At the same time, trends in the last decades towards unhealthier dietary patterns have made public health practitioners and clinicians interested in understanding the main causes of these changes. The epidemic of obesity has been attributed, at least partially, to shifts in population diets. As stated by Geoffrey Rose in his 1985 paper 'Sick individuals and sick populations,' one can differentiate between two types of causes: the causes of cases and the determinants of incidence rates. The first, in this case, would look at why two individuals in the same population have different dietary patterns and try to discover which individual factors are different between them. The second type of cause would look at two different populations with different dietary patterns or at shifts in the same population over time. The determinants of incidence rates are the ones we need to study if we want to understand why dietary patterns have worsened over time and why some populations have higher rates of obesity or diabetes due to unhealthier dietary patterns. In summary, the determination of diet is a social behavior where availability, accessibility, affordability, and acceptability of different foods play a key role.

Mass influences on population diets include all components of the food system: from production and agriculture policies, processing, and transportation to marketing, retailing, and servicing. These mass influences are different across countries/regions and have changed over time within populations. Therefore, if we were able to understand these social determinants of population diets, we might be able to tackle the decreasing healthfulness of population diets and the associated increases in obesity and other metabolic diseases (especially diabetes). Effective policies to combat unhealthy diets go beyond the individual and need to take a population perspective.

One aspect of the food system that is amenable to policies and more proximal interventions is the local food environment. The places where we buy food and eat can exert great influences over individual dietary behaviors. Considering the large differences in local food environments within the same city, region, or country and the shifting patterns over time in food availability, accessibility, or affordability, local food environments represent a good example of a mass influence on population diets.

Definition of the Local Food Environment

The local food environment can be defined as all aspects of the local environment that influence dietary behaviors. According to Glanz et al., it encompasses three domains: the community food environment (food outlets and their accessibility), the organizational food environment (home, school, work, etc.), and the consumer food environment (availability, affordability, and acceptability). A further elaboration of this model includes macrolevel environment influences, such as societal norms and culture, industry, policies, and other systems related to the local food environment (such as the transportation system) (Figure 1).

The community food environment includes physical food outlets. These are both food retailing (food stores) and food service outlets (restaurants). Most research in this area has focused on different geographic measures that characterize the community food environment: count, count per surface (count/sq. mi. or count/sq. km.), count per population, etc. Moreover, the type and accessibility (both geographic, as in distance and availability of a transportation network, and temporal, as in business opening hours) of these outlets can be of interest on their own. Certain types of food stores are assumed to carry healthier foods (like supermarkets in the United States or fruit and vegetable stores in other locations), and some types of restaurants are assumed to be inherently unhealthy (fast-food restaurants).

The organizational food environment serves specific population groups, including workers (at worksites), students (at schools), and individual families (at home). Other parts of this domain also exist, like churches, nursing homes, and hospitals. Of these, the school food environment has probably received the most attention. Several intervention programs have aimed at improving school meals in many countries.

The consumer food environment includes socially determined influences on diet, such as availability, affordability, and acceptability of healthy foods. All these have been shown to exert influence on dietary behaviors and have been target of several interventions over the last decades. Measurement aspects of these three domains of the local food environment will be described in subsequent articles. While this is beyond the scope of this article, it is of great relevance to consider more upstream and downstream determinants of population diet. The effects of government policies (such as the Farm Bill in the United States and the Common Agricultural Policy (CAP) in the European Union or trade agreements such as NAFTA or the European Union in itself) can have enormous impacts on what type of foods is available and at what price. Industrial and agricultural practices are also of utmost importance, and they are interconnected with government policies. Food culture and other social norms that determine what type of foods is acceptable also steer dietary behaviors with great strength. The interplay between industry pressures,

Creating healthy food and eating environments: policy and environmental approaches. *Annual Review of Public Health* 29: 253–272.

government policies, and cultural aspects of food results in the food environments we see today.

Risk regulators of the effects of the food environment are also of great importance. Some of these are determined more upstream from the food environment and have more to do with cultural and societal norms (e.g., gender differences in eating preferences), while others are more proximal, like peer effects that have been shown to be a potent determinant of diet.

In the following headings, we will elaborate on the effects that the food environment has on diet and dietary-related conditions, ways to measure the food environment, and potential interventions upon it.

Food Environment and Eating Patterns

There is a growing interest in understanding the relationship between the local food environment and eating patterns, especially in identifying which aspects of this local food environment are the most determinant. However, this remains challenging due to conceptual and methodological issues (such as defining average dietary patterns or the assessment methods to use) and other complexities (such as dynamism of the food environment or the influence of individuals' characteristics).

Over the last 2 decades, several studies have looked at associations between the food environment and diet, finding associations in both directions, which may arise doubts on the understanding of this relationship. Larson et al. review found a positive association between a better access to a supermarket (or large grocery stores) and a healthier dietary intake. Franco et al. found a positive association between healthy dietary patterns and neighborhood availability of healthy foods. Other studies have found that a greater fast-food access is related to an unhealthier diet. However, most of these studies used cross-sectional study designs.

Three seminal systematic reviews assessed the evidence for the effects of the food environment on dietary intake. These studies showed consistent evidence for existing inequalities in food access in the United States and a greater availability to either healthy or unhealthy food items relating to a healthier or

unhealthier dietary intake. The scientific literature has also highlighted that studies suffer from great methodological limitations, a lack of longitudinal studies, and that there is a need to provide more standardized and validated measures when assessing this relationship between the local food environment and dietary intake.

When assessing diet regarding food environment, research is important to define how to collect dietary information and which appropriate measures are being used. Although there is no standardized measure of the overall diet available yet, some measures, such as the healthy eating index, have been created to describe diet quality. The most common dietary outcome measure is fruit and vegetable intake, due to the vast evidence linking fruit and vegetable consumption with a healthier status. Other dietary outcome measures include fast-food consumption, used to assess the relationship between unhealthy food exposure and a poorer dietary intake. Including multiple dietary outcomes may be the best way to study the food environment–diet relationship.

Influence of the Food Environment on Diet-Related Health Outcomes

Larson et al. and other seminal studies found that low-income, African-American, and rural communities tend to have a poorer food environment than white, urban communities in the United States. The food environment research has aimed then at understanding whether these food environment inequalities may affect health disparities in body weight and other diet-related health outcomes such as diabetes. These studies hypothesized that a higher access to supermarkets should be associated with a lower BMI, while a higher access to convenience stores or fast-food restaurants may be associated to higher BMI and obesity rates.

Different studies have provided mixed results: Supermarkets have been associated mostly with lower BMI indices and lower risk of obesity, and areas with higher density of fast-food restaurants tend to have higher obesity rates. However, most of these studies suffer form design and methodological problems: most were cross-sectional and were difficult to compare due to their variations in the food environment measures and analysis.

Although there are many health outcomes that might be affected by inequalities in the food environment, the most commonly health outcome measured to date is obesity. The evidence in the United States is mixed, which can be explained by the complexity of obesity. Therefore, better study designs and more accurate measures of the food environment are needed.

Measuring the Food Environment

The operational definition and measurement of the local food environment remains a major challenge in food environment research. Three main issues arise regarding the measurement of the local food environment: the conceptualization and definition of relevant features of the local food environment, the spatial scale to be used in the different studies, and the measurement methods to be used.

Following the conceptual model described earlier, adapted from Glanz et al., the three main domains of the food environment to be considered are the community food environment (focusing on food access), the consumer food environment (addressing availably, food quality, and affordability), and the organizational food environment (lunches in workplaces, schools, etc.). Given our focus on the local food environment especially as it relates to food stores or services, and its relation to individual dietary behaviors, we will leave out the organizational food environment. We define the main features of the food environment as food access, food availability, food affordability, and food quality. This terminology can slightly vary within the literature, and previous work has defined dimensions of the food environment research as availability, accessibility, affordability, acceptability, and accommodation. Acceptability refers to people's attitudes, and accommodation would refer to certain food stores' attributes such as opening hours and the type of payment being accepted.

Food availability refers to the actual foods that are available within a food store. Although there is no standardized measure of healthy food availability, the Nutrition Environment Measures Survey has shown great reliability and validity to measure the food availability of different types of healthy food items. However, these in-store audits are rather expensive and resource-consuming. Evidence in the United States has found that high-income neighborhoods do have a greater availability of healthy food choices than low-income areas, and most studies have found disparities in food availability by racial and socioeconomic characteristics. Studies in other countries have shown different results, including inverse gradients (low-income areas with higher healthy food availability) in studies in the United Kingdom. Conclusions about the association between this availability and dietary patterns are challenging due to this large heterogeneity of measurement methods.

Food accessibility measures usually rely on geographic information systems (GIS) and secondary databases, commonly commercial or business datasets (such as InfoUSA or ESRI's Business Analyst). The main limitations are that these data are usually cross-sectional and that there is no standardized categorization to determine the type of food store or restaurant. Food access can be operationalized as proximity to food outlets, density (e.g., count of supermarkets within the geographic boundary), or distance to the closest food store (straight Euclidean distance or network distance that more closely represents real distances for people). Several food store types (such as supermarkets or large grocery stores) have been considered as 'healthy' or 'low-BMI,' whereas others (e.g., convenience stores) have 'unhealthy' or 'high-BMI.' Therefore, food access is commonly considered as a proxy for healthy food availability. However, different studies have shown that the quality and cost of healthy food items do vary by store type, highlighting the needs for direct observations. Moreover, in an international context, the same type of store may carry a widely different balance of healthy and unhealthy stores. For example, studies in Southeast Asia or Central America reveal that supermarkets carry a much unhealthier balance of food compared to autochthonous stores.

An example of the study of food availability can be found in Figure 2. In this case, we have studied healthy food availability by the type of store in two cities in two very different food

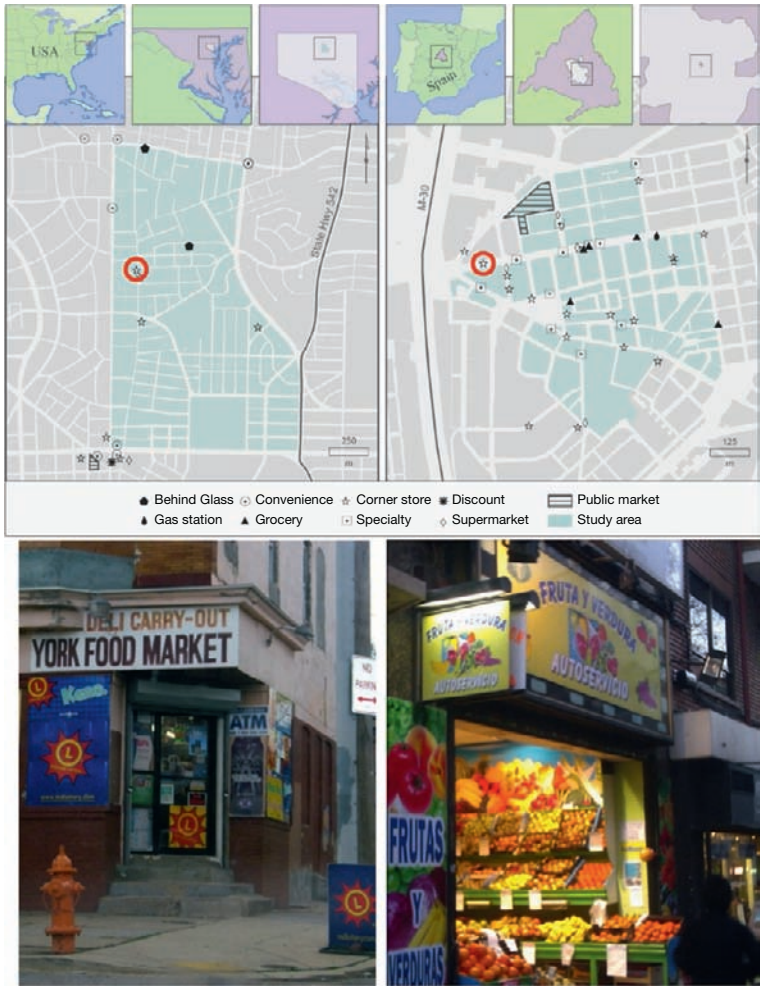

Figure 2 Comparison of two neighborhoods of similar relative socioeconomic status in Baltimore (the United States) and Madrid (Spain). Below, two stores (marked in map) in each neighborhood.

systems (Baltimore, the United States, and Madrid, Spain). As the maps show, the Madrid food environment is richer and has a greater variety of food stores, while several areas of the comparable neighborhood in Baltimore are underserved in terms of food stores. This highlights the intricate interconnections between the food environment and other aspects of the food systems like transportation networks or use of cars, urban form, and urban planning. The bottom part of Figure 2 highlights the two most common types of food stores in Baltimore and Madrid, respectively. The fruit and vegetable store is widely available in Madrid and carries mostly fresh produce, compared with Baltimore's corner stores carrying mostly processed foods.

Food affordability refers to the cost of foods. This can be measured also objectively or subjectively. Some studies use absolute (e.g., food baskets or food price indices of certain food items), whereas others rely on relative measures, such as food cost relative to income and purchasing power. Subjective measures focus on the perceived cost of food items for people. Several studies in the United States suggest that healthy food cost vs. unhealthy food cost varies by geographic areas and that there is no clear pattern regarding whether healthy or unhealthy food options are more expensive. These inconsistent findings may be explained by the large variety of measures being used to assess food affordability.

Food quality measures tend to be more subjective than the other food environment constructs (e.g., degree of bruising on fruits). It is usually measured by rating appearance and freshness of selected food items (commonly fruits and vegetables). Food quality has been found to vary by store type, with convenience or corner stores selling lower-quality foods than grocery stores or supermarkets. High-quality food has also been associated with socioeconomic status. However, this feature remains understudied and might be particularly context-relevant.

Features of the food environment can be measured both objectively and subjectively. Objective assessment methods usually include GIS measures or systematic social observation (e.g., in-store audit tools). Subjective measures, such as perceived food availability and food purchase behaviors, have been also used to deeply understand how residents interact with their local food environment. Additionally, other factors that may influence food-purchasing behaviors (e.g., time, transportation, and food preferences) need to be taken also into account when studying this relationship. A list of these measures is available at the National Institutes of Health National Cancer Institute

website on Measures of the Food Environment: Defining Measures (Instruments and Methodologies).

As a result of this use of different operational definitions and methodologies, comparisons across studies and drawing conclusions about the influence of the food environment on dietary intake or diet-related health outcomes remain a challenge. There is therefore a current need to develop better valid and reliable methods for measuring the local food environment to solve this lack of comparability and inconsistent results.

Interventions in the Local Food Environment

Food environment interventions have become a popular strategy to address the obesity epidemic and other diet-related health outcomes.

Several small-store intervention trials have been conducted in the United States and other countries to improve the food environment and associated dietary behaviors. A recent review by Gittelsohn et al. found that intervention strategies included increasing the availability of healthier foods (particularly produce) and point-of-purchase promotions (shelf labels and posters). Several of the trials reviewed showed significant effects for increased availability of healthy foods, improved sales of healthy foods, and improved consumer knowledge and dietary behaviors. Most effective food environment interventions were those that included actions both at the supply side (increased healthy food options) and at the demand side (included health communication components for both store owners and clients).

Food environment interventions within large grocery stores and supermarkets have been also published. Most interventions included combinations of point-of-purchase promotions and advertising of healthy food choices.

Finally, in order to create long-term, sustainable changes in our local food environments, it is crucial to include several steps in the development of food environment interventions:

1. Development of formative research to gain knowledge on the local food environment and the most appropriate implementation practices.
2. Identification of the local food environment-specific characteristics and selection of intervention domains and components.
3. Interventions should include wholesalers and distributors into multilevel food system change programs.
4. Clear and well-designed evaluation methods should be included in the intervention plans.
5. Engaging policy makers and main stakeholders is key to modify the food environment.
6. Conducting and evaluating pilot interventions.

Conclusions

The determination of diet is a social behavior where availability, accessibility, affordability, and acceptability of different foods play a key role. The places where we buy food and eat can exert great influences over individual dietary behaviors, so that local food environments represent a good example of a mass influence on population diets. Features of the food environment can be measured both objectively and subjectively. There is a current lack of comparability due to a huge heterogeneity in the use of operational definitions and methodologies. More standardized and reliable methods are therefore needed in order to understand the relationship between the food environment and dietary patterns and diet-related health outcomes. Food environment interventions have become a popular strategy to address the obesity epidemic and other diet-related health outcomes.

Food Fortification: Rationale and Methods

MG Venkatesh Mannar and NA Khan, Micronutrient Initiative, Ottawa, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

To grow and flourish, a country requires a strong, healthy, and educated population. A country whose population is undernourished has higher rates of morbidity and mortality, and its human capital is diminished. Globally, undernutrition impedes the development of people and entire nations.

The nutritional status of a population is reflected most dramatically on the height and weight of its children. High rates of stunting (low height for age indicating chronic malnourishment), wasting (low weight for height indicating acute malnourishment), and underweight (low weight for age) among children in the developing world are the typical indicators of undernutrition and the greatest problems to be addressed.

A less visible but equally important measure of nutritional health within a population is the micronutrient status of the people. The consumption of vitamins and minerals is essential for growth, brain development, and immunity against disease. The vitamins and minerals used for fortification typically include vitamins A and D, folic acid and other B-complex vitamins, iodine, iron, and zinc. Among these, five nutrients – vitamin A, iodine, zinc, iron, and folic acid – are critical. When the intake or absorption of essential vitamins and minerals from the diet is inadequate (commonly referred to as 'hidden hunger'), individuals and communities suffer serious consequences, including learning disabilities, impaired work capacity, illness, and death. Although other indicators of global development have shown improvement, progress in reducing micronutrient malnutrition has been slow, leaving over 2 billion people suffering from a range of deficiencies.

Micronutrient deficiencies can be prevented and even eliminated if populations consume adequate quantities of the bioavailable forms of required vitamins and minerals on a continuous and ongoing basis. A number of complementary solutions are available to ensure adequate micronutrient intake. They include vitamin and mineral supplementation, food fortification, promotion of dietary diversification, homestead food production, and public health measures such as immunization and malaria and parasite control.

Food Fortification as Part of a Comprehensive Solution to Micronutrient Malnutrition

According to the *Codex Alimentarius* (a collection of internationally accepted food standards, codes of practice, and guidelines), food fortification or enrichment means the addition of one or more essential nutrients to a food (whether or not it is normally contained in the food) for the purpose of preventing or correcting a demonstrated deficiency of one or more nutrients in the population or specific population groups. Food fortification is also permitted when it is necessary to restore nutrients lost during processing, handling, or storage or to maintain the nutritional equivalence of substitute foods (e.g., nondairy milk beverages). It could be a medium- to long-term solution to alleviate specific nutrient deficiencies. The World Bank has recognized that fortification and other interventions to control micronutrient deficiencies offer the largest opportunity to improve lives and accelerate development at such a low cost and in such a short time.

Food fortification involves the identification of commonly eaten foods that are centrally processed so that fortification could be dovetailed into the food production and distribution systems. This also means that fortification within the existing food patterns does not change the dietary practices of the population and so does not require special individual compliance. Staple foods and condiments are the obvious choice for fortification, given their consistent consumption by large sections of the population.

Food fortification is not a new concept. In the developed countries, food fortification policies have evolved in response to public health needs. The addition of nutrients to staple foods was introduced nearly 70 years ago as a means of dealing with micronutrient deficiencies prevalent in those countries where practices that began as short-term voluntary fortification policies later became mandatory. As a result, several nutritional deficiencies have been eliminated, partly because those nations have been fortifying widely consumed foods such as flour, salt, juices, margarine, milk, and sugar for decades. However, in many developing countries, fortification is much less prevalent because the choice of vehicles is limited.

Efforts are also under way to produce staple crops (such as rice, maize, sweet potato, cassava, common beans, and wheat) that are dense in minerals and vitamins through plant breeding and genetic modification – a process referred to as 'biofortification.'

Fortification Vehicles

Common food vehicles that can be fortified include wheat and wheat products, corn, rice, milk and milk products, cooking oils, salt, sugar, breakfast cereals, and condiments. As processed foods gain popularity and market reach in the developing world, they offer new channels for micronutrient delivery. Potential food vehicles can be sorted in a three-tier pyramid (Figure 1).

Staple foods at the base of the pyramid are cost-effective to fortify on a mass scale. Basic foods such as breads and biscuits, packaged cereals and flours, and dairy products are in the middle. Value-added foods such as condiments, snacks, candies, and convenience and ready-to-eat foods are at the top.

Fortifying less expensive staple foods at the base of the pyramid results in broader dissemination of micronutrients throughout the population – particularly to the poor. Also, fortifying foods at the base of the pyramid increases the likelihood of fortifying products through the other tiers of the pyramid, because staple foods are generally used to produce

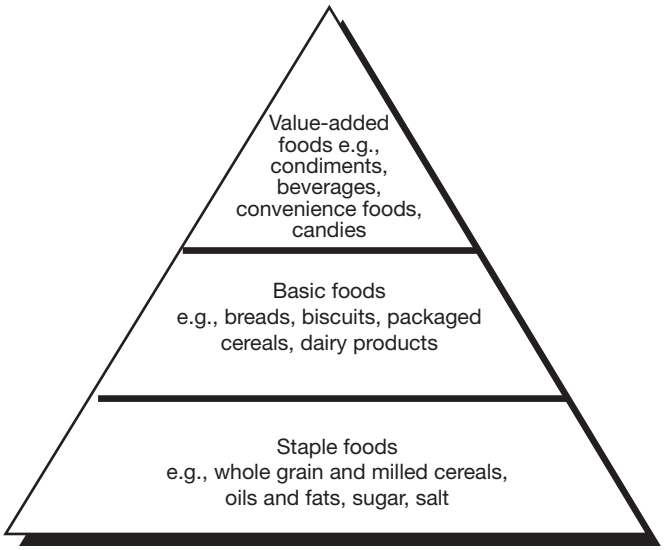

Figure 1 Food product pyramid.

Table 1 Examples of foods for fortification

Food vehicle	*Nutrients*
Salt	Iodine (and iron)
Wheat and maize flours	Iron, folic acid, vitamin A, and B vitamins
Rice	Iron, vitamin A, and B vitamins
Cooking oils and fats	Vitamins A and D
Sugar	Vitamin A
Condiments (sauces)	Iron
Milk	Vitamins A and D, iron
Complementary foods	Multiple vitamins and minerals

basic and value-added foods. Each food vehicle offers specific opportunities and constraints.

Table 1 provides examples of typical food vehicles and nutrients added. A multifaceted approach to fortifying more than one food vehicle is a good strategy, especially when a universally consumed vehicle is not available.

Cereals

Staples such as rice, corn, and wheat that are milled at centralized locations have the potential to reach large populations and are used in several countries as vehicles for multiple nutrients. When staple cereals are milled at the community level, it poses a challenge because of quality and safety constraints. For fortifying whole grain cereals like rice, there is now a technology to produce an extruded rice-shaped premix. Developed countries have long fortified breakfast cereals with a range of vitamins and minerals.

Fats and Oils

Cooking fats and oils offer an option to deliver fat-soluble vitamins such as A and D. While they are often centrally refined and packed, there is still the challenge of a large proportion being sold in loose unbranded form. Packaging in opaque containers is critical to protect vitamins from degradation.

Condiments

Salt, sugar, spices, and sauces are attractive carriers with great potential. They are consumed regularly and some are processed centrally. In Central America and some African countries, sugar has been a successful vehicle for vitamin A. Guatemala's sugar fortification program has virtually eliminated vitamin A deficiency, and big reductions have been seen in El Salvador and Honduras. Recent studies in India show the promise for salt double-fortified with iron and iodine.

Dairy Products

Fortifying milk with vitamins and minerals is an option where milk is processed in dairies.

Value-Added Products

Given global demographic shifts from rural to urban areas, a larger proportion of the population can now be reached via commercially processed foods and value-added products. However, the most vulnerable populations consume these higher-priced products (such as snack foods or beverages) only sporadically.

Type of Fortification Based on Population Reach

There are several types of fortification described in the succeeding text. Their respective suitability is based on the target population and the nature of industry compliance.

Mass Fortification

Foods widely consumed by the general population are fortified, where the population has an unacceptable public health risk of being or becoming deficient in specific micronutrients. Examples include the fortification of cereals, oils, vegetable fats, milk, sugar, and condiments.

Targeted Fortification

Fortification is aimed at specific subgroups of the population, thereby increasing the intake of that particular group, rather than that of the population as a whole. Examples are complementary foods for young children, food rations used in emergency situations, and foods aimed at preschool and school-aged children.

Infants and children under the age of 24 months have a different dietary pattern than adults. While exclusive breastfeeding is universally recommended for children up to the age of 6 months, industrially produced fortified complementary foods are recommended by pediatricians as an essential part of an infant's diet beyond the age of 6 months, complementary to breast milk and homemade foods.

Fortified infant cereals are commonly fed to young children in North America and Europe. Programs that supply fortified complementary foods to infants and young children have also been introduced in several developing countries. Where there are few centrally processed complementary foods, alternative mechanisms include home fortification in which micronutrient mixes in daily dose sachets have been successful.

Market-Driven Fortification

Food manufacturers take a business-oriented approach to fortify some products as value-added products, usually complying with the specifications for permissible nutrients and quantities in order to increase sales and profitability. Typically, such products are purchased by higher-income groups.

Mass and targeted fortification programs would focus on those micronutrients that are in the greatest need by the general population. Cost becomes a factor and it is important to have the collaboration of different stakeholders, particularly those in the government and the milling industries.

On the other hand, market-driven fortification might lean toward those micronutrients that have the greatest recognition and appeal to the intended market – usually the higher socioeconomic group that would purchase the premium products. Cost is generally not an issue in this situation.

Mandatory Versus Voluntary Fortification

Within a country, food fortification can be mandatory or voluntary. Mandatory fortification stipulates that certain foods be fortified with specified nutrients and levels. With voluntary fortification, the addition of micronutrients by food processors is permitted for certain foods following specified standards set by the government. Examples are the fortification of breakfast cereals and addition of calcium to orange juice in industrialized countries and oil fortification or soy/fish sauce in some developing countries. Mass fortification is usually mandatory, though not always. Examples are flour fortification and salt iodization. Targeted fortification can be either mandatory or voluntary, whereas market-driven fortification is voluntary.

Essentials of Food Fortification

The actual mechanics of adding the nutrients to the food are technically simple. The technology of food fortification also considers cost, bioavailability, sensory acceptability, and storage stability. In planning a food fortification program, there are essential technical considerations:

- The food used as a vehicle should be consumed in fairly constant amounts so that fortification levels can be accurately calculated. To do this, it is important to understand the consumption patterns of the food vehicle across the country. If it is for targeted fortification, the consumption pattern of the specific target group is needed.
- The chosen food should be processed centrally in large enough units to permit controlled fortification.
- The addition of the micronutrients should be compatible with the existing food production and distribution systems. There should be minimum loss of the nutrient during processing, storage, and final preparation of the food.
- There should be no change in taste, appearance, or color of the final product.
- The food should be affordable so that low-income groups, who are more vulnerable to malnutrition, consume it.

Depending on the food processing methods, adding micronutrients can be facilitated using different approaches to maximize the nutrient retention:

- Dry mixing – for cereal flours, powdered milk, and powdered beverages. This is one of the common mechanisms used for the addition of the nutrient premix to the food.
- Dissolution in water – for liquid milk, drinks, and fruit juices and for making bread, pasta, and cookies.
- Dissolution in oil – for the lipid-soluble vitamins to enrich oily products like margarine.
- Spraying – as in iodization of salt and in cornflakes where the nutrients do not withstand the cooking or extrusion step.
- Adhesion – as in sugar fortification where the vitamin A in powder form is adhered to the surface of the sugar crystal by vegetable oil.
- Coating – as in rice where the vitamins are sprayed over the grain as a coating.
- Extrusion and dry mixing – simulated rice-shaped premix of micronutrients produced through an extrusion process and dry-mixed with regular rice.
- Encapsulation – as in double fortification of salt where an iron compound is encapsulated to prevent interaction with iodine and the food matrix.
- Micronization – as in salt fortification where the particle size of an iron compound is reduced in order to increase its bioavailability.

Figure 2 depicts a simplified framework of how fortification of cereal flour takes place.

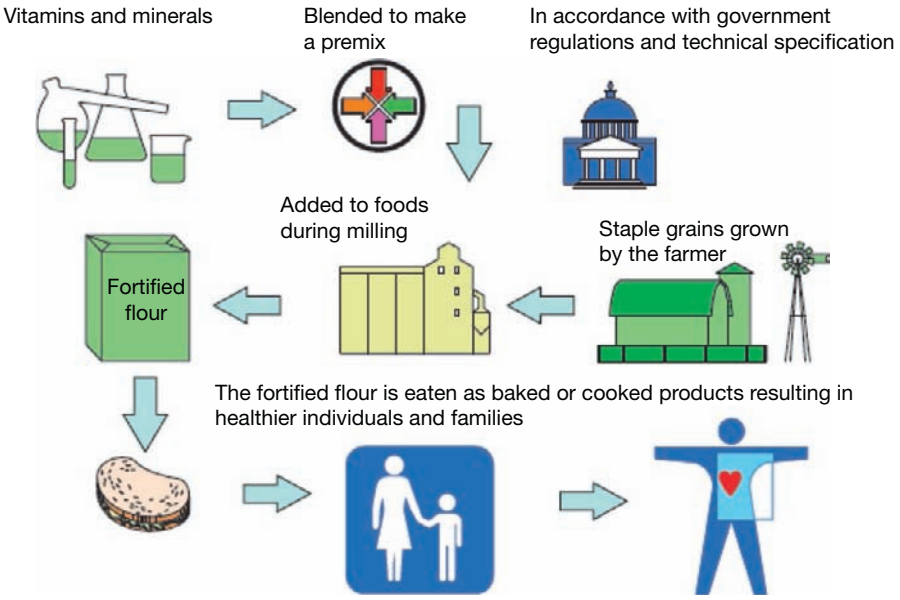

Figure 2 Process for fortifying cereal flour.

Table 2 WHO recommendations for average micronutrient fortification levels

			Fortification level (ppm) according to flour consumption (g day^{-1})			
Micronutrient	*Flour extraction rate*	*Compound*	*<75*	*75–149*	*150–300*	*>300*
Iron	Low	NaFeEDTA	40	40	20	15
		Ferrous sulfate	60	60	30	20
		Ferrous fumarate	60	60	30	20
		Electrolytic iron	NR	NR	60	40
	High	NaFeEDTA	40	40	20	15
Folic acid	Low or high	Folic acid	5.0	2.6	1.3	1.0
Vitamin B12	Low or high	Cyanocobalamin	0.04	0.02	0.01	0.008
Vitamin A	Low or high	Vitamin A palmitate	5.9	3	1.5	1
Zinc	Low	Zinc oxide	95	55	40	30
	High	Zinc oxide	100	100	80	70

Choice of Nutrients' Chemical Form

The chemical form of the nutrients being added (fortificants) influences the bioavailability, chemical stability, appearance, and homogeneity of the fortified food product. The choice depends in part on its solubility in the gastric juice and on its impact on sensory characteristics of the food itself. Table 2 presents the current World Health Organization recommendations for average micronutrient fortification levels based on flour extraction rates, type of fortificant, and estimated average per capita flour consumption.

The iron compounds used for fortification may be classified as follows: soluble in water, slightly soluble in water and highly soluble in dilute acid as in gastric juice, insoluble in water and poorly soluble in dilute acid, and chelated iron compounds. Highly water-soluble compounds like ferrous sulfate have excellent bioavailability and are suitable for a variety of applications but could create problems of unacceptable taste and color in the presence of high moisture and lipid contents. In such situations, less soluble forms of iron are chosen to ensure consumer acceptance. Due to its high bioavailability, use of sodium iron EDTA (chelated iron) is recognized more recently as the fortificant of choice for soy sauce, fish sauce, and whole-wheat/maize flours.

Research and development efforts have enhanced the effectiveness of fortification technology. In the case of vitamin A, work is ongoing to reduce loss of nutrient potency in storage through the addition of antioxidants and other stabilizers. Better refining procedures and packaging have significantly improved the stability of iodine compounds in salt and vitamin A in cooking oils. In the case of iron, stabilizers and absorption enhancers could be added along with the fortificant to retain it in an absorbable form or improve absorption. The structure of the iron compounds can also be modified to improve absorption.

Food Fortification Policy and Implementation

When a country or region is ready to implement food fortification, the process begins by identifying the commonly eaten foods that can act as vehicles for one or more micronutrients.

Food fortification aims to provide meaningful levels of the nutrient (usually 30–50% of the daily adult requirements) at normal consumption of the food vehicle. The levels also need to take into account variations in food consumption so that the safety of those at the higher end of the scale and impact on those at the lower end are ensured. Cost, bioavailability, sensory acceptability, and storage stability are some of the criteria that determine the best match between the nutrient and food vehicle.

The addition of vitamins and minerals to foods is typically regulated under food and drug laws that list nutrients that can be added to foods and specify food vehicles. The maximum and minimum amounts at which the specific nutrients can be added to each food are also specified.

Economics

The benefits of fortification can extend over people's entire life cycle. The economic benefits of food fortification include reduced morbidity, improved work capacity and cognitive ability, and, by preventing malnutrition, ultimately reduced health-care costs. Fortification leads to a healthier population and children will have a stronger ability to enhance academic performance. It can thus be one of the most cost-effective means of overcoming micronutrient malnutrition. The economics of food fortification has played an important role in its implementation in public policy.

The start-up cost for food fortification is relatively inexpensive for the food industry, and recurrent costs are rapidly passed on to the consumer. For example, adding iodine to salt costs between 2 and 7 cents per kg, which is $<5\%$ of the retail process of salt in most countries. The cost of fortifying a kilogram of flour with iron, folic acid, and other B vitamins varies between 0.2 and 0.3 cents. Even though absolute costs are low, the incremental cost could sometimes pose challenges. Premix is the single greatest expense in fortification programs, accounting for 70–90% of recurring fortification costs. In higher-income industrialized countries, such costs are generally absorbed into the consumer price of the fortified food.

However, this is not always the case for lower-income countries. Millers and food processors operate on thin profit margins in risky business environments, and poor consumers are highly price-sensitive and cannot necessarily absorb the additional costs of premix. As a result, in many instances, premix costs can be a serious deterrent to private sector involvement and compliance in fortification programs. Programs would need to maximize the impact of food fortification and make trade-offs as to which micronutrients to include, given the need for the industry to absorb these costs.

Standards, Regulations, and Quality Assurance

For governments to undertake effective food fortification activities, they must first ensure that laws and regulations provide legal authority and an adequate regulatory framework. Effective regulatory controls through established fortification standards protect consumers against the risk of purchasing and consuming nutritionally inadequate, deceptively mislabeled or misbranded, impure or unsafe foods. Regulations also create a level playing field for food manufacturers and sellers.

The quality assurance program includes controls for raw material quality, good manufacturing practices for production and packaging, and quality testing of the final product. Documentation and training are important components. Quality assurance and control systems should also be prioritized, as they provide ongoing assessment that food is being adequately fortified. Furthermore, regular assessment of a program's performance through the collection and dissemination of quality assurance and control data enables program managers to identify specific manufacturers who may require further support.

Partnerships for Sustainable Food Fortification

Through taking part in voluntary and mandatory food fortifications, food companies have played a historic role in protecting the people of the world's rich nations from the devastating effect of vitamin and mineral deficiencies. Effective and sustainable fortification will be possible only if the public sector (with a mandate and responsibility to improve the health of the population), the private sector (with experience and expertise in food production and marketing), and the social sector (with grassroots contact with the consumer) collaborate to develop, produce, and promote fortified foods.

Food fortification is perceived by the public and private sectors from slightly different angles. In the public sector, the addition of essential nutrients to foods is widely accepted because it is considered one of the cost-effective solutions to the challenge of nutritional deficiency among large segments of the population. However, for the private sector, there has to be a business case for food fortification, either because it is required by law or because it can be positioned as a value-added product. While the public sector is set up to work primarily for the public good, the private sector is not established for purposes of benevolence. Though public–private partnerships are conceptually appealing, it is important to recognize and respect the realities of the fundamental difference between the two sectors.

Consumer Awareness

Even when there is little or no cost differential between a fortified food and unfortified food, consumer awareness is an important issue for the acceptance of a newly fortified product. Consumers must be made aware of the benefits of fortified foods through a credible source. Effective communication to consumers is an essential but often overlooked part of effective fortification interventions. By demanding nutrient-fortified foods, consumers empower themselves to achieve their full social, physiological, and economic potential.

Monitoring and Enforcement

As food fortification programs expand around the world, there will be an increasing need to monitor the quality of the fortified food (in terms of its micronutrient content) and evaluate

its contribution to the alleviation of micronutrient deficiencies. Monitoring activities at various levels in the distribution chain – from production or importation to wholesale, retail, and household levels – should ensure that a fortified product contains a sufficient amount of the micronutrient and that it reaches the target population. Availability of data on anemia and nutritional deficiencies to policy makers is critical in advocating for a national fortification project.

As an indicator of effectiveness, a biological impact evaluation will determine whether the micronutrients are being well absorbed and are reducing the prevalence of deficiencies in the population. During evaluations, problems not identified in the initial stages may be identified.

For example, it is well recognized that folic acid fortification has profoundly improved the nutritional status of women of childbearing age and has a substantial effect on the original target by reducing neural tube defects. However, a need for protocols to evaluate large sections of the total population has been identified. The possibility remains that certain segments of the exposed population, such as those at risk of B12 deficiency, may benefit less and may even experience some adverse effects from an increase in folic acid intakes. (To avoid this potential problem and to improve the effect of folic acid fortification, it is recommended that B12 also be added along with folic acid during population-wide fortification.)

Global Experience with Food Fortification

Food fortification has played a major role in the health of the populations in several developed and developing countries over the last 70 years, and many nutritional deficiencies have been eliminated. Multiple studies have demonstrated the effectiveness of food fortification in eliminating micronutrient deficiencies.

The current low levels of iron deficiency in the United States are attributable to fortified sources. Almost one-quarter of iron intake in the US diet comes from fortified sources, especially flour products. In Canada, flour fortification with B vitamins began in Newfoundland in 1944. Within 4 years, deficiencies that were earlier found in nearly 20% of the population had dropped to negligible levels. After 1998, following the introduction of mandatory folic acid fortification of cereal-grain products in the United States, Canada, and Chile, there has been a 30–70% reduction of neural tube defects in newborn.

Over the past 20 years in the developing world, the fortification of a wide range of foods has grown rapidly. Adding iodine at an annual cost of no more than 10 cents per person has been especially successful. Since 2006, a significant population in more than 110 countries has access to iodized salt and nearly two-thirds of the salt consumed in the developing world is being iodized. This is protecting nearly 70 million newborn each year from the threat of mental impairment caused by iodine deficiency, reducing the incidence of goiter and iodine deficiency disorders and contributing to national productivity.

As of October 2013, globally, 78 countries have legislation to mandate the fortification of at least one major cereal grain. Of these, 77 countries fortify wheat flour, 12 countries fortify maize products, and 5 countries fortify rice. All 77 mandatory countries fortify wheat flour with at least iron and folic acid except Australia (which does not include iron) and Venezuela, the United Kingdom, and the Philippines (which do not include folic acid). Approximately 31% of the world's industrially milled wheat flour is fortified with at least iron or folic acid through these mandatory and voluntary efforts (Figure 3).

Building on the success of salt iodization, double fortification of salt with iodine and iron is gaining ground and can be integrated with established iodization processes. Double-fortified salt is currently being produced in India and has the potential to be distributed through commercial channels and

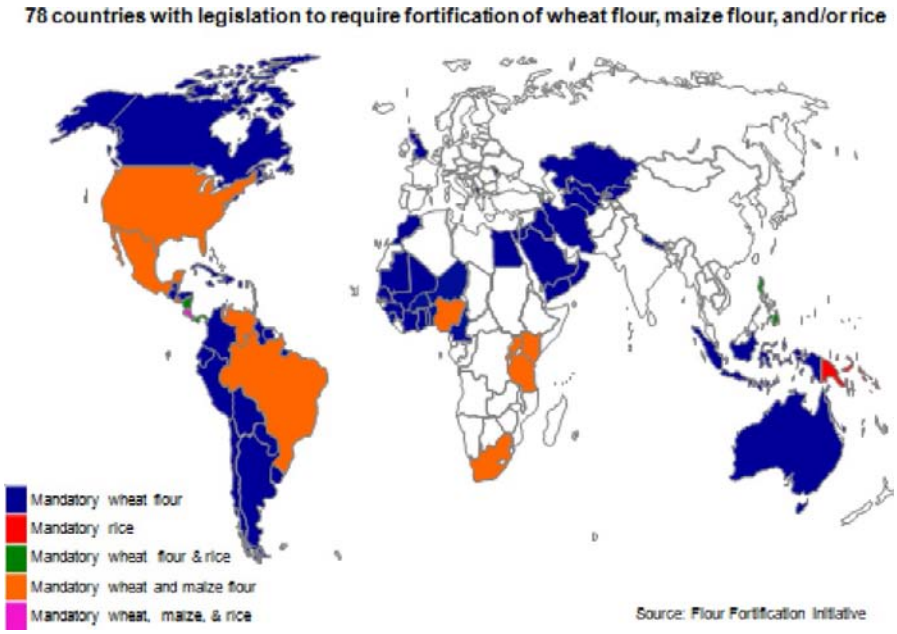

Figure 3 Countries with legislation requiring the fortification of wheat flour, maize flour, and/or rice.

public programs to reach economically weaker sections of the population in many countries.

Case Study: Folic Acid Fortification of Wheat Flour

By the early 1990s, there was convincing evidence that the daily provision of 400 mcg of folic acid to women at least 1 month prior to conception and in the early months of pregnancy helped prevent the birth of children with neural tube defects.

Several international studies called for public health measures to ensure that the diet of all women of childbearing age has an adequate amount of folic acid. The civic and public sectors led by the March of Dimes and US Centers for Disease Control and Prevention advocated for change in the US standard for enriched flour to include folic acid. In March 1966, the United States amended legislation to require folic acid, with full implementation by January 1998. Canada also made it mandatory shortly thereafter.

Following advocacy by several international agencies, including the Micronutrient Initiative, more than 60 countries have mandated the addition of folic acid to flour. Several evaluations in Canada and the United States have shown significant reduction in neural tube defects (NTDs) following flour fortification. The incidence of neural tube defects after fortification has fallen by 30–70% in countries where flour is fortified with folic acid.

Key features of successful fortification programs include the following:

- Strong political commitment and enforcement of regulations
- Early private sector involvement and willingness to comply with regulations
- Public sector backing, with endorsement of medical organizations
- Financial support by donors
- Active consumer education to raise awareness and promote demand

Ultimately, the long-term sustainability of fortification programs is ensured when consumers are willing and able to bear the additional cost of fortified foods.

Issues and Challenges

Notwithstanding the considerable progress in food fortification over the past decade, there are major challenges to ensure that undernourished people, especially in developing countries, receive meaningful amounts of micronutrients through improved access to fortified foods. For example, although significant success has been achieved with salt iodization, in many countries, the groups without access to iodized salt are those most vulnerable and in greatest need for protection against iodine deficiency. While the relatively easier task of getting the large- and medium-scale units to comply has been achieved, compliance by small- and some medium-scale salt producers continues to pose challenges. Thus, the strategies used to achieve 70% coverage of iodized salt globally will not necessarily result in addressing the challenge for the remaining 30% of the population.

The sustainability of fortification programs is complicated by the fact that national programs consist of numerous components, including the preliminary assessment of micronutrient deficiencies, development of fortification standards and legislation, procurement of fortification equipment by food manufacturers, implementation of communication and social marketing activities, execution of quality assurance and control systems, and assessment of health impact. Each component requires input and consensus from the government ministries, standards bureaus, industry partners, civil society, and international agencies that provide funding and technical support.

Within a national fortification project, challenges related to legislation, quality assurance and control systems, social marketing, and monitoring and evaluation can be addressed with modifications to project implementation.

Finally, it is imperative that local ownership and a plan for sustainability be built into each program, so that fortification efforts can be properly implemented and sustained. National mechanisms to reduce the cost of key inputs, such as the premix revolving fund in Uzbekistan, provide an example of how domestic financing can facilitate the adoption of fortification by numerous manufacturers. Funding and technical support from international development and public health agencies can help governments accelerate the expansion of their national fortification programs. Specifically, funding to purchase fortification equipment and to temporarily subsidize micronutrient premix is a key incentive to facilitate the adoption of fortification by food manufacturers.

The time needed for a fortification intervention to become effective in developing countries is likely to be much longer than in developed countries. Such vehicles as salt and flour are often processed in a large number of widely dispersed cottage-scale industries that are not professionally managed.

As food fortification policies evolve, the goal is to achieve a balance between addressing nutrient needs and preventing excessive nutrient intakes. The challenge is that food fortification levels are also influenced by pressures to harmonize national standards with other regulatory jurisdictions.

In addition to these programmatic challenges, there are differences in perceptions about fortification. While it is well established that food fortification has positive impacts on a population's health and well-being – easily outweighing any potential risk – historically, there has been public opposition (in some countries) to the addition of a foreign substance to food or water. It is important to understand different viewpoints but equally important to move forward, in a responsible way, with what is most beneficial to a large number of people whose lives would otherwise be compromised without essential vitamins and minerals in their diet.

The Way Forward for Food Fortification

A well-planned food fortification program can provide meaningful quantities of essential micronutrients to large populations on a permanent, cost-effective, and self-sustaining basis. Food fortification efforts must be integrated within the context of a country's public health and nutrition situation and be a clearly defined component of an overall micronutrient strategy that uses a combination of interventions to address key deficiencies. Fortification levels must meet meaningful proportions of nutrient needs without the risk of excessive intakes. It must be recognized that national fortification projects take time to establish and require ongoing support to respond to specific performance issues and broader shifts in market

structure and consumption patterns. From a management perspective, the long-term success of fortification projects requires that they must actively and continually be improved upon and modified in order to remain effective and relevant.

Food Fraud

MZ Tsimidou, SA Ordoudi, N Nenadis, and I Mourtzinos, Aristotle University of Thessaloniki, Thessaloniki, Greece

© 2016 Elsevier Ltd. All rights reserved.

