelling can be mechanical. If shelling is manual as with walnuts, this is reflected in the price of the oil.

The nuts themselves can be roasted before being extracted or the paste that results from grinding the shelled nuts can be roasted. This makes the taste of the oil more pronounced and characteristic. Nut oil production is usually small scale and limited to hydraulic or screw pressing of the paste. Purification of the resulting cold-pressed oil is limited to a filtration step. Extracting the press cake with a solvent increases the oil yield but the resulting crude oil needs refining.

Pumpkin seed oil (Cucurbita pepo)

This oil originated from southeast Austria and the surrounding regions of Slovenia, Croatia, and Hungary where seed production is about 8000 tonnes. The pumpkins ripen in the autumn, and then, the seeds are harvested manually and dried before being processed. The oil content of the dried seeds ranges from 38% to 49%. It takes 30–40 pumpkins to obtain 1 liter of oil and the pumpkin flesh is discarded.

According to Murkovic, the seeds are processed in small batches of 50–100 kg. They are milled into a paste, and then, a small amount of water is added prior to roasting. During the heating, the water evaporates so that the temperature can rise to about 115 °C, which causes the oil to emerge from the subcellular structures. Many chemical compounds are formed during roasting including the typical aroma that is associated with the nutty flavor. The oil also dissolves the green color that is present in the thin seed coats. The roasted paste is expelled hydraulically and a dark green oil with a nutty flavor results. It can be sent to a settling tank or be filtered to get rid of meal particles. The press cake contains some 14% oil and is used as animal feed.

Major Vegetable Oils without Entry of Their Own

Corn germ oil (Zea mays)

Corn germ oil is a by-product of the corn oil milling process. Most corn that is harvested is used as feed but the proportion of the corn that is milled is increasing because of bioethanol production. During the wet milling process, the germ is isolated from the starch using cyclone separators, washed, and dried. The dried germ contains about 50% oil, in which the oil constitutes about 85% of the total amount of oil present in the corn. The oil is produced by first expelling the germ and then extracting the expeller cake with *n*-hexane. Global annual corn production is 700 million tonnes but corn oil production is only 400 000 tonnes.

Crude corn oil can be dark reddish in color. It is refined either by alkali neutralization followed by bleaching, dewaxing, and deodorization or by degumming the oil to a residual phosphorus content below 5 ppm P, bleaching dewaxing and steam refining. The dewaxing step that comprises cooling the oil to cause the high-melting wax components to crystallize is only necessary when the corn oil is to be sold as salad oil. When the corn oil is to be used as a liquid component in margarine, the dewaxing step can be omitted.

Corn oil contains 13–17% saturated fatty acids and hardly any linolenic acid (18:3). Its main fatty acid is linoleic acid (18:2) at 55–62% followed by oleic acid (18:1) at 22–28%. Its unsaponifiable content is high at 1.3–2.3%, which is in line with its high tocopherol content. This provides the oil with a longer shelf life than would be expected given its high content of polyunsaturated fatty acids.

Cottonseed oil (Gossypium hirsutum)

Cottonseed oil is a by-product of the cotton industry and its production forms the cradle of the modern oil refining processes and many of its analyses. Cottonseed oil is exceptional in that its alkali refining process is carried out on the miscella. The miscella resulting from the solvent extraction is partially evaporated and mixed with the press oil so that a miscella strength of 60–70% results. Caustic of 14–20% strength is used in 10–40% excess and mixed with the miscella at a temperature of 50–55 °C. After a holding time of 10–12 min, the soapy and oily phases are separated. The soapy phase is sent to the meal desolventizer and the oily phase is further evaporated to yield neutral oil. A fully refined oil results after bleaching and deodorization.

Cottonseed oil contains around 55% linoleic acid (18:2), 22–26% palmitic acid (16:0), 19% oleic acid (18:1), and a few minor acids. Because of the rather high palmitic acid content of the oil, it throws a deposit on cooling that consists of dipalmitoyl glycerol and other high-melting triglycerides. Cooling happened in winter in large storage tanks and the cold-stable supernatant had therefore been 'winterized.' Nowadays, the oil is winterized when intended for salad oil by refrigerating the oil and removing the precipitate by filtration.

Rice bran oil (Oryza sativa)

When brown rice is polished to produce white rice, a rice bran fraction results that contains about 15–20% oil that can be obtained by solvent extraction. However, most bran emerging from rice mills is not extracted. It may be used in aquaculture or as fertilizer. Consequently, of the potential 4–7 million tonnes of rice bran oil *per annum*, less than 2 million tonnes is actually produced by bran extraction. Often, the oil is of poor quality and ends up in soap-making plants.

Fresh bran contains a lipase enzyme that causes the oil to hydrolyze very fast. To prevent this hydrolysis, the enzyme must be inactivated by heat or acid. A heat treatment can be applied by passing the bran through an expander, which has the additional advantage that it produces collets that facilitate percolation during the extraction process.