Definitions

No universal official definition exists for food fraud. In Table 1, the working definitions for food fraud proposed by different bodies and authorities over the last decade are quoted. The definitions for food adulteration or, better, economically motivated adulteration (EMA) are also given in the same table. Under this general term, intentional practices such as dilution, substitution, contamination, artificial enhancement, counterfeit, transshipment or origin masking, mislabeling theft, and resale of products are covered. The frequency of detection of such events varies dramatically among them (Figure 1) indicating that combating fraud needs international collaboration as it is repeatedly stressed in international fora by leading members of the Food Fraud Think Tank.

History and Occurrence

Food fraud has been widely evidenced in the everyday life of human communities over the millennia. Combat of food fraud and related punishments is the result of political decisions that reflect the character of each regime and is documented in written texts and ethical rules for what is fair trade and transaction. Mesopotamian, Hebrew, Egyptian, Greek, and Roman authorities had provisions on good practices, inspectors for the integrity of precious commodities or goods (grains, wine, etc.), and penalties and punishments for those that offended the public interest and often jeopardized the health of citizens. Rigorous were the punishments in the feudal system in medieval Europe according to many treatises on food adulteration. Islamic laws have been very specific for *haraam* transactions, food fraud and adulteration included. Similar was the case in the vast Chinese sovereignty over the centuries. The move from agricultural to industrial economies in Europe and the United States (eighteenth and nineteenth centuries) resulted in urbanization and the disengagement of people from food production for family needs. Adulteration of basic goods (bread, fats, wine, and honey) or precious goods (spices) for profit was, thus, steadily increased and supported by the advance in scientific knowledge on the composition of foods and properties of various chemicals. Indeed, food sophistication and its detection prevailed in parallel in those centuries. Thomas Wakley, Arthur Hill Hassall, and Harvey Washington Wiley are the personalities that played a crucial role in the endorsement of food regulations in Britain and the United States in the late nineteenth and early twentieth centuries. They fought against food adulteration using scientific means, by raising the public indignation against it, and succeeded in passing laws that considered the fraudulent food sales as criminal offense. The two great wars, the intermediate period of economic crisis and the subsequent division of countries into blocks of different ideologies and interests, delayed the harmonization of food law on a global scale. It was only after 1980 that the discussions for international standards were accelerated with emphasis to food safety and hygiene rules. Endorsement of new standards for food composition and food additives became a lesser priority as novel issues such as the advance of new technologies for food preservation (e.g., irradiation), food production through genetic modifications of organisms and biotechnology, cloning, and, more recently, food applications of nanotechnology captured the concern of both the society and authorities on health implications for generations to come. Currently, incidents in the global market are of growing concern as it is recognized that there is an inherent weakness within the food chain that allows the involvement of criminal organizations in food fraud, whereas the capacity of authorities is limited and action is rather taken *a posteriori* than *a priori*. Austerity programs even in developed countries, overpopulation, and continuous immigration of a large number of people form the background scenery. The two most recent events, the melamine and the horse meat scandals in China and the European Union, respectively, revealed the vulnerability of the food sector to fraud and the need to undertake strict measures. The Poison Squad initiative (1902) inspired the flying squad of the Danish Food Administration practice a century after (2006) to contest effectively illegal practices. The scientific community together with the international authorities takes advantage of informatics to organize databases with evidence for fraud practices and methods of analyses and prioritize foods for which more attention should be paid. Records in these databases may differ significantly depending on their source (e.g., scholar or mass media ones). Scholar references include mainly in-house adulteration experiments, carried out by the scientists to develop tools for food authentication. Real cases of adulterated products analyzed after the event is spotted by the authorities are also presented. The mass media records mostly cover what comes to their attention from the local or international authorities and are often misinterpretations of scientific information. All in all, latest tables based on these databases indicate that the most at risk of fraud products are olive oil, fish, organic foods, milk and dairy products, grains, honey and maple syrup, coffee, tea, spices (saffron, chili powder, and black pepper), wine, and certain fruit juices. Figure 2 illustrates events recorded in the United States and the rest of the world. Most of these categories of food products can be found in the early reports by F. Accum and A.H. Hassall, though the adulterants differ considerably.

Cases of EMA: Health Implications in the Twenty-First Century

Some cases with serious economic and health implications are briefly discussed in the succeeding text in alphabetical order. The means of detection are also stressed. The information is

Table 1 Definitions/content of 'food fraud' and related issues

Term	*Definition*	*Source*
Adulterated food	A legal term meaning that a food product fails to meet federal or state standards. Adulteration usually refers to noncompliance with health or safety standards. The act does not define or use the term 'economic adulteration' or 'economically motivated adulteration'	1
Economically motivated adulteration (EMA)	The fraudulent, intentional substitution or addition of a substance in a product for the purpose of increasing the apparent value of the product or reducing the cost of its production for economic gain	2
Intentional adulteration	May take several forms, including (1) acts of terrorism; (2) acts of disgruntled employees, consumers, or competitors; and (3) economically motivated adulteration not addressed by traditional Hazard Analysis and Critical Controls Point (HACCP) or other food safety systems, and likely will require different kinds of controls. The Food and Drug Administration (FDA) is taking the action described in this proposed rule to implement the intentional adulteration provisions in Sections 103, 105, and 106 of FSMA	3
Food fraud	A collective term used to encompass the deliberate and intentional substitution, addition, tampering, or misrepresentation of food, food ingredients, or food packaging, or false or misleading statements made about a product, for economic gain. Food fraud is a broader term than either the EMA defined by the FDA or the more specific general concept of food counterfeiting. Food fraud may not include 'adulteration' or 'misbranding,' as defined in the Food, Drug, and Cosmetic Act (FD&C Act), when it involves acts such as tax avoidance and smuggling	4
EMA	The fraudulent addition of nonauthentic substances or removal or replacement of authentic substances without the purchaser's knowledge for economic gain to the seller	5
Food fraud	Unlike the United States, the EU has no generally acknowledged definition of food fraud, the current EU legislative framework being largely focused on food safety. The only general guideline can be found in Regulation 178/2002 on the general principles and requirements of food law, which states that the labeling, advertising, presentation, and packaging 'shall not mislead consumers,' although in practical terms, the application of this provision varies largely among member states, and the number of controls in this area is extremely limited. As a result, food fraud remains largely undetected, especially when there are no public health or food safety implications. It is therefore difficult to determine the current scope of food fraud in the EU, although most parties contributing to this report indicate that it seems to be on the rise	6
Food fraud	Food fraud is committed when food is deliberately placed on the market, for financial gain, with the intention of deceiving the consumer. Although there are many kinds of food fraud, the two main types are the following: ● The sale of food that is unfit and potentially harmful, such as – recycling of animal by-products back into the food chain, – packing and selling of beef and poultry with an unknown origin, – knowingly selling goods that are past their 'use by' date. ● The deliberate misdescription of food, such as – products substituted with a cheaper alternative, for example, farmed salmon sold as wild and basmati rice adulterated with cheaper varieties, – making false statements about the source of ingredients, that is, their geographic, plant, or animal origin. Food fraud may also involve the sale of meat from animals that have been stolen and/or illegally slaughtered and wild game animals like deer that may have been poached	7
Food fraud	The deliberate placing on the market, for financial gain, foods that are falsely described or otherwise intended to deceive the consumer	8

mainly obtained from food defense publications, project reports, presentations, and media reports available in databases that are web-accessible. The financial crisis, rising of food prices and consequent demand for cheap products, lack of focus of authorities to detect fraud, and lack of heavy penalties to fraudsters are the driving forces behind all of them.

Alcoholic Beverages

Methanol is the usual alcohol volume-increasing adulterant in such type of beverages. Between 2008 and 2011, bootleg liquor consumption in India led to hundreds of deaths. Cheap cough medicines, methanol, or even ammonium nitrate, high doses of which are quite toxic for humans, were among the commonest adulterants reported. In 2011, the UK Revenue and Customs officials seized 12 000 l of adulterated vodka that contained methanol. In 2012, 24 people died in the Czech Republic and Poland after consumption of liquor adulterated with methanol. The perpetrators and source of the adulteration are still unknown. Other incidents involve the addition of chemical substances with similar to alcohol symptoms. For instance, since 2012, adulteration of brand name alcohols with pills containing antiretroviral drugs (ARVs) and formaldehyde is under investigation in Kenya. ARVs are freely available and used to treat people infected with Human Immunodeficiency Virus (HIV), causing symptoms like those of a hangover. The material is cheap (about $26/60 pills) and used to produce alcohol, which is then sold for about $100. The alcohol is put in bottles bearing stolen labels.

Dairy Products

Besides the easily detected dilution of milk with water, the major adulterant type of the last decade became the addition of exogenous nitrogen source to cause a false-positive increase in the total protein content, which is usually extrapolated from its content using the Kjeldahl or Dumas methods. In 2005, a food poisoning scandal was revealed when dairy products from a Chinese company were found to contain hydrolyzed protein, which is produced during the leather softening process. Hydroxyproline, a hydrolysis product of animal collagen, was the key marker for the detection of this type of fraud. Two years later, the well-known melamine scandal emerged. Melamine cannot be metabolized in mammalian bodies and has resulted in sickness and deaths of human infants and animals in the last years. For instance, in 2007, more than 300 000 Chinese babies were hospitalized, and six died due to acute kidney injury, nephrolithiasis, and urolithiasis. All of them were found with distal tubular necrosis and intratubular crystals of melamine; some of them also suffered from chronic tubulointerstitial nephritis. All these symptoms were associated with the accumulation of melamine–uric acid or melamine–cyanuric acid crystals in the kidneys. During 2003–04, the fraudulent addition of sugar and starch in powdered milk, intended for use in infant formulas, caused the death of at least 13 infants in China. The formula was sold under multiple brand names so it was difficult to identify the counterfeit. Despite the detection of this type of adulteration, withdrawal of fraudulent products from consumption was difficult for a long time. In India, at least 2 tons of milk and 30 tons of dairy sweets containing urea, starch, formaldehyde, or hydrogen peroxide were destroyed by local authorities in 2011. Urea had been added to skimmed or expired milk powder to increase the total soluble solid value. Consumption of milk containing more than $\sim$70 mg dl^{-1} of urea can cause severe health problems for human beings. Other rich in protein foods and feeds have been found adulterated with illicit sources of nitrogen.

Fish and Seafood Products

Fish traded in fillets (salmon, trout, plaice, and lemon sole) or as fish fingers (crab) and caviar are the major target for EMA. Surimi, due to overexploitation of sources, is no longer a cheap substitute for crab sticks. DNA analysis seems to be the answer to speciation problems related to fish trade. Toxic chemicals

such as malachite green, chloramphenicol, and formaldehyde that had been used as a means to extend the shelf life of the fish products and claim 'freshness.' In all cases, the products were distributed in certain Asian countries (China and India). One case of intentional contamination has been reported in 2002 and involved the illegal exports of Baltic salmon with high level of dioxins from Sweden to other EU countries where it was sold in restaurants and grocery stores. Dioxins accumulate in the fatty tissues of the salmon, affecting the human reproductive system and causing cancer.

Fruit Juices and Concentrates

Citrus juices are frequently adulterated or misbranded. The price of grapefruit juice is always lower than that of orange juice, so their admixture can be expected. Misbranding of fruit juices made from imported concentrates remains as common practice over the decades. Widespread adulteration of drinks for athletes, juices, tea drinks, fruit jams, jellies, and syrups with phthalates such as diethylhexyl phthalate was discovered in 2011 by US federal agencies. The products had been exported from 34 Taiwanese companies to at least 22 countries abroad. Seven food companies in Taiwan were found to be involved in the scandal. Phthalates, added as clouding agents, had not been readily tested for, and the reaction to this adulteration was slow in the United States. Pomegranate juice, being a highly priced product that is frequently marketed for health-promoting action, is vulnerable to adulteration. In 2006, the product of a known company labeled as '100% pure pomegranate juice' with 'no added sugar or sweeteners' was found to contain high-fructose corn syrup and only trace amounts of pure pomegranate juice. It is still unclear whether the adulteration occurred at the source in the Middle East or by the manufacturer. A competing juice manufacturer uncovered the adulteration and brought legal action against the perpetrating company.

Grains, Cereals, and Products

The major cases of adulteration reported during the last decade involve the mislabeling of nonorganic grains as organic, addition of dyes and flavor enhancers in noodles or corn bun dumplings, and substitution of basmati rice by cheaper sources. In 2013, 100 000 tons of nonorganic grains being sold across Europe as organic was discovered in Italy. Fake companies and counterfeit certifications were used in transactions, and 16 people were arrested by the Italian police for the $72 million fraud.

Honey and Other Natural Sweeteners

Important types of adulteration of honey have to do with the mislabeling of the type and origin of the product, illegal feeding of bees with sugar, and thermal treatment that increases the content of hydroxymethylfurfural. Transshipment and origin mislabeling are top-rated issues within this category of products. From 2008 to 2012, Chinese honey declared as originating from other countries (such as Indonesia, Malaysia, Mongolia, Thailand, and Vietnam), or as sugar syrups other than honey, in order to avoid antidumping duties was imported to United States. The incident may have been uncovered as part of increased investigations into the evasion of antidumping duties in the honey trade by US Customs and Border Protection. Chinese honey has been found contaminated with chloramphenicol, an antibiotic that can cause a rare but serious condition called aplastic anemia in humans.

Meat and Products

Major counterfeit problems of the last decade involve the addition of antibiotics to organic meat and of banned synthetic dyes to pork to imitate beef's color. Injection of chicken with hydrolyzed porcine and bovine proteins that act as bulking agents of breasts is another common issue. In 2012, the Irish Food Safety Authority identified horse DNA in food products that were labeled as containing ground beef. The incident affected 13 European countries and various products, including beef burgers and frozen meals. Long supply chains and a wrong interpretation of the regulation about the supply of raw ingredients for ground beef may have contributed. The European Commission reacted by changing the classification of desinewed meat so that it could be no longer called 'meat,' but mechanically recovered meat. The discovery of undeclared horse meat led to concerns that phenylbutazone, a veterinary drug used as a painkiller, may have entered the human food chain. A joint risk assessment prepared by the European Food Safety Authority and the European Medicines Agency concluded that the illegal presence of residues of phenylbutazone in horse meat is of low concern for consumers due to the low likelihood of exposure and the overall low likelihood of toxic effects. Still, the prohibition of the use of phenylbutazone remained active. The two authorities pointed out the need of strengthening the traceability of horse meat in the food chain across the European Union including a horse passport system.

Olive Oil

Olive oil, a food staple in the warmer regions around the Mediterranean, has gained popularity among consumers from nonproducing countries all over the world. Moreover, expansion of olive tree cultivations to the southern hemisphere, the United States, Turkey, Iran, and China opened discussion on revision and updating of international standards for compositional data such as upper limits for linolenic acid content, trilinolenin, and other ECN 42 triacylglycerol concentrations and that of certain phytosterols to avoid adulteration with cheaper oils. Olive oil is often adulterated with seed oils and olive residue oil. Esterified oil, which is prepared by reesterifying low-grade olive oil or olive oil soap stock recovered from alkali refining, has also been used to adulterate olive oil products. More recent are the reports on fraud with desterolized or deodorized olive oil under mild conditions. Oils having a similar composition (hazelnut oil and high-oleic sunflower oil) or lower price (palm, avocado, and canola oils) have been used as common olive oil adulterants. The most recently reported cases of olive oil frauds are those where sunflower oil, artificially dyed with beta-carotene or copper complexes of chlorophyll (e.g., E141) to match the color of olive oil, was used as a substitute or diluent of the product. US federal, European, and Australian legislation were recently updated to strengthen official control. Extra virgin

olive oil, the most expensive commercial category, is also often misbranded as was experienced in the Chinese market for a lower-quality product labeled as a high-quality one from a Mediterranean country. 'Cold pressed' and protected designation of origin (PDO) labeling need specific certification to be trusted.

Spices and Extracts

Black pepper, cumin seeds, paprika, turmeric, curry, chili, and saffron are highly susceptible to fraud. According to official reports, saffron, the dried stigmas of *Crocus sativus* flowers, has been extensively adulterated during the last decade with other parts of the *C. sativus* flower, dyes, and other plant materials. Substitution by almost 90% per weight was discovered in commercial brands of high-quality saffron. A systematic problem with transshipment and mislabeling of Spanish saffron has been also reported during the last decade. Officials reported that only 1% of Spanish saffron on the marketplace is actually derived from Spain. Imports from countries such as Iran were used to either extend or replace Spanish saffron, which was sold for about double the price. Importers also falsified the Spanish label of authenticity. This appears to be a systemic problem. Spices diluted with lead chromate and lead tetroxide and substitution of Chinese star anise with toxic Japanese star anise are some of the most hazardous cases of spice fraud. In the last 15 years, the fraudulent addition of the synthetic Sudan dyes (I, II, III, and IV) has been reported as a means to artificially enhance the color of red- or orange-colored chili and curry powders imported mainly from India. Sudan (I), alone or in mixtures with other Sudan dyes, is used due to low cost and high stability. Sudan dyes are metabolized by the microflora of the human skin and those in the gastrointestinal tract to carcinogenic colorless amines. Since each type of the dye is degraded to different hazardous metabolites in the human body, the toxicity of which may be enhanced by their simultaneous presence in foods, it is of utmost importance to develop highly efficient analytic tools. Sudan dyes were found in a series of products (sauces) from different manufacturers in Great Britain.

Detection

Analytic techniques that provide physical, chemical, or biochemical information for foods are the front line to detect fraudulent practices and concomitantly dissuade their incidence. From the ones available, liquid and gas chromatographies (GC) and infrared spectroscopy (IR) seem to be the workhorses of official control laboratories. Mass spectrometry used alone or hyphenated to chromatography follows in popularity. Despite the high capital cost, its applicability in the near future is expected to increase in the food authentication sector due to its high efficiency. Electrophoretic and immunochemical techniques present more targeted applications. The potential of Raman and nuclear magnetic resonance (NMR) spectroscopies seems very promising. Most of the mentioned techniques offer multiple pieces of information in one experiment obtaining, thus, the fingerprint of a series of constituents. Unscrambling of the hidden information is then achieved through chemometrics; results are stored to form analytic databases. Last but not least, the advance of molecular markers for the certification of product provenance is a powerful tool to combat EMA.

Chromatographic Techniques

Chromatographic techniques provide speciation and sensitivity owing to the resolution of complex mixtures into their constituents. Data acquired with a detector (UV, mass spectroscopy (MS), etc.) are used for targeted or nontargeted analysis. In the latter case, the concentration of various constituents, peak areas/heights, or even the chromatogram as a continuous signal (after peak alignment with suitable algorithms) can be examined with chemometrics to detect adulteration.

High-performance liquid chromatography (HPLC) procedures for many classes of compounds or individual food components are available to check food adulteration. Oligosaccharide determination was shown to detect the addition of soy milk to cow's milk ($\geq 5\%$), corn syrups ($\geq 5\%$), and industrial syrups either directly added or via bee feeding ($\geq 10\%$) to honey. Using the ISO 11292 method for the determination of free and total carbohydrates in coffee (≥ 10 pmol) and detection of adulteration with wheat, soybean, their mixtures, or husks was proved to be feasible after chemometrics. Triacylglycerol analysis may serve detection of lower-quality seed oil addition (1–3%) to virgin olive oil and sesame oil, as well as of pork ($\geq 2\%$) in beef. A caseinomacropeptide was proposed as an index of cheese whey addition to milk (detection limit $= 1\ \mu g\ ml^{-1}$), whereas 29 amino acids assisted the detection of orange juice adulteration. Determination of tryptophan (limit of detection $= 1\ mg\ l^{-1}$) could serve as an index of soy sauce adulteration with acid-hydrolyzable vegetable protein. Phenolic compounds, namely, neoeriocitrin and naringin, are proposed markers of bergamot juice addition to lemon juice ($\geq 1\%$), whereas arbutin for pear juice addition to apple juice ($\geq 2\%$). The simultaneous detection of melamine ($5\ \mu g\ g^{-1}$) and the related triazine by-products ammeline ($5\ \mu g\ g^{-1}$), ammelide ($5\ \mu g\ g^{-1}$), and cyanuric acid ($90\ \mu g\ g^{-1}$) in wheat flour is of high importance for public health. HPLC coupled to GC was used to determine the addition of virgin (5%) and refined (10%) hazelnut oil in olive oil via filbertone detection. The coupling to IRMS (isotope-ratio mass spectrometry) improved the detection of honey adulteration with C4 and C3 sugars via determination of $\delta^{13}C$ values of the separated sugars. The recent development of ultrahigh pressure-operating (up to 15 000 psi) HPLC systems that enables analysis with sub-2 micron columns providing richer profiles in significantly shorter time is useful for fingerprinting as shown for pineapple, orange, and grapefruit juices and their admixtures detected with chemometrics down to 1%.

GC was the first strong tool for the detection of adulteration of oils and fats through fatty acid methyl ester (FAME), triacylglycerol, or sterol analysis. For example, the peak areas of FAMEs and squalene obtained with GC-MS were valuable for the accurate detection of extra virgin olive oil adulteration with sunflower, corn, peanut, and coconut oils with chemometrics and multivariate calibration model construction for the precise determination of the levels of adulterants. With a similar approach, the addition of lard or beef tallow ($\geq 5\%$) to

canola oil was possible. Currently, sophistication is also examined through the exploitation of volatiles fingerprint. Thus, the GC-MS determination of 9(E),11(E)-18:2 FAME traces was proposed for lower-quality deodorized olive oil addition to virgin olive oil and that of a lupane skeleton and lupeol for hazelnut oil presence (<4%). Inulotriose detection in honey indicated adulteration with high-fructose syrups of inulin, whereas that of difructose anhydrides the presence of high-fructose corn syrup and inverted syrup (≥5%). Solid-phase microextraction/GC-MS and chemometric treatment of the data estimated accurately 25% addition of apple puree to strawberry puree or detection of roasted coffee adulteration with roasted barley (≥1%).

Spectroscopic Techniques

IR is popular since analyses require no or minimal sample preparation, instruments are simple in operation, and the incorporation of Fourier transform facilitates the rapid and simultaneous measurement of various constituents in liquid and solid samples. Near-IR (NIR) (14 000–4000 cm^{-1}) penetrates more into the sample and can be used to examine samples in NIR transparent packing, water absorbance is not strong as in mid-IR (MIR) (4000–400 cm^{-1}), and portable equipment is available for on-site examination. The lower sensitivity to some minor constituents and the fact that due to the complex spectra multivariate regression is necessary for quantification are limitations. Nonetheless, to use the whole spectra (fingerprint), both preprocessing and chemometrics are necessary with NIR or MIR. Much research has been carried out in detecting adulteration of edible oils such as virgin olive oil (with high oleic or linoleic sunflower, pomace olive, canola, or hazelnut oils at level ≥10%), honey (with >7% beet invert sugar or >10% high-fructose corn syrup), milk (with ≥1 g l^{-1} urea and ≥5% starch, dextrin, urea, melamine, and ammonium nitrate), fruit juices (beet and cane invert sugars in apple juice with an error of prediction of 1.3% and 1.8%, respectively), and meat. Addressing a 'hot' issue, MIR could detect and quantify horse meat in minced lean beef at levels ≥2%.

MS can record the volatile profile from the headspace of a sample through proton transfer reaction (PTR-MS); multiple elements via ionization with inductively coupled plasma (ICP-MS); various nonvolatile constituents by direct infusion and electrospray ionization, by matrix-assisted laser desorption ionization (MALDI), or very recently via direct analysis in real time (DART) techniques; and isotope ratios (IRMS) after sample gasification. So far, the latter four have been applied to detect adulteration. MALDI is coupled to time-of-flight mass analyzer (TOF-MS) to determine macromolecules. Powdered milk addition to fresh cow milk (≥1%) via detection of diagnostic peptides related to thermal changes induced to milk proteins upon powder production and cow milk addition (≥5%) in sheep or goat milk using phospholipid markers and hazelnut oil (≥5%) to virgin olive oil by analysis of extracted polar components are few applications. DART/TOF-MS detected addition of pork to minced beef and vice versa at 10% via the triacylglycerol profile of isolated fat and hazelnut oil to extra virgin olive oil at 6% and 15% via the examination of the triacylglycerol and polar compound profiles, respectively. The $^{13}C/^{12}C$ ratio assisted the detection of low-cost sugar cane and high-fructose corn syrup addition in valuable natural products such as honey, royal jelly, mulberry pekmez, and most juices (except for pineapple). The $^{14}N/^{15}N$ ratio supplied additional information on the possible addition of yeast powder as a source of protein in royal jelly. Conversion of ethanol into the more stable ethylene and determination of nonexchangeable hydrogen ($^{2}H/^{1}H$) stable isotope ratio indicated ethanol addition in wine from other sources. The combination of $^{2}H/^{1}H$ and $^{18}O/^{16}O$ ratios diagnosed water addition to fruit juices and wines since plant water versus ground/rainwater is richer in ^{18}O and ^{2}H due to losses in ^{16}O and ^{1}H isotopes upon leaf evapotranspiration. IRMS can be coupled to an elemental analyzer or a chromatograph to increase the wealth of information.

Raman spectroscopy presents similarities to IR considering sample preparation. Analysis of samples already packed in plastic/glass packaging is possible, water interference is minimal, and portable equipment is available. Raman has been used to detect addition of soybean, rapeseed, sunflower, and corn oils (≥5%) in olive oil, high-fructose corn syrup and maltose syrup (10–40%) in honey (individually or as a mixture), and margarine (≥10%) in butter. Worthwhile is the detection of the toxic paraffin added in rice (>0.003), of melamine in milk (≥0.04%), and of banned horse meat at 25% in beef with the aid of chemometrics.

NMR spectroscopy provides simultaneous quantitative determination of compounds without prior separation (targeted analysis) or a fingerprint (nontargeted analysis) to be treated with chemometrics. Nontargeted ^{1}H and ^{13}C spectra examination detected hazelnut oil addition (≥8%) to olive oil. Targeted analysis with more elaborate sample preparation and chemometrics permitted admixing detection of olive–hazelnut, olive–corn, olive–sunflower, and olive–soybean oils (≥5%). Synthetic triacylglycerol detection in butter (≥1%) was obtained from the ^{13}C NMR spectra determination of the regioisomeric distribution of C4 between the sn-1,3 and sn-2 positions. Low-field NMR (60 MHz) was recently shown to detect sunflower or red palm oil and hazelnut oil addition in extra virgin olive oil down to 10% and 11%, respectively, and high-fructose corn syrup to blossom honey (≥10%) exploiting the ^{1}H spectra. NMR data fused with that of UV-vis have been used for Sudan III and IV detection in culinary spices. Site-specific natural isotope fractionation (SNIF)-NMR technique determining the relative deuterium and specific deuterium site locations in molecules easily detected sugar beet addition to orange juice, vanillin adulteration with a synthetic one from guaiacol or lignin or biotechnologically derived, and addition of molasses spirit to rice spirits (≥8%). SNIF-NMR is used officially (EC 2676/1990) to detect wine chaptalization.

Electrophoresis and Related Techniques

Protein electrophoresis to detect cow milk in goat milk (≥1%), bovine milk in caprine or ovine samples (≥5%), and soy milk in cow milk (≥5%) has been reported. Sodium dodecyl sulfate - Polyacrylamide gel electrophoresis (SDS-PAGE) detection of a glycomacropeptide was proposed as an index of whey addition to milk (≥1%). Electrophoretic patterns of the fish muscle myogens can be useful to detect surimi adulteration since they are characteristic of the species and remain unaltered during

processing/preservation. The sarcoplasmic protein electrophoresis is suitable for raw fish species identification, thus detecting substitution of species with less valuable ones when fishes are devoid of their external characteristics. However, in the case of heat-processed fish, this is feasible only for those species containing heat-stable parvalbumins.

Capillary electrophoresis (CE) progressively is gaining popularity due to high resolution, simplicity, versatility, and low operating costs despite its low reproducibility and sensitivity. The ratio of the sum of nonbovine β-lactoglobulins (ovine or caprine) to the total β-lactoglobulins obtained with CE-MS was useful to detect bovine milk addition in caprine or ovine milk ($\geq$5%). The CE-UV profiles of methanol-soluble paprika proteins facilitated detection of paprika addition ($\geq$5%) in high-quality smoked paprika 'pimentón de la Vera.' Nonprotein amino acid analysis with CE-MS made feasible the adulteration detection of virgin olive oil with soy oil ($\geq$2%). CE-MS detection of carnitines not present in virgin olive oil provided information for seed oil addition (2–10%) in virgin olive oil.

DNA analysis relying on polymerase chain reaction (PCR) and amplification using concepts such as restriction fragment length polymorphism, random amplified polymorphic DNA, and amplified fragment length polymorphism is the most suitable approach to verify the identity and quantity of species present in meat, dairy, and marine products. This is possible even after thermal processing because nucleic acids are more thermostable than proteins. Addition of pork meat to poultry ($\geq$1%) with a sensitivity of 0.1% was possible using cytochrome b and 12S rRNA as target genes for the two kinds of meat, respectively. Newly designed primers targeting porcine mitochondrial displacement permitted detection of pork without any cross amplification by other animal species with 10 pg of pig DNA limit of detection. The PCR assay was suitable in raw, cooked (60–100 °C), autoclaved, and microwave-treated samples. A pair of canine-specific primers detected minimum 0.1% of canine meat in frankfurter formulations comprising various animal and plant species and subjected to heating. Mitochondrial DNA fragments for horse, dog, cat, bovine, sheep, porcine, and goat minced meat differentiated species, and adulteration of 5%, 2.5%, 1%, and 0.5% in all combinations of possible admixtures was detected. Real-time PCR increasing the quantitative range of conventional PCR (from 1.5–2.0 log cycles to at least 5–6 log cycles) and employing fluorescent probes for visualization instead of electrophoretic separation and staining is faster and more sensitive. Thus, pork detection in beef burger formulations or commercial meatballs at $\geq$0.01% and surimi addition to soy-based vegetarian food at $\geq$1% have been reported using porcine cytochrome b, α-skeletal actin gene, and betaine aldehyde dehydrogenase 2 gene specific primers.

Immunochemical Methods

Enzyme-linked immunosorbent assay (ELISA) available in variable formats is the most popular. Although DNA methods are the most specific/sensitive for meat species identification, they require expensive equipment and training. Thus, ELISA is preferred for the routine analysis of numerous samples. Rate-limiting steps in application are the narrow availability of antibodies and standards and the generation of on-demand antibodies that can react normally at extreme pH, in the presence of high salt or solvent concentrations.

A monoclonal antibody-based ELISA assay permitted the detection of chicken and turkey meat added in cooked (100 °C, 15 min) red meat. The specificity of the 5D2 antibody to different species (pork, beef, lamb, deer, horse, duck, chicken, and turkey) and tissues (serum, gizzard, heart, and liver) examined showed that detection at <1% was feasible. Sandwich ELISA detected 0.05% added pork in chicken, 0.1% pork in beef mixtures, and 0.05% pork meal in soy-based feed, raw and heat-processed meat (132 °C, 2 h), and feed products. Test kits providing information for cooked, raw, and thermally processed meat and animal feed are available including horse meat detection at <1–2%. Available kits are also for milk and cheese examination to detect cow milk addition to goat or sheep milk, goat milk addition to sheep milk or cheese at levels 0.01–2%, and bovine casein in goat and sheep cheese at 0.5%. A useful application of ELISA is the determination of melamine in milk, milk powder, and feed samples via monoclonal antibodies produced by hybridoma technology, which provided high sensitivity and specificity.

Differential Scanning Calorimetry

Differential scanning calorimetry has been used to detect fats/oils and honey adulteration. It is fast and requires minimal or no sample preparation and no solvent use. The detection of hazelnut oil in olive oil ($\geq$5%) and high-oleic sunflower ($\geq$20%), refined olive, refined olive pomace, sunflower, and corn oils in extra virgin olive oil ($\geq$1–1.2%) has been described. Treatment of sample heating profiles with chemometrics permitted the detection of lard in admixtures with beef tallow or chicken fat ($\leq$1%). The linear dependence between enthalpy value of water phase transitions and its content can assist the detection of addition to butter ($\geq$5%), whereas measurement of the glass transition temperature (Tg) allows the determination of honey admixtures with industrial syrups (beet and isoglucose) at 5–10%.

Conclusions

Food fraud occurs since the very distant past. Rigorousness of authorities and advanced systems of detection are needed to increase trust in food manufacturers, retailers, and importers and ensure protection of public health.

Food Intolerance: Lactose Intolerance

VK Lule, S Garg, and SK Tomar, National Dairy Research Institute (NDRI), Karnal, India

Introduction

Lactose is a major disaccharide present in milk. It is composed of two simple sugars, glucose and galactose. Cow, goat, and buffalo milk contains less lactose than human milk. It has several applications in the food industry. Because of its physiological properties, it is widely used in sweets, confectionery, bread, and sausages; lactose provides good texture and binds water and color. To be absorbed, lactose needs to be hydrolyzed in the intestine by a β-galactosidase enzyme, lactase-phlorizin hydrolase, generally called lactase. This enzyme hydrolyzes lactose into the simpler sugars in order to digest and absorb the sugars. In adults with lactase deficiency (also called lactase nonpersistence (LNP)), lactose is not digested in the upper bowel and reaches the lower bowel, where it is fermented by gut microorganisms, which produce hydrogen, carbon dioxide, and methane gases. Undigested lactose also draws water into the intestinal lumen through its osmotic effect, which increases motility and can cause diarrhea. Symptoms include abdominal pain, bloating, and flatulence. Thus, low lactase levels cause lactose malabsorption (or lactose maldigestion). When lactose malabsorption gives rise to symptoms, this is called lactose intolerance (LI), that is, lactose malabsorption is the physiologic problem that manifests as LI.

Lactose maldigestion does not lead to symptoms of LI in all LNP subjects, and a small percentage of LNP subjects remain free of symptoms even after ingesting large amounts of lactose. Although rarely life-threatening, the symptoms of LI can lead to significant discomfort and disrupt the quality of life.

Males and females are equally affected by LI. Lactase deficiency in adults is a normal developmental phenomenon characterized by the down-regulation of lactase activity, which occurs soon after weaning in most ethnic groups. Lactose maldigestion increases with age during adulthood. Of those women who are lactose intolerant, 44% regain the ability to digest lactose during pregnancy. This is probably due to slow intestinal transit and bacterial adaptations during pregnancy.

Historic and Geographic Perspective on LI

The people with a low prevalence of lactose maldigestion (northwest Europeans and certain East African pastoral groups) have long traditions of consuming milk, much of it in lactose-rich forms. This suggests a geographic or cultural-historical hypothesis based on the assumption that in the hunting-and-gathering stage, human groups everywhere were like most other land mammals in their patterns of lactase activity. That is, in the normal individual, lactase activity would drop at weaning to low levels, which prevailed throughout life. With the beginning of dairy farming, however, significant changes occurred in the diets of many human groups. As a result, there may have been a selective advantage for those aberrant individuals who experienced high levels of intestinal lactase throughout life. In classic evolutionary terms, the condition of high intestinal lactase activity throughout life, or lactase persistence, would come to be typical of such a group.

Children of some ethnic groups (e.g., Thai) commonly lose lactase at 1–2 years of age while in others (e.g., Finns) lactase persists until later in life (10–20 years of age). According to some estimates, approximately 70% of the world's population has primary lactase deficiency. The frequency of lactose maldigestion varies widely among populations but is high in nearly all but those of Northern European origin.

Lactase deficiency in Europe has been reported to vary between 4% (in Denmark and Ireland) and 56% (in Italy). In South America, Africa, and Asia, more than 50% of the population is reported to have LNP, and, in some Asian countries, this rate is almost 100%. A study of gene-identified LI in a Dutch Caucasian elderly population is associated with lower dietary calcium intake and serum calcium levels but is not associated with bone mineral density or fractures. The paradox reinforces the complexity of the disease and the importance of biologic, genetic, and as yet undetermined factors in the etiology of osteoporosis. The lactase persistence trait is more common in populations that practice cattle herding and dairy farming, and it is related to genetic selection of individuals with the ability to digest lactose.

Definitions of Various Types of LI

- *Lactose intolerance* is a clinical syndrome of one or more of the following: Abdominal pain, diarrhea, nausea, flatulence, and bloating after the ingestion of lactose or lactose-containing foods. The amount of lactose that will cause symptoms varies among individuals, depending on the amount of lactose consumed, the degree of the lactase deficiency, and the form of food in which the lactose is ingested.
- *Lactose malabsorption* is the physiologic condition that manifests as LI and is attributed to an imbalance between the amount of ingested lactose and the capacity for lactase to hydrolyze the disaccharide.
- *Primary lactase deficiency* is attributable to a relative or absolute absence of lactase that develops in childhood at various ages in different racial groups and is the most common cause of lactose malabsorption and LI. It is also referred to as adult-type hypolactasia, LNP, or hereditary lactase deficiency. The most common type is found in ~70% of the world's population. In this condition, the production of

lactase declines over time, often beginning about 2 years of age; between the ages of 5 and 14 years, the majority of the population undergoes a genetically programmed reduction in lactase synthesis, resulting in only 5–10% of the lactase levels of infancy. This reduction, known as primary lactase deficiency, is not related to the continued intake of milk or lactose. Symptoms may not be experienced until late adolescence or adulthood, and the prevalence of this type of lactase deficiency in different ethnic groups is highly variable. Researchers have discovered that some people inherit genes from their parents that may cause a primary lactase deficiency.

- *Secondary lactase deficiency* is a lactase deficiency that results from a small bowel injury, such as acute gastroenteritis, persistent diarrhea, a small bowel overgrowth, cancer chemotherapy, or other causes of injury to the mucosa of the small intestine (e.g., celiac sprue, gluten-induced enteropathy, and tropical and non-tropical sprue). It can present at any age but is more common in infancy. Rotavirus infection may also be associated with diarrhea and LI in infants. Denudation of the brush border of the jejunal mucosa, which is associated with diarrhea, can lead to the loss of the other two disaccharides, maltase and sucrose. Continued diarrhea may also lead to severe complications such as monosaccharide intolerance. Other conditions that give rise to secondary lactose maldigestion include giardiasis and *Ascaris lumbricoides*. Tolerance to lactose can be improved by treating the underlying cause.
- *Congenital (Neonatal) lactase deficiency* is extremely rare. Affected newborn infants present with intractable diarrhea as soon as human milk or lactose-containing formula is introduced. Unless this is recognized and treated quickly, the condition is life-threatening because of dehydration and electrolyte loss. Teleologically, infants with this type of deficiency would not have been expected to survive before the twentieth century, when no readily accessible and nutritionally adequate lactose-free human milk substitute was available.
- *Developmental lactase* deficiency is now defined as the relative lactase deficiency observed among preterm infants of less than 34 weeks' gestation. Lactase activity usually develops late in pregnancy, so a preterm infant will not develop this enzyme function. Thus, greater the degree of prematurity, the greater the reduction in lactase activity in infants. This condition usually improves as the intestinal mucosa matures.

Pathophysiology of LI

Lactase is found most abundantly in the villus enterocytes of the jejunum (at the beginning of the small intestine), and it specifically only hydrolyzes dietary lactose into glucose and galactose for transport across the cell membrane. As it is found at the tip of the intestinal villi, it is therefore more vulnerable to attacks that cause cell damage than are other disaccharidases, which are located deeper. Absorption of lactose depends on the enzyme activity and the transit time of lactose through the jejunum mucosa. Insufficiency in lactase activity or its deficient state (hypolactasia) results in unabsorbed sugar, which attracts fluid (approximately triple the predicted amount) osmotically into the bowel lumen. Because the intestine cannot maintain a high electrochemical gradient between its contents and blood, there is an increase in the volume and fluidity of the gastrointestinal contents.

In addition to these factors, unabsorbed lactose reaches the colon, and fermentation is carried out by colonic microflora. As a consequence, gas is produced and monosaccharides that cannot be absorbed by the colonic mucosa are released, thus increasing the osmotic pressure and drawing more fluid into the bowel, resulting in symptoms such as flatulence, abdominal bloating, loose stools, abdominal cramps, and diarrhea (Figure 1). However, the development of symptoms depends on the amount of lactose ingested, intestinal transport, individual sensitivity, subjective expectations, stomach emptying frequency, and the colonic fermentation of lactose by microbiota. Sometimes there is a chance of the colonic flora producing toxins that, when reabsorbed into the body, cause harmful effects on a range of tissues, including neurons, heart cells, muscles, endocrine cells, and cells of the immune system.

Prevalence of LI

In most mammals, the synthesis of lactase declines to subtle levels after weaning. The phenomenon of the persistence of lactase production beyond weaning is seen only in humans, and it is more prevalent in the peoples of Northern Europe, which could be due to their regular consumption of milk and dairy products as part of their daily diet. However, it is not true with people in other parts of the world, where the regular intake of milk stops when breastfeeding ends. Although 70% of the world's population is deficient in lactase levels, not all suffer with LI symptoms because there are many nutritional, age, and genetic factors involved in their ability to tolerate lactose, creating variations between different individuals. The prevalence of LI in different age groups and pregnant women is discussed below.

In Children

Later childhood and adolescence is an important transition period for lactose digestion, data suggest based on diverse populations. Lactose persistence is observed in children younger than 3 years old; however, between 3 and 11 years, the beginning of genetically controlled LNP is recognized (Table 1). It has been observed that older children and young adults are increasingly unable to digest relatively small amounts of lactose. This results in increased symptom production, recognition of discomfort, and avoidance of lactose-containing products, which provoke symptoms.

A continuous decrease in lactase level is noted in children from 1 to 5 years old and through adolescence. The age of onset and its prevalence differ among various populations. Approximately 20% of Hispanic, Asian, and black children younger than 5 years show evidence of lactase deficiency and lactose malabsorption, whereas white children typically do not develop symptoms of LI until after 4 or 5 years of age. Recent molecular studies of lactase-phlorizin hydrolase (lactase) have correlated the genetic polymorphism of messenger RNA

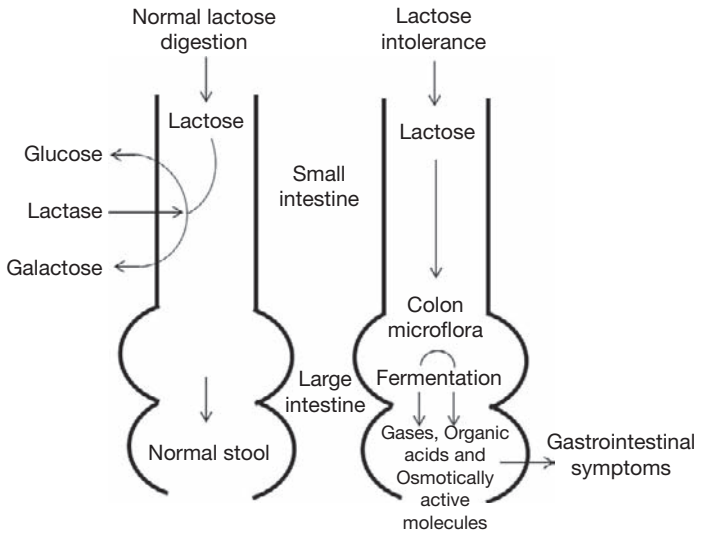

Figure 1 Lactose intolerance.

Table 1 Genetically determined lactase levels in healthy individuals by age and lactase persistence

	Lactase level	
Age lactase level	*Low lactase nonpersistent individual*	*High lactase persistent individual*
Fetal period	Low	Low
Birth	High	High
Weaning	Decline	High
3–12-year-old child	Reduced	High
Adolescent	Low	High
Adult	Lower	Average
Elderly	Lowest	Decline

expression with persistence of lactase activity, demonstrating early loss (at 1–2 years of age) of messenger RNA expression and enzyme activity in Thai children and late (10–20 years of age) loss of activity in Finnish children.

Most lactase-deficient individuals experience onset of symptoms in late adolescence and adulthood. Because of the variation of dairy intake in each individual's diet and in the amount of lactose contained in different products, symptoms may vary and be modified by diet and milk-containing foods.

In Adults

There is some evidence that intestinal lactase activity does not continue to decline with age because there were no differences in the prevalence of hypolactasia between older and younger adults. However, the prevalence of hypolactasia is more common in adults than in children. The progressive increase in the prevalence of lactose maldigestion increases with age, reaching reported adult levels of approximately 70% of the world's adult population. The exceptions are the populations of Northern and Central Europe and some Middle Eastern populations as well as groups of primarily European descent in Australia, New Zealand, and North America. The highest rates of lactose maldigestion were in South America and Africa, with approximately 50–70% of the population affected, and especially some Asian countries, where almost 100% of the population was affected. The prevalence of LI varies significantly between different groups and selected populations (Table 2).

A recent Finnish study notes flatulence as the most severe symptom in maldigesters whereas abdominal bloating is most frequently reported by individuals self-identifying as lactose maldigesters. Moreover, microbiota may play a role in the presence and intensity of lactose-related symptoms. Data suggest that increased levels of colonic bacteria, as well as their diversity, may play a role, as a result of their increased fermentative capacity, in inducing the symptoms associated with LI.

Pregnant Women

Milk is considered to be one of the most nutritious foods during pregnancy, but the lactase levels in some individuals in a number of racial and ethnic groups may be insufficient to hydrolyze commonly consumed amounts of lactose, resulting in lactose maldigestion and possibly milk intolerance. The role of lactose digestion in pregnant women is of special interest because pregnant women are frequently the targets of nutrition education. LI in pregnant African American women was studied using the breath hydrogen response to 240 ml of low-fat (1%) milk. The researchers reported the prevalence of lactose maldigestion in early pregnancy (13–16 weeks), late pregnancy (30–35 weeks), and 8 weeks' postpartum as 66%, 69%, and 75%, respectively, compared to nonpregnant African American women (the control group), who had a prevalence of 80% (Table 3).

Less than 25% of pregnant lactose-maldigesting women reported any symptoms with 240 ml of low-fat (1%) milk. Implications for fetal growth and development remain to be answered by further study. However, symptoms may be further reduced when the milk is consumed with other foods. The level

Table 2 Prevalence of lactose maldigestion in selected populations

Population	*Country*	*% Lactose maldigestion*	*Population*	*Country*	*% Lactose maldigestion*

of digestion and absorption of a range of nutrients in the consumed milk is unknown. It is necessary for pregnant women to discuss their ability to tolerate milk with a nutritionist; they should also ask for other food options.

Lactose, Calcium Absorption, and Bone Mineral Content

Recent evidence indicates that dietary lactose enhances calcium absorption and, conversely, that lactose-free diets result in lower calcium absorption. Thus, LI (and lactose-free diets) theoretically may predispose people to inadequate bone mineralization, a problem now recognized in many disorders affecting pediatric patients. The effect of lactose-free diets in childhood on long-term bone mineral content and the risk of fractures and osteoporosis with aging remains to be clarified. Calcium homeostasis is also affected by protein intake, vitamin D status, salt intake, and genetic and other factors, making long-term studies essential to determine the risks of each or all of these factors to bone health. In general, populations at risk for LI report a lower calcium intake as a result of the decline in the intake of milk and milk products. Data from National Studies in the United States indicate African American and Hispanic women have lower intakes of calcium compared to non-Hispanic women.

An Institute of Medicine Report concludes that the disparity in calcium intake "may be explained in part by the much higher prevalence of LI among African-Americans and Hispanics, sometimes resulting in their subsequent avoidance of milk." One solution to this problem is to educate lactose-intolerant groups about alternative calcium-containing foods, reinforce appropriate cultural patterns and dietary practices that include alternatives to milk, and identify other culturally acceptable calcium-containing foods.

Recent studies suggest that, in the future, genetic testing may be useful for identifying individuals at increased risk of lactase deficiency and consequent diminished bone mineral density, potentially allowing early intervention with dietary manipulation or nutrient supplementation. Recent research has even suggested that gene-replacement therapies might someday be available for susceptible individuals.

Diagnosis of LI

Usually, diagnosis can be made on the basis of the history, supported by dietary manipulation. Several tests have been used to diagnose LI (some of them are discussed below). Two formal tests, namely (a) the serum glucose level (lactose tolerance) test and (b) the breath hydrogen level test, are commonly used.

(a) *Lactose tolerance test*: In this test, a series of blood samples are obtained to measure blood glucose levels after the administration of approximately 1–1.5 g of lactose per kg of body weight. The test is positive if intestinal symptoms occur and the blood glucose level increases less than 20 mg dl^{-1} (1.1 mmol l^{-1}) above the fasting level. However, false-positive and false-negative test results occur in 20% of normal subjects because of the influence of variable gastric emptying and glucose metabolism.

(b) *Breath hydrogen test*: This test measures the rise in breath hydrogen after ingestion of 25–50 g of lactose. The test is based on the principle that carbohydrate in the colon is detectable in the pulmonary excretion of hydrogen and other gasses. A rise in breath hydrogen concentration greater than 20 ppm over baseline after lactose ingestion

indicates hypolactasia. Due to its greater accuracy, this test has been used more frequently than the lactose tolerance test, and it was found to be positive in 90% of patients with lactose malabsorption.

(c) *Stool acidity*: This test can be used to diagnose LI in small infants, for whom other forms of testing are risky or impractical.

(d) *Intestinal biopsy*: An intestinal biopsy can confirm LI following the discovery of elevated hydrogen in the hydrogen breath test. However, given the invasive nature of this test and the need for a highly specialized laboratory to measure lactase enzymes or mRNA in the biopsy tissue, this approach is used almost exclusively in clinical research.

Treatment of LI

Treatment of LI should not be aimed at reducing malabsorption but rather at improving digestive symptoms. Reduction of lactose intake rather than exclusion is recommended because most patients with self-reported LI can tolerate at least 12 g of lactose (equivalent to 250 ml of milk) without experiencing symptoms, and, if taken with other foods, up to 18 g of lactose can often be tolerated. It should be emphasized that the amount of lactose in tablets (<500 mg) is very unlikely to cause gastrointestinal complaints under any circumstances, whereas symptoms after intake of small amounts of dairy products should raise a suspicion of a true food allergy to a protein in cow's milk.

Observational studies report improvement of abdominal complaints with lactose restriction in up to 85% of IBS patients with lactose malabsorption. However, in randomized controlled trials, no significant improvement was found using dietary or enzyme-replacement treatments. This lack of efficacy in well-designed trials may be because lactose is only one of many poorly digestible, fermentable carbohydrates and dietary fibers in the diet. Therefore, for patients who have lactase deficiency, lactose restriction will rarely provide complete symptom relief.

Lactase enzyme replacement is another option although this changes the taste of food when mixed with the dairy products because the glucose and galactose produced by lactose digestion are sweeter than the original sugar. Varieties of preparations are available over the counter but may not be equally effective.

Fermented milk products, such as yogurt, dahi, bifidus milk, skyr, kumiss, and kefir, have been shown to be tolerated by lactose-intolerant individuals. The starter bacteria in these products partially digest the lactose into glucose and galactose (and the glucose to lactic acid); in addition, the semisolid state of these products slows gastric emptying and gastrointestinal transit, resulting in fewer symptoms of LI. The starter cultures (lactic acid bacteria) used in fermented milks alter the intestinal flora and may have beneficial effects in IBS patients that persist even after treatment.

Aged cheeses tend to have lower lactose content than other cheeses and, thus, may also be better tolerated. Predigested milk or dairy products with lactase are available in some countries and will often permit a lactose-intolerant individual to be able to take some or all milk products freely.

Finally, although lactase expression is not upregulated by lactose ingestion, tolerance may be induced by repeated lactose dosing due to adaptation of the intestinal flora.

Restricting lactose intake is a sensible treatment for LI, but patients should be reassured that absolute exclusion is unnecessary. If patients are unwilling to reduce milk intake, then lactase supplementation is appropriate.

Long-Term Effects of Lactose Restriction

Although restricting dietary lactose may improve gastrointestinal complaints, long-term effects of a diet free of dairy products may be of concern. Dairy products are the major source of calcium in many individuals. Current guidelines suggest a daily calcium intake of 1000 mg day^{-1} for adults, 1300 mg for adolescents, and 1200 mg for people more than 50 years old. Drinking three cups of milk per day has been recommended to obtain this amount of calcium.

There is also some evidence in the published literature that a low intake of dairy products is associated with a higher risk of fractures in women, although much less so in men. No study has addressed the safety and effectiveness of calcium replacement for patients with LI; however, it seems reasonable to recommend increasing calcium intake from other sources for patients who restrict their intake of dairy products and who have a low threshold for calcium replacements in the presence of other risk factors for osteoporosis.

Conclusion

LI is a perceived barrier for dairy intake. When the LI is due to lactose maldigestion, it is generally managed relatively easily, and thus one of the barriers impeding dietary adequacy is eliminated. Health professionals need to recognize that LI, whether real or perceived, should not be a significant barrier to improving dietary adequacy. They should understand also that LI becomes irrelevant if their patients are unlikely to drink milk, despite the relative ease with which symptoms can often be abated when they do so. Such individuals require special attention from nutrition professionals as it is not a simple task to achieve dietary adequacy without dairy, given contemporary foods and eating patterns. Further studies are required to provide high-quality evidence to support/compare the efficacy of various strategies adopted to treat LI.

Food Labeling: Applications

KA Roche, Themis Food Advisory, Cork, Ireland

© 2016 Elsevier Ltd. All rights reserved.

Food labels provide specific mandatory and voluntary information on the physical and nutritional properties of food products as well as instructions for their safe storage, preparation, and consumption. A food label can also be used to advertise, market, and promote a brand. Customers use the information on food labels as a guide in making decisions on which foods to purchase. Food labels are applied to prepacked food as single, large wraparound, or peel-and-seal labels. Food labels can also be printed directly onto the container or the product itself. As food manufacturing processes improve and food supply chains become more complex and globalized, more information is required on the durability and safety of food. Governance is needed to control the application of food labeling to effectively inform and protect the consumer, and this is achieved through international food laws and regulations. Such regulations prescribe the type and minimum amount of information that is to be provided and how it is to be presented.

Definition of Food Label (Labeling)

A food 'label' refers to the display of written, printed, or graphic material on the packaging, container, or wrapper directly surrounding a food product. The purpose of a food label is to provide information that will help the consumer make informed food choices. Traditionally label information would have been based on the physical character of the food (weight, net content, ingredient information, and identification of manufacturer). However with improvements in science and technology (e.g., food processing aids, additives) the ability of food processors to alter the characteristics of food has led to an increasing demand from consumers for more detailed nutritional and safety information. Food labels generally have a product name that describes the food; an ingredient listing, which will include any additives and allergens; nutritional information; net weight; country of origin (not mandatory for all food products); a durability date; and instructions for storage or cooking where necessary.

Food labeling refers to all food labels and any written, printed, or graphic material accompanying the food packaging. Food labels are also used to market a food product using comparative and noncomparative claims, nutrition claims, and health claims.

Food Labeling Legislation in Europe

In Europe the labeling of foodstuffs is coordinated throughout the European Union (EU) (28 member states to date) under the basic rule that the consumer must not be misled. Each member state has its own national Food Authority. The European Food Safety Authority, established in 2003, is an independent body that provides scientific advice and support for community legislation. Food law in the EU is governed by directives and regulations. Directives, on the one hand, prescribe a specific objective, and it is the responsibility of each member state to implement it and to define how to do so. A regulation, on the other hand, comes into effect as prescribed in all member states on a specific date, and its enforcement is enabled in each member state by the introduction of a national statutory instrument. The Food Information to Consumers (FIC) Regulation 1169/2011 came into force across Europe on 13 December 2014. Each member state introduced a statutory instrument to implement the regulation, which included guidelines for national authorities on enforcement and penalties.

Food Labeling Responsibilities in Non-EU Countries

Food labels must comply with regulations to protect consumers from inaccurate, misleading, or insufficient information that may result in deception, illness, or fatalities (e.g., due to anaphylaxis). Even though food distribution has become more globalized, the national rules and procedures are still very diverse. Codex Alimentarius is a collection of internationally recognized food standards and codes of practice to ensure food safety. Codex standards have been adopted into national legislation by many countries. However, bringing a new product to an international market requires detailed examination of the food regulations within the country of import, hence the relevant authorities for each country should be consulted accordingly. The United States Department of Agriculture (USDA) Foreign Agricultural Services also provides useful reports on food laws and regulations in 202 countries and regions (as of 01/01/2015). The prevailing food labeling regulations in Canada, Japan, China, India, the United States, Australia, and New Zealand are outlined next. These are subject to revision and should be checked for updates.

In Canada the Food and Drug Regulations, published in 2003, detail the labeling regulations for both food and drugs. These were amended in 2012 to include labeling of allergens, gluten sources, and sulfites. The responsibility for food labeling is shared by Health Canada and the Canadian Food Inspection Agency (CFIA). In Japan the Consumer Affairs Agency has published a single Food Labeling Standard, based on the Food Labeling Act (Act No. 70 of 2013), which is expected to come into force in April 2015. There will be a 5-year transition period to allow manufacturers to implement mandatory nutrition labeling on all prepacked foods. In China the general rules on Pre-packaged Food Labeling (GB7718) were implemented in 2005. China's Ministry of Health released the National Food Safety Standard for Nutrition Labeling of Prepackaged Food (GB 28050-2011) in 2011. In India a new regulatory authority was established in 2011, the Food Safety and Standards

Authority of India (FSSAI). The FSSAI requires prepackaged food to contain certain mandatory information as outlined in the Packaging and Labeling Regulations of 2011. One requirement specific to labels in India is the symbol to declare if a food is vegetarian or nonvegetarian.

In the United States, food labeling is regulated by the Food and Drug Administration (FDA) for all foods except meat, poultry, and egg products, which are regulated by the Food Safety Inspection Services. In the United States food products are governed by the Federal Food, Drug and Cosmetic Act (FD&C Act) of 1938 and the Fair Packaging and Labeling Act (1967). Nutrition labeling is required on most food labels since 1994 (Nutrition Labeling and Education Act). In 2014 the FDA put forward a proposal to revise the Nutrition and Supplement Facts Label. Food labeling in Australia and New Zealand must conform to the National Food Standards Code (Part 1.2) developed in 2002 by Food Standards Australia New Zealand (FSANZ). The Food Act 2003 implements the Food Standards Code and is enforced by the New South Wales Food Authority. FSANZ has been asked to review food labeling laws over a 3-year period, which ends in 2015, and make recommendations to Australian and New Zealand Food Regulation government ministers.

Mandatory Food Labeling

Voluntary labeling elements such as branding and marketing claims can dominate a label and relegate the presentation of essential mandatory information. To avoid this, the presentation of mandatory information is governed by legislation, and although there may be some regional differences from country to country, there are certain elements common to all food labels. In Europe, the FIC Regulation 1169/2011 came into force on 13 December 2014. Under the FIC regulation, food business operators at all stages of the food chain are responsible for providing mandatory information. This allows the end retailer to accurately label the food product for sale to the final consumer. Listed next are details of the 12 mandatory requirements that must be displayed on a European food label in a mandatory minimum font size. For the purpose of illustration, an example of how these are applied to specific food products is provided in each case; also included are some comparisons with other non-EU countries.

Product Name

The product name must not mislead the consumer. In Europe the name must be a legal, customary, or descriptive name. The name must inform the consumer of the nature of the product, but if the product is a recipe dish then it may also need an attached description to distinguish the contents from other similar products on the market. For example, Jam is a legal name with a reserved description, Mayonnaise is a customary name and recognized as a creamy sauce used as a condiment in all countries, Lasagne is a customary name in Europe but there may be recipe variations from country to country (vegetarian or meat), so a descriptor would also be required.

In the United States and Canada 'standards of identity for food' are the mandatory requirements that determine what a food product must contain to be marketed under a certain name. These standards ensure the label accurately displays what is inside the package. For example, Mayonnaise has a specific description under the Code of Federal Regulation (21 CFR 169.140). Only products that satisfy these conditions can use the name Mayonnaise.

List of Ingredients

In most countries the ingredients on a food label are listed by their common name in descending order by weight of the prepackaged product. The order or percentage must be calculated when added at the mixing bowl stage.

Some products may contain a compound ingredient – an ingredient made up of two or more ingredients, for example, the tomato sauce (peeled tomatoes, tomato juice, olive oil, salt) in a cheese pizza would be a compound ingredient. In Europe compound ingredients must be declared unless they are present in less than 2% of the final food product. In Australia compound ingredients must also be declared unless they make up less than 5% of the final product. However, in all countries, if an ingredient is present in less than 5% but a known allergen, then it must be declared.

Food additives

With an increased working population, busier lifestyles, and advances in manufacturing technology, food processing has increased dramatically since the nineteenth century. This has led to a requirement for alternative methods to aid food production for mass consumption. Food additives are substances added intentionally to foods to perform certain technological function, such as to sweeten, color, or preserve a food product. In European labels food additives must be identified by category followed by the specific name or European registration number, 'E number.' The E number is a code for substances that are approved by the EU for use as food additives on product labels. For example, in the ingredients listing of light mayonnaise (see Table 1), the category Preservative is listed followed by the preservative name potassium sorbate. This could also have been displayed as Preservative (E202). The E number can communicate information clearly across most languages. E numbers are also used on food labels in Australia, New Zealand, South Africa, and Israel. Only additives approved by the Ministry of Health, Labor and Welfare may be used in foods and beverages for sale in Japan. Under Japan's new Labeling Standard, if a

Table 1 Ingredient listing for light mayonnaise

Ingredients: Water, Rapeseed oil (25%), Pasteurized free range ***egg*** (6%), Modified maize starch, Spirit vinegar, Sugar, Salt, Preservative (potassium sorbate), Thickener (xanthan gum), Lemon juice concentrate, ***Mustard*** flavoring, Antioxidant (calcium disodium EDTA).

product is labeled for sale to the consumer, then the label must include the net content of each food additive and the name and address of the additive manufacturer in a separate line under the other ingredients.

China recently published an update on the standard for Food Additive usage (GB 2760-2014), which takes effect in May 2015. Under the new regulation, food categories have been modified, and there will be restrictions of the use of food additives as both flavoring and processing aids.

A small proportion of the population can have adverse reactions such as allergies or intolerances to certain food additives, be they derived from natural or synthetic sources. In addition, some food products may contain or be derived from genetically modified organisms (GMOs), which some consumers may not wish to consume. The labeling of sweeteners, colors, preservatives, and GMOs is discussed next.

Sweeteners

Sweeteners are ingredients that sweeten like sugar (sucrose), but may be low-calorie synthetic substitutes. Under EU legislation, food products containing a *sweetener* or *sweeteners* must include the statement 'with sweeteners' on the label accompanying the name of the food product. The relationship between sweeteners and negative health effects has been studied for many years by many different regulatory agencies, and after rigorous safety assessments and the establishment of safe levels of use, certain sweeteners have been approved as food additives. The low-calorie tabletop sweetener aspartame contains the amino acid phenylalanine. People who have the inherited disease phenylketonuria (PKU) are unable to metabolize phenylalanine effectively. If aspartame is listed in the ingredients by its E number, E951, then the label must also include the statement 'contains aspartame (a source of phenylalanine)' so that people who suffer from PKU can avoid consuming these products.

Colors

The color of a food product is an important part of the consumer's sensory experience of the product. Moreover, the color of a food can indicate whether it is fresh or stale, has a particular flavor, or contains certain ingredients. For example we expect a red apple to be sweet and a green apple to be sour. However, color can be lost during processing or storage of foodstuffs. Although the coloring of food has been carried out for over 100 years the artificial colors used in food today are subject to regulation, and only those established as being safe are permitted to be used in food. In Europe, studies by the University of Southampton linked certain artificial colors to hyperactivity in children. Although not banned under legislation, since 2010 any food or drink containing one or more of the so-called Southampton Six artificial colors (i.e., sunset yellow (E110), quinolone yellow (E104), carmoisine (E122), allura red (E129), tartrazine (E102), and ponceau (E124)) must carry the health warning 'may have an adverse effect on activity and attention in children.'

In the United States, the FDA divides food color additives into the two categories: those subject to certification (artificial colors) and those exempt from certification (natural colors). The FDA certified nine color additives that can be added to foods in the form of dyes (water-soluble) or lakes (fat-soluble). Certification-exempt additives are extracts from natural foodstuffs giving both color and sometimes flavor. In 2014 the FDA released a new list of color additives that are under review for safe use in foods, drugs, cosmetics, and medical devices. In Canada food additives are regulated under the Food and Drug Regulations and associated Marketing Authorizations. All permitted food additives are referenced in the Marketing Authorisation for Food Additives that may be used as Colouring Agents (SOR/2012-204).

Preservatives

Food can be preserved by physical or chemical methods or a combination of both. Physical methods of preserving food include refrigeration, dehydrating, freeze-drying, and UV-C radiation. Chemical preservatives are substances (natural or artificial) added to food to slow down food spoilage caused by bacteria, fungi, or yeasts. These preservatives can control contamination and help maintain food freshness and quality. In the ingredients listing for light mayonnaise (see **Table 1**), the category Preservative is listed followed by the preservative name potassium sorbate. This could also have been displayed as Preservative (E202). In Europe the preservative sulfur dioxide or sulfites at concentrations of more than 10 mg kg^{-1} in the final product is an allergen and must be highlighted in bold in the list of ingredients (can cause a reaction in people sensitive to asthma).

Genetically modified organisms

This is a controversial issue with consumers in Europe. Under the 1997 novel food regulation, genetically modified (GM) foods only required labeling if the GM content could be detected in the final product. This was updated by Regulation 1892/2003, whereby all food products that use GMOs at any stage of production are subject to labeling requirements, even if the GM content is not detected in the final product. However in reality this can be difficult to monitor so a threshold was introduced. Food products that have GM content equal to or less than the 0.9% threshold would not require labeling provided the presence is due to unavoidable cross contamination during or postharvesting.

Japan, Australia, Russia, Brazil, and China all require the labeling of GM foods on their prepacked products. The United States currently has a voluntary labeling system for GM foods. Consumer demand for transparency in the last 5 years has led to many individual states passing GMO labeling laws. Food industry groups are lobbying for the FDA to study GM traits and crops (compared to non-GM foods) and set standards for GM labeling, which they believe would build consumer support for biotechnology.

Allergens

Even though the list of allergens varies slightly from country to country, food regulatory authorities agree that for safety reasons allergens must be highlighted on prepacked foods. In Europe under the FIC regulation there are 14 allergens that, if present in prepacked food, must be highlighted in the ingredient listing in a font style that distinguishes it from the rest of the text. Most European manufacturers highlight (in bold or

capitals) the allergen itself or display the allergen in brackets immediately after the relevant ingredient. For example, in light mayonnaise the allergens egg and mustard are highlighted in *italics* (see Table 1).

The presentation of allergen information on nonprepacked food (i.e., loose food, food packed on the business premises at the consumer's request) is also mandatory. For some countries this presentation can be verbal but national legislation in Ireland and France requires the written display of allergen information for nonprepacked food for all businesses dealing with food, that is, restaurants, bakeries, farmers markets, hospitals, bars, crèches, fast-food outlets, distance selling, and so on.

In Australia there are nine common food allergens (peanuts, tree nuts, milk, eggs, fish, shellfish, wheat, sesame, and soy) that must be declared on packaging. FSANZ is currently working on the recommendation for the presentation of allergens emboldened both in the ingredients list and in a separate list. In Canada food labeling laws were amended in 2012 to include labeling of allergens, gluten sources, and sulfites (if present in more than 10 ppm). There are currently 13 allergens that must be identified if present on an ingredient listing. In Japan there are seven allergens (peanuts, milk, eggs, buckwheat, wheat, crab, shrimp/prawn) that require mandatory labeling and 20 allergens for which labeling is recommended. Similar to European labeling, if the product contains the same allergen in multiple ingredients (e.g., an egg salad would also contain eggs in the mayonnaise), the allergen must be listed each time after the ingredient.

Quantitative Ingredient Declaration

In the EU a quantitative ingredient declaration (QUID) is displayed as a percentage of the characterizing ingredients that are displayed on (or associated with) the name of the product. In the example (Table 1) light mayonnaise is made from a combination of rapeseed oil, egg yolks, vinegar, or lemon juice, therefore the primary ingredients – the rapeseed oil and egg – are QUID at 25% and 6%, respectively.

Net Quantity

Net quantity is required in metric units on all foods (FIC, Article 23). The units of volume for liquids are liters (l), centiliters (cl), or milliliters (ml), and the units of mass in the case of all other products are grams (g) or kilograms (kg).

Durability Dates

The date of minimum durability of a foodstuff is the date until which a food retains its specific properties when properly stored. There are two types of date markings, a best-before date or a use-by date. Most nonperishable foods with a long shelf life such as tinned beans or pasta, which do not require refrigeration, have a best-before date. A use-by date is required for foods that are highly perishable, may require refrigeration, and are likely after a short period to be an immediate danger to human health, for example, raw and cooked meats, milk, and yogurts. In Europe, under the FIC regulation, frozen products require a best-before date and a date of freezing on the label. Manufacturers use shelf life testing to calculate the durability date for each product. In Canada if fish has been frozen and thawed prior to sale, then it must include the words *previously frozen* on the label.

Storage

In Europe (FIC Regulation 1169/2011) storage conditions must be included if necessary to maintain the quality of the product. For a perishable product like the light mayonnaise example in Table 1, the label would read 'Storage: Keep refrigerated for 1 month after opening.'

Instructions for Use

Manufacturers must provide instructions for use for any foods that need specific preparations to avoid food poisoning and ensure they are safe. In Europe, uncooked meat and meat preparations intended for supply to the final consumer must bear a notice indicating that such products must be cooked before consumption. If cooking is necessary then the label must contain instructions on preparation, cooking, or reheating.

Business Name and Address

A food label must contain the name (or business name) and address of the manufacturer or seller within or outside the EU (FIC Regulation, 1169/2011). The contact details must be precise enough to enable a customer to contact the named agent where necessary. A website address or telephone number alone is not acceptable.

Country of Origin

In the EU, country of origin labeling is currently mandatory for certain products such as beef, fish, honey, olive oil, wine, fresh fruit, and vegetables, and after 1 April 2015, mandatory origin labeling will be extended to whole cuts from poultry, pork, sheep, and goats. The origin declaration of meat as an ingredient is currently under discussion in the European Commission. General labeling rules require that the origin of a product must be declared where its absence might mislead the consumer as to the true origin, whether due to misleading pictures, maps, or flags.

In the United States, country of origin labeling has been mandatory since 2013 for certain meat products (beef, pork, lamb, chicken, goat meat), wild and farm-raised fish and shellfish, perishable agricultural products, ginseng, peanuts, pecans, and macadamia nuts.

In Australia all packaged food must carry country of origin information. This can be presented as a statement identifying the country where the food was produced or grown or the country where the food was manufactured or packaged. In New Zealand the country of origin labeling is voluntary, but the contact details of supplier must be labeled should further information be required.

Table 2 Nutritional information for light mayonnaise[1]

	Light mayonnaise		
Nutrient	*Per 100 g Light*	*Per portion (per 15 g)*	*% RI[a] per portion*
Energy	1190 kJ/288 kcal	179 kJ/43 kcal	2.1%
Fat	28 g	4.2 g	6%
- of which saturates	2.4 g	0.4 g	2%
Carbohydrates	7.4 g	1.1 g	0.4%
- of which sugars	3 g	<0.5 g	0.6%
Protein	0.8 g	<0.5 g	1%
Salt	1.8 g	0.28 g	4.7%
Omega 3 fatty acids	2.5 g	0.4 g	

[a]Reference intake of an average adult is 8400 kJ/2000 kcal.
[1]All information, with the exception of % RI, were extracted from SuperValu Light Mayonnaise label with permission from Musgrave Retail Partner, Ireland.

Nutritional Declaration

In Europe a nutritional declaration is not mandatory on food labels until 13 December 2016, with some exceptions; that is, if making a nutrition or health claim or if a food label currently displays nutritional information, this must be updated to comply with the FIC format. The regulation prescribes the layout and sequence of the nutritional declaration (see light mayonnaise example in Table 2).

In Europe the mandatory information (energy, fat, saturated fat, carbohydrate, sugars, protein, and salt) must be presented per 100 g or 100 ml of finished product. Vitamins and minerals permitted for use in foods are listed in Annex III of the FIC Regulation 1169/2011. These can only be included if present in a significant amount (15% of the reference intake). Reference Intake (RI) has replaced the recommended daily allowance (RDA) and if used must be accompanied by the statement "reference intake of an average adult is 8400 kJ/2000 kcal." The nutritional information per portion and %RI is considered voluntary information but if included it must be presented as prescribed in the regulation.

In the United States nutritional information is presented under the heading 'Nutrition Facts' but the information is displayed as the amount per serving rather than per 100 g. The nutritional facts label is required on most prepacked food; for exemptions see further reading. After 20 years the FDA put forward a proposal in 2014 to revise the Nutrition and Supplement Facts Label. The new recommendation proposes removing 'calories from fat' and focusing on the total calories. Certain information will be emphasized (larger font and bold type) such as calories, serving sizes, and percentage daily value. The daily value is a single term based on the amount of nutrients (daily reference values) and the amount of vitamins and minerals (reference intake values) present in a food. The proposal moves the information on % daily value to the left of the column on the nutritional table. The FDA has also proposed changes to the serving size to realistically reflect how much people typically eat at a single sitting according to 2010 Dietary Guidelines for Americans. Added sugars will be included on the label; these are the sugars added during food processing. The update will require some changes in the mandatory declaration of certain nutrients if present in the food: Calcium and iron remain on the label, potassium and vitamin D must be included. However, vitamins A and C will now be voluntary. The consultation process closed in August 2014, and the information must be examined before a final ruling on proposed changes to the labeling regulation.

Canada introduced mandatory nutritional labeling for most prepackaged food in 2005. The Nutritional Fact Table presented information on the calories, 13 core nutrients, and % daily value of nutrients. In June 2014 the CFIA published the Food Labeling Modernization Initiative, which proposes changes to food labels based on recent scientific information. New guidelines on serving size based on current information, more information on sugars, and added sugars is presented either on the table or in the ingredients listing. Similar to the United States, there are changes in nutrients of concern to public health such as potassium and vitamin D, with removal of vitamins A and C from the table. The consultation process is now closed, and the information must be examined before a final ruling on the proposed changes to the labeling regulation. Prepacked food in Australia and New Zealand display a nutritional table very similar to the European model.

Front-of-pack nutritional labeling

Additional nutritional information can also be presented in Europe as a voluntary front-of-pack nutrition label (or nutritional lozenge) (see Table 3).

This was introduced to provide consumers with the most important information (energy, fat, saturates, sugars, and salt) at a glance. The United Kingdom introduced a traffic light color coding element to the nutritional lozenge whereby green was low, yellow was medium, and red was high in a particular nutrient. If this system was applied to the light mayonnaise example, then fat would register as yellow, and saturates, sugar, and salt would all be colored green. This traffic light system has been criticized by some EU states as being oversimplistic for foods with multiple components and for being discriminatory and undermining free trade in the EU. As a result, the use of the UK traffic light system is currently under investigation by the European Commission.

Table 3 Front of pack nutritional information for light mayonnaise (displaying nutrient values and the % reference intake per portion (15 g) of light mayonnaise)

Energy	Fat	Saturates	Sugars	Salt
179 kJ/ 43 kcal	4.2g	0.4g	<0.5g	0.28g
2.1%	6%	2%	<1%	4.7%

Energy per 100 g: 1190 kJ/ 288 kcal.

Alcoholic Strength

In the EU, beverages with more than 1.2% alcohol by volume must declare their actual alcoholic strength on the label. Canada, Australia, New Zealand, and China have similar labeling requirements for declaration of beverages more than 1.1%, 1.15%, and 1.2%, respectively. Japan and the United States do not specify the minimum amount but do require the alcohol content to be displayed on the label.

Minimum Font Size

Under the FIC regulation in Europe, all prepacked food labels must display the mandatory information in a minimum font size. In Europe if the surface area of the package is 80 cm^2 or more, then the font used must have a minimum *x*-height of 1.2 mm (Times New Roman size 8 approximately). If the pack's surface area is less than 80 cm^2 then the font may be displayed with an *x*-height of 0.9 mm (Times New Roman size 6 approximately). The minimum font size required for labels in Japan is 8-point for all characters. In the United States and Canada the letters and numbers on the principal display panel must not be less than one-sixteenth of an inch in height.

Claims on Food labels

Codex Alimentarius defines a claim as:

> Any representation which states, suggests or implies that a food has particular characteristics relating to its origin, nutritional properties, nature, production, processing, composition or any other quality.

Food and safety authorities around the world monitor and regulate claims displayed on food labels. In Europe nutrition and health claims are highly regulated. The Community Register contains all the claims submitted, but only the authorized claims (the EU positive list) can be used on food labels.

Nutrition Claims

A nutrition claim is made when a food highlights a specific benefit provided by a particular nutrient in the food product. Before a food label can make a nutrition claim, it must first prove that the nutrient in question is present (or absent) in a 'significant amount,' 15% of the DRI. To do this food products must complete a nutritional analysis. For example, a food label that displays the words 'source of vitamin C' must show that vitamin C was present in the final product at 15% of the RI. Comparative claims such as claiming a product is 'light' or 'low fat' must adhere to the definition and conditions of use outlined in Community Register database. If the product is a 'light' mayonnaise, then it must show that the fat content of the mayonnaise has been reduced by at least 30% when compared to a similar product. The light mayonnaise in Table 2 was more than 30% lower in fat (28 g) than a standard mayonnaise (79 g of fat).

Health Claims

A health claim is any claim that shows a relationship between food and health. There are three types of health claims authorized for use on food products in Europe: disease risk reduction claims and children's health and development (Article 14), general function health claims (Article 13), and claims based on new scientific evidence (Article 13.5). Most of the authorized general function health claims can be used if the particular nutrient in the food product fulfills the criteria required to make the claim. For example, the light mayonnaise (Table 2) contains omega-3 fatty acids, contributed from the egg used to make the mayonnaise. The omega-3 is presented in the table as 2.5 g per 100 g of mayonnaise. This was greater than the amount necessary (>0.3 g) and fulfills the criteria required to make the health claim 'Source of alpha-linolenic acid, which helps maintain a healthy blood pressure.'

Food Supplements

In the EU, food supplements, defined as 'foodstuffs,' are governed by the general labeling rules of the FIC regulation 1169/2011. However, under Food Supplement Regulation 1924/2006 there is some additional information on daily dosage and health warning statements that must also be included on the label. Food supplements can display nutrition and health claims on the label as long as the nutrient in the supplement is on the EU positive list and fulfills the criteria for each claim. It is important to have each food product scientifically analyzed (for shelf life testing and nutritional information) to substantiate any claims.

In the United States there are three claim categories, regulated by the FDA, that can be used on food labels: (1) health claims, (2) nutrient content claims, and (3) structure or function claims. Health claims such as 'adequate calcium throughout life may reduce the risk of osteoporosis' can be used if authorized by the FDA and meet the required criteria. Nutrient content claims 'low in sodium' or 'high in folate' must only be used with nutrients that have an established daily value and meet the criteria for the particular claim. Structure of function claims describe the role of a nutrient in maintaining normal structure of function in the human body, for example 'calcium builds strong bones.'

In Australia a new standard to regulate nutrition and health claims (currently voluntary) became law in 2013 with a 3-year transitional period for food businesses to comply. Under the new food standard, nutrition claims will need to meet certain criteria as set out in the standard. Health claims fall into two categories: general-level health claims, such as 'calcium is good for bones,' and high-level health claims, such as 'calcium may reduce the risk of osteoporosis.' General health claims can be based on one of 200 preapproved claims or self-substantiate the food health relationship claim by following the requirements in the Food Standard. As of October 2013 there were 13 preapproved high-level health claims. Health claims will not be permitted on foods high in saturated fat, sugar, and salt. They will only be permitted on foods that meet the nutrient profile scoring criterion. As in Europe, the manufacturer must substantiate that the claims are truthful and not misleading to the consumer.

Food Poisoning: Classification

E Eymar, C Garcia-Delgado, and RM Esteban, University Autonoma of Madrid, Madrid, Spain

© 2016 Elsevier Ltd. All rights reserved.

What is Food Poisoning?

Unavoidably, in addition to nutrients, food also contains harmful substances that may be poisonous at low doses, and even chemicals that are harmless in small amounts, but may be damaging in large quantities. They may enter the food accidentally or intentionally, during growth, cultivation, or preparation. They can be formed in the food through the interaction of chemical components, accumulated during storage, or they may be concentrated from the natural components of the food. Microorganisms may be introduced directly to infected food from animals, workers, other foods, or the environment during food preparation. Poisonous substances may be produced by the growth of bacteria and molds in food. In some cases, the term food poisoning (or foodborne disease or foodborne illness) is used to denote gastrointestinal complications that occur following recent consumption of a particular food or drink. In a wider perspective, food poisoning, or food toxicity, is a term used to imply the adverse effects caused by the direct action of a food or food additive on a host recipient without the involvement of immune mechanisms.

Poisons: Toxins and Toxicants

Before the establishment of the food poisoning classification, several concepts should be defined. The term 'toxin' generally refers to toxic substances produced by biological systems such as plants, animals, fungi, or bacteria. They are generally metabolic products that have evolved as defense mechanisms for the purpose of repelling or killing predators or pathogens. The term 'toxicant' is used for toxic substances that are produced by, or are a by-product of, anthropogenic (human-made) activities.

These toxic substances can produce, according to their exposition and doses, different types of intoxications: acute (toxicity elicited immediately following short-term exposure to a harmful substance), subchronic (toxicity caused by repeated dosing over an extended period, but not one that constitutes a significant portion of the normal life span), and chronic (result of long-term exposure to a toxic substance).

Food Poisoning Classification

There are several considerations when classifying food poisoning. In the literature, different classification methods can be found, such as according to an incubation period, the chemical structures of toxics, the toxicological targets, or classifications related to the tolerance setting for toxic substances. Substances such as pesticide residues, drugs used in food-producing animals, heavy metals, chlorinated organics, nitrosamines, nitrosamides and N-nitroso compounds, mycotoxins, furan, and others have tolerance settings. We can find other substances, such as toxins present in fish and shellfish, preformed bacterial toxins, and others, for which tolerances may not be set.

In this article, a simple classification of five groups will be used to describe the toxic substances according to their origin:

- Biological pollutants
  - Bacterial intoxications
  - Bacterial infections
  - Foodborne animal parasites (protozoa, flatworms, roundworms, and tapeworms)
  - Viruses
  - Prions and transmissible spongiform encephalopathies
  - Mycotoxins
- Toxic substances of natural origin
  - Sea products
  - Higher plants
  - Higher mushrooms
  - Miscellaneous
- Chemical pollutants and/or residues
  - Inorganic substances
  - Organic substances
    - Environmental pollutants (Dioxins, dibenzofurans, and polychlorinated biphenyls)
    - Substances intentionally added to food (Pesticides and veterinary drugs)
- Food additives
- Toxic substances formed during food processing, preparation, storage, and intake.

Biological Pollutants

The biological pollutants, including foodborne bacteria, viruses, and microbes (pathogens) cause most illnesses in the world; this includes estimating the number of biological pollutants as causes of foodborne illnesses without a known cause. This group also includes foodborne animal parasites, prions, and mycotoxins. The last estimates made in the United States (2011) indicate that, each year, roughly one in six Americans (or 48 million people) gets sick, 128 000 are hospitalized, and 3000 die of foodborne diseases associated with these biological pollutants. Nontyphoidal *Salmonella*, *Toxoplasma*, *Listeria*, and norovirus caused the most deaths; nontyphoidal *Salmonella*, norovirus, *Campylobacter*, and *Toxoplasma* caused the most hospitalizations; and norovirus caused the most illnesses. Bacterial-related foodborne diseases can be classified as either intoxications or infections.

Bacterial intoxications

Foodborne intoxications result when toxins or poisons from bacteria are present in the ingested food. These toxins are generally odorless and tasteless, and they are capable of causing disease even if the microorganisms have been eliminated. *Clostridium botulinum* (in improperly canned foods),

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00317-2

Staphylococcus aureus (in meat, eggs, and milk), and *Bacillus cereus* (in starchy foods) are the most important pathogens that cause bacterial intoxications. Table 1 shows the most important pathogens, their occurrence, main transmission routes, symptoms, and possible complications or chronic sequelae.

Bacterial infections

Foodborne infections result from eating a food containing a large amount of disease-causing microorganisms, which are capable of producing or discharging a toxin once they are ingested. Nontyphoidal *Salmonella* (in raw or undercooked food of animal origin), *Clostridium perfringens*, and *Campylobacter* spp. (in water and raw products) are the most important bacterial infections contributing to domestically acquired foodborne illnesses. Table 1 outlines information about the most important pathogens responsible for bacterial infections and their occurrence, main transmission routes, symptoms, and possible complications or chronic sequelae.

Foodborne animal parasites (protozoa, flatworms, roundworms, and tapeworms)

Parasitic Protozoa and Worms (MS 770 Zoonoses)

Protozoa important in food and water include *Cryptosporidium*, *Giardia lamblia*, *Entamoeba histolytica*, *Toxoplasma*, and *Cyclospora*. They are parasites, and exposure occurs via ingestion of water contaminated with fecal material from an infected animal or via ingestion of food that was irrigated or washed with contaminated water.

Cryptosporidium's most common symptom is profuse, watery diarrhea, along with nausea, vomiting, and cramping. Fever can also accompany these symptoms. As noted, the severity and duration of diarrhea usually is increased in immunodeficient people.

The symptoms from exposure to *Giardia lamblia* (*Giardia intestinalis*) generally consist of especially malodorous diarrhea, malaise, abdominal cramps, flatulence, and weight loss. Giardiasis is self-limiting in most people.

Entamoeba histolytica is capable of infecting a wide variety of hosts, which causes invasive disease in humans. When symptoms do occur, they usually begin within months after amoe-

Table 1 Foodborne bacterial intoxications and toxic infections

Pathogen	*Occurrence*	*Main transmission routes*	*Symptoms*	*Possible complications or chronic sequelae*
Bacterial intoxications				
Clostridium botulinum (MS 170–172)	Soil, water, plants, and intestines of animals and fish	Home-cured ham and sausages. Improperly canned foods, garlic in oil, tightly wrapped foods	Early symptoms from 4 h to 8 days after eating include unspecific gastrointestinal symptoms and paralysis, including paralysis of the breathing muscles.	Botulism is a serious, sometimes fatal, disease caused by a potent neurotoxin formed during growth of *C. botulinum.*
Staphylococcus aureus (MS 654–656)	Human and other animal skin, hair; in nasal passage and throat (staphyloenterotoxicosis; staphyloenterotoxemia)	Food handler to food (meat, meat products, poultry, egg products, salads, bakery products, milk and dairy products)	When ingested, the enterotoxin may rapidly produce symptoms (1–6 h), which commonly include nausea, abdominal cramping, vomiting, and diarrhea.	In more severe cases, dehydration, headache, muscle cramping, and transient changes in blood pressure and pulse rate may occur.
Bacillus cereus and other *Bacillus* spp. (MS 50-52)	*B. cereus* is widespread in the environment, often isolated from soil and vegetation	Cereals, rice, soups, vegetables, puddings, sauces, creams, other starchy foods	*Diarrheal type*: watery diarrhea, abdominal cramps, and pain. Emesis rarely occurs. *Emetic type*: nausea and vomiting	Other clinical manifestations of *B. cereus* invasion and infection include severe systemic and pyogenic infections, gangrene, septic meningitis, cellulitis, panophthalmitis, lung abscesses, infant death, and endocarditis.
Bacterial toxic infections				
Salmonella spp. (MS 606–608)	Intestines and feces of animals; *Salmonella enteriditis* in eggs	Raw or undercooked food of animal origin, mainly meat, poultry, eggs, and milk	Fever, headache, nausea, vomiting, abdominal pain, and diarrhea appearing 9–72 h after infection, lasting 1–7 days.	In ~2% of culture-proven cases, reactive arthritis may occur after ~3 weeks; also Reiter's syndrome
Campylobacter jejuni (MS 105–107)	Intestines of animals and birds, raw milk, untreated water, sewage sludge	Contaminated water, raw milk, raw or undercooked meat or poultry, or shellfish	Headache, fever, and muscle pain 2–5 days after ingestion; later severe abdominal pain, nausea, and diarrhea (sometimes bloody). May last 7–10 days.	May lead to reactive arthritis and neurological disorders in 2–10% of patients.

(*Continued*)

Table 1 (Continued)

Pathogen	*Occurrence*	*Main transmission routes*	*Symptoms*	*Possible complications or chronic sequelae*
Yersinia enterocolitica (MS 763–764)	Soil, water, often isolated from pigs, cats, dogs, birds, and beavers	Meats, oysters, fish, raw milk	Fever and abdominal pain, frequently also gastroenteritis with diarrhea and/or vomiting within 24–48 h after infection; may mimic appendicitis.	Can cause 'primary septicemia' in individuals with underlying chronic disease (e.g., diabetes, cirrhosis, AIDS, leukemia). This form is associated with 50% mortality.
Shigella spp. (MS 627)	Human intestinal tract, food, water	Person-to-person by fecal-oral route or fecal contamination of food handled by workers with poor personal hygiene	Diarrhea and dysentery (diarrhea with blood and mucus in the stools), vomiting, abdominal cramps, rectal pain and fever, appearing 12–50 h after infection and lasting a few days to 2 weeks.	Reiter's syndrome, reactive arthritis, and hemolytic uremic syndrome. Some strains are associated with fatality rates of 10–15%.
Vibrio parahaemolyticus (MS 724–725)	Contaminated fish and shellfish, especially oysters	Raw seafood or cooked seafood contaminated with raw product; improper refrigeration of seafood products	Diarrhea, abdominal cramps, nausea, vomiting, fever, and bloody diarrhea. Incubation period is 4–90 h. Duration of illness is 2–6 days.	Although the illness is generally mild or moderate, *V. parahaemolyticus* can also cause septicemia in susceptible people.
Mycobacterium bovis (MS 477)	Water, soil, cows, animal and human feces, nasal passage, saliva	Unpasteurized milk and dairy products; meat products	Fever, night sweats, fatigue, loss of appetite, and weight loss; other symptoms depend on the part of the body affected.	If lungs affected: chronic cough, blood-stained sputum, or chest pain If gastrointestinal tract affected: diarrhea, abdominal pain, and swelling. The disease may result in death, if untreated.
Brucella spp.	Symbionts and plant pathogens, intracellular animal pathogens, and environmentally ubiquitous bacteria	Unpasteurized milk and soft cheeses made from the milk of infected animals; brucellosis transmitted from animal hosts to humans highly contagious, but rarely transmitted from human to human	Intermittent fever, chills, sweating, weakness, malaise, headache, and joint and muscle pain	Complications may include symptoms of endocarditis or myocarditis, such as shortness of breath, arrhythmia, edema, or chest pain; meningoencephalitis, such as severe headache, stiff neck, confusion, or seizures; or spondylitis, such as back pain.
Vibrio cholera Serogroups O1 and O139 (MS 724–725)	Aquatic environments, freshwater and saltwater. It grows there naturally or can get into the water from the bowel waste of infected people (sewage).	Ingestion of water, ice; unwashed, contaminated food; and seafood that is raw, improperly cooked, or cross-contaminated by a raw product	Abdominal discomfort and diarrhea that may vary from mild and watery to acute, with rice-water stools. Vomiting also occurs in some cases.	Cholera gravis, the most severe form of cholera infection, is characterized by severe fluid and electrolyte loss from vomiting and profuse, watery diarrhea. Complications include tachycardia, hypotension, and dehydration.

bas first enter the body. The severity of the symptoms associated with intestinal amebiasis range from mild diarrhea to a severe, dysentery-like illness with mucus and blood in the diarrhea, as well as abdominal distention.

Toxoplasma gondii are ubiquitous parasites found around the world. In some locations, up to 95% of the local human population has been infected with *T. gondii*. People can become infected by different ways, such as eating raw or undercooked, contaminated meat—and not only meats, such as pork and beef, but also seafood, such as clams and oysters.

Cyclospora cayetanensis is more common in areas around the tropics, and people who travel to those areas are at

higher risk of getting this illness. Symptoms begin about a week after eating the contaminated food. They include diarrhea (sometimes explosive), loss of appetite, weight loss, cramps, bloating, nausea, and tiredness.