Crude rice bran oil often shows a high wax content of 4% or even more. This is much higher than the wax contents encountered in sunflower seed oil or corn germ oil. Whereas these latter oils are usually dewaxed during a cold neutralization step or dewaxed after the oils have been alkali-refined and bleached, dewaxing tends to be the first step in refining rice bran oil. It can be carried out by storing the oil in settling tanks and allowing it to cool so that a wax deposit is formed and a clear supernatant oil is obtained by decantation. A better way is to dewax the oil at the oil mill while as miscella.

That also holds true for the alkali refining. When this process is carried out on the miscella, very little oil is lost with the soapstock and the neutralized miscella hardly contains any residual soap. This option is, however, not open to stand-alone refineries. They have to neutralize the oil either by mixing an excess caustic into the oil and suffer neutral oil loss or by physical refining, also called steam refining because steam is invariably used as stripping agent during this process.

However, physical refining demands that the oil has a low phosphatide content ($P < 10$ ppm) and that the oils have been bleached. Various degumming processes are available that ensure this low residual phosphorus content.

Rice bran oil contains 22% palmitic acid, 2% stearic acid, almost 40% oleic acid, some 35% linoleic acid, and hardly any linolenic acid. Consequently, and also because of the presence of ferulic acid esters of phytosterols, the so-called oryzanols, which are powerful antioxidants, the oil is very stable. In addition, the oil has been proclaimed to be healthy on the grounds of epidemiological comparisons and that it lowers blood serum cholesterol levels.

*Sesame seed oil (*Sesamum indicum*)*

Sesame seeds are grown in China, India, Myanmar, and Sudan. There is relatively little international trade. The main fatty acids in sesame oil are 9% palmitic acid, 6% stearic acid, 41% oleic acid, and 42% oleic acid, and the oil also contains small amounts of palmitoleic acid (16:1), linolenic acid (18:3), arachidic acid (20:0), gadoleic acid (20:1), behenic acid (22:0), and lignoceric acid (24:0).

Small operators limit their oil production to pressing the seeds that contain 50–60% oil, but larger operators extract the cake and degum, neutralize, bleach, and deodorize the crude oil. The oil is remarkably stable because during bleaching, the sesamolin present in the oil is converted into several phenolic compounds that have antioxidant properties. The hull of the sesame seed also contains antioxidants since the oil that was extracted from whole seeds was found to be more stable than the oil resulting from dehulled seeds.

Sources and Production

Carrots (*Daucus carota* L.), parsnips (*Pastinaca sativa* L.), and beets (*Beta vulgaris* L.) are horticultural crops that are grown on a relatively small scale compared with staple food crops, such as rice, maize, and wheat. Unlike cereal grains and dry legumes, many horticultural crops have a relatively short shelf life, requiring ready access to cold storage, which limits their long-distance distribution, especially in less-developed countries. Nonetheless, because all of these vegetables are root crops, their shelf life is long when kept in cold storage, unlike leafy green vegetables, such as spinach and lettuce, although the leaves of carrots and beets can also be consumed.

Plants contain vascular systems that allow them to move water (xylem) and nutrients (phloem) throughout the plant. Besides orange, carrots are found in other colors. In unusually pigmented carrots and beets, the xylem and phloem are readily identifiable (Figure 1). Carrots and beets with more than one color are sometimes referred to as functional foods or designer vegetables. Purple color in carrots is usually darker in the outer phloem of the root and sometimes only on the root surface.

Carrots are available around the world (Table 1) and do well in cooler climates. The first definite records of carrots being used as a root crop are in Afghanistan and surrounding regions of Central Asia around 1100 years ago, when purple and yellow carrots were described. There are some indications that carrot may have been a root crop in the Roman Empire, but records are ambiguous. The color of carrots is an important part of the history of this crop. Orange carrots were first recorded in Europe in the 1500s and are the predominant color of the crop in all growing regions of the world today. Red carrots are primarily of Asian origin and are still common today. Purple carrots predate orange carrots and were one of the first types to be consumed by humans in Central Asia and the Middle East. Although no longer widely grown, white carrots, which lack pigment, were developed as a fodder crop for feeding livestock in Europe.

Biofortification is the process of breeding crops for enhanced nutritional value. Biofortification of orange carrots has resulted in carrots with high levels of α- and β-carotene (Figure 2) with an emphasis on breeding for deeper uniform orange color. Studies have shown that these carrots provide a little extra vitamin A when fed at similar levels in animals and humans, but substantial extra amounts of α- and β-carotene, which both have antioxidant activity, are made available to tissues. Other color combinations have been bred and include purple-white, purple-yellow, purple-orange, purple-red, purple-orange-red, red-orange, and orange-yellow.

Parsnip is a vegetable plant in the family *Apiaceae*. The plant was domesticated in the Mediterranean and was consumed in Roman times. Some confusion exists in historical accounts of this vegetable due to its similarity with carrot, to which it is related. White carrots exist but are not the same vegetable as parsnips. Parsnip is biennial and produces a rosette of leaves and a swollen taproot during the first season of growth. It is well adapted to cool growing regions and substantial production occurs in Canada.