Among the worms, three types can be distinguished:

- Tape worms such as *Taenia* (exposure by eating undercooked pork or beef; these worms can cause diarrhea, nausea, pain, and a change in appetite)
- Roundworms, nematodes such as *Anisakis*, *Gnathostoma spinigerum*, *Trichinella spiralis*, *Ascaris lumbricoides*, and *Trichuris trichiura* (exposure by eating raw and undercooked fish; the symptoms range from tickling caused by a worm crawling up the throat to stomach or abdominal pain, nausea, vomiting, and diarrhea, from mild to severe, as well as allergic reactions)
- Flatworms, helminths, *Fasciola hepatica*, *Diphyllobothrium* species (found in raw and undercooked fish; symptoms usually are mild abdominal discomfort, diarrhea, and changes in appetite, and they may begin in about 10 days after ingestion; these kinds of worms can infect people who eat undercooked meat, especially from wild game)

Viruses (MS 727)

A number of different viruses, such as norovirus, the hepatitis A virus, the hepatitis E virus, rotavirus, and others, cause gastrointestinal illness in humans. Although norovirus usually causes a mild illness, it is a leading cause of foodborne deaths because it affects so many people. Examples of foods that have caused norovirus illnesses are fruits, vegetables, meats, and salads prepared or handled by an infected person. Oysters grown in contaminated water are another example. Norovirus infections are characterized by nausea, explosive vomiting, watery diarrhea, and abdominal pain. Hepatitis A virus can cause long-lasting liver disease and typically spreads via raw or undercooked seafood or contaminated raw produce. Infected food handlers are often the source of food contamination.

Prions and transmissible spongiform encephalopathy (MS 80)

In both humans and cattle, a disease-causing prion is a protein that has taken the wrong shape. Normally, the correctly shaped prion protein helps the brain and nerves work properly, but when it is the wrong shape, it can result in variant Creutzfeldt–Jakob disease (vCJD) in humans. Although this disease made headlines when it appeared in the mid-1990s, it is important to remember that, of the entire population of the world, only 217 cases of vCJD have been reported, and added safety regulations for feeding cattle appear to be working to prevent the disease.

Mycotoxins (MS 478-480)

Mycotoxins are secondary metabolites produced by fungi that infect a variety of crops, including cereals, nuts, spices, and, in some cases, fruits. The most important mycotoxins found in food are:

Aflatoxins. There are six different aflatoxins (B1, B2, G1, G2, M1, M2) produced by *Aspergillus flavus* and *Aspergillus parasiticus*. They cause hepatic cirrhosis and cancer, especially aflatoxin B1. They can occur in nuts (peanuts, almond, pistachios, and Brazil nuts), corn, other cereals, and milk.

Ochratoxins. The ochratoxins are a group of structurally related secondary metabolites produced by *Penicillium verrucosum* and *Aspergillus ochraceus*; ochratoxin A is the main and most toxic of these mycotoxins. It is nephrotoxic in almost all animals, producing hepatotoxic, teratogenic, and immunotoxic effects at higher doses. The ochratoxins can be present in barley, corn, wheat, rye, oils, seeds, coffee beans, wine, and poultry.

Tricothecenes. These mycotoxins are produced by the fungi *Fusarium* (such as *F. poae*, *F. sporotrichioides*, *F. graminareum*, and *F. culmorum*) and are subdivided into different categories, such as type A, which includes T-2 toxin and HT-2 toxin. The most important tricothecenes are type B, including deoxynivalenol and nivalenol. These toxins inhibit protein synthesis in the cells and induce apoptosis. The tricothecenes can occur in corn, barley, rice, wheat, milk, and other substances.

Fumonisins. Fumonisins are mycotoxins from *Fusarium* spp. They are present in corn and other cereal grains. Ingestion of fumonisin B1 during the first trimester of pregnancy causes neural tube defects and other disturbances in fetal sphingolipid profiles.

Zearalenone. Zearalenone, produced by *Fusarium graminearum*, are associated with hematoxicity, hepatotoxicity, estrogenic activity, and a decrease in fertility acting as an endocrine disruptor. Zearalenone can occur in corn, other cereal grains, soybeans, and animal feed.

Patulin. Patulin, produced by *Penicillium expansum*, causes embryotoxicity and chromosomal damage. It appears in spoilt fruits and fruit juices, especially apple juice.

Citrinin. This mycotoxin, produced by *Penicillium citrinum*, causes convulsions, paralysis, coma, gasps, and respiratory arrest, and it can be present in wheat, barley, rye, and oats.

Toxic Substances of Natural Origin (MS 698)

This group includes substances generated by animals and plants during metabolism or by microorganisms used in or present in food. Some of these natural substances are potent toxins with adverse and, in some cases, lethal effects. Clinical evaluation of human poisoning caused by this type of toxin is sometimes complicated by questionable identification of the plant or animal species of origin and the inability to quantify the patient's level of exposure.

Sea products

A variety of toxins are produced either by edible organisms (fish, shellfish) themselves or the sea plankton or algae that are ingested by the fish or shellfish. Consequently, these toxins can be classified as shellfish toxins (saxitoxins, gonyautoxins, okadaic acid, brevetoxins, domoic acids, and azaspiracid) and fish toxins (tetrodotoxin and ciguatoxin). The most common diseases caused by marine toxins in order of incidence are scombrotoxic fish poisoning, ciguatera poisoning, paralytic shellfish poisoning, neurotoxic shellfish poisoning, and amnesic shellfish poisoning.

Table 2 summarizes the sources of various natural toxins, as well as the sea organisms containing those toxins, their location, symptoms, and the toxic mechanisms involved in their toxicity.

Higher plants

Plant-based food products constitute an important source of nutrients and also a number of bioactive compounds whose effects may be considered as positive, negative, or both. Some of these substances have been considered to be endogenous plant toxins and/or antinutritional factors due to their adverse physiological effects on the humans or animals who frequently consume these foods. Nevertheless, their effects are generally reduced after the foods containing such compounds are adequately processed.

Nevertheless, a number of plants are potentially toxic because they contain cyanogenic glycosides from which HCN may be released by hydrolysis. Certain varieties of lima beans, bitter almonds, peach seeds, apricot, plum and cherry stones, cassava, and sorghum are among plants that produce large amounts of cyanide.

Furthermore, some legume species contain certain amino acids that can be associated with several diseases. Among them are human lathyrism (neurolathyrism and osteolathyrism), which has been associated with the presence of some amino acids in several species of *Lathyrus*, such as *L. sativus*.

Vicine and convicine are glucosides of divicine and isouramil (pyrimidine derivatives) that occur in *Vicia faba*. Their consumption by sensitive individuals, mainly in the form of fresh or dried beans, could lead to a disease known as favism. This disease is characterized by hemolytic anemia in people who are genetically deficient in the enzyme glucose-6-phosphate dehydrogenase.

Alkaloids (from the pyrrolizidine group, solanine group, or xanthine group) are present in different plants, such as solanine in potatoes (*Solanum tuberosum*), and they have mutagenic, carcinogenic, neurotoxic, and cardiotoxic effects in addition to inhibiting cholinesterase.

The term *antinutritional factor* means that a substance interferes with the bioavailability of nutrients, resulting in various activities such as inhibition of growth; a goitrogenic response; or damage to certain tissues, such as pancreas or

Table 2 Toxins in sea products (shellfish and fish), endogenous plant toxins, and antinutrients

Food toxins from the sea	*Toxins*	*Sources of toxins*	*Toxic mechanisms*	*Symptoms*
Shellfish toxins				
Paralytic shellfish poisoning (PSP) (shellfish)	Saxitoxins, gonyautoxins Occurrence: worldwide	*Alexandrium* spp., *Gymnodinium* spp.	Voltage-gated sodium channel I	Tingling of perioral area, gastrointestinal problems, numbness of extremities, disturbed muscle coordination, respiratory distress, paralysis
Diarrheic shellfish poisoning (DSP) (shellfish)	Okadaic acid Occurrence: worldwide	*Dinophysis* spp.	Inhibition of protein synthesis and phosphatases; tumor-promoting effects	Nausea, vomiting, diarrhea, and abdominal pain (30 min to several hours after ingestion)
Neurotoxic shellfish poisoning (NSP) (shellfish)	Brevetoxins Occurrence: USA, Caribbean, New Zealand	*Karenia brevis*, *Chattonella marina*, *Chattonella antiqua*	Neurotoxin acting via voltage-gated sodium channel 5	Nausea, numbness of perioral area, paresthesia, disturbed motor control, severe muscular pain
Amnesic shellfish poisoning (ASP) (shellfish)	Domoic acids Occurrence: North America, Europe	*Pseudo-nitzschia* spp.	Activation of the kainite glutamate receptor	Severe headache, loss of short-term memory, can be fatal
Azaspiracid shellfish poisoning (AZP) (shellfish)	Azaspiracids Occurrence: Europe	*Protoperidinium crassipes*	Voltage-gated calcium channel	Nausea, vomiting, severe diarrhea, and stomach pain
Fish toxins				
Puffer fish (*Takifugu niphobles*) Blue ring octopus (*Hapalochlaena*)	Tetrodotoxin Occurrence: Japan, South Pacific		Specific blocker of sodium channels	Paresthesia in mouth, dizziness, headache, muscular paralysis, and collapse
Amberjack (*Seriola spp.*) Moray (*Gymnotorax javanicus*)	Ciguatoxin Occurrence: tropical and subtropical	*Gambierdiscus toxicus*	Voltage-gated sodium channel 5, voltage-gated calcium channel	Gastrointestinal, neurological, cardiovascular, and general symptoms

(*Continued*)

Table 2 (Continued)

Food toxins from the sea	*Toxins*	*Sources of toxins*	*Toxic mechanisms*	*Symptoms*
Barracuda (*Sphyraena spp.*) Mackerel, Tuna, Bluefish, Bonito, Sardines, Anchovies	Scombroid Occurrence: worldwide		Transformation of histidine in histamine	Allergic reaction

Endogenous plant toxicants	*Toxins*	*Plant species*	*Toxic mechanisms*	*Symptoms*
Alkaloids (MS 20)	Pyrrolizidine group	Coltsfoot (*Tussilago farfara*)	Mutagenic, carcinogenic	Ascites, edema
	Solanine group	Potato (*Solanum tuberosum*)	Inhibition cholinesterases	Neurotoxicity
	Xanthine group	Coffee (*Coffea Arabica*)	Neurotoxic, cardiotoxic	Coffee syndrome
Cyanogenic glucosides	Amygdalin, dhurrin, linamarin	Bitter almonds, peach seeds, apricot, plum and cherry stones, cassava, lima bean, sorghum	Toxicity of cyanide (HCN) with high affinity to cytochrome oxidase	Acute: hyperventilation, headache, nausea, coma, death through cytotoxic anoxia Chronic: nerve injuries, konzo
Toxic amino acids	Hypoglycin A	*Blighia sapida*	Bind to coenzyme A, carnitine	Hypoglycemia
	Vicin, convicin	Horsebean (*Vicia faba*)		Favism
	DABA, β-ODAP	Vetch (*Vicia sativa*), grass pea	Decrease glutation in erythrocytes deficient in G6PD Bind to glutamate receptor	Lathyrism
Toxic lipids	Erucic acid	Rapeseed and mustard oils, and other seed oils of *Brassica* spp.	Oxidation of glutamate and inhibition of ATP synthesis in the cardiac mitochondria	Growth retardation, formation of fatty deposits in cardiac muscle
Saponins (MS 610)	Steroidal and triterpenic saponines (Glycyrrhizin)	Soybean, sugar beet, peanuts, spinach, broccoli, alfalfa, apples, potato, licorice	Surfactant activity, decomposing cellular membranes	Nausea, vomiting, diarrhea, dizziness, elevated blood pressure, cardiac arrythmia
Polyvalent antinutrients				
Lectins or hemagglutinins (MS 367)	Proteins, lipoproteins, or glycoproteins (i.e., ricin)	*Ricinus comunis,* Leguminosae Black beans, soybeans, lima beans, kidney beans, peas, lentils	Specifically bind to saccharide groups from cell membranes, affecting nutrient absorption; capable of agglutinating erythrocytes	Inflammation of intestinal mucosa, epithelial destruction, edema and lymphatic tissue hemorrhage
Tannins (MS 683)	Tannins that are hydrolyzable (gallic, digallic, ellagic, tannic acid) Condensed tanins (flavonoids)	Tea, coffee, grapes, wine, cocoa, tropical fruits	Bind proteins, inhibiting digestive enzymes and reducing iron bioavailability	Liver injury, esophageal cancers
Phytic acid (MS 544)		Bran, germ seeds, grains, legumes, nuts	Influence iron, magnesium, zinc, and copper absorption	Symptoms of iron and zinc deficiencies
Gossipol		Cotton seed oil	Interferences with iron and proteins	Toxic to erythrocytes *in vitro*

(*Continued*)

Table 2 (Continued)

Endogenous plant toxicants	*Toxins*	*Plant species*	*Toxic mechanisms*	*Symptoms*
Mineral assimilation				
Glucosinolates (MS 354)	Sinigrin, progoitrin, glycobrassicin after hydrolysis produce isothiocyanate (goitrin), thiocyanate, nitrile	*Brassica* spp. (cabagge, broccoli, brussels sprouts, cauliflowers, radishes)	Thiocyanate inhibits assimilation of iodine by the thyroid gland	Goiter
Oxalic acid	Oxalates	Spinach, tomatoes, tea, beet leaves	Influence calcium, iron, magnesium, and copper absorption	Kidney disease and stones, rheumatoid arthritis, gout
Enzyme inhibitors				
Protease inhibitors	Trypsin (Kunitz inhibitor; Bowman-Birk inhibitor)	Soybeans, beans, peas, beets, cereals	Bind the inhibitor to the enzyme, decreasing the nutritional value of proteins	Growth retardation, pancreatic hypertrophy
Amylase inhibitors	Stable proteins (phaseolamin)	Beans, wheat, cereals	Delay digestion and absorption of carbohydrates	

liver. However, an antinutritional factor might cause no symptoms if the food containing this factor is consumed at the normal level usually present in a varied diet. Among antinutritional factors present in higher plants are lectins, proteins or glycoproteins that agglutinate in the red blood cells of some blood groups. Some lectins, such as ricin, from *Ricinus communis*, are highly toxic.

Phytic acid and its salts are often considered to be antinutrients because they are capable of binding minerals, proteins, and starch. The adverse effects of phytates are related to decreasing mineral bioavailability. In addition, oxalic acid decreases calcium absorption in monogastric animals, and it influences the absorption of other minerals.

Enzyme inhibitors

Other types of antinutrients are enzyme inhibitors and some phenolic compounds that can reduce protein digestibility and mineral bioavailability, or interfere with the reproductive performance of experimental animals.

Table 2 shows a detailed list of toxins and antinutrients found in higher plants, indicating some of their characteristics and adverse effects, as well as their occurrence in plants.

Higher mushrooms

Worldwide, hundreds of mushroom poisonings are fatal each year. Toxins from higher mushrooms are typically classified according to the incubation period: short or long. A mushroom with a long incubation period is normally more dangerous than one with a shorter incubation period. Among mushrooms with long incubation periods are cyclopeptidic (*Amanita phalloides*), which causes the most fatalities, orellanic (*Cortinarius* spp.), and gyromitric (*Gyromitra* spp.); the syndromes produced by these mushrooms are the most important. The mushroom *Amanita phaloides* produces hepatotoxic cyclopeptides (amatoxins, phallotoxins) whose effects are to block the synthesis of mRNA and to inhibit RNA polymerase II. *Cortinarius orellanus* is a nephrotoxic mushroom that generates two types of toxins, called orellanines and cortinarines. Their main symptoms are nausea, paresthesia, anorexia, gastrointestinal disorders, headache, and renal insufficiency. The mushrooms *Gyromitra esculenta* and *Gyromitra giga* contain gyromitrin (methylethylhydrazine). After hydrolysis in the stomach, this toxin is converted into monomethylhydrazine (MMH). At first, MMH elicits intermittent gastrospasms and weakness, and, later, hepatic insufficiency and hemolysis that can lead to death.

Mushrooms with short incubation periods produce various types of symptoms, such as:

- *gastrointestinal* (incubation time: 1–6 h) due to mushrooms from genus *Entoloma*, *Omphalutus*, *Lactarius*, and *Boletus*, which produce toxins such as illudins, vinyl glycine, and bolesatine that cause vomiting, profuse diarrhea, and abdominal pain after ingestion.
- *inebriating* (30 min–2 h) due to *Amanita muscaria* or *Amanita pantherina*, which produce isoxazols, such as ibotenic acid and muscimol, that have toxic effects such as ataxia, excitotoxicity, and brain lesions.
- *cholinergic* (30 min–2 h) produced by the toxin muscarine present in mushrooms from the genus *Inocybe* or *Clitocybe*, which causes blurred vision, hypersalivation, lacrimation, and bronchial secretions.
- *hemolytic* (3–4 h) caused by repeated ingestion of *Paxillus involutus*, which may produce immunohemolytic anemia, with vomiting, diarrhea, abdominal pain, and decreased blood volume.
- *hallucinogenic* (30 min–1 h) caused by mushrooms from the genus *Psylocibe*, which produce psilocybin and its metabolite psilocin that creates visual and mental hallucinations, changes in perception, euphoria, and panic attacks.

- *coprinic* (10–30 min) generated by the toxin called coprine, which exists in mushrooms called *Coprinus atramentarius*. It is toxic only in the presence of ethanol because of the inhibition of ethanol in the metabolism. The symptoms are facial reddening, nausea, vomiting, malaise, agitation, and palpitations.

Miscellaneous

Biogenic amines are found in a wide range of foods, both animal- and plant-based foods. Serotonin, tyramine, dopamine, and norepinephrine are natural components of fruits and vegetables, such as bananas, tomatoes, avocados, potatoes, oranges, and spinach. In addition, much larger amounts of amines, mainly tyramine, are found in fermented foods such as aged cheeses. Usually, the presence of such amines in the diet has little effect on blood pressure because the amines are rapidly metabolically converted by monoamine oxidases (MAOs) and diamine oxidase, except in people who take drugs containing MAO inhibitors.

Avidin is an egg white protein that binds to biotin, resulting in the avidin-biotin complex, which is resistant to digestive enzymes, thus inhibiting the absorption of this vitamin by the intestine. This adverse effect may cause problems of biotin deficiency when large amounts of uncooked eggs are ingested. Cooking eggs denatures avidin, so its capacity to bind biotin is lost.

Thiaminase is an enzyme, found in raw fish, which splits the vitamin thiamin (B1) into two rings. Also, in plants, there are some phenolic compounds, such as tannins, that destroy thiamin.

Vitamins are bioactive substances that are necessary in small amounts. The ingestion of too much of a vitamin could result in hypervitaminoses, especially in the case of vitamin A. A continuous consumption of high doses of vitamin A can produce symptoms such as loss of appetite, tiredness, dermatitis, headache, and muscular and bone pain.

Chemical Pollutants

Inorganic substances

Most inorganic substances occur in nature in rocks, minerals, soil, water, and air, but, today, many of these substances can be readily found because anthropogenic activities have increased our environmental exposure to chemical elements, such as arsenic, which for centuries has been used as a poison; or heavy metals, such as cadmium, lead, mercury, and others. All of them are also present (at increasing levels) in food products such as fish, shellfish, vegetables, and edible mushrooms, with subsequent concern for food safety. These chemicals enter into the food chain from different sources. Some of them are geochemical pollutants that plants absorb from soil, while others are environmental pollutants that can be found in food because of carelessness in industrial and other activities carried out by humans. Table 3 compiles some of the most important inorganic elements, the foods in which they frequently appear, and their most remarkable effects. The toxic effects are due to different mechanisms, and they depend on the type of ingestion (acute or chronic).

Organic substances

In food, two types of organic substances with toxicological incidences can be found:

- Environmental pollutants, the most important of which are called *persistent organic pollutants* (dioxins, dibenzofurans, and polychlorinated biphenyls), are the unwanted by-products of industrial processes and waste incineration that accumulate in the environment and human body.

Table 3 Chemical pollutants

Inorganic substances	*Chemical species*	*Presence in food*	*Toxic effects*
No metals			
Arsenic (As) (MS 42–43)	As(III) more toxic than As(V)	Seafood, fish, meat, water	Acute: Diarrhea, abdominal cramps, nausea, vomiting, alteration of the cardiovascular system and central nervous system (CNS) Chronic: Carcinogen
Fluorine (F)	Fluorides (F^-)	Sodium chloride, sea fish, tea, water	Acute: Severe corrosive effect Chronic: Fluorosis of teeth
Radionuclides (MS 584)	Sr-90; I-131	Enter into food chain from water, plants, and animals after exposure in contaminated areas	Sr-90: Bone cancer, leukemia I-131: Damage to the thyroid gland
Heavy metals			
Lead (Pb) (MS 416–417)	Pb^{2+}	Water, food crops, pastures, meat, milk, fish, shellfish	Degenerative effects on nervous system, digestive tract, hematopoiesis system
Mercury (Hg) (MS 456–457)	Inorganic (Hg^+, Hg^{+2}, Hg^0) Organic (R-Hg^+, R-Hg-R')	Seafood (predatory species: shark, swordfish)	Necrotic damage in cells' renal tubules, disorders of the CNS, teratogen, brain atrophy
Cadmium (Cd) (MS 96–97)	Cd^{2+}	Food crops, cereals, tubers, rice, fish, shellfish	Osteomalacia, hypertonia, infertility, chronic pulmonary and renal insufficiency, carcinogen
Chromium (Cr) (MS 161–162)	Cr(II), Cr(III); Cr(VI) more toxic	Processed lean meat, full-grain products, cheese, brewer's yeast, legumes, spices	In high doses: Carcinogen and teratogen

(*Continued*)

Table 3 (Continued)

Organic substances	*Toxicant*	*Presence in food*	*Toxic effects*
Environmental pollutants			
Organochlorine compounds	Dioxins (TCDD), polychlorinated dibenzofurans (PCDF), chlorinated biphenyls (PCB), and brominated biphenyls (PBB)	From soil, plants, and water to food animals and fish (chicken, pork, salmon) and animal feed	Liver lesions, adrenal atrophy, kidney abnormalities, chloracne, carcinogen, adverse reproductive effects
Substances intentionally added to food			
Pesticide residues MS 534–535	Organochlorinated (OC; family of DDT, lindane, and cyclodienes) Organophosphates (OP) Carbamates Pyrethroids	Plant, fruits, water	Neurotoxic OC: Disruption of nerve impulse transmission by interfering with Ca^{2+} and Cl^{-} concentrations OP and carbamates are inhibitors of acetylcholinesterase Pyrethroids bind voltage-gated sodium channels
Veterinary drugs and feed additives	Adrenoceptor agonist (clenbuterol) Anthelmintic agent (closantel, ivermectin) Antimicrobial agent (antibiotics) Antiprotozoal agent (diclazuril, imidocarb) Beta-adrenoreceptor-blocking agent (carazolol) Glucocorticosteroid (dexamethasone) Growth promoter (trenbolone acetate, zeranol) Insecticide (cypermethrin, deltamethrin, trichlorfon) Production aid (abamectin, melengestrol, estradiol 17 β) Tranquilizing agent (azaperone) Trypanocide (isometamidium)	Milk, muscle, fat, skin, liver, kidney meat (pigs, sheep, cattle, rabbits, goats, chickens, turkeys, other poultry); regulated by the Maximum Residue Limits (MRL)	Direct toxic effects Immunologic effects Mutagen, carcinogen, teratogen Effects on intestinal biota (antibiotics) Endocrine disruption (production aid, growth promoters)

Inorganic and organic substances.

These compounds are highly toxic and can cause reproductive and developmental problems, can damage the immune system, and can interfere with hormones to cause cancer.

- Organic compounds intentionally added to food during food production are substances such as pesticides and veterinary drugs. They are found worldwide in the environment and accumulate in animal food chains. Their presence in food is regulated by Maximum Residue Limits (MRLs). Countries throughout the world have their own versions of MRLs.

Table 3 lists the foods that can contain these organic toxins as well as their toxic effects.

Food Additives

Food additives are substances intentionally added to food to perform specific functions, such as preservatives, bleaching agents, antioxidants, sweeteners, coloring agents, and flavoring agents, among others. Food additives are one of the most studied classes of compounds regarding their toxicity. Food additives can be classified according to their sources, such as from substances that are isolated from edible plants or from living material, substances that naturally occur in foodstuffs but are obtained by chemical synthesis, and substances that are not found in nature. In Europe, every additive has an E-number, and each is classified according to its function in food. As with any other substance used for food production, the toxicity of the additives must be assessed by different toxicological tests. In addition, some substances have to be revised, and, in some cases, they have been removed from the authorized list of additives. The most interesting additives from a toxicological point of view are preservatives, antioxidants, sweeteners, coloring agents, flavoring agents, and flavor enhancers (Table 4).

Toxic Substances Formed During Food Processing, Preparation, Storage and Intake

A variety of chemicals is formed during the food production process or during cooking. A large group of substances is generated in food products after high temperatures are applied during processing or cooking, or after heat is combined with several acid treatments (chloropropanols). Other toxic substances come into contact with food during the packaging process, such as phthalates or bisphenol A in plastics. Table 4 summarizes these kinds of substances. In this group, several toxic compounds can be formed in the human body after the

Table 4 Food additives and toxicants formed during food processing, preparation, storage, packaging, and intake

Additive group	*Substance*	*Use in food*	*Effects*
Preservatives	Benzoic acid; sodium benzoate (E 211)	Acidic foods such as salad dressings, carbonated drinks, jams, and fruit juices	Weight loss, diarrhea, internal bleeding (mice)
	Nitrite and nitrate	Meat, meat products	Methemoglobinemia, carcinogens, nitrosamine precursors
Antioxidants	Propyl gallate (E 310)	Used to retard or prevent rancidity in lard, edible fats, and oils	Estrogen antagonist; respiratory distress in asthmatics
	Butylated hydroxytoluene (BHT) (E 321)	Used to retard or prevent rancidity in lard, edible fats, and oils	Asthma, eczemas
	Butylated hydroxyanisol (BHA)	Commercial stabilizers (antioxidants) for food fortification or animal feeds	Metabolic inductor with increasing risk of mutagen formation
Sweeteners	Saccharin (E-954)	Sweetener most commonly used	Carcinogen: contradictory results
	Sodium cyclamate (E 952)	Sweetener, diet drinks, gums, dressings	After metabolization produces cyclohexylamine, carcinogenic; its use has been partially rehabilitated
	Aspartame	Diet products (soft drinks, jams, cereals)	Metabolized to Phe, Asp, and methanol; increased risk for phenylketonurics
Coloring agents	Amaranth (E-123)	Soft drinks, ice creams, salad dressings	Allergic reactions
	Tartrazine (E-102)	Cakes, deserts, cheese, liquors	Allergic and intolerance reactions, migraines, blurred vision
Flavoring agents	Methyl anthranilate	Used to imitate Concord grape flavor	Allergenic
	Diacetyl (2,3-butane dione)	Used for artificial butter flavoring in margarines or similar oil-based products	Bronchiolitis obliterans, a severe respiratory illness
Flavor enhancers	Monosodium glutamate	Used to supply meat-like flavor	Headache, drowsiness

	Production/origin	*Substances*	*Food*	*Effects*
Formed with high temperatures				
Polycyclic aromatic hydrocarbons (PAH) (MS 550)	Combustion products come into direct contact with food	Benzo(a)pyrene	Smoked and grilled meat	Carcinogenic
Heterocyclic aromatic amines (HAAs) (MS 377)	Generated in the crust of meat products as a result of heat treatment	Imidazoquinolin (IQ) and derivatives MeIQx, DiMeIQx, and Phe-P-1	Meat and fish cooked at temperatures higher than 150°C	Carcinogenic
Acrolein	Intermediate of production of acrylamide	$CH_2=CHCHO$	Foods with carbohydrates, vegetable oils, animal fats, and amino acids	Carcinogenic
Acrylamide (MS 5)	Reaction of asparagine with reducing sugars	$CH_2=CHCONH_2$	Bread, cookies, crackers, cereals, coffee	Carcinogenic
Furan	After heat treatment of certain foods		Brewed coffee, cereals, chili, salty snacks, soups containing meats	Possible carcinogen
Chloropropanols	Formed during production of hydrolyzed vegetable proteins (hydrochloric acid treatment at high temperatures)	3-chloropropane-1,2-diol (3-MCPD) 1,3-dichloropropanol (1,3-DCP)	Soups, gravy mixes, stock cubes, savory snacks, soy sauce	Carcinogenic
Packaging process				
Phthalates	Used in plastics with a wide range of applications	Di-n-butyl phthalate (DBP) Diethyl phthalate (DEP) Benzyl butyl phthalate (BBP)	Fatty foods (dairy, fish, meat, oils)	Endocrine disruptor affecting human sex hormone production
Bisphenol A	Polycarbonate and epoxy resins used in heating containers for foods, metal cans		Drinking water, leaches from plastic food and beverage containers, human breast milk	Endocrine disruptor affecting hormone production, mimicks estrogens
Semicarbazide	Formed by heating azodicarbonamide used as a foaming agent in plastic seals and food packaging materials		Food sold in glass jars, baby foods	Weakly carcinogenic

intake of several foods containing substances such as nitrites used as food additives (nitrocompounds such as nitrosamines and nitrosamides are considered to be potent carcinogens after metabolic activation).

Conclusions

Throughout history, people have identified a large number of potentially dangerous components present in food, ranging from substances with high acute toxicities to those with low acute toxicities but chronic adverse effects after continuous intake in the diet. Consequently, we need to classify all substances, of both natural and synthetic origin, in order to understand all the possible adverse effects that they produce after being ingested. The knowledge of their presence in food and the effects that they produce on the human body is the key to adequate food safety and healthy nutrition.

Food Poisoning: Epidemiology

CR Gibert, Public Health Agency, Barcelona, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The World Health Organization defines a foodborne disease as "any disease of a toxic or infectious nature caused by consumption of contaminated water or food." Despite certain shades of meaning, the terms 'foodborne disease' and 'food poisoning' are frequently considered as equivalent.

Foodborne diseases are caused by a wide variety of pathogenic microorganisms, which enter into contact with humans through ingestion of food, and may be bacteria, viruses, protozoa, or prions. Different toxins must also be included as causal agents: natural toxins, such as poisonous plants or mushrooms; poisons incorporated into foods in their production, such as pesticides and heavy metals; or biological toxins produced in the food itself, such as *Staphylococcus aureus* toxin.

Food may become contaminated at various points between production, processing, and preparation, by a variety of mechanisms:

- Foods which are a primary source of microorganisms. For example, microorganisms present in the raw meat of some animals may persist if appropriate hygiene and heat treatment measures are not taken, or for example, the presence of *Salmonella* in eggs may be due to either internal contamination in the hen's ovary or to contamination of the shell by the bird's own feces.
- Foods contaminated by the water they grow in or are irrigated with. For example, fish and shellfish may be contaminated if they lived in contaminated waters, while fruit, vegetables, and cereals may become contaminated through irrigation with untreated water.
- Foods contaminated by processing techniques involving poor hygiene practices. For example, using contaminated equipment to process milk.
- Foods contaminated due to insufficient heat treatment. For example, the temperature of pasteurization eliminates the majority of vegetative forms of *Clostridium* spp., but not the spore forms.
- Foods contaminated through inappropriate manipulation after heat treatment, whether directly from workers' hands or through cross contamination between hands, equipment, or surfaces that are contaminated, or through defective conservation measures.

Foodborne diseases are common and do not usually result in severe illness, however they may produce considerable morbidity and mortality, and consequently social alarm, as happened in Germany in 2011 when there was an outbreak of more than 3800 cases of gastroenteritis caused by a Shiga toxin-producing *Escherichia coli* (O104:H4), with more than 20% of cases subsequently presenting hemolytic–uremic syndrome, followed by death in approximately 4.5% of cases.

The most common clinical presentation of these diseases is gastrointestinal symptoms (diarrhea, abdominal pain, vomiting), although they may also present extraintestinal symptoms such as neurological or systemic conditions. The severity of this entity may range anywhere between an asymptomatic or slight affectation not requiring medical care, to illness requiring hospitalization, and to death.

In general, the intensity of the clinical presentation of a foodborne illness is directly related to the concentration of microorganism or toxin present in the ingested food. The minimum microorganism concentration necessary to produce infection (minimum infective dose) may vary between 10 and 100 cells in the case of *Shigella* or *Campylobacter*, to as many as 10^5–10^6 cells in the case of *Salmonella enterica*. Even so, not all exposed individuals manifest symptoms, nor do the symptoms present with the same intensity. The infective dose may be affected by individual factors such as age, nutritional status, immunological status, the presence of underlying diseases, or by factors related to the microorganism such as virulence or its adaptation to the medium.

These diseases can present severe complications such as hemolytic–uremic syndrome from infection by *E. coli* O157:H7, Guillain–Barré syndrome, which appears following infection by *Campylobacter jejuni*, or reactive arthritis following an episode of salmonellosis. The clinical manifestations considered together with incubation period and duration of the illness are normally indicative of the agent involved, and information about these diseases may be found in other chapters of this encyclopedia.

An outbreak of a foodborne disease is considered to occur when symptoms affect two or more people who ate food or a meal at the same time and place. For certain diseases, however (e.g., botulism or gastroenteritis due to *E. coli* O157:H7), a single case is sufficient to launch an investigation and initiate the corresponding prevention and control measures.

Epidemiological Surveillance

Epidemiological surveillance of foodborne diseases is defined as the systematic collection, analysis and interpretation of information, which permits planning, execution and evaluation of the pertinent prevention and control activities.

Foodborne disease surveillance is not well-standardized globally, and it is executed using a variety of information sources, such as mandatory notification, outbreak investigations, microbiological notification, sentinel surveillance, hospital discharge, diagnosis registries, and death registries. Quality of surveillance data varies widely by information system, and care must be exercised in drawing conclusions based on comparisons between them.

Foodborne diseases are often under-reported:

- The majority of people with symptoms of acute gastroenteritis rarely seek medical care;

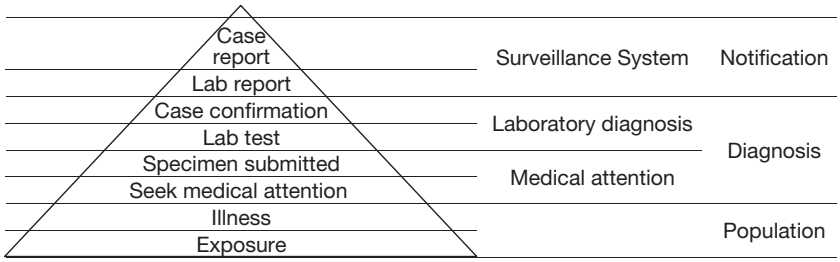

Figure 1 Foodborne disease information system. Adapted from CDC, www.cdc.gov.

- In many cases the physician does not request collection and analysis of biological samples;
- In some cases the laboratory receiving samples is unable to reach a diagnosis;
- It can be very difficult to connect separate patients of foodborne illness whose cases have sought medical care separately;
- The appropriate surveillance institution is not notified of the case.

As Figure 1 shows, information can get lost at different levels in the information system.

Knowledge about foodborne diseases is continually advancing, both in regard to identification of causal agents or vehicles of transmission, as well as in regard to prevention and control measures; hence the epidemiology of these diseases is not static, but rather constantly changing. In this sense, new challenges must be faced: emergence of new pathogens, or reemergence of known pathogens, the appearance of resistance to antibiotics, growth of population nuclei for which food supply demands must be met, population changes leading to a rise in numbers of vulnerable persons, changes in eating habits, changes in food production, or the increasing of international trade of food products.

Changes in Causal Agents

In the developed world, certain diseases common in the early twentieth century such as typhoid fever, cholera, brucellosis, or trichinosis, have now been controlled thanks, for example, to strategies of disinfection of water for human consumption, wastewater treatment, processes of food sterilization and pasteurization, or veterinary controls in livestock. These are now diseases which are documented sporadically and primarily in travelers to developing countries or to areas with poor hygiene conditions.

In recent decades, new pathogens, or new routes of transmission of known pathogens via food, have been identified. In these cases, questions always arise which must be answered by research, whether clinical (diagnostic criteria, clinical spectrum, treatments, complications, sequelae); microbiological (available diagnostic media); epidemiological (population incidence and/or prevalence, transmission routes, incubation periods, risk factors); or research related to prevention and control measures necessary (types of contaminated food, impact of food processing). For example, in the last 30 years, *E. coli* O157:H7 and the Norwalk virus have been identified as pathogens producing foodborne diseases.

Also, new variants of known microorganisms have spread over large geographical areas. This was the case with *Salmonella typhimurium* DT104, which first appeared in the 1990s among cattle in Europe and the United States but not Australia; and also the case with *Yersinia enterocolitica* serogroups O3 and O9, which was related to pork consumption and appeared in Europe and Japan in the 1970s and in the United States in the 1980s; or the case with *Vibrio parahaemolyticus* O3:K6 which appeared in Southeast Asia in the 1990s related to consumption of raw oysters, and which subsequently spread to the United States.

There has also been the appearance of resistance to antibiotics in known microorganisms, whether due to overuse of antibiotics by humans, in the case of those for which humans are the main reservoir (e.g., *Shigella* and *Salmonella typhi*), or through use of antibiotics in agriculture, in the case of those for which animals are the reservoir (quinolone-resistant *Campylobacter jejuni* or ceftriaxone-resistant *Salmonella*). All these have spread over large geographical areas in only a few years. For example, the highly resistant strain of *Salmonella* Newport (resistant to nine antibiotics) first appeared at a local level in the United States in 1999, and 3 years later, had spread nationwide. Another example is the outbreak of infection by *Salmonella* Heidelberg (resistant to four antibiotics) which was responsible for 136 cases in 34 states of the United States in 2011, ground turkey meat identified as the vehicle. Since resistance to antibiotics complicates treatment of microbe-vectored disease, prudent use of antibiotics, in both humans and animals is an urgent public health priority.

Recently, certain pathogens which act opportunistically have been identified as causing severe illness in vulnerable population groups (immunocompromised persons, the elderly, children), but which may be asymptomatic or cause only mild episodes of gastroenteritis in the healthy population. This is the case with *Vibrio vulfinicus*, which causes severe bacteraemia or necrotizing fasciitis in patients with alterations of hepatic function or iron overload, but rarely causes infection in healthy individuals.

Changes in the Population

In the last few decades, changes in population demographics and mobility have occurred which have affected the risk of contracting a foodborne disease. Population aging has led to a rise in numbers of people with more underlying diseases, with weakened immunological systems, with lower absorption of nutrients and higher levels of hospitalization and medical

treatment, who, consequently, are more susceptible to these types of infections. Due to advances in modern medicine, increased survival among persons with immunodeficiency, chronic diseases, or under aggressive treatments has also led to an increase in the numbers of people more susceptible to certain types of infections, including foodborne diseases. On the other hand, high population mobility, whether due to migratory processes, or to occupational, social, religious, or leisure-related activities, means that travelers are exposed to pathogens different from those of their country of origin, and that they may even transport pathogenic microorganisms to other countries.

Changes in people's eating patterns have also led to the emergence of new risks. The wide availability now of typical foods and traditional home-made dishes as store-bought products, and the new market of food imported from foreign countries, either as primary produce or as prepared dishes, has led to an increase in the variety of available foods. At the same time, this has meant an increase in the variety of pathogens which may affect the population. Hence, whereas at the beginning of the twentieth century it was extremely difficult to find, for example, a European who had tasted some product from Japan, such as sushi, now a century later it is difficult to find a European who has not tasted it.

Changes in Food Production

As a result of changes in the food industry, both foods and pathogens, have ceased to be local, spreading beyond country boundaries. In the past, foodborne disease outbreaks were processes which affected a limited number of people who had consumed some particular food together in the same meal and who approached the local medical services within a short period of time. Thus, it was a local process in which a common cause was easily identified. Nowadays, a food product may contain ingredients from very different geographical locations, and may be distributed widely around the world, making more difficult not only the investigation of a foodborne disease outbreak, but even identification of the outbreak. One of the first examples in modern times was that of the infection by *Cyclospora cayetanensis* detected in the United States and Canada due to consumption of food products which contained raspberries from Guatemala. A paradigmatic example is that of the use of herbs and spices. These are produced at a local level, commercialized worldwide, and are used as ingredients in many food products. Hence, their contamination can lead to foodborne disease outbreaks resulting from seasoning foods with contaminated lots of herbs or spices. Studies have been published relating these ingredients to different causal agents. For example, in 2007, fresh basil contaminated with *Salmonella* Senftenberg affected 51 people in the United Kingdom, Denmark, the Netherlands, and the United States; in 2009 and 2010, red and black pepper contaminated with *Salmonella* Montevideo affected 272 people from 44 different states in the United States.

New practices in livestock feeding have also been related to increased prevalence of diseases in humans. This was the case of bovine spongiform encephalopathy. Animals given feed enriched with meat and bone from other animals was presumed to have caused, from 1986 onward, an epidemic of bovine spongiform encephalopathy which affected approximately 178 000 animals in the United Kingdom and which, in 1996, was detected in humans as new variant Creutzfeldt–Jakob disease.

New population trends in the consumption of 'ecological' foods have led to a rise in the production of foods for which 'natural' fertilizers are used instead of chemical products, or untreated water, or even waste waters. These natural fertilizers are used to irrigate fruit, vegetables, and other green crops. These practices have contributed to an increase in the risk of contamination of these food products by pathogens, as was the case in a huge outbreak of infection by *E. coli* O157:H7 in 1996 that affected more than 9000 schoolchildren in Osaka, Japan, due to ingestion of white radish sprouts. Moreover, an increase in the consumption of fresh fruit and vegetables and changes in their processing have also led to an increase in outbreaks involving these types of foods.

New food handling techniques, whether in regard to processing, packaging, transportation, storage, or refrigeration, permit the supply of foods over large distances and over longer periods, although they do not completely eliminate the risk of containing pathogenic agents. For example, there have been reports of salmonellosis outbreaks related with prepared foods which only needed a final cooking in a microwave- or conventional oven, but where, in practice, this was not done sufficiently or completely. There are also reports of geographically extensive outbreaks related with improperly processed canned food contaminated by spores of *Clostridium botulinum*.

Epidemiology of Foodborne Disease

Worldwide, foodborne diseases are the cause of considerable morbidity and mortality. In the developed countries, they are considered an ever-growing public health problem, while in developing countries or war zones where food supply is a problem, foodborne diseases constitute one of the most critical public health problems.

National and international studies are attempting to estimate both incidence and patterns of foodborne diseases, yet there are still few good global estimates. These attempts to estimate incidence and patterns of foodborne diseases are frustrated by several factors. These diseases are clearly underreported, and those countries which perform surveillance of them use different information systems, making comparisons difficult. Also, the causes underlying foodborne illness vary widely with the geographical area under study, and surveillance is not always directed at the same causal agents. Moreover, the foods involved in transmission of infections are not the same in different geographical areas, nor are they processed and handled in the same way.

Country-level studies have been published which aimed to determine foodborne disease patterns. These studies do not use identical methodologies, thus, prudence must be exercised in comparing their findings. In Europe, data collected by the WHO Food Safety Department over the period from 1998 to 2001 suggest that infection by non-typhoidal *Salmonella* spp. is one of the most common foodborne infectious agents, with incidences ranging from 6.2 to 137 cases per 100 000 persons. Infection by *Campylobacter* spp. is another very common agent,

with incidences between 30 and 96.3 cases per 100 000 persons. Other bacterial infections present lower incidences: *Shigella*, between 0.9 and 7 cases per 100 000 persons; *E. coli* non-VTEC (verotoxin-producing *E. coli*) and *Clostridium botulinum* under 2 cases per 100 000 persons. Trends for both *Salmonella* spp. and *Campylobacter* spp. have continually risen over the last two decades.

It has been estimated that during the period 1996–2000 in the United Kingdom 1 724 315 cases of foodborne diseases occurred every year, with 21 997 hospital admissions and 687 deaths. Salmonellosis and infection by *Campylobacter* were the most common causes.

A study conducted in the United States during the period 2000–2008 estimated that every year, 31 major pathogens are responsible for 9.4 million cases of foodborne diseases, 55 961 hospital admissions, and 1351 deaths. The majority are caused by Norovirus (58%), non-typhoidal *Salmonella* spp. (11%), *Clostridium perfringens* (10%) and *Campylobacter* spp. (9%).

In Australia, a study conducted around 2002 estimated that a total of 5.4 million cases of foodborne diseases occurred every year, with an associated 3640 hospital admissions and 76 deaths.

New Challenges

Changes in the population and in different aspects of food production and consumption impose new challenges not only for foodborne diseases surveillance and research, but also for the prevention and control measures needed.

Thus, whereas in the past foodborne disease outbreaks were acute processes with high attack rates affecting population groups at a local level and related to events involving manipulation of food near the point of consumption, nowadays, geographically widespread outbreaks are becoming more common, involving low levels of contamination of foods that are widely distributed. In such cases, the outbreak may be detected through an unusual concentration of cases, by detection of some unusual pathogenic agent or through laboratory identification of some specific subtype.

In these new scenarios, the information systems necessary for epidemiological surveillance of these diseases must be more sophisticated in order to cope with such challenges. Various international initiatives have been developed with the goal of determining the pattern of these diseases at regional level: (1) The WHO Global Salm-Surv is an international program launched in 2000 which potentiates surveillance based on laboratory diagnoses, with the participation of various institutions in France, Denmark, and the Netherlands, as well as the United States, Canada, and Australia. (2) The WHO Sentinel Sites Project aims to assess patterns of foodborne diseases based on the setting up of various types of sentinel surveillance.

As examples of national-level networks, Enter-Net in the European Union is a surveillance network for two types of human intestinal infections (*Salmonella* and *E. coli* VTEC); FoodNet in the United States is a sentinel surveillance network for a specific list of foodborne pathogens; PulseNet (also in the United States) is a national network for molecular subtyping of pathogenic strains; and OzFoodNet (in Australia) is a national network for foodborne disease surveillance.

The more scattered presentation of foodborne disease implies a need to identify apparently sporadic cases that appear in more than one territory, as the result of contamination of foods which are widely distributed. In cases in which outbreaks may transcend local, or even national boundaries, it is necessary to develop public health strategies which include analysis of epidemiological data at regional, national, and international levels, the routine identification of microorganisms causing an outbreak by molecular epidemiology, and improvements in the communication of information between different epidemiological teams. Thus, more robust collaboration at local, regional, national, and international levels between experts in epidemiology, microbiology, and food safety may be the key to success in the investigation of a foodborne disease outbreak.

Identification of new pathogens, or of new transmission routes of known pathogens, represents a new challenge for surveillance systems. Both formal and informal surveillance strategies must be developed to permit early detection, and appropriate epidemiological research techniques must be developed in order to respond to questions that arise with the principle aim of establishing the corresponding prevention and control measures. Achievement of such responses will require considerable effort and dedication on the part of epidemiological surveillance teams.

Despite all these changes, the methodology of investigating a foodborne disease outbreak is not substantially different, although nowadays it must be more multidisciplinary, requiring participation of clinicians, epidemiologists, laboratory personnel, as well as experts in food safety, risk management, and communication. The process of investigating a foodborne disease outbreak represents a unique opportunity for obtaining information, especially when faced with diseases caused by new pathogens, or new transmission routes of known pathogens. Such investigations may contribute different types of information, depending on the population affected by the outbreak, from data on clinical affectation of patients, through to information about food production processes. Furthermore, basic surveillance data can provide more detailed information about affected cases.

Epidemiological study of the food-related origin of isolated gastroenteritis episodes can be considerably more difficult, since it implies identifying the common link between different cases being able to count on a laboratory diagnosis that confirms the common etiology. The growing use of surveillance networks such as Enter-Net in the European Union, PulseNet in the United States or OzFoodNet in Australia permits the identification of outbreaks that go beyond purely local settings. This makes it possible to differentiate sporadic cases from geographically scattered outbreaks.

Similarly, the necessary prevention and control measures must also be more sophisticated than measures applied in the past. Thus, while strategies such as disinfection of water for human consumption, treatment of waste waters, sterilization and pasteurization of foods, routine assessment of food handling practices, and human and animal vaccinations must be continued, it is also necessary to develop prevention and control measures to face new challenges involving the entire food

industry (from primary production to the consumer), contemplating national, or even international, levels of action.

Hazard Analysis Critical Control Point (HACCP) is a strategy which allows the identification, assessment and control of food safety from the start of production through to consumption. HACCP was originally developed in the 1960s by Pillsbury Co., for NASA, to strengthen the safeguards for food safety on manned space flights. When properly implemented, this has been a highly useful tool for the food production industry to monitor the processes. In this sense, inspections of finished food products have given way to the identification, along the entire food production chain, of a series of critical points that may be susceptible to improvement through the implementation of multiple prevention and control measures. This approach can be applied to small-scale production, as well as to large-scale manufacturing. It must, however, be complemented by microbiological analyses of the products, and by the maximum availability of epidemiological information.

Examples where HACCP has played an important role arose in 2000 in the United States and in 2009 in Europe. In the United States, a cluster of infection by *Salmonella enteritidis* was detected via molecular epidemiology, associated to consumption of an orange juice. Subsequently, 88 further cases of infection were detected in a total of eight states. A critical point was identified in the use of an alternative to pasteurization of the juice. As a result, these practices were modified in accordance with federal legislation. In two European countries (Hungary and Italy), local but persistent increases were detected in infections by *Salmonella* Goldcoast, which were eventually found to be related with contamination in the chain of production of pork products.

This article is reproduced from the *Encyclopedia of Food Sciences and Nutrition*, volume 4, pp. 2659–2664, © 2003, Elsevier Science Ltd.

Introduction

Foodborne disease (food poisoning) has been defined by the World Health Organization as "a disease of infectious or toxic nature, caused by, or thought to be caused by, the consumption of food and water." It involves a large (>40) and diverse range of agents, the number of which continues to increase yearly as new agents are identified. Table 1 lists those agents currently considered to be involved in diseases transmitted by foods.

The main sources of many of these organisms are domestic and wild animals (including fish and birds). Enteroviruses, *Salmonella typhi*, and *Vibrio cholerae* are of human origin and *Clostridium botulinum*, *Bacillus* spp., and mycotoxigenic molds are general environmental contaminants.

Food poisoning is usually thought of as acute gastroenteritis (fever, abdominal pain, and diarrhea, often with vomiting) of the type caused by infectious disease-causing bacteria such as *Salmonella enterica* and toxin-forming bacteria such as *Staphylococcus aureus*. However, a number of the newly identified (often called 'emerging') food-poisoning microorganisms cause a wide range of nonintestinal symptoms. For example, *Listeria monocytogenes* causes illness ranging from a mild flulike illness to meningitis and life-threatening infections of the central nervous system. In addition, it has been recognized within the last 20 years that a number of classical gastroenteritis-causing bacteria, such as salmonellae and *Yersinia enterocolitica*, may cause extraintestinal infections as sequelae to intestinal disease; these include reactive arthritis, Reiter's syndrome, ankylosing spondylitis, and pericarditis. The wide range of symptoms caused by foodborne disease-causing agents, many of which mimic illness of a nonfood-poisoning nature, may cause some difficulty in identifying a food cause and establishing the extent of a foodborne disease incident.

This article considers the epidemiology of foodborne diseases, the procedures used for testing foods for the causative agents, tracing the source and cause of a food-poisoning incident, and the recall of contaminated food.

Epidemiology

When considering the sources of foodborne disease-causing microorganisms, it is important to recognize that virtually all raw agricultural products will from time to time be contaminated with low concentrations of such organisms, and as a result of cross-contamination and recontamination, they will also contaminate cooked and other processed food products. Although salmonella are regarded to be zoonotic, and thus of animal origin, they are frequently found in soils and water, and human carriers may be the source. Organisms of human origin, such as the previously mentioned enteroviruses and *Salmonella typhi*, may also contaminate various parts of the food chain, for example, via human carriers contaminating food during preparation for consumption or from human sewage contamination of foods during their growing, such as the contamination of vegetables with night soil or molluscan shellfish harvested from waters contaminated with raw human sewage.

Thus, the original source of an agent causing foodborne disease may be difficult or impossible to establish with any degree of certainty and it may only be possible, and in many cases only appropriate, to identify the circumstances and actual foodstuff that caused a particular food-poisoning incident. In many cases, this will be the result of poor food handling (including preparation in advance for consumption) allowing survival or growth of the pathogen. For example, whereas the main source of the contamination of foods with salmonellae and *Campylobacter* is poultry, provided the poultry is properly cooked, these bacteria will be killed, and if the cooked poultry is then protected from recontamination, they will not cause illness. Thus, while the source of salmonella contamination of cooked poultry is most likely to be the raw poultry, the cause of any salmonellosis arising from its consumption is most likely to be the result of poor hygienic practice during preparation. In this example, identification of the source of the original contamination is much less important than identifying the circumstances that led to the contamination of the cooked poultry. However, where contamination of a raw ready-to-eat food occurs, it is important to identify the source of the contamination to prevent its recurrence.

Further, when considering the cause of a foodborne disease incident, it is important to recognize that such illness is dose-related (the larger the concentration of the organism or the amount of toxin present in a food at the time of consumption, generally, the greater the severity and extent of illness within a group of persons consuming the contaminated food). It is seldom that all persons exposed to an infective or intoxicating dose of a pathogen will show disease symptoms and symptoms will often vary widely in those who are ill. The minimum concentration of an agent necessary to cause illness is frequently referred to as the minimum infective dose (MID). The MID of many food-poisoning bacteria is unknown, but it is generally accepted that the infective dose of classical causative agents of enteric disease, such as *Campylobacter*, *Salmonella typhi*, and *Shigella*, is 10–100 cells, whereas the MID of others such as the food-poisoning salmonella (now all classified as *Salmonella enterica*) is generally regarded to be of the order of 100 000–1 million cells for a healthy adult. However, the infective dose and hence the risk of illness arising from a contaminated food are affected by many factors. Factors that may reduce the infective dose include high virulence of a particular strain, age, health status of the individual exposed to the agent (in particular, immune status), nutritional

deficiencies in diet, and underlying disease. There is much evidence that there are in some food substances that protect infective agents from destruction by stomach acids. Thus, fats in high-fat foods such as full-fat cheeses, chocolates, and salamis may significantly reduce the infective dose of an agent; for instance, the infective dose of salmonellae may be only a few cells (<10) in these foods. Therefore, when considering the significance of a particular concentration of an agent in a food, in relation to it having caused illness, it is important to take these facts into consideration and also to remember that in any food collected after a food-poisoning incident, the numbers of microorganisms may have increased or decreased depending on how that food has been stored subsequent to the incident. With respect to microbial toxins, these are often more persistent in foods than their producing organisms but may increase in amount as the result of the presence of the producing organism or decrease as a result of biologically, chemically, or physically induced breakdown.

Case Histories

Hepatitis A and Frozen Raspberries

Twenty-one persons who consumed a mousse made from frozen raspberries developed jaundice found to be caused by the hepatitis A virus. Investigation of the incident suggested that contamination had occurred during harvesting or packaging of the raspberries. Cases of hepatitis had been reported in the area where the raspberries had been picked and the sanitary conditions in the places where the pickers were housed were found to be poor. Sanitary conditions were improved and basic food hygiene instruction was given to the pickers. There were no more reported incidents from this source.

Salmonella and Chocolate

The uncommon salmonella serotype *Salmonella napoli* caused 245 cases of salmonellosis among children. These were traced back to the consumption of contaminated chocolate bars from a single factory. The factory was very modern and clean but untreated river water was used for the water circulation system that kept the chocolate molten during transportation around the factory; *S. napoli* had previously been isolated from river water in the region of the factory. Contamination of the chocolate probably occurred as a result of microleaks in the pipes of the water circulation system, resulting in the seepage of water into the chocolate. Chocolate manufactures agreed to a code of hygienic practice following this incident.

Salmonella and Salami Sticks

A number of cases of salmonellosis, mainly among infants and children, occurred as a result of the consumption of salami sticks. The salami sticks were manufactured using traditional methods but with a very short maturation period. The short maturation period was not sufficiently long to destroy any salmonella present in the meat used in the manufacture of the salami. Thus, very small numbers survived. This survival was prolonged by the practice in retail outlets in the United Kingdom of storing the sticks in chill cabinets; no cases were reported in continental Europe where the sticks were stored at ambient temperatures. The manufacturers reviewed their manufacturing procedures, introducing a heating step in the process, thus guaranteeing the destruction of any salmonella that might survive the usual salami-manufacturing process.

Staphylococcus aureus and Pasta

Epidemiological and microbiological tracing attributed 47 cases of staphylococcal food poisoning, occurring in several European countries, to a single source of lasagna. The source of the problem was traced back to the contamination of the eggs used in the manufacture of the pasta and was believed to be associated with the hygiene of equipment used to transport the eggs. As a result of this incident, a code of practice was drawn up by the pasta industry requiring the use of pasteurized eggs in pasta manufacture and improved hygienic design of the equipment used for the preparation of the pasta.

Clostridium botulinum and Yogurt

After 27 cases of botulism were traced to the consumption of a locally produced yogurt containing hazelnuts, the source was identified as canned hazelnut puree; this was part of a batch of low-calorie products prepared using artificial sweetener. Unfortunately, the manufacturer of the hazelnut puree had not recognized that the heat process used for commercially sterilizing the normal high-sugar product was not suitable for the low-calorie product. Sugars reduce the available water (a_w) to a level at which spores of *C. botulinum* are unable to initiate

vegetative growth and are thus unable to grow and form botulinum toxin; the organism grew well in the sugar-free product that had a much higher a_w. The outcome of this incident was to inform producers of these and other products of the need to obtain expert advice on the required heat process before reformulating a canned food. Also, the national code of practice for low-acid canned foods was revised to clarify all requirements for the production of microbiologically safe low-acid canned foods.

Testing Foods for Foodborne Disease-Causing Microorganisms

Foods may be tested for foodborne pathogens for a variety of reasons; the main reasons are listed in Table 2.

Microbiological testing of foods has been widely applied by health authorities and industry as a means of identifying foods that have levels of microorganisms or their toxins in excess of those regarded to be acceptable and therefore are unsafe or unacceptable for human consumption for other reasons. Such testing was at one time believed to give adequate protection to the consumer and was the linchpin of microbiological control strategies practiced by governments and industry for much of the twentieth century. This was despite the recognition more than 30 years ago that such testing gave little or no assurance of microbiological safety or quality. This can be illustrated by reference to the most stringent testing plan applied internationally for examining baby food for salmonella. In this plan, a sample comprising 60 individual sample units is taken from a batch of baby food, and from each sample unit, an analytic sample unit of 25 g is taken and examined for salmonella (total analytic sample is thus 1500 g); the pass criterion is no detection of salmonella in any of the analytic units examined. Even when this pass criterion is met, there is 50% probability that up to 1% of the sample units in the food batch will be contaminated. Clearly, this degree of confidence is not acceptable, particularly when considering that such a sampling plan may be applied to test the acceptability of a baby food.

It is such considerations that have led to a total reappraisal in recent years of the value of such testing as a means of assuring the microbiological safety of a foodstuff. This has led to the wide-scale introduction of hazard analysis and critical control point (HACCP)-based control systems whereby the potential hazards associated with manufacture of a food in a particular processing plant are identified using a structured hazard analysis procedure and locations where these hazards can be effectively controlled are identified. These locations are called critical control points and means for their proper control (including means of monitoring that control is maintained) are identified.

Table 2 Uses of microbiological testing

Investigational testing	Suspect contaminated food
Compliance testing	Governmental regulations; industry standards and purchasing specifications
Monitoring	Authorities monitoring imported and domestic foods; industry monitoring products and processes
Verification	Good manufacturing practice and hazard analysis and critical control point

As a result of the introduction of HACCP as the prime means of assuring the microbiological quality and safety of foods, microbiological testing has become less important as a primary control function and increasingly is used mainly by industry for the purpose of verification of HACCP. However, where HACCP is not applied, the industry or a health authority may apply microbiological testing if there is a need to obtain a judgment about the acceptability of a foodstuff. For instance, it may be appropriate for use in a buying specification for a microbiologically sensitive raw material from a new supplier or by a health authority on a consignment of imported food, where microbiological testing is the most appropriate acceptance criterion. For such a purpose, it is important that statistically based sampling plans are used so that the degree of confidence in the result obtained is known; methods of analysis should also be agreed. One of the two types of sampling plans may be used for such acceptance sampling. The first and most widely used are the two- and three-class attribute plans established by the International Commission on Microbiological Specifications for Foods. Such plans not only were developed principally for testing foods in international trade for their acceptability but also are widely used by industry in buying specifications.

Two-class plans have a single limit that distinguishes between an acceptable concentration and an unacceptable concentration of a microorganism or toxin and is used in sampling plans for foodborne pathogens.

Three-class plans are used principally for determining the acceptability of levels of general microbial contaminants and indicator organisms and have two limits: One is a lower limit generally established by good manufacturing practice requirements and the other is an upper limit based on some index of unacceptable quality. The other main type of plan used is the standard variables plan that is based on knowledge of microbial distributions in batches of foods and can be used when such distributions approximate to log normality. This limits their use principally to industry, where their advantage over attribute plans is greater accuracy and hence greater confidence in decisions based on their use.

The choice of a sampling plan and testing procedures for investigative sampling that may, for example, be used to identify the level of contamination in a suspect consignment of food or to investigate food involved in a food-poisoning incident is more difficult than acceptance sampling. One major problem is that there will usually be no information on either the likely incidence of contaminated product units or the level of contamination; these factors set requirements for the number of units of product that should be examined and the size of the analytic unit that should be tested. In investigative sampling, unlike acceptance sampling, random sampling may not be the most appropriate procedure. For example, the location of the product units in relation to possible source of the contamination may suggest that cluster or stratified sampling may be more appropriate.

Tracing the Origins of a Foodborne Disease Incident

Investigation of the cause of an outbreak or case of foodborne illness will usually require a number of procedures depending on the type and circumstances associated with the incident.

These may include extensive testing of food and clinical samples for likely causative agents, the use of epidemiological analytic techniques to link illness to a common source if a number of cases of illness are involved, field investigations by public health and industry experts to find the cause, and specialist food-processing knowledge to identify what measures need to be taken to prevent its recurrence.

The tracing of the source and cause of an outbreak of foodborne disease associated with a well-defined event, such as a banquet, is usually a relatively easy matter. A list of foods consumed by the ill persons is compared against a list of items consumed by persons who are not ill, and using simple statistical correlation procedures, any significant differences in foods consumed by the two groups are identified and further investigated to find the most likely food source. Tracing the source of sporadic cases in a community is much more difficult, and in addition to an extensive use of well-founded epidemiological procedures, investigators need a certain amount of serendipity, backed up by specialist laboratory resources, in order to be successful.

Laboratory Investigations

Samples of suspect foods, together with clinical samples, should be collected and transported under conditions that protect them from external contamination and minimize changes in the concentration of any food-poisoning agent that may be present, for example, in sealed sterile containers in a suitably cool box. Details of the history of the sample, for example, where and when and by whom and how, together with information on symptoms of illness should be submitted to the laboratory as these will help in selecting the most appropriate method of analysis. On receipt by the laboratory, the samples should be documented, properly stored, and examined as soon as possible. Such examinations must be undertaken by laboratory staff who have been trained in the microbiological examination of foods as well as clinical specimens; they should be particularly knowledgeable of the analytic procedures to be applied. These should be performed in accredited laboratories operating to recognized good laboratory practice standards and using procedures and methods that have been approved by an appropriate accreditation organization. The microbiological examination of a foodstuff can be problematic and a number of pitfalls may trap the unwary or careless. For instance, examination of food specimens in the same room where clinical specimens are examined is bad practice; a heavy microbial load in a clinical specimen can easily cross-contaminate a food sample, where only light contamination with the same organism in the clinical specimen is sufficient evidence to implicate a food as the source.

Initial laboratory findings should always be interpreted with care. Isolates and where appropriate original specimens should be submitted to a reference laboratory with expertise in the suspect agent of concern in order to confirm an initial finding and, if appropriate, to apply modern 'fingerprinting' and typing methods such as DNA-based subtyping methods. There are many examples of foods being erroneously implicated in a food-poisoning incident because of poor laboratory practice. There have also been many examples where failure to identify a causative agent, or a food source, has been the result of failure of the laboratory to apply the correct isolation or detection method. The microbiological examination of foods is not an exact science, although continued improvements in detection techniques in recent years have considerably improved our ability to detect pathogenic agents in foodstuffs.

Epidemiological Investigations

Two main analytic tools are used by epidemiologists to trace the source of a foodborne disease incident: case-control studies and cohort studies. For both, the first stage is to review and document all available information. In an investigation of an outbreak, a questionnaire is prepared to detail when and what was consumed and symptoms of illness. This questionnaire is used in preliminary interviews with persons affected by the outbreak to obtain basic information as to the likely cause. A case definition is also agreed, that is, what symptoms should be searched for, as it is important when case searching (in order to identify the extent of an incident) that only the most likely cases are identified.

In a case-control study, a series of questions based on the preliminary questionnaire are asked to the persons identified as corresponding to the case definition (case group) and persons who have not been ill (control group). These two groups are matched as far as possible with respect to age, sex, socioeconomic group, and place of work or residence. Controls are often based on consultation with the general practitioners of the persons who have been ill. Based on information in the completed questionnaires, differences between items consumed by the ill and well groups are identified and any statistically significant differences subjected to further investigation. One problem with this procedure is that it is common in food-poisoning incidents to have symptomless cases and these may well be mistakenly identified as part of the control group.

In the analysis of the case data, the following are the most important:

1. Time to onset of illness. Based on knowledge of the incubation period of the illness, it is possible to determine the period of exposure to infection. This information may then be plotted as a histogram relating the frequency of cases chronologically to the date of onset of illness. This so-called 'epidemiological' or 'epidemic' curve can then be used to identify whether or not there has been secondary transmission of illness and whether or not it is a point-source outbreak, for example, a single meal, or a common-source outbreak, for example, a number of cases from the same source, such as a retail establishment, occurring over a particular time period.
2. The place where infection occurs. A map is drawn of known cases, and researchers look for relationships, such as clusters, that may assist in identifying a source.
3. The persons involved. Analysis of information on individual cases such as age, sex, medical history, occupation, home situation, and any travel history may also help one to form hypotheses as to the source of infection.

In a cohort study, a group of people is identified by some other means than illness. For example, this might be all the persons who attended a conference at which it is suspected that a meal was consumed that led to illness. The persons are divided into two groups according to whether or not they ate a particular

meal; the attack rate in the group eating the meal and that of the group not eating it is calculated. If there is found to be a statistically significant correlation for the consumption of a particular meal, the next stage is to determine the attack rates for persons eating and not eating a particular menu item. By this means, if successful, a particular menu item will be identified as the source of the agent that caused the illness.

Environmental Health Investigations

As part of an investigation into a foodborne disease incident, health inspectors may visit and investigate the identified source, for example, the place where a foodstuff implicated in a food-poisoning incident was manufactured or prepared for consumption. This may involve a detailed examination of the hygienic practices and the collection of product and environmental samples for laboratory examination. If an infectious disease is suspected, food handlers may be asked to submit samples for microbiological examination. Where a source of contamination has been identified, the health authority is most likely to require assurance that the condition that caused the contamination has been corrected prior to allowing the product to be returned to the marketplace. Such assurance may require evidence that checks have been done by a third party to confirm that satisfactory control measures are in place. If a HACCP plan is in place, this plan will need to be revalidated.

Withdrawal of a Suspect Food

If a distributed food is found by a health authority or a producer to be contaminated with a concentration of a pathogen or toxin exceeding a legal limit or exceeding a level generally regarded to be hazardous to health, this food should be withdrawn from sale as soon as possible and, if necessary, the public informed.

Before announcing the public withdrawal of a food, it should be ascertained, as far as is technically possible, that this food is unsafe to eat. Wherever possible, the results of microbiological analyses or evidence clearly linking cases of illness to an implicated food item should be available to the health authority and/or producer, as adverse publicity is likely to result from a public recall that may cause much damage to the reputation of the producer. The prudent producer may not wish to run the risk of even worse publicity arising from an incident occurring as a result of failure to inform the public and may voluntarily withdraw the product and inform the public of this.

Authorities will take different actions concerning the extent of a recall depending on a judgment as to the health risk involved by allowing food to remain on sale or in the hands of a consumer. Thus, a recall may only be required down to the distribution level, for example, distribution warehouse, if it is judged that any food remaining on sale is unlikely to cause further illness. A similar decision may well be made for a food containing a level of microorganisms exceeding a legal limit but where no illness has been reported. However, if it is judged that serious illness could result from product on sale or in the hands of consumers, recall down to retail level would be the minimum requirement and a public warning (via the media) would usually also be required. It is important that a recall is properly coordinated by the owner or supplier of the food; for this to be effective, a food company should have a documented recall procedure in place. As part of this procedure, a recall coordinator should be appointed whose role is to coordinate the recall, to liaise with the public and the authorities on progress with the recall, and to act as the spokesperson in contact with the media.

When carrying out a public recall, it is important that this is done as fast and thoroughly as possible. Thus, there will be the need for press statements via the media and communication to customers (and retailers) via e-mail or fax, advising them of the recall. In the case of a national or international recall, the health authorities will inform their contacts via established networks and, if a particular ingredient is involved, may work with the supplier to identify and advise producers who may be using this ingredient in further products. Effective coding of food batches and maintenance of records of distribution are essential requirements as production failures will inevitably occur from time to time.

Food Systems: Food Miles

P Mundler, Université Laval, Laval, QC, Canada

Introduction

The phase 'food system' encompasses all factors relating to food including all actors (people and groups) and processes and infrastructure associated with food production and its movement from farms to consumers. Food systems are also networks shaped by economic, social/political, and environmental circumstances. Food miles, a newer concept coined by Professor Timothy Lang, are the total miles food travels from the farm to the consumer. Food miles are one way to look at the environmental impact of food but are also a useful concept to help contemplate society's broader relationship to food and food producers. The average distance food travels has been increasing with current estimates at over 1500 miles. In Britain, a major study commissioned by the government estimated that in 2002, the annual social cost of increased transportation of food equaled £9 billion per year (about US$15 billion). This cost includes the increase in greenhouse gas emissions in addition to road maintenance and traffic congestion costs.

Many interesting food travel anecdotes exist. A 2007 British Broadcasting Corporation (BBC) story tells of Scottish langoustines (a small relative of lobster) being caught in Scottish coastal waters and then traveling to Thailand through the port of Rotterdam. After the langoustines arrive in Bangkok, they are shelled by hand and then travel to Holland where they are breaded. Next, the langoustines return to the United Kingdom for consumption, having traveled 17 000 miles. Most African agricultural products consumed in Europe or North America are processed in India or elsewhere in Asia before being distributed. One brand of Tanzanian coffee travels nearly 5000 miles just to be roasted and bagged. Cashew nuts harvested in the north of Ivory Coast are sent to India and Vietnam where the nut is extracted manually, sorted, and bagged before being shipped worldwide for consumption.

The concept of food miles has caught the public interest. There is a website (www.foodmiles.com) to help consumers estimate the distance their food travels in addition to providing other environmental information. There is disagreement regarding the use of food miles as an indicator for evaluating food systems. Some justify the use of food miles based on favoring local food production, which would minimize at least one environmentally related criterion (distance). The critics of food miles argue that it legitimizes a new form of market protectionism, it is too narrow of an indicator, and it is not a definitive environmental or economic measure.

Food System Definition

The phrase food system refers to all factors involved with food production, processing, distribution, storage, consumption, and associated waste management. The concept is often summarized by the image of the 'farm to fork' or 'field to table.' In the literature, many food system representations are frequently in the form of a chain or network. For any food system, there are products (inputs and outputs), actors (farmers, wholesalers, processors, distributors, consumers, and regulators), and modes of coordination (by the market, by standards, and by one or more agencies). A food system is always linked to a biophysical context (e.g., potential agronomic, climatic characteristics, or accessibility to seafood), an economic and social context (e.g., income, population, or eating habits), and a level of technological adoption (e.g., food preservation techniques).

Transition from Traditional to Modern Food System

One way to describe the food system is chronologically from the traditional to the modern system. The traditional food system fits the rural economies, where agriculture is the main industry. A large portion of the local agricultural production was consumed on the farm or in nearby villages, and only a small amount of agricultural surpluses (extra product) was sold on local markets. The farms were diversified, with little mechanization and little if any use of manufactured chemical inputs. Agricultural products were sold almost exclusively in their raw form (sometimes animals were sold live), at the farm, at local markets, or in small shops. There were no food safety standards or food traceability systems (method of tracking food back to the farm). Local diets depended on what was grown locally and would vary according to local production and the season. Famines might occur if the local supply was insufficient. There were few losses due to waste, but many losses would occur due to storage problems. Food systems similar to this traditional system are still found today in many developing countries where consumers rely on local foods.

Over time, farms and food operations have grown larger due to technological advances and mechanization. These factors favor large operations and lead to 'economy of size,' where average per unit costs normally decline with greater production. Lower average costs tend to increase profits, which create pressure for the food businesses to become larger. Small multicrop farms gave way to large specialized farms. Local wholesale markets began to shrink or disappear with the creation of worldwide 'grower-shippers' who grow crops in multiple locations to ensure year-round supplies and can deliver product virtually anywhere in the world. At the same time, small, locally owned grocery stores disappeared with the simultaneous growth in large supermarkets. This modern large-scale food system shall be called the conventional food system.

The conventional food system serves primarily urban and suburban economies in the developed world. This system brings food into areas where food is generally not produced. With this system, the economic importance of agriculture is low and farmers represent only a very small part of the country's population (frequently $<4\%$). The farming systems

are normally specialized with a high degree of mechanization and technology. Agricultural production is frequently concentrated in productive areas, which may be thousands of miles from the population centers.

With the conventional food system, consumers eat more processed food products and less raw and unprocessed foods. Products are transformed into specialized foods, which are sold through global food sales networks. Often, the processed food has higher fat and sugar levels and less fiber than raw or less processed foods. There are public and private food safety standards as well as food traceability. Within this system, food storage (including cold storage) is effective with minimal losses. Food losses are normally observed after the sales to the final consumer (e.g., if the food has reached its expiration date). Subject to the eating preferences of consumers, diets can be diverse because consumers have access to a vast number of products from around the world. Under the conventional system, consumers on average consume more meat than under the traditional food system due to taste preferences and lower costs of meats. The conventional food system can be credited with having widely reduced food insecurity, reduced the percentage of income spent on food, and also contributed to food deserts and obesity. A recent United Nations report states that unhealthy diets, which are partially due to the conventional food system, are now a greater health threat than tobacco.

Concerns Regarding Sustainability and Emergence of Alternative Food Systems

Although the conventional food system is productive and delivers massive quantities of inexpensive food, there are negative features. Farms under this conventional model are large and use more fertilizers and pesticides. Given the size and intensity of production, these systems are not sustainable and pose a threat to the integrity of ecosystems. Crop fertilizer use in the United States has been implicated in many cases of ground water contamination as well as the large ocean 'dead zone' where the Mississippi River empties into the Gulf of Mexico. In addition to the negative environmental aspects (negative externalities) of the conventional food system, critics also point to an adverse impact on employment and the community. Further, the global trade liberalization undertaken since the Uruguay Round of world trade negotiations has made the food system more sensitive to economic shocks. In assessing the sustainability of a food system, important considerations include the availability of food to all, system food security, and the ability to preserve natural resources. Although the ancient or traditional food system has evolved in much of the developed world into the conventional food system, there are still traditional food systems of varying sorts in many countries including the most developed. Most countries have multiple food systems existing side by side. Many cities have a local farmers' market operating within a short distance from a superstore selling thousands of food products. Since there are many alternative food systems frameworks, including farmers' markets and community-supported agriculture, systems differing from the conventional food system have become known as alternative food systems.

For the remainder of this article, we will compare and contrast the conventional food system and the alternative food system, as two ends of a spectrum. They will be our 'ideal types' for comparison along the approach developed by the sociologist, philosopher, and political economist Max Weber. An 'ideal type' is a simplified approximation of something that can be used for comparison or other analysis.

Comparisons Between the Conventional and Alternative Food Systems

A distinguishing feature of the conventional food system is its large scale and heavy use of mechanization and other technology. As mentioned before, technology and mechanization are accompanied by large production volumes and lower average costs. Large crop fields exist where frequently one crop is grown for as the eye can see. Large quantities of chemicals, pesticides, and fossil fuels are used. Processing and distribution centers are also large. Food in this model is increasingly processed, not only to meet the desires of consumers but also to lower costs and improve transportation and storage. As part of the food processing, considerable fats, salt, and sugars are added, while natural fibers are reduced, resulting in food that is generally considered less healthy.

Contrasted with the conventional food system, alternative food systems emphasize a connection between consumers and producers. They promote the economic and social benefits of local agricultural production, which can be processed locally by a small business. Alternative food systems are thought to have less detrimental impacts on the environment, generate more employment, and deliver food considered healthier than industrial food. Food produced in alternative food systems is usually considered to taste better than the same food produced under the conventional food system. In moving away from a conventional food production system, one is moving away from large-scale economies, and thus, one would expect higher costs and possibly higher energy use per pound of food delivered. However, when comparing costs of conventional versus alternative food systems, it is difficult to determine and include costs of increased obesity, fewer good jobs, and environmental costs associated with the conventional food system. In Table 1, several important features of the conventional and alternative food systems are compared.

The conventional food system is oriented toward efficiency and profits. Consequently, the conventional food system has been able to provide food in abundance and at overall declining inflation-adjusted prices. At the same time, it has been criticized for its environmental impacts due to intensive use of resources, externalities, and social impacts due to the concentration of actors and the resulting loss of jobs. The question of food healthiness and safety of the conventional food system is complex. On the positive side, the conventional food system is very efficient and delivers an enormous amount of food with relatively few food problems (on a per person basis). This is accomplished through the use of processing and preservatives, which limits food microbial contamination. As mentioned earlier, processed foods are high in sugar, salt, and fat, which contributes to an unbalanced diet, leading, in part, to increased obesity, food allergies, and other ailments. Another concern regarding the size (and speed of food movement) of the conventional food system is the challenge of monitoring food safety, because when there are cases of food contamination, many consumers can quickly become ill or die. Given the size

Table 1 Important food system features

Feature	*Conventional food system*	*Alternative food system*
Ways of improving farmer income	Specialization and growth; lower costs	Diversification and fewer intermediaries between the producer and the consumer to capture more value
Division of labor	High degree of labor specialization and labor concentration	Lower level of labor specialization and fragmented actors
Product quality	Uniform and homogeneous products fit best with the industrial framework; higher level of processing; consistent quality and overall safety record	Products are less homogeneous and often vary by producer; product less processed and thus fresher with better taste; product more often local and linked to geographic region (authentic)
Target markets	Mass markets and differentiated technological product (e.g., health food)	Markets are normally closer and differentiated by reference to the place of production (geographic identification), or by the farmer or artisan nature
Desired performance	Price competitiveness, improving productivity of labor and land through intensification and specialization	Competitiveness through quality (emphasis on taste and freshness); sustainability through crop rotation and growing multiple crops
Area requirements	Dense and concentrated in areas with high agricultural potential	Can be intensive but normally with some dispersion due to crop rotation or multicrop farm planning
Innovations	Technological	Organizational
Environmental performance	Efficient use of inputs; capable of meeting specific targets; improving carbon footprint; large disperse negative impacts due to production concentration	Goal of environmental sustainability in concert with vision of integrating all farming and food aspects as a system, including agronomy, animal welfare, worker/owner benefits, and rural development
Types of business qualifications	Traceability; government or private certification of production processes	Growing use of geographic identification as quality indicator; government or private certification of production process (such as US Organic)
Food Miles	On average long distance	On average less distance
Functions of agriculture	Primarily produce raw materials for industry	Multiple: produces food, maintains open spaces, provides jobs for rural people, and helps support rural economies

difference and the multiple dimensions of the conventional and the alternative food systems with respect to overall food healthiness and food safety, both systems have pros and cons, and a more detailed comparison is beyond the scope of this article.

The alternative food system improves upon many of the negative features of conventional agriculture including fewer negative environmental impacts and less processed food. Other benefits include a renewing of the social ties between those who produce the food and those who consume it. The alternative systems also employ fewer pesticides and have a better distribution of the food dollar (with more value going to the farmers). While many benefits of alternative food systems are noted, it has been criticized for its inefficiency and inability to address the food needs of the world's population as a result of low productivity and higher cost of food production. On the social level, consumers would need to cook more under the alternative food system and use more energy, as they would buy less processed products and more raw food products. In the next section of this article, we will discuss the assertion that lower food miles decrease the negative impact of a food system.

Does Reducing Food Miles Necessarily Improve the Environmental Performance of the Food System?

While no one disputes that food travels longer distances, the impact of food miles on energy consumption and greenhouse gas emissions has been the subject of extensive research. The conclusions of these studies are mixed. Most authors agree on how improvements might be made, such as using trains for transportation when possible and avoiding empty return truck trips. Some also conclude that the reduction of food miles can significantly reduce costs and also reduce the negative environmental impacts of food distribution. Others argue that the environmental impact of local food production and distribution is heavily penalized by low product volumes and inefficiencies. The critics also show that food transportation energy is a small portion of total food system energy and is less relevant.

How can these differences in researcher conclusions be explained? To begin with, the measurement of energy expenditure in food distribution presents many methodological difficulties. When considering the food system, how wide should the scope be? Will we consider differing sources of energy? What units of measurement will be used? Which energy expenditure value is used? Is the use of greenhouse gas emissions a good proxy for overall environmental impact? How can different situations be compared? Depending on the choices made, the results appear very different, sometimes to the advantage of the conventional food system, sometimes to its disadvantage. The review of existing literature shows numerous findings regarding food system energy usage and greenhouse gas emissions. Some consider the whole system, while others focus solely on distanced traveled. For tractability (being able to identify and aggregate all impacts), many studies reduce and

focus on one environmental criterion such as energy use or greenhouse gas emission per food unit (e.g., grams of CO_2 greenhouse gas emission per apple).

The Life Cycle Analysis Approach

The life cycle analysis (LCA) approach to evaluating food systems attempts to consider the environmental balance of the entire food system. For researchers using this approach, food miles are only one of many uses (expenditures) of energy. Other food system energy expenditures include the production technologies used to produce the food, as well as the energy to process and store the food. To illustrate, consider a comparison between vegetables grown closer to the equator where the sun provides enough energy for the vegetables to grow and ripen naturally and the same vegetables being grown in a greenhouse and sold locally. With the vegetables grown closer to the equator, less energy is needed in production, but more in transportation. With vegetables grown in greenhouses, more energy is needed in production and less in transportation. Various studies show that the gain in energy obtained from the sun in the production phase of the vegetables is much higher than the energy necessary for transportation.

Other examples exist where one or more strong efficiencies can outweigh transportation environmental costs. The government of New Zealand maintains that New Zealand lamb production has such a low carbon footprint that it more than offsets the environmental costs of ocean shipping. This low environmental impact is due to the sheep being rangeland-fed, the rangeland requiring little fertilizer and few pesticides, and also the high efficiency of container ship transportation. The New Zealand government concluded that the carbon footprint is generally lower if consumers in London, England, consume New Zealand sheep rather than English sheep.

Transportation by large container ships is very efficient with regard to fuel consumption per food unit, as 10 000 km by container ship is roughly equivalent to 400 km by truck for the same amount of food weight. There are efficiencies claimed in food processing also, as in the aforementioned case of the Scottish langoustines. The company's director maintains that a study shows a lower carbon footprint with peeling langoustines by hand in Thailand than with peeling by machine in Scotland.

The most common method of assessing the overall environmental performance of alternative food systems is LCA. This valuation method qualifies and quantifies all impacts of a product (or service) throughout its life cycle from production to distribution to the consumer (from the product's 'cradle to grave'). The LCA method has become a standard tool (ISO 14040) and has been employed in considerable research. LCA is considered a multicriteria method given the method's focuses on the overall impact of the product on the environment, energy, raw materials, water, emissions, waste production, etc.

To employ the LCA analysis, one first determines and evaluates the flow of raw materials and energy coming into and leaving each stage of the product's life. Next, environmental impacts are measured or estimated based on values (coefficients) calculated from previous research (e.g., truck manufacturer specifications on fuel use per mile). To allow comparisons, one determines and adopts 'functional units' for comparing products with the same function. In a recent study comparing the impacts of canned tomatoes (diced and paste) produced in California and distributed in Michigan with tomatoes produced and distributed in Michigan, the functional units adopted were kilogram of canned tomatoes (diced and paste). The results showed that overall the two scenarios had similar energy use and greenhouse gas emissions, but the California tomatoes had a much higher use of developed water sources. The impact of transporting the tomatoes from California to Michigan was offset by more productive California growing conditions including less soil amendments being required. An interesting result was that tomato paste contains approximately 4.5 times as much raw product equivalent than the diced tomato product. It was found that in some cases, using concentrated products for cooking would have lower environmental impacts than using the whole products. In this study, the environmental impact of transportation appears ultimately negligible, especially if transportation of the canned product is by train.

The previous examples illustrate the important finding that food miles represent only a small part of the energy expenditure (or environmental impact) of a food system. For the United States as a whole, a study published in 2000 estimated that transportation accounted for less than 20% of total energy consumed in the food system. Many studies regarding food system energy consumption conclude that the highest energy costs within the food system are not from transportation but from agricultural production, processing, and energy used by households to obtain, store, and cook their food.

LCA is a useful method used to identify all environmental impacts of a product or service. The LCA method provides an overall view but at the same time shows the complexities of the analysis since for each life step of the cycle, strengths and weaknesses can be highlighted. The LCA method is detailed and relies on current or recent estimates of impacts from other sources. Due to this reliance on other research, some authors consider LCA more of a decision support tool than a decision making tool.

Research on Food Miles

Although the distance traveled by food contributes moderately to the overall energy consumption of the food system, environmental impacts can be reduced by shortening travel. It is for this reason that various research projects have been conducted seeking to compare the respective impacts of long food chains (represented by the conventional food system) and short food chains (represented by the alternative food systems). There are two primary approaches to carrying out food mile studies and each has important methodological challenges. One approach is based on typical scenarios, while the other calculates specific food travel measurements.

Food miles studies based on evaluating typical scenarios begin with noting all supply chain stages through which the product will pass. Once these stages have been identified, the average distance the food travels between each stage is calculated (farm to wholesaler, wholesaler to processor, etc.) and assigned a transportation energy usage. The amount of energy used for each transportation leg is normally not directly

measured, but rather relies on average fuel consumption based on, for example, truck manufacturer specifications. In other cases, researchers rely on previously published results, such as those found in published LCA studies. This shows a methodological link between the LCA and a food miles scenario analysis.

Food miles studies based on actual measurements examine the specific miles traveled and energy or other environmental impacts for each stage of the supply chain from production to consumption. In a detailed example, Elmar Schlich and colleagues at Justus Liebig University in Gießen (Germany) calculated the total energy used at all stages in the supply chain for local German lamb compared with lamb imported from New Zealand. The New Zealand lamb is slaughtered and frozen on-site, transported by truck to a port, and then shipped to Germany on a container ship. While on the ship, the New Zealand lamb remains at its constant frozen temperature, and once in Germany, it is transported by truck to a distributor. The German regional lamb travels far fewer kilometers but travels in smaller vehicles and therefore has less fuel efficiency on a per kilogram bases. In all the cases studied by the research team, they concluded that the large transport distances traveled do not automatically imply high final energy consumption. From their point of view, these results highlight what they call 'ecology of scale,' where the concentration (production, transport, etc.) has a positive influence on any final energy consumption per unit produced or transported.

Most of the examples studied show a decreasing relationship between final energy utilization per food unit produced, and company size. Advantages do not automatically come from shorter food miles, but often come from logistical efficiencies due to large and specialized companies.

There is criticism of these works on multiple grounds. These studies could conclude that a country or region should abandon many traditional agricultural products in favor of products produced on the other side of the world. For example, it might be recommended that all of Europe abandon commercial apple production and only eat apples from Chile. One limitation is that frequently, all forms of energy are treated as the same, and this is questionable since all forms of energy do not have the same consequences for the environment. Moreover, some studies focus only on final energy and not all the elements used in the analyses of life cycle including air and water emissions.

Do food miles studies help us compare long food supply chains (conventional food system) with short food supply chains (alternative food system)? Not really, since under both the conventional and alternative food system scenarios, the product is assumed to be sold to the consumer via the same distribution method. This may not be the case since the consumer may acquire the product at a local farmers' market and not the grocery store. For these reasons, some researchers have focused on comparing the energy expenditure required for mass food distribution to local food distribution systems. These studies then incorporate another dimension – the path of the consumer. In order to deliver a product from field to plate, the food must be passed to the consumer, and this normally involves a smaller, less efficient, passenger vehicle. Often, the most expensive food travel leg in terms of energy is the 'last mile,' which is the trip made by the food consumer who inefficiently carries a relatively small amount of food in his or her personal vehicle. These results again led many authors to question the supposed energy savings from 'localism' in the food industry, and they show that short chains are often penalized by lower quantities sold, despite the short distances.

One unresolved issue regarding food miles studies is whether they have appropriately modeled the actual consumer trip patterns. In reality, some percentage of farmers' market shoppers are combining their visit with other trips ('trip chaining'). Thus, many farmers' market shoppers may not be making a special trip, but rather stopping at the market on the way home from his or her work, picking up a child, etc. According to a study in the Rhône-Alpes region (France), food distribution in a short supply chain can achieve good results when the choice of distribution sites allows consumers to avoid specific shopping trips.

Consumers seeking alternative food systems are thought to be more committed to environmental protection and thus more likely to consider low-impact methods of obtaining their food. More and more consumers are sensitive to the energy balance of their food choices and prefer less impact transportation, such as taking their bicycle to the farmers' market. If they visit a pick-your-own (or U-pick) farm to obtain food, it is frequently to also spend an afternoon outdoors and perhaps offer an experience for the children.

Conclusion

The scientific research on the impact of food miles on the energy requirements of the food system concludes that transportation has a low overall impact. This finding is due to the fact that for food, transportation energy is relatively small compared to energy required for production and processing. Therefore, the supposed benefits of 'eating local' in terms of energy consumption and other environmental measures are often questioned.

Thus, it is restrictive and probably scientifically unwise to assess the food system sustainability based solely on food miles. For this reason, many studies take a much broader perspective, along the lines of the LCA discussed earlier. A comprehensive approach would be similar to the LCA approach but be broader than only environmental (including energy) factors. Evaluating food systems should focus on the entire economic, social, and environmental benefits of each food system. Many argue that alternative food systems have other favorable indicators including a more equitable distribution of the value added (income) from farming, as well as a positive recognition of the family farm and farming as a desirable profession. Alternative agriculture can also be more harmonious with the development of the local economy, preservation of biodiversity, the greater 'naturalness' of products, etc. The sustainability of the food system must be studied in its entirety and cannot be reduced only to the extent of food miles or even energy consumption.

The methods of evaluating food systems are complex and a comprehensive analysis is even harder. How should we evaluate the benefit of local job creation in this era of disappearing jobs? Local agriculture also helps maintain open space and

contributes to biodiversity. An LCA that puts all measurements in terms of grams of food per kilowatt of energy is overly simplistic when trying to capture these multidimensional aspects. A study comparing bakeries on energy usage will likely conclude that the best bakery for reasons of efficiency is the large industrial bakery, and not the local artisanal bakery. However, there are non-energy use-related benefits to having a local bakery including great fresh bread and local employment, and it is a challenge to compare these multiple dimensions simultaneously.

In considering food miles, the length of the food system supply chain is important. Many alternative food systems have shorter food supply chains. This is quite a contrast to the lengthy food travel examples provided earlier under the conventional food system. The alternative food supply chains are still underdeveloped and significant improvements can be made. Urban sprawl pushes agricultural production further from the town or city center, thus increasing the distance between consumers and their food. Land prices near cities are also frequently prohibitive for farming. Urban and rural planning can play an important role by preserving farmland in the immediate outskirts of cities to promote local agriculture and also by promoting the location of food distribution sites within the urban centers.

Although of limited scientific use, food miles can be an important image that spurs consumers to reflect upon their relation with food. Consumer preferences do shape production practices as we have seen with the introduction and growth of free run and free range eggs. Perhaps we are seeing 'food miles' as a consumer focal point being replaced by the related 'local food' concept. This concept has been officially recognized and has gained national attention and support in the United States. In 2014, the US Department of Agriculture announced it will make a US$ 78 million investment in local and regional food systems, including food hubs, farmers markets, aggregation and processing facilities, and distribution services.

Foodborne Pathogens

M D'Agostino and N Cook, Fera Science Ltd., York, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Foodborne pathogens are one of the leading causes of illness and death in less developed countries. In developed countries, they are responsible for many millions of gastroenteritis cases every year. As the scale of globalization of food commodities and their associated supply chains continues to grow in response to ever-growing demands of consumers, the challenges posed to the scientific community dealing with methods of detection, surveillance programs, and intervention strategies for ways to reduce, control, or prevent these pathogens in the food supply chains also become more complex and frequent. Over the many decades that the discipline of food science has existed, including the areas of microbiology and chemistry, a huge amount of data and knowledge has been collected by researchers all over the world in response to these challenges. There are several articles within this book that describe in detail the foodborne pathogens currently of most concern. Of course, there is always the possibility that emerging and reemerging pathogens will proceed to contaminate the food chain and challenge researchers in the area, which is why there is a large amount of research still being done around the world to make methods for detection and enumeration more reliable, sensitive, and rapid. Some of the foodborne pathogens, which are described throughout this book, such as *Escherichia coli*, *Salmonella*, *Listeria*, and parasites, have been known agents of food poisoning for many decades, while some others such as hepatitis E virus (HEV) are emerging problems, at least in the sense that they have only been associated with foodborne outbreaks in recent times. These challenges have led to ever more sensitive detection technologies being employed: both qualitative and quantitative nucleic acid detection methods, for example, polymerase chain reaction (PCR), real-time quantitative PCR, digital PCR, and loop-mediated amplification, to name but a few.

The increase in the number of methods for detection of foodborne pathogens highlights the importance given to this area by government regulators and food manufacturers, but it also necessitates the need for harmonization and standardization of these methods in order for them to be fully compatible with current existing 'gold standard' culturing methods, many of which are still considered to be the most reliable. This is due to the fact they are tried and tested for many years and that, crucially, they only detect living organisms. There is, however, a general recognition in the food industry that the detection of nucleic acids and therefore the presence of certain pathogens within certain parts of the food supply chain signify that a failure of the manufacturing process has occurred, since the pathogen should not be present – whether alive or dead. There are of course exceptions to this, depending on which stage of the process is being monitored, but in recognition of this, there are major efforts in researchers' laboratories to find ways of detecting viable microorganisms apart from traditional culturing techniques, such as the use of propidium monoazide (PMA), which is reported to be able to distinguish live cells from dead cells. A light-induced photoreaction occurs that causes the binding of the PMA with the DNA, which is released when a cell dies. This then renders the DNA from the dead cells nonamplifiable by PCR, while the DNA protected within living cells is not affected. There is a mixed response to this technique, due to reproducibility issues; however, it appears to be the closest that researchers have come to answering the 'dead or alive' issue that has been a challenge in the molecular microbiology area for many years. Foodborne pathogens and the problems they cause within the food industry have been around for a long time, and there is no indication that this situation will decrease any time soon, so the need for continued research into the characteristics of these pathogens, how they survive, how they spread, their routes of contamination, and how they react with each other, continues to be answered. The following paragraphs provide a brief outline of some of the major foodborne pathogens described more thoroughly elsewhere in this book by experts in the field.

Aeromonas

The genus *Aeromonas* belongs to the Aeromonadaceae family and comprises Gram-negative, non-spore-forming, rod-shaped, facultative anaerobic bacteria. There is high intra- and interspecies genetic variability, resulting in the genus having a complex taxonomy. *Aeromonas* can be found in terrestrial and aquatic environments and some animals. *Aeromonas* species constitute a potential risk when consuming raw seafood. They are also commonly detected in raw vegetables and can be a risk. They are able to grow at low pH values or high NaCl concentrations and at refrigeration temperatures. They can therefore represent a risk in some processed foods and salads. *Aeromonas* species possess several virulence factors that might confer on the bacterium the ability to cause disease symptoms, although currently, knowledge of *Aeromonas* virulence mechanisms is incomplete. *Aeromonas* infections of the gastrointestinal tract may result in enteritis, which can vary from mild to severe with cholera-like symptoms. Septicemia and peritonitis can also be possible outcomes.

Bacillus

Bacillus spp. are ubiquitous in the natural environment and can be common contaminants of foods. They are rod-shaped, facultative anaerobic Gram-positive bacteria. They form dormant endospores when nutrients become scarce or when the population of the bacterium is high. When conditions become favorable, the endospores germinate and vegetative cells emerge. They are adapted to growth at a wide range of temperature and pH conditions and therefore can easily multiply in food matrices, where they can cause spoilage. *Bacillus* spp. can

contaminate a wide variety of foods including meats, milk, vegetables, and fish. Several species have been implicated as foodborne pathogens, the most common being *Bacillus cereus*. Foodborne outbreaks have mostly been associated with consumption of rice or rice products. Other foods, such as herbs and spices, potatoes, and pasta, have also been implicated. The spore-forming capacity can cause foods that have been left too long at room temperature or reheated to constitute a risk. During growth, *B. cereus* produces an emetic toxin, which can induce vomiting after ingestion, and an enterotoxin, which can induce diarrhea.

Campylobacter

Campylobacter species are curved- or spiral-shaped, microaerophilic Gram-negative bacteria. The most significant foodborne pathogenic campylobacters are *Campylobacter jejuni* and *Campylobacter coli*. These species live in the intestines of livestock, particularly poultry. Consumption of undercooked poultry products is a particular risk for infection by *Campylobacter*. Cross contamination of other foodstuffs from uncooked poultry products can also be a disease risk. *Campylobacter* causes a disease characterized by fever, abdominal pain, diarrhea, nausea, and vomiting. Postrecovery complications may arise and can include Guillain–Barré syndrome, arthritis, and inflammatory bowel disease. *Campylobacter* spp. possess several invasion and virulence factors including surface structures such as flagella. A toxin can also be produced.

Clostridium

Clostridium species are anaerobic spore-forming Gram-positive rod-shaped bacteria. These bacteria can tolerate a variety of environmental conditions, and the spores are tolerant to heating including boiling. There are two main foodborne pathogenic types: *Clostridium botulinum* and *Clostridium perfringens*. They cause differing disease syndromes from each other.

Clostridium botulinum

Clostridium botulinum is highly prevalent in the environment and can be found in soils and waters. It can also be present in the intestinal tracts of animals and can contaminate vegetables and fruits. The disease syndrome that it causes is commonly termed botulism. Foods associated with transmission of botulism predominantly include home-preserved (pickled and canned) foods particularly vegetables and cured meats. Honey has been implicated in cases of botulism in infants. *Clostridium botulinum* produces several types of toxin, and these can be lethal on ingestion of very small quantities. The toxin acts on the nervous system and can cause muscle weakness and paralysis; in serious cases, respiratory failure can occur. These conditions can be preceded by nausea, vomiting, and diarrhea.

Clostridium perfringens

Clostridium perfringens is prevalent in the environment and may be found on kitchen surfaces. Food can become contaminated during preparation. *Clostridium perfringens*, like *Clostridium botulinum*, produces several toxins, although these are not as hazardous as the botulinum toxins. The clinical symptoms of *Clostridium perfringens* food poisoning are generally mild and include abdominal cramps, nausea, and watery diarrhea.

Enterobacteriaceae

Enterobacteriaceae are Gram-negative, rod-shaped facultative anaerobes. They are either motile or nonmotile and are non-spore-forming. Enterobacteriaceae can cause a wide range of illnesses, which include wound infections, urinary tract infections, gastroenteritis, meningitis, pneumonia, septicemia, and hemolytic uremic syndrome. Not all are regarded as truly pathogenic – some are regarded as opportunistic. They are ubiquitous in the environment and have been detected in soil, water, plants, and the gastrointestinal tract of animals and humans. Due to its widespread distribution, it can easily contaminate the food chain. The family includes a number of important foodborne pathogens such as *Salmonella*; *Yersinia enterocolitica*; pathogenic *Escherichia coli*, including *Escherichia coli* O157:H7; *Shigella* spp.; and *Cronobacter* spp. Some members of the Enterobacteriaceae family also cause food spoilage such as *Erwinia* spp. and *Pectobacterium* spp. In the food industry, Enterobacteriaceae are commonly used as indicator organisms that can indicate poor hygiene practices or failure of a manufacturing process. The various members of the Enterobacteriaceae family are more thoroughly described throughout this book.

Listeria

Listeria is a genus of bacteria that contains ten species. *Listeria monocytogenes* and *L. ivanovii* are considered pathogenic microorganisms for humans and animals, respectively. *Listeria* spp. are Gram-positive, facultatively anaerobic, rod-shaped, and motile and are different to many other bacteria in that they have the ability to grow at low temperatures, such as refrigeration temperatures. They can be found widely in the environment, in soil, in water, and in some animals, such as poultry and cattle. They can also be found in raw milk products and processed meats and in ready-to-eat foods. They can often be found to persist in processing plants in areas such as drains. The infection caused by *Listeria* is known as listeriosis, and it can pose a major risk for pregnant women, older adults, and those with a weakened immune system. Listeriosis can lead to miscarriage, stillbirth, or lifelong health problems.

Staphylococcus

Staphylococci are Gram-positive, nonmotile, and catalase-positive bacteria. They are ubiquitous in the environment. The genus includes at least 40 species, most of them being harmless and normally residing on the skin, hair, and mucous membranes of humans and other animals. They can cause food poisoning when poor hygiene practices are used by food handlers and by improper storage temperatures. *Staphylococcus aureus* is the most pathogenic species; therefore, if foods become contaminated with *Staphylococcus aureus* and its subsequent toxin, there is a risk of contracting gastroenteritis as the toxin is resistant to heat and will not be destroyed by cooking. Many different types of food can potentially become

contaminated by *Staphylococcus*, especially those that have had a lot of handling and require little or no further cooking, for example, pasta, ham, salads, egg, tuna, potato, sandwiches, cream pastries, and other bakery products. Staphylococcal infection can cause a variety of symptoms including nausea, diarrhea, vomiting, severe stomach cramps, and a mild fever. Good personal hygiene is key to preventing contamination of foodstuffs, so are good hand washing techniques, not preparing foodstuffs if wounds or sores are visible on the hands or wrists, good cleaning practices in the kitchen, and proper storage of foods, especially perishable foods as already mentioned, at refrigeration temperatures. Antibiotic-resistant strains of *Staphylococcus* such as methicillin-resistant *Staphylococcus aureus* can cause life-threatening infections if they enter the bloodstream.

Yersinia

Yersinia are a group of Gram-negative, non-spore-forming, oxidase-negative, catalase-positive, lactose-negative, and facultative anaerobic rods (or coccobacilli). *Y. enterocolitica* is one of three human pathogenic species in the genus *Yersinia*. They are a genus in the family *Enterobacteriaceae*. They can be transmitted by the consumption of contaminated food products including vegetables, milk products, and meat. Optimum growth temperature is about 30 °C, and they, like *L. monocytogenes*, can grow at refrigeration temperatures. They can also survive the freezing process. Symptoms of *Yersinia enterocolitica* infection (yersiniosis) include diarrhea (which may be bloody in severe cases), mild fever, abdominal pains, and possibly vomiting.

Parasites

Parasites infect hosts and derive nourishment and protection from them. Many are transmitted through environmental pathways including soil, water, and person-to-person contact. Parasites live and reproduce within the tissues and organs of infected human and animal hosts and are often excreted in feces. A range of symptoms, dependent on the type, for example, protozoa and helminths, can be displayed by an infected person. They can cause a high burden of disease and suffering but are somewhat overlooked especially in the food industry, as compared with other causes of foodborne diseases such as bacteria and viruses. Parasite-contaminated foods can include undercooked pork, fruits and vegetables, fresh produce, and undercooked freshwater fish. A ranking exercise conducted in 2012 for foodborne parasites was performed in order of importance from a global perspective to identify the most relevant transmission vehicles. The top 8 ranked parasites include (in order of ranking out of 24 recognized parasites) *Taenia solium*, *Echinococcus granulosus*, *Echinococcus multilocularis*, *Toxoplasma gondii*, *Cryptosporidium* spp., *Entamoeba histolytica*, *Trichinella spiralis*, and Opisthorchiidae.

Viruses

Viruses are obligate intracellular parasites that depend on a host cell to replicate. Unlike bacteria, they are unable to multiply in foods or the environment. They are known to be environmentally stable, with the ability to survive adverse conditions, and can be resistant to extreme pH conditions and enzymes in the gastrointestinal tract. Many have low infectious doses. They are generally transmitted via the fecal–oral route through contaminated foodstuffs, water, person-to-person contact, fomites, and aerosolization. Contamination of foods can often occur due to poor hygiene practices at all stages of the food supply chain including production, processing, and retail. Infection can occur by several routes including ingestion of foods that have been irrigated with contaminated water and that have been contaminated by infected food handlers. Education in good hygiene practices are thus a vital component in reducing the burden of illness associated with foodborne viruses. The foods most associated with viral contamination include fresh produce (e.g., strawberries, raspberries, and other berry fruits), bivalve molluscan shellfish (e.g., raw oysters), fruit juices, deli meats, and other ready-to-eat foods such as leafy greens and salad onions. The viruses most associated with foodborne diseases include human noroviruses (HNoVs), hepatitis A virus (HAV), HEV, and other enteroviruses. A summary of each is given in the succeeding text.

Human norovirus

HNoVs are considered to be the viruses that cause the greatest number of foodborne virus outbreaks worldwide. They belong to the Caliciviridae family and are one of five major genera within this family. They are nonenveloped and possess a single-stranded positive-sense RNA enclosed in a protein capsid. They can be divided into five genogroups (GI–GV), with GI, GII, and GIV being the genogroups that infect humans. Currently, there is no reliable/reproducible method of culturing noroviruses in the laboratory, which has delayed the development of potential control measures such as vaccines. HNoV is also known as 'winter vomiting bug,' and symptoms of the resulting gastroenteritis include vomiting, diarrhea, abdominal cramps, fever, and malaise. The symptoms of this self-limiting disease usually appear very rapidly and disappear just as fast; however, shedding of infectious virus can be prolonged, sometimes for weeks, which is perhaps why the transmission through food handlers who have returned to work, even though they may feel better, is a common route of infection. This highlights the need for scrupulous hygiene, especially for food handlers after using toilet facilities.

Hepatitis A virus

HAV is a positive-sense single-stranded nonenveloped RNA virus belonging to the Picornaviridae family of viruses. There are six genotypes (I–VI) with genotypes I–IV associated with human illnesses. HAV is transmitted mainly via the fecal–oral route and person-to-person contact. It is highly stable in the environment. It can withstand high levels of acidity. If infection occurs, there are no specific treatments apart from appropriate aftercare. Symptoms include jaundice, dark urine, fever, weight loss, and vomiting, and these can last up to 6 weeks. A vaccine is available, which provides immunity for up to and over 20 years. HAV-contaminated berry fruits (especially frozen berries) have been implicated in several large outbreaks.

Hepatitis E virus

HEV is a nonenveloped RNA virus and is a member of the genus *Hepevirus* in the Hepeviridae family. It is primarily transmitted through the fecal–oral route mainly via contaminated drinking water. It is found worldwide but has a high prevalence in South and East Asia. Symptoms of HEV infection are similar to that of HAV, including jaundice, loss of appetite, enlarged liver, abdominal pain, nausea, vomiting, and fever. In acute case, it can lead to acute liver failure and death. Pregnant women are at a greater risk of death from HEV. There is a 20% mortality rate in pregnant women in their third trimester. It has a long incubation period, and therefore, confirmation of its association with particular foodstuffs is difficult; however, during a recent study conducted in UK slaughterhouses, HEV RNA was detected in 13% of 40 pig feces and 3% of 40 pig liver samples. HEV RNA was not detected in 40 samples of muscle meat in a processing plant; it was found to be in 10% of 63 sausages purchased at retail. Other studies in the United States and Europe have shown similar findings. Ingestion of raw shellfish has been identified as the source of sporadic cases in endemic areas.

Foodborne Viruses of Human Health Concern

DH D'Souza and SS Joshi, The University of Tennessee-Knoxville, Knoxville, TN, USA

Introduction of Foodborne Viruses

Annually, in the United States, according to the Centers for Disease Control and Prevention and the report by Scallan et al., among the 31 pathogens that cause an estimated 9.4 million foodborne illnesses, human noroviruses (hNoVs) alone are reported to be responsible for an estimated 5.5 million 58% foodborne illnesses, 26% hospitalizations, and 11% deaths. Viruses have unique properties and are less complex and different from bacterial pathogens, being smaller in size (typically nM). Viruses are obligate intracellular parasites that are dependent on a host cell to replicate and therefore cannot multiply in foods or the environment, although they can survive in the environment outside their respective hosts. Foodborne viruses are generally environmentally stable, can survive adverse conditions, and are resistant to extreme pH and conditions of the gastrointestinal tract and its enzymes. They reportedly have low infectious doses, where as few as 10–18 human noroviral particles can cause illness per the report by Teunis et al.

Enteric viruses are reported to be transmitted through the fecal–oral route by contaminated food and water, via person-to-person, via contact with contaminated surfaces, and through aerosols. Viral contamination of foods often occurs due to poor hygienic practices of infected food handlers, where public education and enforcement of hygienic practices can play significant roles to help reduce outbreak incidence. Fecally polluted waters that flow into farmlands can contaminate crops and produce items, and also, shellfish can accumulate viruses in their gastrointestinal tract. These contaminated fresh produce and shellfish when eaten raw or undercooked can cause illness. In addition to fresh produce and filter-feeding shellfish, at-risk foods associated with viral outbreaks include juices, bakery items, deli meats, and other so-called ready-to-eat foods or undercooked foods. Viruses that are reported to be associated with foodborne and waterborne diseases include hNoVs, hepatitis A virus (HAV), rotaviruses (RVs), hepatitis E virus (HEV), adenoviruses (AdV), sapoviruses, astroviruses, Aichi virus (AiV), parvoviruses, and other enteroviruses.

Human Noroviruses

hNoVs are considered as the major causes of nonbacterial gastrointestinal outbreaks worldwide. HNoVs belong to Caliciviridae family that consists of five major genera, *Norovirus*, *Sapovirus*, *Vesivirus*, *Lagovirus*, and the recent addition of *Becovirus* or *Nebovirus* as reported by Scipiono et al. HNoVs were first reported to be discovered in an elementary school outbreak in 1968 in Norwalk, Ohio, where 50% of the students and teachers developed gastrointestinal illness, from which the name 'Norwalk-like' virus was derived by Albert Kapikian. HNoV transmission occurs all year round; however, outbreaks peak in winter and the so-termed winter vomiting disease is characterized by mild gastroenteritis and symptoms including fever, nausea, vomiting, abdominal cramps, and headaches. Recent reports indicate that emerging virulent strains are found to be capable of causing death in the elderly or immunocompromised. Their average incubation time is 24–48 h and the self-limiting symptoms last from 18 to 48 h, with virus shedding that occurs for 72 h (and even longer, >1 week). This is an important consideration for food handlers/workers, who need to maintain good hygienic practices to prevent transmission upon return to work after their symptoms subside. In addition to outbreaks associated with food settings, HNoV outbreaks have been reported to occur yearly on cruise ships, in elderly care facilities, and in closed environments.

Noroviruses are small nonenveloped containing a single-stranded positive-sense RNA that is enclosed in a capsid (outer shell protein), about 27–32 nm in size, with a buoyant density of 1.33–1.41 g cm^{-3}. HNoVs have icosahedral symmetry, with a capsid that comprises 90 capsomers protruding from the shell made of 90 dimers of capsid protein. The genome is about 7.3–7.7 kb long with three open reading frames (ORFs), namely, ORF1 that encodes a polyprotein that produces the RNA-dependent RNA polymerase and other proteins such as the viral protein genome-linked and N-terminal protein; ORF2 that encodes the major capsid protein, viral protein 1 (VP1); and ORF3 that encodes a minor viral structural protein, viral protein 2 (VP2). Based on sequence information, the genus *Norovirus* is further divided into five genogroups, GI, GII, GIII, GIV, and GV, and GI, GII, and GIV are reported to specifically infect humans. GIII includes bovine enteric calicivirus that is known to infect cattle, and GV infects mice. These genogroups are further subdivided into at least 32 genetic clusters to date. In GI and GII, 8 genotypes are currently recognized in GI and 19 genotypes are recognized in GII. HNoV GII.4 has been found to be the predominant cause of 70–80% outbreaks in the United States and Europe (mostly associated with health care settings).

HNoV is reported to bind to the histoblood group antigens in human intestinal epithelial cells, and the site of replication is considered as the upper intestinal tract by some researchers. Genetic determinants for these blood group antigens are known to play a role in susceptibility of an individual to HNoV infection. Human volunteer studies have shown that H type I antigen likely serves as the receptor for hNoV, encoded by the fucosyltransferase (*fut2*) gene where recessive individuals that lack the type I antigen are reported to be inherently resistant to HNoV infections.

With regard to survival, researchers have shown that HNoV GI and HNoV GII can persist in the environment for prolonged periods, depending on several factors including temperature and moisture. HNoVs are reported to survive at low pH of 2.7 and can retain infectivity after 60 °C for 30 min and after exposure to 20% ether at 4 °C for 18 h. Their resistance is found to be higher in foods and they are also reported to be

resistant to free residual chlorine of 0.5–1.0 mg ml^{-1} by researchers. HNoVs are known for their low infectious dose ranging from 18 to 100 virus particles. Teunis et al. reported that the infectious dose for Norwalk in human subjects ranged from 0.1 (at a dose of 10^3 NV genomes) to 0.7 (at 10^8 virus genomes). In a study by Atmar et al., the human infectious dose (50%) for Norwalk strain was reported to be approximately 1320 genomic equivalents as detected by RT-PCR.

The inability to cultivate HNoVs in the laboratory has hindered the development of vaccines as well as effective control measures. There is no vaccine available to date against HNoV infection. Cultivable surrogates such as feline calicivirus (FCV-F9) and murine norovirus (MNV-1) have been extensively used to understand the antigenicity of HNoVs and evaluate methods of inactivation. Recently, Tulane virus (TV) and porcine enteric sapovirus have been considered as alternate surrogates. The cultivable HNoV surrogate, FCV-F9 of the Caliciviridae family, is a small rounded, nonenveloped, single-stranded RNA virus with a 7.7 kb genome and has 3 ORFs, being similar to HNoVs in these features. However, as it is transmitted via the respiratory route and is also reported to be sensitive to low pH of 2–4 and pH 10 by Cannon et al. and other researchers, it may not completely mimic the survival of HNoV in the environment.

The other cultivable HNoV surrogate, MNV-1, is currently the only norovirus that replicates in the laboratory in murine macrophage RAW 264.7 cells. MNV-1 belongs to GV norovirus, with sequence similarity to GII noroviruses that mainly infect humans. MNV-1 is similar to HNoVs in immunologic, biochemical, genetic, and molecular properties, as MNV-1 is an icosahedral, nonenveloped, single-stranded RNA virus containing 3 ORFs and is 28–35 nm in size. Although it causes a different disease in mice, it is transmitted via the fecal–oral route similar to HNoVs. Unlike FCV-F9, it is reported to be less sensitive to pH within ranges of 2.0–10.0; however, the thermal inactivation parameter processes like pasteurization (at 63 °C) were reported in literature to be similar for both FCV-F9 and MNV-1.

Recently, TV representing a new genus *Recovirus* of the Caliciviridae family was reported to be isolated from the stool samples of a captive juvenile rhesus macaques (*Macaca mulatta*) at the Tulane National Primate Research Center. TV is 36 nm in diameter and icosahedral in symmetry, with a short genome of 6.7 kb, containing 3 ORFs without the poly(A) tail. Sequence homology and phylogenetic analysis of the nonstructural proteins of TV have revealed them to have the highest identity with HNoVs.

TV has been reported by several researchers to be readily grown *in vitro* in LLC-MK2 (rhesus macaque kidney) host cells. TV is also reported to bind to histoblood group antigens like HNoVs, suggesting that the antigenic determinants may be related and/or comparable to HNoVs. Studies have reported no significant differences in heat inactivation parameters between MNV-1 and TV, though MNV-1 was found to be more pH-stable and more tolerant to chlorine than TV. Therefore, the choice of appropriate cultivable surrogates for HNoVs currently remains debatable.

Regarding the application of cultivable surrogates for inactivation studies, 200 mg ml^{-1} sodium hypochlorite, 2% trisodium phosphate, ozone at 6.25 ppm, hydrogen peroxide vapors (30% w/w), heating at 72 °C, and high hydrostatic pressures of 450 MPa after 5 min at 20 °C were reported in literature to cause some though varying levels of inactivation of the cultivable HNoV surrogates, FCV-F9 and MNV-1. Even though inactivation strategies are based on the evidence obtained from surrogate studies such as the ones mentioned earlier in the text, this information may not be completely applicable to HNoV itself. Appropriate conclusions should be drawn from feeding studies using the actual HNoVs that have been subjected to the treatments described previously.

Treatment and Prevention Strategies for HNoV

There is no specific antiviral treatment against HNoVs. Gastroenteritis and dehydration can be treated by oral or intravenous fluid therapy. There is no vaccine currently available against HNoVs, the major barrier being the inability to culture them *in vitro*. Studies using human volunteers reinfected with HNoV after exposure showed these volunteers to be susceptible to the same strain as well as heterologous strains, suggesting either short-term immunity or none. HNoV spread and contamination can be prevented by proper sanitation and hygienic food handling practices or by appropriate treatment regimes such as heat, chemicals, or other processing conditions listed earlier in the text (refer to **Table 1** for recent outbreaks).

Hepatitis A Virus

HAV of the Picornaviridae family is a positive-sense single-stranded nonenveloped RNA virus ranging in size from 27 to 32 nm, similar to HNoVs. The genome is 7.5 kb in length and, unlike HNoVs, consists of a single ORF. The P1 region of the genome encodes three major viral structural capsid proteins, VP1, VP2, and VP3. P2 and P3 regions encode proteins required for RNA replication and the formation of virions. Only one serotype of HAV has been identified to date and a single exposure is reported to render lifelong immunity. However, genetic diversity in the strains worldwide led to their classification into seven genotypes designated I–VII that is known to infect either humans or simians.

The largest foodborne viral outbreak was reported by Halliday et al. where 292 301 cases of HAV were attributed to eating raw clams in Shanghai, China, in 1988. The average incubation period of HAV is long (unlike the short incubation period of HNoVs), about approximately 28 days with severe symptoms that can last for 4–6 weeks that include jaundice, dark urine, vomiting, fever, and weight loss. Among older children and adults, infection is usually symptomatic for 2 months, with jaundice occurring in 70% of patients. There are four phases reported for HAV infection: the first phase is the asymptomatic incubation phase, which lasts for 10–50 days, followed by three symptomatic phases, namely, the preicteric phase that lasts for several days to weeks, characterized by fatigue, nausea, loss of appetite, fever, dark urine, diarrhea, and pale stools; the icteric phase with jaundice; and the convalescent phase.

There are only a few strains of HAV that are cell culture-adaptable. These strains produce cytopathic effects causing cell death and hence used in research involving survival and inactivation studies.

HAV is also highly stable in the environment and reported by several research groups to retain infectivity in mineral water

stored at room temperature even after 10 months, after a month at ambient temperatures on environmental surfaces, and for >4 h on hands, during prolonged storage of spinach leaves at 5.4 °C, and on romaine lettuce leaves after 12 days in a sealed-atmosphere plastic package at 4 °C.

HAV is also reported by researchers to survive at low pH of 3.75 over 4 weeks and at pH 1.0 even after 5 h, after 60 min at 60 °C. However, HAV is reported in literature to be inactivated in shellfish after heating at 85–90 °C for 1.5 min and at 450 MPa hydrostatic pressure for 5 min. These survival features play a significant role in the transmission of HAV.

Treatment and Prevention Options for HAV Infection

Once a person is infected with HAV, there are no known specific treatment options available. However, symptoms of HAV infection are reported to be alleviated by appropriate patient care that includes adequate hydration, nutrition (fatty foods are recommended to be avoided), rest, and antiemetics. For prevention, immunoglobulin therapy is reported to be effective when administered within 2 weeks of viral exposure (through passive immunity). As preventive measures, inactivated and heat-killed vaccines against HAV are commercially available, which provide immunity against HAV for almost >20 years or a lifetime. The US Centers for Disease Control and Prevention (CDC) recommend routine vaccination against HAV for children aged between 12 and 23 months. When economically feasible, vaccination of food handlers is also recommended to prevent HAV transmission and to prevent outbreaks (refer to Table 2 for recent outbreaks).

Hepatitis E Virus

HEV is a small nonenveloped 7.2 kb single-stranded positive-sense RNA virus, 32–34 nm in size, primarily transmitted through the fecal–oral route, usually through contaminated water. HEV of the genus *Hepevirus* in the Hepeviridae family has a genome containing three ORFs. ORF1 codes for a nonstructural polyprotein that forms helicase, protease, and a RNA-dependent RNA polymerase. ORF2 encodes the capsid protein and ORF3 encodes a replication and cytoskeleton synthesis phosphoprotein. Thus far, four genotypes of HEV have been reported with genotypes 1 and 2 affecting humans and genotypes 3 and 4 infecting swine.

The average incubation period for HEV infection is reported to be between 2 and 10 weeks, with two distinct phases of illness. The preicteric phase is known to be characterized by fever, anorexia, vomiting, and abdominal pain, while the icteric phase is characterized by jaundice and is self-limiting. Viral shedding is reported to occur 1–2 weeks before and 2–4 weeks after the symptoms appear. A significant rise in serum alanine aminotransferase and aspartate aminotransferase occurs, which is used as detection methods of liver injury. Due to its long incubation period, the association of HEV with particular foods has not been clearly established; however, recent studies report that HEV gt3 transmission is linked to uncooked pork meat consumption. There is no specific treatment except patient care as described earlier in the text for HAV symptom alleviation. PEGylated interferon administration has been reported for use in chronic infections with some level of moderate success. Vaccine trials have been under study to determine preventive measures (refer to Table 3 for outbreaks).

Rotavirus

RV of the Reoviridae family has a multilayered nonenveloped icosahedral capsid, ranging from 60 to 100 nm in size, and is easily distinguishable from HNoVs or HAV by electron microscopy. RV genome comprises 11 segments of double-stranded RNA that code for structural (VP1–VP8) and nonstructural

proteins. These proteins form the multilayered capsid of the mature virus that encapsulates the core genome. The complete virion is called a triple-layered particle and is infectious. The structural proteins VP7 and VP4 make up the outermost core layer. Seven RV groups are reported from A to G, with groups A, B, and C reported to be associated with human infections and genotypes G1P8, G2P4, G3P8, G4P8, and G9P8 the most commonly identified worldwide.

RV is a common cause of acute gastroenteritis in children younger than 5 years. RV was first discovered by Bishop et al. using electron micrographs of intestinal and stool biopsies of pediatric gastroenteritis patients that showed a typical wheel shape and hence the *Latin* name 'rota' meaning wheel. The incubation period for human RV is reported to be around 1–3 days. The reported symptoms occur 48 h after RV infection that include watery diarrhea, abdominal pain, vomiting, and dehydration, with severe diarrhea resulting in high mortality rates worldwide. Tate et al. reported that in the 1980s, there were 870 000 deaths linked to RV infection globally, with current numbers around 450 000 per year, and developing countries such as the Democratic Republic of the Congo, Ethiopia, India, Nigeria, and Pakistan accounted for greater than half of total RV-related deaths, with India accounting for 22% (98 621) of deaths. Many RV outbreaks are known to occur due to contaminated water, unhygienic practices, and unsanitary conditions.

Human RV is also reported to survive and retain antigenicity after 5 mg ml^{-1} chlorine treatment for 60 min. Heating at wet (100 °C) and dry (60 °C) conditions for periods of 1–20 min and high-pressure processing (HPP) at 350 MPa at 4 °C have been reported by researchers to have some effects on RV titers. Commercial cranberry and grape juices at native pH and natural substances such as persimmon extract and wattle extract (0.5% solution) are also reported in literature to cause some reduction in RV titers.

Animal model systems have been developed to study and improve strategies for protection against infection from various RV serotypes/isolates. Two Simian RV strains SA11 and Rhesus rotavirus (RRV) are being used as reference strains worldwide and some of the currently available reassortment vaccines are reported to be based on the RRV strains. As a preventive measure against human RV infection, the World Health Organization recommends vaccination that is reported to have significantly reduced RV-related gastroenteritis and mortality (refer to **Table 3** for outbreaks).

Aichi Virus

AiV of the genus *Kobuvirus* in the Picornaviridae family was reported by Yamashita et al. to be first isolated in 1989 from patient stool samples in a gastrointestinal outbreak involving oysters in Aichi, Japan. AiV virions are icosahedral and 30 nm in diameter with three capsid proteins. AiV has a positive-sense single-stranded RNA and a poly(A) tail, with a single ORF encoding for structural proteins VP0, VP1, and VP3. The nonstructural proteins include 2A, 2B, 2C, 3A, 3B, 3C, and 3D. Three distinct genotypes of AiV are reported as A–C. AiV-related gastrointestinal cases have been reported from Asian, African, European, and South American countries indicating its geographic spread and prevalence. AiV is reported to survive (without reduction) HPP treatment of 600 MPa for 5 min, heating at 50 and 60 °C for 30 min, 10% chloroform, and MEM (pH 3.5) for 3 h. However, AiV is reported to show some inactivation by 240 mW s cm^{-2} of ultraviolet light treatment and suggested to be useful for AiV reduction on fresh produce like strawberries, green onions, and lettuce by some researchers.

Sapovirus

Sapovirus of the Caliciviridae family is a 7.5 kb positive-sense single-stranded RNA virus, 41–46 nM in diameter, that is known to infect humans and pigs. Sapporo virus (SaV), the human prototype, was reported by Atmar et al. as being first identified during an outbreak in Sapporo, Japan, in 1977 in an infant home. This virus has ten spikes on the outer surface; sapoviruses are divided into five genogroups. GI, GII, GIV, and GV infect humans and GIII infects pigs. Genomes of GI, GIV, and GV are reported to contain three ORFs and GII genomes are reported to contain two ORFs. RNA-dependent RNA polymerase and a major capsid protein (VP1) are encoded by ORF1, a small protein is encoded by ORF2, and ORF3 encodes for a protein whose function is currently unknown. Outbreaks of SaV are less frequent than HNoV; however, significant increases in SaV outbreaks have been reported to occur in various settings (closed populated environments) such as elementary schools, high schools, hospitals, and hotels. SaV is also reported to be associated with treated and untreated sewage and river water. The average incubation time is ~24–48 h with symptoms like fever, diarrhea, nausea, abdominal pain, chills, and malaise. Human SaVs like HNoVs are currently uncultivable.

Porcine sapovirus (Cowden strain), an enteropathogen that causes gastroenteritis in gnotobiotic pigs, is as another HNoV surrogate that is reported to be cultivated in the swine kidney cell line, LLC-PK. Both porcine SaV and HNoV have been reported by researchers to show similar resistance to HNoVs with regard to heat (50 °C for 30 min), treatment with sodium hypochlorite for 1 min, and pH ranging from 3.0 to 8.0. All these findings strongly support the use of porcine SaV as a surrogate to study HNoV.

Adenoviruses

AdV were reported to be first isolated from civilians and Army recruits who had respiratory disease. AdVs of the genus *Mastadenovirus* are 90–100 nm, 26–45 kb double-stranded DNA viruses enclosed in a nonenveloped, icosahedral shell. Fifty-two human AdV serotypes are reportedly proposed in literature according to Jones et al. based on their genomic, physical, and biological properties, which are further divided into six species, *Human adenovirus A to G*. The most widely associated with acute gastroenteritis are reported to include subgenera 'F' carrying AdV types 40 and 41 and 'A' carrying AdV types 12, 18, and 31. HAdV serotypes 40 and 41 are reported to be the second leading cause of viral gastroenteritis in children after RV.

Clinical manifestations of HAdVs reportedly range from upper and lower respiratory tract infections, pneumonia, conjunctivitis to gastroenteritis, and urinary tract infections. HAdVs are known to cause mild and self-limiting disease, and severe clinical presentations, if any, are known to include cystitis, enteritis, encephalitis, and pneumonia. Additionally, reported symptoms include diarrhea, vomiting, dehydration, and fever that develop after an incubation period of 8–10 days and last for 7–8 days, with shedding of virus until 7–14 days after infection.

Astroviruses

Astroviruses are small star-shaped, nonenveloped, single-stranded positive-sense RNA viruses, ~30 nm in size, that were reported by Appleton et al. to be first identified in children suffering from diarrhea in a maternity ward in England that year. Their name originates from the Greek word 'astron' meaning star, due to the five starlike projections on the virus. Astroviruses belong to the family Astroviridae that is divided into two genera: *Mamastrovirus* (which infect mammals) and *Avastrovirus* (which infect avians). Their genome is about 6.8–7.9 kb with a 5′ untranslated region and 3 ORFs, ORF1a, ORF1b, and ORF2. ORF1 encodes a RNA-dependent RNA polymerase and a protease, and the viral capsid is encoded by ORF2. Astroviruses are not easily cultivable *in vitro*; hence, their classification is mostly established and based on nucleotide and amino acid variability of ORF2. To date, there are eight known serotypes reported for human astroviruses (HAstV), and type 1 is reported to be the most prevalent. Along with the genetic diversity of ORF2, HAstV are further classified into two genogroups, A that includes

serotypes 1–5 and 8 and B that includes serotypes 6 and 7. When culturable, HAstV is reported to be grown using the human colon carcinoma host cell line (Caco-2).

HAstVs are reported to be a common cause of gastroenteritis in children with symptoms that develop 2–3 days after infection. These symptoms include diarrhea, vomiting, abdominal pain, headache, and dehydration. However, affected persons may not require hospitalization as symptoms are reported to be self-resolving. HAstV is known to infect the immunocompromised, elderly, and healthy adults, though children under 2 years are most susceptible. Astrovirus is also known to survive in the environment for long periods of time, including water and surfaces for 60 days at 4 °C and in water at 20 °C, and is reported to be resistant to 1 mg l^{-1} free chlorine by researchers. There is little evidence for foodborne transmission of AdV and astroviruses; however, given their fecal–oral route of transmission, infection upon consumption of contaminated food is quite likely to occur.

Parvovirus

Parvovirus of the Parvoviridae family is a small icosahedral, nonenveloped 5 kb single-stranded DNA virus, 18–26 nM in size. It was reported to be discovered in 1974 while testing for hepatitis B surface antigen, with a buoyant density of 1.39–1.42 g cm^{-3}. Three genera are known based on transcription maps, terminal repeats, and mode of replication: *Parvovirus* (autonomous), *Dependovirus* (replication with helper virus), and *Erythrovirus* (invasion of RBCs), and only *Dependovirus* and *Erythrovirus* are reported to infect humans. Parvovirus genome has 2 ORFs that code for viral proteins VP1 and VP2 (the major capsid protein) and nonstructural proteins.

Parvoviruses are also known to survive in the environment, and researchers have reported them to be resistant to pH between 3 and 9 and heat at 56 °C for 60 min. However, they are reported to be inactivated by formalin and gamma radiation. Parvoviruses have been linked to outbreaks involving shellfish. The 'cockle agent' parvovirus was reported by Appleton et al. to be associated with a large outbreak related with contaminated cockles in the United Kingdom that affected around 800 people.

Other Enteric Viruses: Enteroviruses, Toroviruses, and Picornaviruses

Enteroviruses

Enteroviruses of the Picornaviridae family are nonenveloped, ~7.2–8.4 kb positive-sense, single-stranded RNA viruses, 28–30 nM in size. They include polioviruses, coxsackie A and B viruses, and echoviruses; are transmitted by the fecal–oral route; and are associated with humans and animals. Their incubation period lasts from 3 to 7 days and can be transmitted 3–10 days after symptoms appear. They are typically culturable in the lab. Poliomyelitis linked to the consumption of raw milk in 1914 was the first recorded foodborne virus outbreak as reported by Jubb, and other enterovirus outbreaks are linked to contaminated shellfish, marine life, and freshwaters. Immunization against polioviruses worldwide, pasteurization of milk, and appropriate cooking have reportedly led to the decreased transmission of these enteroviruses.

Toroviruses

Toroviruses of the Coronaviridae family and genus *Torovirus* are positive, single-stranded RNA viruses (~28 kb in length) around 100–150 nM in size. They are known to be isolated from feces of children and adults with diarrhea (bovine, equine, and porcine toroviruses are also known in addition to human toroviruses). However, their role in human foodborne gastroenteritis remains unknown.

Picornaviruses

Picornaviruses of the Birnaviridae family are 35 nM, RNA viruses, associated with gastroenteritis in immunocompromised HIV-infected individuals, and reported to be detected in humans with and without diarrheal symptoms. The role of these viruses as well as that of toroviruses in human foodborne gastroenteritis is yet to be understood.

Overall Brief Summary of Detection Methods Used

Historically, foodborne virus detection was based on infectivity assays using live susceptible host cells to determine either cytopathic effect (TCID50) or plaque assays for plaque-forming viruses. However, these methods cannot be applied for HNoVs and wild-type HAV that are yet to be successfully and reproducibly propagated in mammalian cell-culture systems with established protocols. Immunologic-based assays (such as ELISA and immunoelectron microscopy) are used mainly for clinical detection using antibodies against known genotypes of HNoV or HAV. Their disadvantages include limited detection sensitivities, which make them unsuitable for detecting low viral loads, associated with food-related outbreaks. They are however suitable for clinical specimens where the viral load/titer is high.

The challenges associated with detecting low numbers of noncultivable HNoVs and HAV in foods include sample concentration, sample purification, and nucleic acid extraction with simultaneous removal of inhibitors that can negatively impact downstream detection as extensively reviewed before in literature (see 'Further Reading'). Rapid and sensitive robust detection methods are therefore needed to prevent food recalls and outbreaks. As the significant foodborne viruses are RNA viruses, reverse transcription PCR has reportedly been the 'gold standard' for their detection or PCR for the detection of DNA viruses. Typically, specific primers are used to prevent cross-reactivity from the food matrix. However, at times, degenerate primers are used to ensure detection of variants or newly emergent strains. For food samples, however, confirmation of RT-PCR products is needed and essential that requires time-consuming hybridization assays, restriction digestion of amplified products, nested PCR, or traditional sequencing. With the advent of real-time approaches, improved primer and probe design have enabled detection without the need for gel electrophoresis, where simultaneous amplification, detection, and confirmation occur. These approaches use intercalating dyes

such as SYBR green I (confirmation using melt temperature curves is needed), fluorescent hydrolyzing probes such as in TaqMan PCR, and hybridizing probes such as molecular beacons or FRET-PCR and also have been reviewed in literature (see 'Further Reading').

Isothermal nucleic acid amplification is another ongoing trend for rapid detection that eliminates the need for expensive thermocyclers that have been traditionally used in PCR-based approaches. Nucleic acid sequence-based amplification and loop-mediated isothermal amplification are isothermal approaches being researched for HNoVs, HAV, and other foodborne virus detection by several researchers worldwide. Biosensors and microarrays (lab-on-chip) also continued to be researched. As the field of 'omics' continues to advance and next-generation sequencing technologies become relatively inexpensive, it is very likely that these approaches/technologies will be routinely used and/or adapted for rapid foodborne virus detection in clinical and food environments. However, simultaneous advances in sample concentration and purification methods need to occur to match and parallel the advances in detection.

Future Directions for the Prevention and Control of Emerging Foodborne Viruses

Some of the described novel rapid detection methods are not routinely implemented in testing laboratories, due to the disadvantages associated with cost, labor, and sample preparation. It is important to note that novel approaches should not significantly increase the market price of tested products. Timely detection is one way to prevent contaminated food from being released to the market, followed by implementation of efficacious mitigation strategies to control and curb virus spread. Vaccination can help prevent viral spread, although vaccines are not available for some of the foodborne viruses. In the absence of vaccines, good sanitation and hygienic practices are the most important strategies that must be implemented to prevent viral disease transmission. If an outbreak does occur, rigorous control measures should be instituted to prevent transmission. In addition, emphasis must be placed on public education. As stated before by several researchers, together with improved monitoring and detection, effective mitigation and control, immunization, and foodservice and public education, there remains optimism among the global research community in attaining the goal of decreasing and/or preventing foodborne viral disease outbreaks.

Food–Herbal Medicine Interface

M Heinrich, UCL School of Pharmacy (University of London), London, UK

© 2016 Elsevier Ltd. All rights reserved.

Foods are generally seen as nourishing and providing the (human) body with the essential nutrition needed. On the other hand, medicines have a clearly defined role in the treatment and specific prevention of a disease. However, food items more and more become 'functionalized,' that is, they are marketed with a specific (preventive) health claim or with a functional claim, for example, as a sport supplement. 'Functionalities' like keeping a healthy skin and mental well-being are claims made for specific products and are incorporated into new brands of cereals, baked goods, drinks, dairy products, oils and fats, and snacks, as well as into products that are sold specifically to supplement an existing diet.

There is substantial scientific agreement that certain foods have beneficial effects on health. Examples include the following:

- Garlic, turmeric, ginger, and many so-called spices
- Anthocyanin- or flavonoid-rich species like grapes (red wine), cranberry, bilberries, and cocoa
- Carotenoid-rich species yielding vegetables including carrots and tomatoes

These have general health benefits, that is, not specific benefits that could be linked to treating or preventing a specific disease.

Products with acclaimed or well-demonstrated health benefits have become an important element of the food market. It is impossible to assess the total value of this segment of the food market since it is difficult to delineate and it is fragmented in a wide range of niches. On the other hand, it is clear that it is a fast-developing and changing market, which very heavily relies on incorporating 'novel' products generally derived from local or traditional knowledge. The most recent boom product seems to be chia (the seeds of *Salvia hispanica* L., Lamiaceae). Other botanical drugs, which in recent years were pushed onto the global markets, include goji (*Lycium barbarum* l., Solanaceae), mangosteen (*Garcinia mangostana*), and açai (*Euterpe oleracea* Mart., Arecaceae). Thus, in general terms, there are two essential themes that need to be covered in such an overview:

– The interface of food and medicine
– The development of local and traditional resources into global commodities

The following addresses these themes within the framework of the current regulatory mechanisms and ambiguities.

The Regulatory Framework

The regulatory framework governing such products varies from country to country and highlights that this situation is in fact far more complex. Here again, products sit at the (varying) borderline between what is classified as a food (or a food supplement) and what is classified as a medicinal product. For example, in the United States, herbal medicines are generally regulated by the US Food and Drug Administration (FDA) as 'dietary supplements' (www.fda.gov/Food/DietarySupplements/). In the European Union, on the other hand, there is a clear distinction between foods that are sold with a specific claim and (herbal) medicines. In December 2006, the regulation on nutrition and health (i.e., preventive) claims made on foods was adopted by the European Council and Parliament. For the first time, this regulation lays down harmonized rules across the European Union for the use of nutrition claims such as 'low fat' and 'high fiber' or health claims such as 'reducing blood cholesterol' (http://ec.europa.eu/food/food/labellingnutrition/claims/).

Using five botanical drugs commonly sold in five countries as an example, **Table 1** highlights the diverse regulatory status of, in botanical terms, very similar preparations. In some countries, a well-developed unique regulatory framework for herbal medicines exists (e.g., the listed medicines in Australia), while in other cases, no, or a much looser, regulation is used that generally combines food supplements and herbal medicines.

The terminology used in this area is complex and often confusing. For example, in the United States, a dietary supplement is a product taken orally that contains a 'dietary ingredient' intended to supplement the diet. The 'dietary ingredients' in these products may include vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites. Dietary supplements can also be extracts or concentrates and may be found in many forms such as tablets, capsules, softgels, gelcaps, liquids, and powders (http://www.fda.gov/Food/DietarySupplements, accessed 7 August 2014). The more popular is nutraceutical. It is generally defined as a type of food substance that helps maintain health and prevents illness. This term is also used interchangeably with concepts like nutraceutical or functional food and food supplement. The concept of nutraceuticals was introduced in 1989 by the American medical doctor Stephen L. DeFelice claiming that "[t]he nutraceuticals revolution will lead us into a new era of medicine and health, in which the food industry will become a research-oriented one similar to the pharmaceutical industry" (DeFelice, 1995. *Trends in Food Science & Technology* 61, 59). He concludes that once the vastness of the potential nutraceutical market will be appreciated, "nutraceutical research will begin to flourish mightily owing to the energy and creativity of corporate capitalism" (p. 61).

However, these concepts are not identical. Functional foods are foods normally consumed in the diet that have scientifically been assessed to have health benefits. Dietary supplements are ingestible preparations purposefully added to the diet to benefit health but are not necessarily derived from foods (i.e., from plants, fungi, or animals consumed as food).

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00772-8

Table 1 Examples of the regulatory status of some common products used as a functional food/nutraceutical and/or medicine

	The United Kingdom	*Australia*	*Russia*	*The United States*	*Germany*
Ginkgo	Food supplement/traditional medicine	Listed medicine[a];[a]	Food Supplement	Dietary supplement	Medicine
Echinacea	Medicine/traditional medicine/food supplement	Listed medicine[a];[a]	Medicine	Dietary supplement	Medicine
Cimicifuga	Traditional medicine	Listed medicine[a];[a]	Medicine/food supplement	Dietary supplement	Medicine
Siberian ginseng	Food supplement	Listed medicine[a];[a]	Medicine	Dietary supplement	Medicine/food supplement
Mangosteen	Food	Food	Food	Food/dietary supplement	Food

Traditional medicine – a product registered under the Traditional Herbal Medicinal Products Directive of the EU

[a]Listed medicine – according to the Australian regulations, a listed medicine has a lower level of claims and these medicines are not evaluated for efficacy, but product sponsors must hold evidence to support the claims they make about the product.

Nutraceuticals, on the other hand, are products with biological functions that are derived only from foods. Similar to dietary supplements, they generally are consumed in a form that resembles a medicinal product, and they usually are sold over-the-counter (OTC). These distinctions, however, are complicated by the fact that many substances fall within all three categories. For example, beta-carotene not only occurs naturally in fruits, vegetables, and grains but also is manufactured (e.g., extracted from plants or animals and purified) and sold as a dietary supplement and as a nutraceutical.

The Food–Medicine Interface and Commercial Development of (New) Products

All such products are often sold with remarkable health claims, such as being able to slow the aging process. However, these claims are problematic and difficult to substantiate. Since foods are not used in the treatment of diseases, in many regulatory systems, the claim that nutraceuticals can treat disease is deemed inappropriate for a food substance. In addition, in some 'therapeutic' areas, grossly fraudulent claims and adulterated products plague the market.

A now classical example of an unsuccessful development is *Hoodia gordonii* (Masson) Sweet ex Decne (Apocynaceae), first developed with the goal of commercializing a medicinal product and then, after this was not possible, a food supplement. *Hoodia pilifera* (L.f.) Plowes (Apocynaceae) and *H. gordonii* are succulent, slow-growing desert plants in southern Africa and have traditionally been used by indigenous groups to suppress thirst and hunger (especially during long stays in the desert). Since the nineteenth century, *H. pilifera* has been known to quench thirst. The discovery of this 'drug lead' has specifically been linked to the Khoisan people, but other groups could equally lay claim on this traditional knowledge. During the early 1960s, research started focussing on nutritional and safety aspects. In 1983, the appetite suppressant effect of the plant extracts was established. In the 1990s, phytochemical research at the Council for Scientific and Industrial Research (CSIR) of South Africa identified two hunger-suppressing pregnane glycosides from *H. gordonii*, which in 1997 were then patented. Very quickly, this patent attracted the industry's interest, and Phytopharm (a small UK-based company) took a lead in further developing it. The focus was on the extracts' and compounds' appetite suppressant and later their antidiabetic effects. In 1998, the product (labeled P57) was sublicensed to Pfizer and the company started clinical studies for treating obesity. The ultimate goal of this R&D effort was a *fully licensed medicine* on the basis of a characterized extract with a defined amount of the active constituent for the treatment of obesity. Developing the drug required considerable clinical and preclinical research, but in July 2003, Pfizer unexpectedly returned the license to Phytopharm. In late 2004, the food giant Unilever stepped in with the strategic goal of developing a *slimming food*, that is, a food supplement, and in 2007, Unilever, too, returned the rights, which has resulted in an end of any serious research and development on *H. gordonii* product

Without doubt, the preparation from *H. gordonii* studied decreased energy intake, which in turn can result in weight loss. However, the side effects including most importantly potentially lethal hypertension, loss of skeletal muscle mass, and also general feelings of gastrointestinal discomfort are so severe that such a product cannot be used as either a food supplement or a (herbal) medicine. Toxic effects could in fact have been predicted by the structure of the pregnane glycosides, but this was ignored during the preclinical, clinical, and later the food supplement development. Importantly, other crucial aspects for developing a product from a local knowledge-based herbal preparation had been ignored or started very late in the development process. *H. gordonii* is a traditional food and medicinal plant of the Khoisan but had been patented without their prior consent. Consequently, these groups and other stakeholders challenged this lack of intellectual and financial recognition, resulting in 2004 in a belated benefit-sharing agreement. On a positive note, this was, in fact, one of the first benefit-sharing agreements and gave the Khoisan a share of royalties derived from the sale of products containing the patented extract. The second unresolved problem had been the supply side of the crude drug. *Hoodia* species are slow-growing, succulent desert plants and the pregnane glycosides cannot be obtained synthetically. Also, the commercial goal has been the development of an enriched extract for use as a medicine or a food supplement. Clearly, the huge number of obese people in the world

would have resulted in an extremely high demand for the botanical starting material. This supply problem is directly linked to the reported high rate of adulteration of commercially available *H. gordonii* products. *Opuntia ficus-indica* (L.) Mill. (Cactaceae) is a cheap and easily available adulterant. Since it is the source of prickly pears, the cladodes are a common waste product of the fruit production. Adulteration is often the responsibility of unscrupulous companies that only have their short-term profit in mind, but it is also linked to the limited supply with *H. gordonii* and to uncontrolled and poorly managed value chains. The limited supply is due not only to the slow-growing nature of the desert plant but also to the need for a certificate based on the Convention on International Trade in Endangered Species (CITES) resulting in the need for permits to cultivate and export the crude drug and the overall high demand by consumers.

This example was presented in some detail in order to not only highlight the complex links between food and medicines but also demonstrate the need for a stringent regulatory framework for any product that makes specific preventive or curative health claims. In other cases, the problems are simply misleading or grossly inappropriate claims have been a problem, as exemplified in the case of açai (*Euterpe oleracea* Mart., Arecaceae), which has been one of the most highly praised nutraceuticals for the last years but which seems to be a boom and bust product. Overall, there is unconvincing and insufficient scientific evidence to validate the acclaimed uses.

Mangosteen (*Garcinia mangostana* L., Clusiaceae) highlights some examples of opportunities that arise out of developing high-value food supplements. It has a long history of use as a medicinal and food plant, mostly in Southeast Asia. Its fruit is an important food product, also used to treat skin infections and wounds and well known for its anti-inflammatory properties. It is also used to treat dysentery, different urinary disorders, cystitis, and gonorrhea. Commercial preparations based on *G. mangostana* are now distributed increasingly all over the world especially as 'liquid botanical supplements.' Central to the biological activity of the species are xanthones, polyphenolic compounds based on a skeleton of a xanthene-9-one with a range of significant *in vitro* biological activities. A serious weakness in our knowledge is the lack of intervention studies or clinical data and it is not yet clear to what extent the *in vitro* findings about pharmacological activities can be extrapolated to specific therapeutic benefits. However, a general use as a food supplement seems to provide adequate health benefits and these can be substantiated with some relevant data.

The general advice is that such products can supplement one's diet but that they cannot be a substitution for a healthy diet nor can they cure any disease. However, and most importantly, due to misleading commercial interests, this is often not spelled out clearly.

Let Food Be Thy Medicine and Let Medicine Be Thy Food

While the preceding text has been very much informed by a debate based on the different regulatory frameworks, increasingly, there also is a renewed scholarly debate about the borderline between food and medicine. Famously, the idea of "let food be thy medicine and let medicine be thy food" (attributed to Hippocrates, 460–377 BC) has continued to stimulate the debate about health, healthy living, and the interface of food and medicine. In the context of ethnopharmacology, Nina Etkin and Paul J. Ross led the discussion toward a (renewed) emphasis on the links between these two elements of human culture. It has been argued convincingly that we should set aside a place for food and try to understand its health-promoting effects. A diverse range of scholarly work has investigated food uses, people concepts about these foods, and a wide range of health benefits of such products and more recently assessed the globalization of local resources.

Taraxacum officinale (L.) Weber ex FH Wigg. (Asteraceae) is another example one can use to highlight the conceptual questions associated with the food–medicine interface. Clearly, dandelion is both a food and a medicine. Historically, it was very widely and is still consumed in salads. Also, in popular European medicine, it is considered to be a 'blood purifier.' It is employed for treating arthritis and rheumatism, as a mild laxative, and for skin conditions like eczemas. The German *Frühjahrskur* (a cleansing diet consumed in the spring) has a long tradition of use as an aqueous decoction or juice of the fresh plant. The therapeutic use is mainly based on the empirical findings over many centuries and certainly not, in a strict sense, evidence-based. Such cleansing could equally well be considered to be a 'health food' or a medical use. Some uses are clearly based on specific therapeutic expectations. The distinction between its medical and food uses is fluid and is clearly culturally constructed. They are linked to specific ways of preparing and consuming dandelion and most importantly to the context of the usage given.

This plant has given rise to some commercial food or herbal medical products. Until now, clinical studies on *Taraxacum officinale* are lacking. Some pharmacological investigations support the empirical local uses in particular to treat digestive disorders. Anti-inflammatory, anticarcinogenic, and antioxidative activities have also been reported. Various polyphenols and sesquiterpenes are responsible for these diverse effects, but not enough is known, and the concentration of individual constituents is rather limited. Hypothetically, a preparation enriched in these secondary metabolites could be developed, which then could potentially be exclusively marketed as a medicine.

There are numerous other examples, and Prendergast et al. provided an excellent, broad, and theoretical perspective on this topic, which is still relevant today.

The Changing Framework

There can be no sharp dividing line between food and medicine. Any such 'line' would be defined based on sociocultural, economical, and regulatory criteria. However, it needs to be ascertained that foods are essentially used to nourish the body by providing the essential nutrients. In a local and traditional context, such a usage would mostly have been limited to small groups of people. The globalization of such uses results in new challenges for maintaining high quality and safety (**Figure 1**).

With value chains of such products becoming more complex, often, the control and knowledge about the product's composition along with the value chain are lost and there is a dramatic increase in risks associated with adulteration or

other changes detrimental to the product's quality. Products claiming aphrodisiac, beautifying, body-building, and aging-preventing effects are a particular problem, since these claims seem to be mostly market-driven.

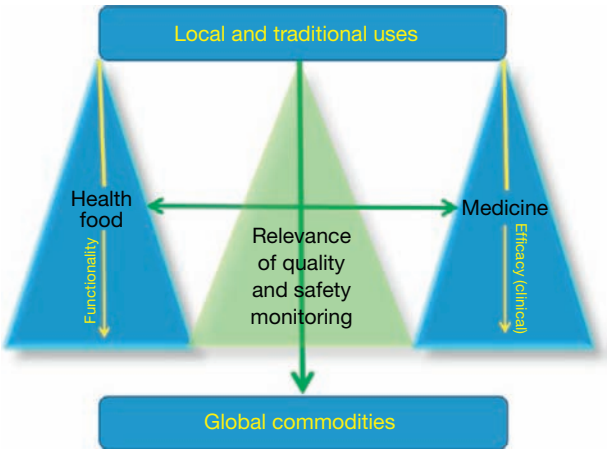

Figure 1 Idealized and simplified scheme highlighting the challenges in the development of locally and traditionally used resources into global commodities at the food–medicine interface. The relevance of quality and safety monitoring increases with a wider use of a commodity, which is generally paralleled by a loss of knowledge about the product's composition along with the longer and more complex value chains that develop with such globalized commodities. With a product's wider utilization, the requirements for quality and safety increase substantially. In the case of food supplements, the development of evidence-based functionalities is essential, while for herbal medicines, an evidence base needs to be built up.

While Figure 1 provides a general overview, Table 2 presents additional details focussing on the differences between healthy foods/food supplements and locally or globally used herbal medicines and the herbal medicinal products derived from them. There is a clear distinction between local (traditional) systems of knowledge and practice and the wider use of products derived from such knowledge in an increasingly globalized market, where most importantly these become commodities that are the end product of complex value chains. There are important differences between the food and the medicine sphere, and commodification is one of the main factors blurring the lines between products that in essence are used either as an element of nourishment or as a substance to cure an illness. While one plant may have both roles (albeit very often different plant parts are used), the context within a culture defines their use.

Health(y) food that has also entered mainstream discussions in many countries is again a popular concept. The global paradox is that the world is suffering from over- and undernutrition (starvation) simultaneously. One element in the debate is the global public health concern about obesity and diseases resulting from it. This has led to calls for dietary changes, including a reduction in caloric intake and modifications to the diets commonly consumed today in many countries especially linked to dietary changes that an excessive intake in saturated fat and sugar has caused. Clearly, this is not an area where the use of supplements needs to be prioritized, but where dietary changes are essential.

Maybe, the main call made within this article is for making the distinctions between foods and medicines clear and transparent. "*Let food be thy medicine and let medicine be thy food*" of Hippocrates is not a justification for blurring the lines between

Table 2 Differences between food supplements and herbal medicines in the context of developing global (or regional) commodities based on local (traditional) herbal medicines or health(y) foods

Health foods/food supplements	*Herbal medicines*
Local and traditional systems of knowledge	
Generally used in well-defined sociocultural and local context, for example, pleasure/enjoyment or as an element of rituals	Used based on a therapeutic need
Food with specific uses in order to keep a balanced self or a balanced community (holistic)	Therapeutic agents used to treat specific illnesses that may or may not be explained on the basis of 'natural' causes
Often not separated from other foods	Parts of complex healing practices and traditions and often a secondary element to, for example, a supernatural intervention
Used regularly	Used only when needed
Commercial (global) products	
Commodities in global or international and regional or local markets	
Not for nourishment but to supplement a diet with *preventive* (or generally poorly defined and substantiated therapeutic) claims	Therapeutic claims based on various levels of evidence (traditional use, well-established use, clinical evidence-based use)
Often poorly defined or very low doses	Mostly therapeutically active agents with a relevant dose
Functionally foods	Presented as medicines with a claim
Often used on a regular basis	Used only when needed (i.e., when a perceived health need exists)
Commonly used based on special expectation, for example, as an agent to 'maintain youth' and secure an 'ideal body' shape (slimming agents, athlete's diets)	Increasingly such products are seen to have a particular place in the treatment of minor; self-limiting diseases and major therapeutic claims are reserved for a minority of the herbal drugs used (i.e., for the products derived from them) as either an OTC product or one dispensed after medical or other health care interventions
Generally with limited regulations in terms of a consistent composition, quality, and therapeutic claims	Regulated as (herbal) medicines of various types or as 'supplements'

supplements and (herbal) medicines but a reminder that medical benefits are linked to changes in an adequate and health diet.

Introduction

The freeze-dryer is traditionally used to dehydrate high-value pharmaceutical products (medicines and therapeutics), biotechnological products (blood cells, plasma, viruses, vaccines, proteins, peptides, etc.), and limited food products (coffee, spices, meats, food ingredients, and dehydrated fruits) and most recently has been utilized to produce nanomaterials, specifically nanoparticles, nanospheres, or nanocapsules.

It is carried out at a low temperature, preserving the functionality, cell viability, or nutritional values even after water is removed in the dehydration process. Industries that are dealing with products with biological origin, especially those that have a high profit margin, find that freeze-drying is a good choice of dehydration to produce products of high quality providing better active ingredient retention, textural properties, and color preservation.

However, the operating cost of a freeze-dryer is very much higher than other dryers as it involves freezing and subsequent drying at vacuum pressure. Moreover, the drying time is long and thus requires high energy demand. Thus, freeze-drying is only commonly used in the pharmaceutical industry and the biotechnology industry where the product profit margin is high. It is not commonly used in the food industry except for those food products that have high value.

It is well known that improper processing of food products will inevitably lead to low-quality products. In the area of food drying, there are more than 500 types of dryers, utilizing different combinations of drying principles that one can select from for drying a food product. Often, for comparison of dryer performance, many characteristics and attributes of the dehydrated products are referred to, and these include drying kinetics, energy efficiency, and product quality, which includes color change, shrinkage, porosity, rehydration attributes, and nutritional values. This article covers the freeze-drying process and describes how it affects the sensory attributes and the retention of bioactive ingredients in the dehydrated products.

Brief Working Principle of Freeze-Drying

Freeze-drying is carried out by means of sublimation of solvent typically water in a frozen product at a low-temperature operating condition. As the dehydration process is carried out at low temperature in the absence of liquid water, deterioration, microbial activity, and chemical reactions are greatly reduced or eliminated, which in turn gives better product quality compared with products dehydrated by conventional methods.

As freeze-drying is operated at a low temperature, it is indeed suitable for drying heat-sensitive products. It involves three stages of operation: The first stage is freezing. At this stage, the operating temperature is reduced to a temperature that is below the melting point of the solvent (normally free water) in the drying materials. The solvent is frozen and becomes solid (ice if the solvent is free water). At this stage, bound water remains in the liquid phase. The second stage is primary drying where the pressure is reduced until vacuum is achieved. The solid form of the solvent is sublimed when the operating temperature is increased in vacuum condition. Theoretically, at the end of the primary drying, all free water is removed. Second drying involves the removal of bound water. The removal of bound water is accomplished by heating the product under vacuum.

Due to the high operating cost, freeze-drying is sometimes combined with other drying methods such as microwave drying in order to reduce its drying time. The application of electric and magnetic fields to the freezing and the freeze-drying process has been attempted by researchers to control the freezing process, and some commercial applications can be found.

Effect of Freezing-Drying on Sensory Attributes

Five sensory attributes are typically measured for freeze-dried food: color, shrinkage, texture, rehydration, and aroma. The aim is to preserve these qualities as close as possible to the fresh food products prior to freeze-drying. In linking the operation of a freeze-dryer to the sensory qualities of the final freeze-dried food, it will be important to distinguish the contributing effect of the initial freezing stage and the subsequent sublimation stage. The first stage is important as it determines the size of the ice crystals formed in the sample, which, in general, in terms of sensory attributes, determines the damage imposed by the frozen ice on the food material. Therefore, sensory attributes such as the texture may be affected in part by the initial formation of the ice crystals during the freezing stage. This in turn may subsequently affect the rehydration behavior of the dried food. The second sublimation stage is further exposed to the vulnerability of product collapse and thermal degradation of the food material. This is due to the exposure of the frozen sample to higher temperatures at this subsequent stage. The subsequent part of this section will describe in detail how each attribute is affected by the two stages of freeze-drying and the strategies to control them.

Types of Sensory Attributes

Color

Color change in air-dried food material is often associated with product browning or degradation. On top of the conventional enzymatic or nonenzymatic reactions leading to color change,

there are mixed reports on the effect of freeze-drying parameters on the color change of a freeze-dried sample. Color change could be due to pigment concentration during the freezing process. There is a chance where such color dissipates during rehydration. In the drying of fruit pulps, color change could also be attributed to the presence of pore structures in the freeze-dried sample, which scatters the reflected light. A similar observation was also reported for freeze-dried meat. A brief list on the different mechanisms of color change is given in a review in 'Further Reading' section.

Shrinkage or collapse

Shrinkage or collapse of the frozen food is the main effect during the sublimation stage as moisture is being removed. Lower sublimation pressure (higher vacuum) is generally associated with lesser shrinkage of the food material. There is a critical sublimation pressure, corresponding to the melting temperature of the sample, from which shrinkage will occur. It is important for the sublimation pressure to be lower than (or equal to) this critical value. In similar veins, lower pressure was also found to produce freeze-dried rice with lower bulk density and a more porous structure. Alternatively, this can be controlled by ensuring a low sublimation chamber temperature as observed in reports on the freeze-drying of agricultural products such as carrots, potatoes, apples, and bananas.

Therefore, it is important to prevent the sample from turning soft during the sublimation stage. Along this line, the concept of glass transition temperature has been introduced to semiquantitatively describe this softening state, in order to better control the shrinkage attribute of freeze-dried food products. This concept in relating the glass transition temperature to the collapse phenomenon can also be applied to foodstuffs with complex structures. The higher the sublimation temperature above the glass transition temperature of the sample, or the lower the glass transition temperature, the higher the extent of shrinkage. A list of glass transition temperatures for solid food and liquid food can be found in the reports cited in 'Further Reading' section.

Texture

Freeze-dried food samples are often rehydrated prior to consumption. However, several factors might change the texture even when water is being rehydrated into the dried sample. The formation of ice crystals in the initial freezing stage might break the cellular structure of the sample leading to softer textures. For soft materials, the sublimation stage might also lead to sample collapse, which will affect the texture attribute. Which aspect is dominant is certainly dependent on the materials considered and the operating conditions.

The texture of freeze-dried strawberries was found to be independent of the operating conditions of the sublimation stage. However, it was found that a slower freezing rate resulted in a significantly softer texture. This was because a slower freezing rate will result in larger ice crystal formation leading to higher cellular destruction during freezing. Such destruction on the integrity of a variety of fruit tissues will result in less firm fruit samples. In some applications, unique electromagnetic or magnetic freezing methods have been introduced to control the ice crystal formation. A review on such unique freezing approach can be found in 'Further Reading' section.

In the freezing of meat, the tenderness of the cooked rehydrated meat is a very important sensory attribute. One main cause for the loss of tenderness is the denaturation and possible aggregation of proteins during the sublimation stage. It is important to control the surface temperature of the meat sample to be lower than the denaturation temperature. Another factor that affects the tenderness is the loss of rehydration capability. It was found that higher rehydrated freeze-dried chicken breast meat produced a more palatable taste and texture.

Rehydration ratio

There are many reports in the literature to suggest that the rehydration ratio is predominantly affected by the initial freezing stage and is minimally affected by the sublimation stage. This is because the rehydration ratio is governed mainly by the size of the ice crystals formed in the initial freezing stage. Larger ice crystals produced at slower freezing rates will lead to a more porous structure. There are experimental reports showing that higher porosity resulted in better rehydration of the freeze-dried food. On the contrary, larger ice crystals might also lead to lower retention of the rehydrated water. This might lead to problems such as 'drippings,' which affect the texture of the cooked rehydrated meat.

For freeze-dried instant food, another sensory or perhaps a desired property of the freeze-dried product is the dissolution rate and wettability. In general, a slower freezing rate will potentially result in a faster dissolution rate of the final product due to the larger pores produced. This trend was observed in the freeze-drying of porridge and fruit pulps. For instant food containing proteins, another factor that has to be considered is the possible denaturation of the protein, leading to subsequent insolubility, should the sublimation temperature resulted in a high surface temperature of the freeze-dried sample.

Aroma

The retention of aroma is perhaps one main advantage in the freeze-drying of extracts. Such application can be found in the freeze-drying of certain higher market value coffee powder or other liquid food. A good review on the retention of aroma in freeze-dried coffee is given in 'Further Reading' section. In general, increasing the concentration of the dissolved solids in the liquid food reduces aroma loss during freeze-drying; this in effect reduces the diffusivity of the aroma compounds within the system restricting the transport out from the sublimating matrix. Another school of thought is that the retention of volatile compounds is due to molecular trapping of the compound in the amorphous and glassy matrix of freeze-dried liquid food. Apart from the liquid food, similar applications in retaining aromas in solid food can also be found in the freeze-drying of tea leaves as an alternative to oven-drying.

Typical Equipment Used for Testing the Sensory Attributes

Color

Color is typically analyzed using spectrocolorimeters. This form of analysis measures the reflected light from the freeze-dried sample at various wavelengths. The results from such an analysis are typically reported in terms of the three-color axis of 'L,' 'a,' and 'b' according to the International Commission on

Illumination. More information on this illumination system can be found in standard handbooks for food processing.

Shrinkage or collapse

This can be visually inspected qualitatively. Some qualitative sensory scale is introduced in the literature for plant-based products and meat/seafood products. For small freeze-dried particulates such as rice, the bulk density or the porosity of the particles can also be obtained as an indication of shrinkage or slight collapse of the internal structure. This can be undertaken with standard mercury porosimeters.

Texture

The standard method is to use penetration tests. This test involves pressing the freeze-dried sample with a probe and measuring the force imposed by the sample at different depths of the penetration. The freeze-dried sample is often rehydrated prior to the penetration test. The outcome from such a measurement would be the strain–displacement curves, which are used to analyze the mechanical strength of the sample.

As mentioned earlier, one approach that can be used to control the texture of the frozen food during the freeze-drying process is to use the glass transition temperature concept. The glass transition temperature at different water activities can be measured using a differential scanning calorimeter for liquid food, food pulps, or even solid food materials, which are to be freeze-dried. Such glass transition properties or the state diagrams of a material can also be developed using viscoelastic measurements.

Rehydration ratio

This is undertaken by measuring the mass of the freeze-dried food before and after soaking in water. The outcome from this test is normally interpreted in terms of the rehydration ratio: the ratio of the mass after water absorption to the mass of the sample after freeze-drying. In these tests, the temperature of the water is normally controlled, and it is sometimes of interest to measure the time it takes to achieve maximum rehydration, another parameter to delineate the rehydration behavior.

Aroma

The standard practice for evaluating aroma relies on human sensory evaluation. However, there are several chemical analysis methods that can be used to provide indicative quantitative measures of the aroma. This is done by measuring the concentration of the compound corresponding to the different aromas, which is of interest in their retention using standard chromatographic techniques. Along that line, a recent development in the food industry has also introduced the concept of an 'electronic nose' and is slowly gaining popularity in the industry.

Additional Note

The control of the sensory attributes was discussed earlier revolving around the freezing and the sublimation stages. The preparation of the sample to be frozen (pretreatment stage) will certainly also affect the control of these sensory attributes. Apart from controlling the freezing rate and the sublimation pressure and temperature, there are myriad pretreatment options and parameters and it is highly material-dependent. In general, fruit and vegetables can be blanched or soaked with organic or inorganic compounds before freezing. For meat products, excess fats will have to be removed prior to freezing. In liquid food, different additives can be included into formulations to induce stability and sometimes the flavor encapsulation capability of the freeze-dried liquid food. These additives may be added to improve the stability (preventing collapse) during the sublimation stage or to control the freezing stage and may even aid aroma retention. In certain scaled-up freeze-drying applications, the state of the initial fresh material also plays an important role more dominant than the effect of freeze-drying parameters. For example, it was found that the degree of ripeness in the zucchinis significantly affected the sensory attributes in contrast to the initially assessed freezing rate. This is an important factor for the freeze-drying of many agricultural products.

Effect of Freeze-Drying on Nutritional Values

The nutritional values of foods can be classified into the categories given in Table 1. The nutritional value changes due to drying (not limited to freeze-drying) are also summarized.

From Table 1, quality changes during the drying process include oxidation in the presence of oxygen, thermal degradation and heat denaturation due to high-temperature drying, enzymatic degradation, and Maillard browning. This results in lower retention of bioactive ingredients in the dehydrated products. In order to maximize the retention of the bioactive ingredients, selection of the proper drying technique is the key.

In this regard, freeze-drying, which is carried out at low-temperature condition, is considered as a good drying method for processing materials that are susceptible to heat denaturation and thermal degradation and Maillard browning that are due to high-temperature drying.

If a nutrient degrades in an aqueous condition, the time of contact with water will influence the retention of the nutrients in the dehydrated products. Thus, conventional freeze-drying may not be suitable as its drying time is typically long. However, one may combine freeze-drying with microwave drying in order to shorten the drying time. It can typically reduce the drying time by about 50–75% if compared with conventional freeze-drying. In certain cases, it has been reported that the retention of bioactive ingredients in the dehydrated food product by microwave-assisted freeze-drying is higher than the conventional freeze-drying.

Certain ingredients especially drugs are pH-sensitive; therefore, the pH profile will have to be carefully monitored during the freeze-drying process. Likewise, certain products are light-sensitive; hence, light exposure during the process should be minimized. This can be easily achieved by ensuring the freeze-drying chamber is covered to avoid light exposure. In general, the dehydration should minimize the time over which the degradations may occur and it is ingredient characteristic-specific.

Research finding about the effect of freeze-drying on the retention of bioactive ingredients and nutrients is well reported, and it is well known that freeze-drying is one of the best ways to remove water from a product while retaining its

Table 1 General nutritional value changes during drying

Nutritional value	*Changes during drying*
Calorie content	Does not change, but calorie per unit mass is increased due to removal of water
Fiber content	Does not change
Vitamin A	Fairly well retained under appropriate drying temperature range
Vitamin C	Mostly destroyed during hot-water blanching and high-temperature drying. It is also sensitive to oxidation
Thiamin, riboflavin, and niacin	Some losses during blanching but fairly good retention if the water used to rehydrate is also consumed
Minerals	Well retained during drying
Proteins	Undergo heat denaturation at relative high-temperature drying, susceptible to light oxidation, and may undergo enzymatic degradation
Lipids	May undergo enzymatic hydrolysis in the initial phase of drying. At low water activity, autooxidation of unsaturated fatty acids may cause rancidity
Carbohydrates	May undergo Maillard browning and changes in flavor under high-temperature drying. Sugar can be caramelized and produce darker pigments that give rise to severe color change issues
Antioxidants such as vitamin C, vitamin E, carotenoids, polyphenols, melanoidins, and indoles	May undergo thermal degradation or heat denaturation

bioactive ingredients. Often, freeze-drying is used as a benchmark for many drying experiments, especially in terms of bioactive ingredient contents. Some of the research findings on the effect of retention of bioactive ingredients are summarized in Table 2.

It should be noted that the freezing step during freeze-drying may damage or destroy some of the ingredients or lower the cell viability; therefore, protective agents are needed in order to reduce the effect of freezing on the quality of the product. It has been reported that the addition of protective agents such as trehalose, adonitol, betaine, glycerol, lactose, skim milk, dimethyl sulfoxide, sugars, and chlorogenic acids could improve the stability of the preserved ingredients and the preservation of other quality attributes such as color.

Concluding Remark

In controlling the sensory quality of freeze-dried solid food materials, the key lies in preserving the structure of the food during freezing and sublimation. The different structures formed during freeze-drying subsequently lead to changes in the rehydration ratio, the texture, the color, and also the taste of the food material. To a certain extent, the structure can be controlled by a combination of pretreatment procedures and manipulation of the freezing and the freeze-drying operating conditions. This is also true for preserving the quality of food pulps, extracts, or liquid foods that are dried. However, an added complexity or perhaps a manufacturing opportunity is in manipulating the formulation of the liquid food. This can be particularly useful in the preservation of flavors and aroma. Since freeze-drying is both capital- and energy-intensive operation due to the cryogenic temperatures and vacuum conditions required in this extremely slow sublimation drying process, it is cost-effective only for high-value and low-volume food products.

Table 2 Research findings about the effect of freeze-drying on the retention of bioactive ingredients

Materials	*Freeze-drying method*	*Research finding*	*Base case*
Apple cubes	Atmospheric freeze-dried	Higher antioxidant activity and polyphenol contents	Convective hot air
Apple slices	Microwave vacuum drying	Higher retention of vitamin C	Convective hot air
Apple slices	Freeze-drying	Higher antioxidant capacity, total polyphenol contents, and ascorbic acids Slightly higher than atmospheric freeze-drying	Convective hot air
Javanese pepper	Freeze-drying	Higher piper content	Oven-drying
Saffron (flavoring, coloring)	Freeze-drying	Higher safranal contents and crocin contents	Sun-drying
Ginger leaves	Freeze-drying	Higher total phenolic content, ascorbic acid equivalent antioxidant capacity, and ferric-reducing power	Microwave-, oven-, and sun-drying

Introduction

Freeze-drying or lyophilization is the operation whereby water is removed from a product by sublimation and desorption. The process consists in, firstly, freezing the product and then exposing it to high vacuum to sublimate the ice.

Lyophilization was known and used as a laboratory technology at the nineteenth century. However, it was after the Second World War when the first industrial applications of freeze-drying were observed. Originally, freeze-drying process was used only in the pharmaceutical industry to obtain antibiotics, cells, and other related products. It was not until the middle of the twentieth century that freeze-drying started to be used in the food industry. Currently, freeze-drying is considered as a valuable alternative to preserve foods.

Since sublimation is the direct transition from solid to gas state without passing through the liquid phase, it occurs only under specific conditions. Sublimation of water takes place when the vapor pressure of water and the temperature of ice are lower than those in the triple point, that is, 0.61 kPa (4.58 mm Hg or 0.006 atm) and 273.16 K (0.01 °C), respectively, as it is shown in the pressure–temperature phase diagram of water (Figure 1). Three major regions are illustrated in the phase diagram (Figure 1) separated by lines. Each region represents the solid (ice), gaseous (steam), and liquid thermodynamic states of water in a closed system. Each point along the separating lines denotes the combination of pressure and temperature where two states occur in thermodynamic equilibrium. In other words, AD line shows the solid–liquid equilibrium, DB line shows the liquid–gas equilibrium, and CD line illustrates the solid–gas equilibrium. The unique combination of pressure and temperature at which the three thermodynamic states of water coexist in equilibrium is shown by point D and it is called the triple point.

The major reason for using lyophilization rather than conventional drying methods among the food industry is because freeze-drying is carried out at low temperature, and consequently, thermal damage is minimized and heat-sensitive nutrients, such as vitamins, among others, remain within the product. Freeze-drying also preserves sensory and some structural and shape characteristics of foods. Likewise, this process has proved to be an alternative to obtain new ingredients and additives in the field of functional foods, ethnic foods, and in the development of new products with innovative characteristics. Nevertheless, freeze-drying is an expensive method and it is used only to obtain high value-added products or if the high quality of the food justifies its use. Moreover, compared with conventional air-drying, which dehydrate foods in a single stage, freeze-drying is an expensive process because it takes longer operation times and consumes large amounts of energy. Energy is required to freeze the product, to maintain the high vacuum in the system, to heat the frozen product to sublimate ice, and to condense water vapor.

Freeze-drying can also be carried out at low vacuum conditions, as well as at atmospheric pressure. However, to make sublimation possible without vacuum conditions, it is essential to produce a large difference between the vapor pressure of the environmental air and that of the food surface to make the sublimation transition. It is only possible by using very dried air all over the frozen food. The use of freeze-drying at low vacuum or at atmospheric pressure is of great interest since the application of vacuum is not necessary, and as a result, the operation costs are considerably reduced.

Freeze-Dryer Basic Components

Freeze-dryers are regularly designed with four basic components: a drying chamber, a vacuum pump, a heat source, and a condenser (Figure 2). The correct selection and operation of these components are critical to reach the benefits of the lyophilization process and depend on the requirements of each product.

The drying chamber is where the frozen product is placed; although the freezing process can be done within the chamber as a first step, in this case, the equipment must have a freezing system (not shown in Figure 2). However, the chamber must be of a vacuum-tight design, and the shelves in the interior require temperature control since heating and cooling processes take place inside the chamber. In addition, an adequate vacuum pump is required to remove the noncondensable gases from the chamber and, subsequently, reach the desirable vacuum level, that is, below 0.61 kPa (4.58 mm Hg or 0.006 atm). The heating source provides the latent heat of sublimation once the frozen product is already at high vacuum conditions. The temperature of the heating source may vary between 243.15 and 423.15 K (−30 to 150 °C; though, the latter being too high to be considered in practical applications) and essentially is determined by the glass transition temperature (T_g) and the moisture content of the food. Finally, the function of the condenser is to collect the water vapor released by the sublimation of ice within product, and it must have sufficient surface and cooling capacity to freeze all the steam generated during the sublimation process. The water vapor contacts the condenser surface and is turned into ice crystals releasing energy; afterward, crystals are removed from the system. Typically, the operational temperature of condensers in commercial freeze-dryers is around 208.15 K (−65 °C).

Freeze-Drying Stages

Freeze-drying is a complex operation and consists of three fundamental stages: initial freezing of the food, primary

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00328-7

drying, and secondary drying. The initial freezing of the food is crucial on the size, shape, and ice crystal distribution; besides, the drying process and the final structure of the freeze-dried food depend on the freezing process. To understand the complete influence of freezing on all the process, it is necessary to comprehend the physicochemical changes taking place during the initial freezing stage.

Freezing

In the initial freezing stage, the food product is cooled to a temperature under its eutectic point, that is, the composition and temperature combination that produces the lowest point at which the product freezes. The purpose of this stage is to freeze all the mobile water originally present in the food. During the freezing stage, it is recommended to reach a food temperature lower than the glass transition temperature (T_g) for each moisture level. Above the T_g, food products are in an unstable rubbery or liquid state; however, below the T_g, products transform into a glassy state or amorphous solid.

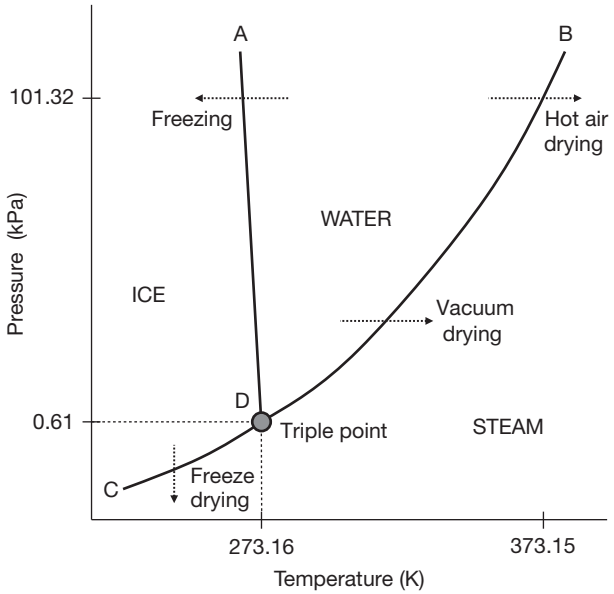

Figure 1 Pressure–temperature phase diagram of pure water in a closed system.

Drying Phases

As it was mentioned earlier in the text, the drying stage is performed in two phases. In the primary drying phase, the frozen product is heated under vacuum conditions to remove ice by sublimation, maintaining the food product below the T_g. Nevertheless, it is necessary to know that the T_g value is continuously changing as the moisture is decreased. If the temperature at the 'ice front' is higher than T_g, water is eliminated by both sublimation and evaporation processes. During the primary drying phase, ~90% of the water in the food is removed by sublimation process. The sublimated water in this phase is mainly composed of all the free water and some of the bound water in the food.

Finally, during the secondary drying phase, the unfrozen bound water is removed by desorption from the dried layer of the product. The result of this mass transfer process is a food product with moisture content between 1% and 3%. This final stage is achieved by increasing temperature and reducing the vapor pressure inside the chamber. The secondary drying requires up to 50% of the time required for the primary drying because of the low pressure of the residual bound water compared with that of the free water at the same process conditions (temperature and pressure), resulting in a long process. Once the secondary drying concludes, that is, when all the free water and bound water are removed, the freeze-drying process is complete.

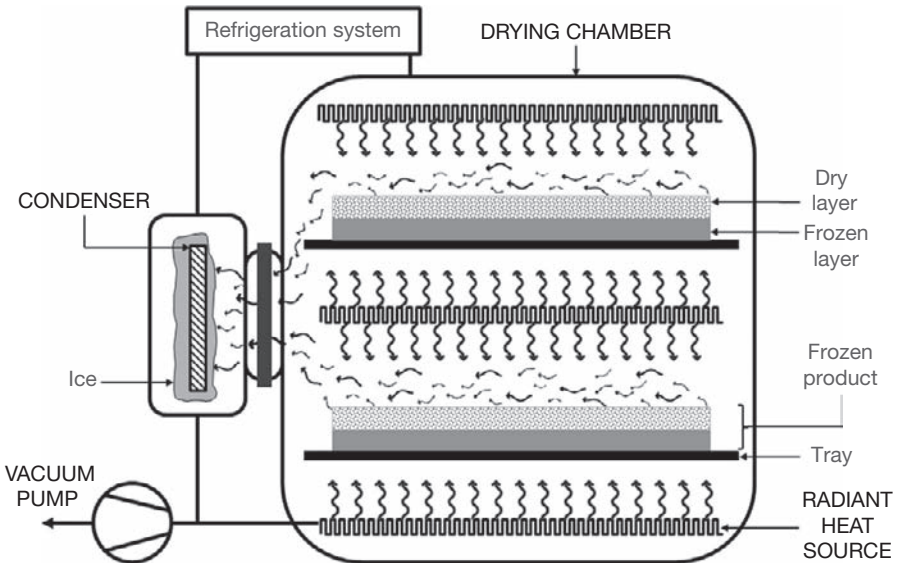

Figure 2 Basic components of a typical freeze-dryer system.

Heat and Mass Transfer

Freeze-drying is a complex operation where both heat and mass transfer processes occur in the interior of the food product. To generate vapor from the ice, energy in the form of heat is transferred to the sublimation zone. Unlike the mass transfer process, which is constantly taking place through the dried layer (mass flux), heat transfer (heat flux) can occur

(a) by conduction through the dried layer (Figure 3(a)) and in the opposite direction of the mass flux – in this case, near the food product is the heat source that irradiates heat to the dried layer;
(b) through the frozen layer (Figure 3(b)) – in this case, the frozen product is in direct contact with the heat source, and the heat transfer is by conduction; or
(c) within the frozen layer (Figure 3(c)) by heat generation using microwaves – in fact, microwaves are currently preferred as a heat source in freeze-drying due to their capability to infiltrate profoundly into the food product, resulting in a uniform and effective heating.

To illustrate the heat and mass fluxes through the freeze-drying operation, a food product with a slab shape is represented with the frozen layer and a dried layer in form of pores (Figure 4).

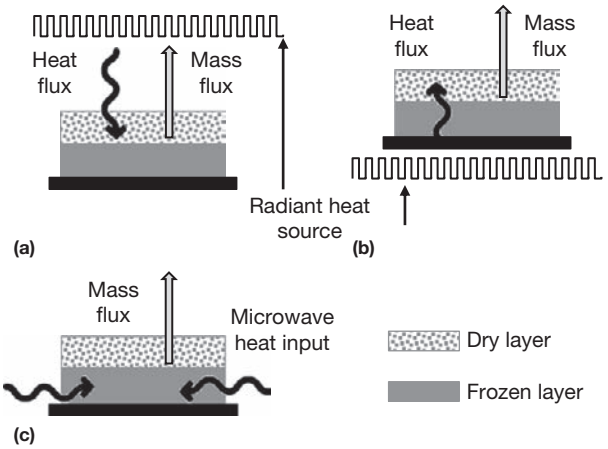

Figure 3 Heat and mass fluxes in different freeze-drying mechanisms.

This illustration assumes a one direction freeze-drying process. The ice front or sublimation point is the limit between the frozen layer and the dried layer. The ice front depends on time, and it is assumed to move at a uniform rate for mathematical and thermodynamic analysis. As ice within the frozen layer sublimates, the steam flows outside the food product, generating pores and channels in the slab.

Freeze-drying, as well as conventional air-drying, is a combined process between mass and heat transfer, and the sublimation rate can be calculated as described in eqn [1]:

$$G = \frac{A(p_f - p_c)}{R_d + R_s + R_o} \quad [1]$$

where G is the sublimation rate (kg s^{-1}); A is the area of the food slab surface (m^2); p_f is the partial vapor pressure of the ice inside the food, that is, the frozen layer; p_c is the partial vapor pressure of water in the condenser; R_d is the transfer resistance of the dried layer in the food slab; R_s is the transfer resistance of the space between the food and the condenser; and R_o is a constant that includes other resistance terms in the process.

At the same time, an external heating source provides the energy to sublimate the ice from the food slab. This energy is the latent heat of sublimation or sublimation enthalpy, ΔH_s. The sublimation rate can be described as a function of the rate of the heat transfer, q, and the sublimation enthalpy as shown in eqn [2]:

$$G = \frac{q}{\Delta H_s} \quad [2]$$

Heat and Mass Transfer Through the Dried Layer

Considering a simplified case where the food product to be dried is heated by radiation through the dried layer (Figure 3(a)), the temperature of the frozen layer is determined by a balance between the mass and the energy transfer; the geometry of the food slab allows no edge effects; the maximum slab surface temperature acceptable, T_s, is reached instantly; the heat flux is adjusted so the slab surface temperature remains constant through all the process; the partial pressure of the water inside the drying chamber is constant, p_s; and all the supplied heat is used to sublimate the ice; then, under

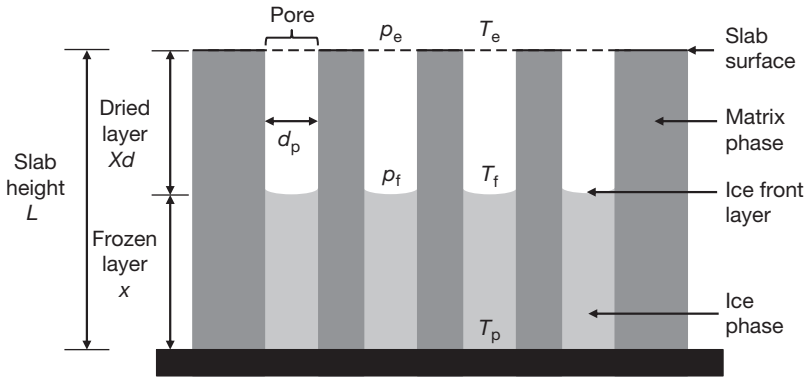

Figure 4 Representation of a freeze-dried food product Slab. d_p, the diameter of the pore; p_e, the partial vapor pressure of the slab surface; T_e, the temperature of the slab surface; p_f, the partial vapor pressure of the frozen layer; T_f, the temperature of the ice front layer; T_p, the temperature of the tray under the food product.

all these conditions, the heat transfer, q (kg m^2 s^{-3}, or J s^{-1}), at any instant is represented by eqn [3]:

$$q = \frac{Ak_d(T_e - T_f)}{Xd} \quad [3]$$

where the term Xd (or $L-x$) refers to the thickness of the dried layer (m) and is a time-dependent variable, k_d is the thermal conductivity of the dried layer (W m^{-1} K^{-1}), T_e is the temperature at the slab surface (K), and T_f is the temperature of the ice front (K).

The sublimation rate, G, can be expressed as shown in eqn [4]:

$$G = -\frac{dW}{d\theta} = \frac{Ab(p_f - p_e)}{Xd} \quad [4]$$

where b is the permeability of the dried layer (kg m^{-1} s^{-1} Pa^{-1}), p_e is the vapor pressure at the slab surface (Pa), W is the water weight of the food slab (kg), and θ is the sublimation time (s).

Since the dried layer thickness, Xd, is a time-dependent variable, the change of weight loss of the food product as a function of time, $dW/d\theta$, can be obtained by eqn [5], considering that inside the interface, between the frozen and dried layers, the moisture content drops from an initial value, m_e, to a final value, m_f:

$$-\frac{dW}{d\theta} = A\rho_s(m_e - m_f)\frac{dXd}{d\theta} \quad [5]$$

where ρ_s is the density of the food product solids on the tray (kg m^{-3}), m_e and m_f are the moisture content (dry basis), and the expression $A\rho Xd$ corresponds to the solids weight (kg). Making the sublimation rate in terms of weight loss from eqn [4] equal to eqn [5], the change of the dried layer thickness depends on both the partial pressure difference and the moisture content difference, as demonstrated in eqn [6]:

$$\frac{Ab(p_f - p_e)}{Xd} = A\rho_s(m_e - m_f)\frac{dXd}{d\theta}$$

$$Xd \cdot dXd = \frac{b(p_f - p_e)}{\rho_s(m_e - m_f)}d\theta \quad [6]$$

The heat transfer flux can be considered equal to the sublimation rate multiplied by the latent heat of sublimation as described by eqn [7]:

$$\frac{Ak_d(T_e - T_f)}{Xd} = \frac{Ab(p_f - p_e)}{Xd}\Delta H_s \quad [7]$$

In order to obtain a relation between the pressure and the temperature, eqn [7] is simplified, resulting in the following expression (eqn [8]):

$$p_f = p_e + \frac{k_d}{b\Delta H_s}T_e - \frac{k_d}{b\Delta H_s}T_f \quad [8]$$

It has been considered that p_e, ΔH_s, k_d, and T_e are constants; therefore, a linear equation that relates that p_f, and T_f is obtained as it is exemplified in Figure 5. Besides, in the same figure, the thermodynamic relationship between p_f and T_f is also shown (curve in Figure 5 can be obtained from any thermodynamics database for equilibrium vapor pressure of ice–vapor system). There is only one intersection point between the two curves, meaning that if the suppositions in the mathematical analysis are true, the temperature of the frozen layer, T_f, remains constant though the freeze-drying operation.

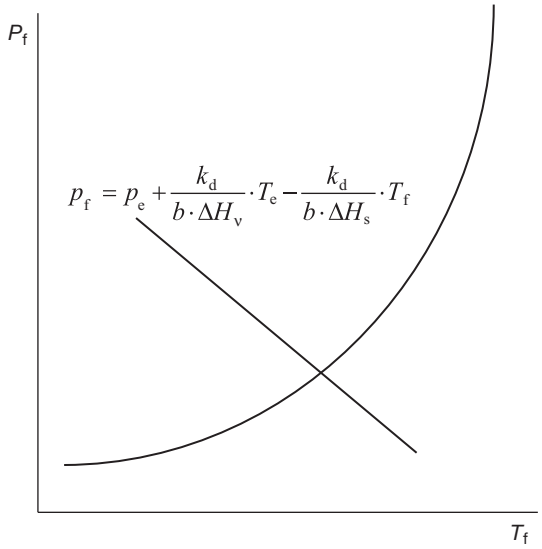

Figure 5 Thermodynamic relationships between pressure and temperature at the ice front layer.

Consequently, eqn [6] can be integrated to calculate the freeze-drying time, since it has only two variables Xd and θ, as demonstrated in eqn [9]:

$$\int_0^{L/2} Xd \cdot dXd = \frac{b(p_f - p_e)}{\rho_s(m_e - m_f)}\int_0^{\theta} d\theta$$

$$\theta_{fd} = \frac{L^2\rho_s(m_e - m_f)}{8b(\rho_f - \rho_e)} \quad [9]$$

where L is the food product slab height (m) and θ_{fd} is the freeze-drying process time. In the same way, due to the equivalence between the mass transfer and energy transfer, eqn [3] can be integrated to obtain the following expression (eqn [10]):

$$\theta_{fd} = \frac{L^2\rho_s(m_e - m_f)\Delta H_s}{8k_d(T_e - T_f)} \quad [10]$$

As it is illustrated in the two last equations, the freeze-drying process time depends on the following variables: the maximum slab surface temperature acceptable, initial and final moisture content, density of the food solids, latent heat of sublimation, food slab thickness, thermal conductivity of the frozen layer, and permeability of the dried layer.

Heat Transfer Through the Frozen Layer and Mass Transfer Through the Dried Layer

Heat can be transferred by conduction through the frozen layer when the food slab is in direct contact with the heat source, as it was exemplified in Figure 3(b). The heat and mass transfer calculations are similar to those in the preceding section; however, some considerations should be taken into account due to the direction of the heat flux and the position of the heat source. As mentioned earlier in the text, in a food slab,

considering no edge effects, the mass transfer of the water vapor is defined by eqn [4]; and the decrement and increment of the frozen and dried layers, respectively, depend on the temperature difference as shown in eqn [11]:

$$Xd \cdot \mathrm{d}Xd = \frac{b(p_f - p_e)}{\rho_s(m_e - m_f)}\mathrm{d}T \qquad [11]$$

In this case, the heat transfer through the frozen layer in the same direction of the mass flux through the dried layer is described by eqn [12]:

$$q = \frac{Ak_f(T_p - T_i)}{x} \qquad [12]$$

where T_p is the temperature of the heated tray under the food product slab, or the heat source plate in contact with the food (K); k_f is the thermal conductivity of the frozen layer (W m^{-1} K^{-1}); and x is the relative height position of the ice or sublimation front and is a time-dependent variable (m).

The relationship between the pressure and the temperature inside the interface of ice is more complicated. In the case of heat transfer through the dried layer, there is a linear relation between p_f and T_f (eqn [8]); however, in the case of heat transfer through the frozen layer, two additional variables, Xd and X, are involved (eqn [13]):

$$p_f = p_e + \left(\frac{k_f}{b\Delta H_s}\right)\left(\frac{Xd}{X}\right)(T_p - T_i) \qquad [13]$$

As it can be deduced from **Figure 4**, Xd is the difference between the slab thickness and the frozen layer height: ($Xd = L - X$). Therefore, eqn [13] can be modified as follows (eqn [14]):

$$p_f = p_e + \left(\frac{k_f}{b\Delta H_s}\right)\left(\frac{Xd}{L - Xd}\right)(T_p - T_i) \qquad [14]$$

Hence, the temperature and the pressure inside the interface are not really independent from the drying time, even if k_f, ΔH_s, Xd, b, p_e, and T_p remain constant. Then, p_f has to be evaluated as a function of Xd. The latter can be achieved assuming an Xd value and assessing its correspondent p_f. This process has to be repeated for several supposed Xd values until a function of Xd is reached. That is, $p_f = f(Xd)$. The function can be substituted in eqn [11] and integrated as demonstrated in eqn [15]:

$$\int_0^L \frac{Xd}{f(Xd) - p_f}\mathrm{d}Xd = \frac{b}{\rho(m_e - m_f)}\int_0^\theta \mathrm{d}\theta \qquad [15]$$

Equation [15] can be solved analytically, or if $f(Xd)$ is a complex function, numerical methods should be used.

Numerous mass and energy transfer models have been developed to describe the freeze-drying process. Most of the models are variants of the sublimation model, which only takes the subtraction of frozen water into account, and the sorption sublimation model, which includes both the frozen water and the bound water. Some of these models have proved to describe experimental drying rates and times successfully. Nevertheless, the application of most of the models has drawbacks, because several processing data and heat and mass transport properties of food products are required, such as water vapor concentration in the dried layer, porosity, mass diffusion, effective thermal conductivity, permeability, and diffusivity within the porous medium, among others.

Impact on Nutrients and Bioactive Compounds

Conventional heat-drying technology is based on the use of hot air to dehydrate the food products. The presence of high temperature, oxygen, and long operation time in conventional drying processes has an important effect on decreasing the sensory and nutritional characteristics of foods. The loss of fat-soluble vitamins (vitamins A and E) due to the oxidative reaction of lipids, the reduction of ascorbic acid and carotenes by heat degradation, the decrease of volatile and phenolic compounds, and the denaturation of heat-sensitive proteins by overheating, which may reduce the protein efficiency ratio and make them nonbioavailable for the organism, are some examples of the effects of heat-drying in foods. In fact, the problems for using heat-drying are not only the loss of nutrients but also the production of harmful substances to human health by different reactions, such as Maillard reaction, degradation of lipids, and Strecker degradation of amino acids.

On the other hand, freeze-drying operational conditions (low temperature and oxygen absence) make this technology an excellent alternative in food drying to prevent most of the high-temperature-related problems. Recently, freeze-drying has also been studied due to the positive effect on the extraction and bioavailability of different compounds, such as flavonoids and anthocyanins, in several fruit and vegetable products. Studies claim that the change in the tissue structures of fruits and vegetables during the freeze-drying process exposes the compounds of interest.

Although many studies have proved that the nutrient losses during the freeze-drying process and the benefits for freeze-drying foods are minimal, recent research results in this field have shown that the composition of some antioxidant compounds and antioxidant activity of several fruits may possibly be affected by freeze-drying. However, a number of operational variables influence the performance of the freeze-drying process and therefore the final product characteristics. The correct selection of the variables – freeze rate, heat flux, chamber vacuum, and temperature – should be enough to avoid any undesirable effect on food. Clearly, variables selection depends on the food and the final desirable characteristics.

Conclusions

Food industry trends are constantly changing. Currently, the increasing consumer demand to obtain secure food products with high quality, fresh-like attributes, and at the same time innovative is a priority for food processors. Therefore, food technologists are looking for alternative technologies with the objective of replacing conventional process operations. In these terms, freeze-drying has shown to be a good alternative for conventional heat air-drying, since it is capable of preserving different foods, food additives, and food ingredients, extending considerably the shelf life of food without losing their native sensory and nutritional properties.

It is well known that freeze-drying process maintains desirable characteristics; however, more research is needed to understand the role that water plays in each food when it is subjected to sublimation and to understand how the control of the operational variables results in high-quality freeze-dried products. The knowledge of the fundamentals of phase changes of water in foods and of the effect of the variables on the process effectiveness and cost can open new opportunities for the application of freeze-drying to obtain high-quality preserved foods and to avoid any possible loss of bioactive compounds in the food product.

Nomenclature

A	Surface area, m^2
a_w	Water activity
Bi	Biot number, hR/k_f
c	Apparent specific heat (including latent heat of phase change), J kg^{-1} K^{-1}
c_f	Specific heat of frozen food (not including latent heat), J kg^{-1} K^{-1}
c_u	Specific heat of unfrozen food, J kg^{-1} K^{-1}
D_v	Diffusivity of water vapor in air, m^2 s^{-1}
D_w	Diffusivity of moisture in solid, m^2 s^{-1}
E_f	Freezing time shape factor (freezing time of infinite slab with the same smallest dimension/freezing time of solid object)
F	Frozen fraction
ΔG_v	Free energy change per unit volume due to crystallization ($\Delta G_v < 0$)
h	Heat transfer coefficient, W m^{-2} K^{-1}
H	Enthalpy, J kg^{-1}
i	Dissociation constant (van't Hoff factor)
J	Nucleation frequency, m^{-3} s^{-1}
j_w	Water diffusion flux, kg m^{-2} s^{-1}
k	Thermal conductivity, W m^{-1} K^{-1}
k_f	Thermal conductivity of frozen material, W m^{-1} K^{-1}
M_w	Molar mass of water, kg $kgmol^{-1}$
p_a	Water vapor pressure in the surrounding air, Pa
p_s	Water vapor pressure at the food surface, Pa
p_{atm}	Atmospheric pressure, Pa
p^*	Saturation vapor pressure of pure water, Pa
q	Heat flux, W m^{-2}
q	Heat flux vector, W m^{-2}
r	Particle (ice nucleus) radius, m
r_{cr}	Critical ice nucleus radius, m
R	Product radius or smallest half-dimension, m
R	Gas constant (8314 J K^{-1} kg mol^{-1} or Pa m^3K^{-1} kg mol^{-1})
t_f	Freezing time (time for the thermal center temperature to fall from T_i to T_c), s
t_{Plank}	Freezing time according to Plank's equation, s
T	Temperature, K
T_0	Freezing point of pure water (273.15 K)
T_a	Temperature of the freezing or thawing medium, K
T_c	Final product center temperature, K
T_f	Freezing point, K
T_{fm}	Nominal mean freezing temperature in Pham's (1986) freezing time method, K
T_g'	Glass transition temperature, K
T_i	Initial food temperature, K
T_s	Surface temperature, K
V	Product volume, m^3
w	Mass ratio of total moisture to dry solids, kg (kg dry solid)$^{-1}$
x_{sol}	Solute mole fraction
x, y, z	Space coordinates, m
∇	Gradient operator, m^{-1}
ϕ_g	Volume fraction of voids
λ_f	Latent heat of freezing (positive) per unit mass of food, J kg^{-1}
λ_{vl}	Latent heat of evaporation or sublimation (positive) per unit mass of moisture, J kg^{-1}
ρ	Density, kg m^{-3}
σ	Surface energy, J m^{-2}
θ	$T - T_0$, temperature in °C (for subscripts, see definitions of T)
τ	Tortuosity factor

Equilibrium Behavior of Ice and Water

Water in foods exists as an aqueous solution containing solutes such as minerals and sugars. As temperature falls below the freezing point, assuming that thermodynamic equilibrium is maintained at every instant, water molecules separate out forming ice crystals and leaving solute molecules behind.

Water's physical behavior is complex and unusual due to the peculiar shape and polarity of its molecules. The water molecule is V-shaped, with an oxygen atom bonded to two hydrogen atoms, the bonds being at an angle of 104.45° to each other. This is close to the value of the tetrahedral angle, and therefore, on freezing, the molecules are linked by hydrogen bonds with each other to form an approximately tetrahedral structure called hexagonal ice (or ice I), which has a lower packing density than liquid water. While most substances become denser as they cool and solidify, liquid water has a maximum density at 4 °C and expands by about 9% upon freezing. The hydrogen bonds are also responsible for the high latent heat of freezing (334 kJ kg^{-1}) and relatively high freezing points compared to species with similar molecular masses. At high pressures, the molecular arrangement of ice changes, giving rise to several distinct solid phases (Figure 1), all denser than liquid water. These other ice phases do not occur naturally on earth and have little or no implications for food preservation.

One interesting result of the expansion of water upon freezing is that, by Le Chatelier's principle, the freezing point of water decreases with increasing pressure (Figure 1) up to 207 MPa corresponding to $T_f = -22$ °C beyond which ice I is converted into ice III. This effect is used in pressure shift freezing and pressure-assisted thawing.

At atmospheric pressure, pure water freezes at 0 °C or 273.15 K (the thermodynamic freezing point). The presence of solutes depresses the water activity a_w and hence the freezing point T according to the relationship

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00329-9

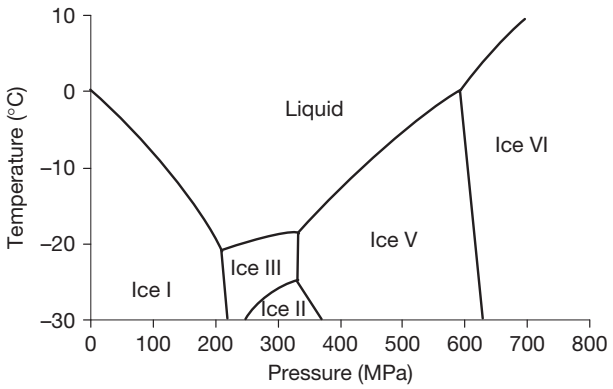

Figure 1 Ice phases.

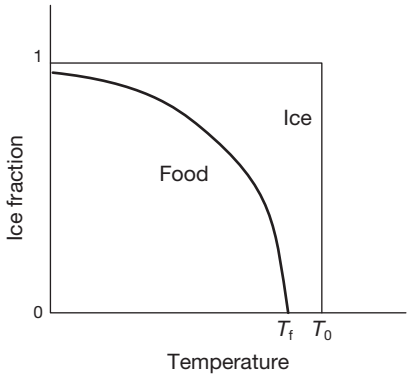

Figure 2 Frozen fraction as a function of temperature for ice and food.

$$-\ln a_w = \frac{M_w \lambda_f}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right) \quad [1]$$

Water activity depends on molar solute concentration x_{sol} and for dilute solutions, where Raoult's law applies, can be calculated from

$$a_w = 1 - i x_{sol} \quad [2]$$

Thus, from eqns [1] and [2],

$$-\ln(1 - i x_{sol}) = \frac{M_w \lambda_f}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right) \quad [3]$$

As ice freezes out, x_{sol} increases and eqn [3] becomes an equilibrium relationship between temperature and solute fraction in the remaining unfrozen solution. The latter depends on how much ice has frozen out; therefore, from eqn [3], we can derive a relationship between frozen fraction and temperature. A frequently used approximate expression is

$$F \approx 1 - \frac{T_0 - T_f}{T_0 - T}, \quad T \le T_f \quad [4]$$

where F is the fraction of unbound (freezable) water and T_f the initial freezing point. Some of the water may be 'bound' to the solid matrix and does not participate in the freezing process. The expression in the preceding text is plotted in **Figure 2**.

The freezing point of a solution reaches a minimum (the eutectic temperature) at the *eutectic composition*, beyond which the solute will solidify before the solvent (**Figure 3**). For a sodium chloride solution, the eutectic temperature is about −21.1 °C. The theoretical equilibrium freezing of an aqueous solution is illustrated on the phase diagram of **Figure 3**: the liquid solution (A) is cooled down until it reaches the freezing temperature at B. Pure ice forms (C) and continues to separate out as temperature falls, leaving a more and more concentrated solution that progresses from B to E, eventually reaching the eutectic temperature and composition E. As temperature continues to fall, the remaining water and solute will crystallize together. As will be seen later, various kinetic effects will intervene to modify this equilibrium freezing process in practice.

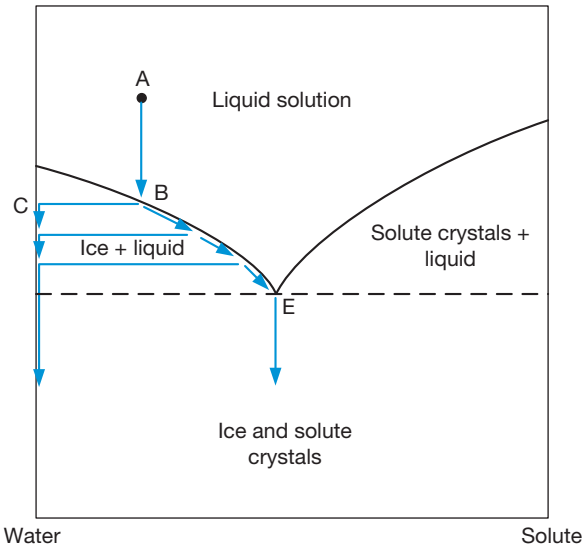

Figure 3 Phase diagram and theoretical equilibrium freezing of an aqueous solution.

Ice Nucleation

Nucleation is the spontaneous arrangement of a group of molecules into a crystal that is sufficiently stable to grow. At temperatures below the thermodynamic freezing point T_f, the crystalline phase has lower free energy than the liquid phase and is therefore the more stable phase. However, this is counterbalanced by the surface energy of the crystal, which predominates when the surface-to-volume ratio is high, that is, when the crystal is small, and causes the crystal to melt. Newly formed crystals, or nuclei, are therefore unstable even at temperatures somewhat below the freezing point, unless and until they reach a certain critical radius r_{cr}.

Homogeneous Nucleation

If a nucleus is surrounded on all sides by liquid, without any neighboring solid surface that may serve as support, the nucleation is said to be homogeneous. The nucleus or crystal can then be assumed to be spherical. Because the temperature is below the thermodynamic freezing point, the crystal phase will have lower free energy than the liquid phase. However, the creation of the crystal surface requires positive free energy. If the free energy change per unit volume due to crystallization is ΔG_v ($\Delta G_v < 0$) and the surface energy per unit area is σ, then the

free energy change associated with a change in the crystal radius dr (i.e., crystal growth) will be

$$\mathrm{d}\left(\frac{4}{3}\pi r^3\Delta G_v + 4\pi r^2\sigma\right) = \left(4\pi r^2\Delta G_v + 8\pi r\sigma\right)\mathrm{d}r \qquad [5]$$

For a nucleus to be able to grow, the free energy change associated with dr must be negative; therefore,

$$r \geq -\frac{2\sigma}{\Delta G_v} \qquad [6]$$

The expression on the right is the critical radius, r_{cr}. In general, therefore, freezing will not start at the thermodynamic freezing point, and the liquid will supercool below this temperature. As temperature continues falling, $-\Delta G_v$ will increase (i.e., the tendency to crystallize becomes greater) causing the critical radius to decrease, which increases the probability or frequency of stable nuclei being formed. According to classical nucleation theory, the homogeneous nucleation frequency J varies with temperature as

$$J \propto \exp\left[\frac{K}{T^3(T_f - T)^2}\right] \qquad [7]$$

The probability of nucleation happening in a given volume of water over a given time interval depends on both the nucleation frequency and the volume. In very small water droplets, nucleation can be substantially delayed until about $-41\,^{\circ}\mathrm{C}$, known as the homogeneous nucleation temperature. Some works have reported lower nucleation temperatures, $-45\,^{\circ}\mathrm{C}$ and even $-70\,^{\circ}\mathrm{C}$. Ice nucleation in foods is usually heterogeneous. In the lab, homogeneous nucleation can be produced in water-in-oil emulsions, which is a common method for studying it. It may also happen in foods such as butter, which contain droplets of water in a fatty matrix.

Heterogeneous Nucleation

In most foods, there are solids whose surfaces act as nucleation sites, causing heterogeneous nucleation. To be a good nucleation promoter, a surface must have a small lattice mismatch with ice, a low surface charge, and some degree of hydrophobicity, that is, it is not wetted by water. Heterogeneous nucleation occurs at temperatures much higher than homogeneous nucleation. Nucleation may also be facilitated by mechanical shocks, agitation, sound waves or ultrasound, or electric fields. The effect of sound/ultrasound is explained by the generation of cavitation bubbles that act as nucleation sites. An explanation for higher nucleation temperatures in an electrostatic field is that the free energy of the crystalline phase is lowered by the presence of the field.

Distributed Versus Surface Nucleation

In the freezing of solid foods, nucleation usually takes place first at the surface of the product where temperature is lowest. These ice crystals then grow into the product as dendrites, and no further nucleation will occur unless there are physical barriers that prevent the growth of existing crystals. In well-stirred liquids, such as in freeze concentration equipment, the product is at uniform temperature and therefore nucleation may take place throughout the material. Distributed nucleation may also take place in a solid that is cooled to a subfreezing temperature and then subjected to a triggering mechanism such as a shock wave, ultrasound, or and electric field. It also happens in pressure shift freezing, where a product is subjected to high pressure (up to 210 MPa), which lowers its freezing point, and then suddenly depressurized causing the freezing point to rise. As mentioned earlier, distributed nucleation may occur also in products where water exists as small droplets in a fatty matrix.

Extracellular and Intracellular Nucleation

In animal and plant tissues that are cellular, freezing usually takes place in the extracellular space, whose large continuous volumes facilitate the growth of crystals. As extracellular crystals form and grow, the extracellular solution becomes more concentrated, causing an osmotic pressure difference between intra- and extracellular spaces. Intracellular water diffuses through the cell membrane to deposit on the growing extracellular crystal, causing the cell to shrink and shrivel.

Whether intracellular nucleation occurs depends on the cooling rate. At slow cooling rates, water has plenty of time to diffuse out of the cell, and the intracellular concentration rises to almost keep up with the extracellular concentration; therefore, the cell is always at a temperature close to its freezing point. Due to the low degree of supercooling, intracellular nucleation will not occur. At very fast cooling rates, the freezing point in the cell falls much more slowly than the local temperature, resulting in a large degree of supercooling in the cell that facilitates intracellular nucleation according to eqn [7]. Intracellular freezing may also be facilitated by mechanical damage to the cell's membrane due to osmotic flux. Slow freezing rates result in large extracellular ice crystals, while rapid freezing produces more numerous but smaller crystals, both intra- and extracellular.

Crystal Growth and Recrystallization

Crystal Growth

Once the critical nucleus size is reached, it will grow. The crystal growth rate is a function of the local degree of supercooling $T_f - T$. At first, growth will be very fast, causing an almost instantaneous temperature rise due to latent heat release. When the local temperature approaches the freezing point, crystal growth will slow down and become controlled by the rate at which heat can be conducted away.

In aqueous solutions such as the liquid part of foods, crystal growth often takes the form of dendrites extending from the surface to the inside, due the phenomenon of constitutional supercooling. As the ice grows, solute is excluded from it and a concentration gradient will form in the liquid, decreasing the freezing point of the solution next to the freezing front. If an irregularity in the front protrudes into the unfrozen zone, it will be in contact with liquid at a lower concentration and hence higher freezing point. The degree of supercooling $T_f - T$, which drives crystal growth, is greater at the tip of the protrusion than at its base (Figure 4); hence, the protrusion will grow faster than the rest of the front and form a dendrite. Further

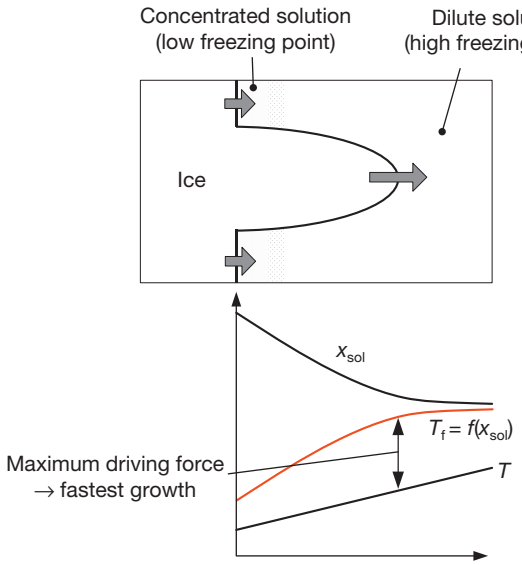

Figure 4 Top: Dendritic growth due to constitutional supercooling; bottom: profiles of solute mole fraction x_{sol}, local freezing point T_f, and temperature. Growth velocity (gray arrows) is approximately proportional to the driving force $T_f - T$; hence, growth is fastest at the tip of the dendrite.

instabilities may cause dendrites to branch and form complex, snowflake-like patterns, trapping solutes in an ice matrix.

Dendritic growth is more likely at faster cooling rate, because at slow cooling rates, solutes will have time to diffuse away and lessen or eliminate the constitutional supercooling effect. This has important implications in the freezing or freeze concentration of liquids such as fruit juice. At low freezing rates, solutes have time to diffuse away from the freezing front, and there is good separation, but at high growth rate, solutes and suspensions become trapped in the ice dendrite matrix. In cellular foods (meats and plants), dendrite growth may cause mechanical stresses and damages to cell membranes, resulting in increased drip loss.

Recrystallization

After freezing, crystals continue to change size and shape, although the process becomes slower the lower the storage temperature. This phenomenon is responsible for the increased graininess of ice cream stored for too long in a freezer. Temperature fluctuations are particularly conducive to recrystallization, as they cause molecules to leave the ice phase and redeposit on another crystal surface.

The principal mechanisms of recrystallization in frozen foods are isomass recrystallization, migratory recrystallization, and accretion. The driving force behind all forms of recrystallization is the minimization of surface energy. Isomass recrystallization happens when irregular crystals gradually take a spherical shape, which for a given mass has the smallest area and therefore lowest surface energy. Accretive recrystallization happens when adjacent surfaces merge, resulting in a reduction in the surface area. Migratory recrystallization happens because small crystals have higher specific surface energy than larger ones (eqn [5]) and are therefore less stable and thus smaller crystals gradually lose moisture to the larger ones and eventually disappear, leading to an increase in the mean crystal size.

The rate of recrystallization depends both on the activation energy for molecules to move from/to the crystal surface and on the diffusion rate from one crystal to another. With very high moisture foods where the crystals are almost contiguous, the process is controlled by the former, while in foods with lower moisture content, the latter will be the controlling factor and recrystallization will be much slower. For meat at temperatures well above the glass transition, an Arrhenius-type dependence has been proposed, with the recrystallization rate doubling every 9 K.

Glass Transition

At very high cooling rates, water molecules may not have time to rearrange themselves into ice crystals. They remain in the liquid phase, with the viscosity increasing until molecular motion becomes negligible, and the liquid vitrifies (turns into an amorphous solid known as glass). The glass transition temperature of pure water is generally believed to be about −137 °C (136 K). This temperature must be reached within milliseconds; therefore, vitrification is very difficult to achieve, especially for large specimen.

Foods consist of or contain aqueous solutions, which have higher glass transition temperatures than pure water due to the reduced mobility of water molecules and are therefore easier to vitrify. The glass transition temperature of the solution varies continuously from that of pure water to that of the solute, which can be quite high. After nucleation has occurred, water molecules separate out to form crystals of pure ice, leaving behind a more and more concentrated solution. Theoretically, as temperature gradually falls, the non-ice phase will also eventually reach its own crystallization point, and from that point onward, the two phases crystallize together as a eutectic mixture (Figure 3). In practice, due to a combination of high solute concentration and low temperature, the solution will become extremely viscous. Due to the very high viscosity, the molecules of the nonaqueous components will not be able to crystallize. These components remain amorphous, with their viscosity continuously increasing until they pass their glass transition point T_g' (point G′ in Figure 5). In practice, especially at fast freezing rates, there may be partial crystallization, resulting in an intermediate process path with a different glass transition temperature T_g (point G in Figure 5).

The glass transition temperature is an important property because food stored below this temperature will have reduced rate of quality loss, at least when the rate of damage is controlled by molecular diffusion. For example, ice recrystallization and water loss by sublimation can be expected to be reduced by storage below T_g'.

Devitrification is the formation of ice crystals in wholly or partly vitrified solutions; it may happen during storage and particularly during thawing, as higher temperatures during this stage facilitate the diffusion and rearrangement of water molecules. Devitrification is rare during food freezing, since most commercial freezing processes are not fast enough to cause vitrification.

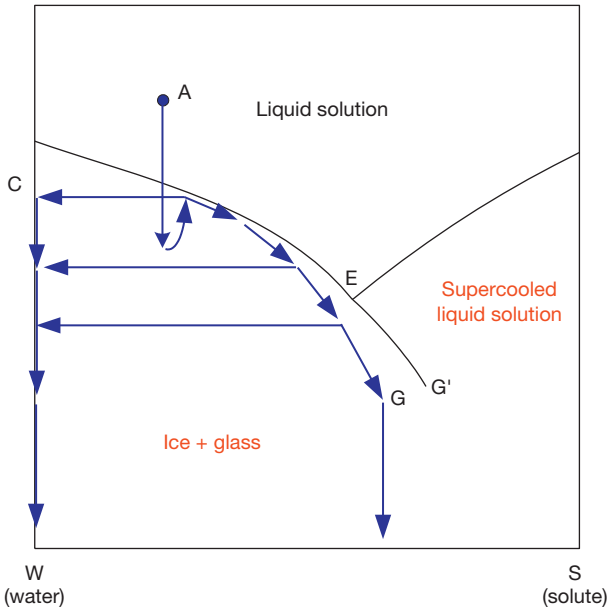

Figure 5 Freezing and glass transition in foods. A–E–G′: very slow freezing with maximum water crystallization up to G′; AG: fast freezing with partial crystallization of water.

Heat Transfer

Temperature Changes during Freezing

Once nucleation has started, the crystals grow very rapidly as neighboring liquid molecules deposit on the crystal's surface, releasing latent heat. The local temperature rises almost instantaneously until it reaches the thermodynamic freezing point, at which time crystal growth slows down and from this point onward can proceed only as fast as allowed by the rate at which heat can be conducted away from the ice crystals: this is the heat transfer controlled phase of freezing. If the liquid is well stirred so that its temperature is uniform, it will remain at the freezing point until it fully solidifies. The temperature therefore exhibits a freezing plateau. Once all the water has solidified, its temperature will fall again towards that of the surroundings. If the product cools and freezes uniformly without any spatial temperature variation, the evolution of temperature will be as shown in Figure 6. For pure water, the temperature curve (a) shows a clear horizontal plateau, while for a solution (b), the temperature falls continuously during phase change due to the increasing solute concentration (see eqn [1]), and the plateau is much less pronounced. For pure water, the cooling curve is thus divided into a precooling period, a phase change period, and a subcooling period, while for foods and other solutions, the latter two periods are less distinct.

Uniform freezing or cooling can only happen in a well-stirred liquid or when the product is very small and the freezing very slow, allowing temperature to equalize at every instant. In the freezing of most solid products, a significant temperature profile will develop, the surface being significantly colder than the core during the cooling and freezing process. After some sensible cooling, including supercooling, nucleation will happen at the surface, and the temperature near the surface jumps quickly to the freezing point. A layer of ice forms at the surface.

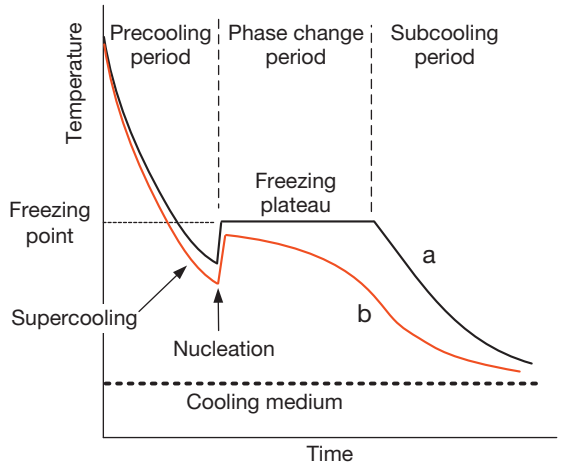

Figure 6 Temperature evolution during the cooling and freezing of a well-stirred liquid. (a) Pure water; (b) aqueous solutions.

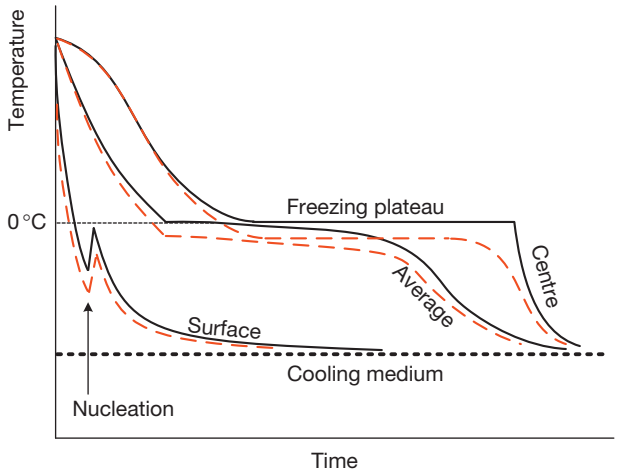

Figure 7 Stages in the freezing of still water (solid line) and that of a solid food (dashed line).

The interface between the frozen and unfrozen regions is called the freezing front. For pure water, the freezing front is quite sharp, and its temperature is the freezing temperature, while for foods and aqueous solutions, the front is diffuse. The outer, frozen region is below the freezing point, while the inner, unfrozen region is above it. Both regions continue to cool as heat is conducted from the inside to the surface. The freezing front gradually moves deeper into the product, usually by crystals growing inward from the surface. Unless freezing is extremely rapid or there are barriers to crystal growth such as plastic films or air gaps, once surface nucleation has occurred, crystal growth will become the principal or only mechanism, and no further supercooling or nucleation will occur.

Once the freezing front reaches the center, phase change is completed. Thereafter, some further sensible cooling will proceed until the ice is equilibrated with the external environment. Each point in the product has gone through the three stages of precooling, phase change, and subcooling but at different times depending on the distance from the surface (Figure 7).

The surface crosses the freezing temperature fairly quickly, while the center cools down to a near-freezing temperature and then remains in that vicinity, in an unfrozen state, for a certain duration. The center temperature still displays an apparent 'freezing plateau' similar to that in Figure 6, but its physical meaning is not identical, since in this case, the plateau starts some time after nucleation occurs at the surface and before phase change commences at the center. It means that, because the unfrozen core is surrounded by a freezing front whose temperature is the freezing point, any point in it (including the center) will tend towards that temperature but cannot cool any further until the freezing front has crossed it. For the product as a whole, there are no well-defined precooling, phase change, and subcooling periods. Nevertheless, we will see that these concepts will be adapted for the calculation of freezing time in solid foods.

Heat Transfer

In almost all food freezing applications, the freezing rate is determined by the rate at which latent and sensible heat can be transferred away from the food. Sensible heat is released throughout the food as it cools, while latent heat is released at the freezing front. In solid foods, these heats must be conducted to the surface and released to the surroundings. Heat conduction in a solid is governed by Fourier's law, which states that the heat flux vector $\mathbf{q}$ is proportional to the temperature gradient ∇T (or $\mathrm{d}T/\mathrm{d}s$ where s is the heat flow direction) and flows in the opposite direction to it:

$$\mathbf{q} = -k\nabla T \qquad [8]$$

where k is the thermal conductivity. The k-value of liquid water is around $0.57\ \mathrm{W\,m^{-1}\,K^{-1}}$, while that of ice is around $2.5\ \mathrm{W\,m^{-1}\,K^{-1}}$; therefore, frozen food has much higher thermal conductivity than unfrozen food. The thermal conductivity of frozen food can be approximately calculated from composition and frozen fraction (Figure 2) using theoretical models or empirical relationships. Figure 8 shows how the thermal conductivities of water and typical foods vary with temperature. A consequence is that under similar conditions, thawing takes much longer than freezing, since during freezing, heat must flow through a frozen outer layer with high thermal conductivity; while during thawing, heat must flow through a thawed outer layer with low thermal conductivity (Figure 9).

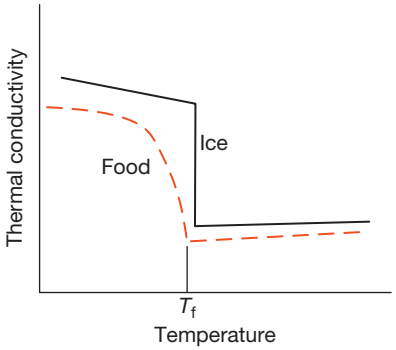

Figure 8 Variation of thermal conductivity with temperature for still water (solid line) and solutions or foods (dashed line).

An energy balance on an infinitesimal volume leads to the heat conduction equation

$$\rho c\frac{\partial T}{\partial t} = \nabla\cdot(k\nabla T) \qquad [9]$$

or in Cartesian coordinates

$$\rho c\frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left[k\left(\frac{\partial T}{\partial x}+\frac{\partial T}{\partial y}+\frac{\partial T}{\partial z}\right)\right] \qquad [10]$$

The apparent specific heat c includes the latent heat of phase change and is defined as

$$c \equiv \frac{\mathrm{d}H}{\mathrm{d}T} \qquad [11]$$

where H is the specific enthalpy of the product. Substituting this definition into eqn [9] gives the enthalpy form of the heat conduction equation, which is often used to calculate temperature changes by numerical methods:

$$\rho\frac{\partial H}{\partial t} = \nabla\cdot(k\nabla T) \qquad [12]$$

Typically, the apparent specific heat of water or foods varies with temperature as shown in Figure 10, with a sharp peak around the freezing point that represents the latent heat. For

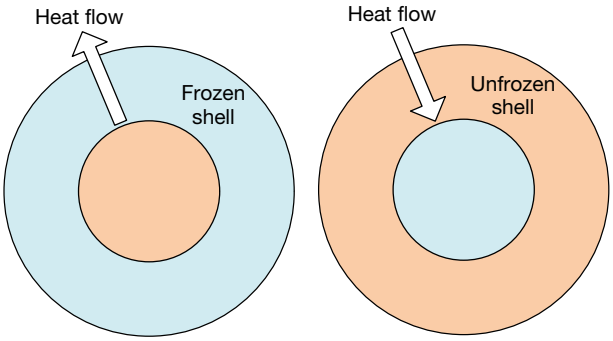

Figure 9 Heat flows through frozen layer during freezing and through thawed layer in thawing.

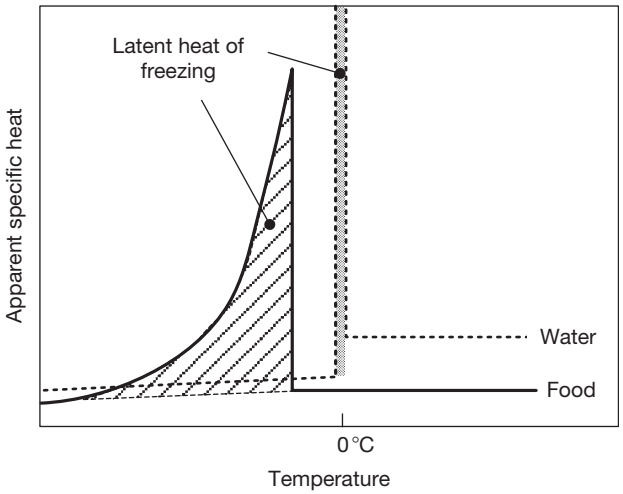

Figure 10 Variation of apparent specific heat with temperature for still water (solid line) and solutions or foods (dashed line).

pure water, the latent heat peak is infinitely tall with zero width, while for solutions and foods, the peak is spread out due to the gradual lowering of the freezing point as ice crystallizes out of the solution.

Freezing Time Calculations

Plank's Freezing Time

The calculation of freezing time has great practical importance as it governs the size of industrial freezers. For all industrial food freezing situations, heat transfer is the controlling factor for freezing rate and freezing time. Plank considers an infinite slab cooled by exposing both faces to a cold medium at temperature T_a. The following assumptions are made:

(a) The phase change takes place at a sharp temperature T_f, at which all the latent heat λ_f is released.
(b) At the surface, the heat flux is given by Newton's cooling law:

$$q|_{surf} = h(T_s - T_a) \quad [13]$$

where h is the heat transfer coefficient, which may include the effect of packaging.
(c) The sensible specific heat of the material is negligible.
(d) The thermal conductivity k_f of the frozen material is constant.

These assumptions lead to Plank's freezing time, t_{Plank}:

$$t_{Plank}(\text{slab}) = \frac{\rho\lambda_f}{T_f - T_a}\left(\frac{R}{h} + \frac{R^2}{2k_f}\right) \quad [14]$$

Plank's equation is inaccurate for practical food freezing problems because of its unrealistic underlying assumptions. However, it is very useful in helping visualize the effects of various physical parameters (product size, heat transfer coefficient, and thermal properties), and it is often used as a starting point to obtain better estimates of freezing and thawing times.

The Biot Number

Plank also derived expressions for the freezing times for an infinite cylinder and a sphere under the same assumptions as in the preceding text. Plank's solutions can be written in the following form for the three basic shapes:

$$t_{Plank} = \frac{\rho V\lambda}{hA(T_f - T_a)}\left(1 + \frac{Bi}{2}\right) \quad [15]$$

Bi is the Biot number:

$$Bi \equiv \frac{hR}{k_f} \quad [16]$$

The first factor (outside the parentheses) on the right of eqn [15] is the freezing time for an object with zero internal resistance to heat transfer, such as a well-stirred liquid, while the second factor, $(1+Bi/2)$, is a correction for internal resistance. During freezing, the latent heat flux has to cross a distance varying from 0 when the freezing front coincides with the surface to R when it reaches the center. The mean distance traversed is therefore $R/2$, and the average internal resistance to heat transfer is $R/2k_f$. The surface heat transfer resistance, which is due to the low velocity in the surrounding fluid next to the surface together with the thermal resistance due to any packaging, is given by $1/h$ (eqn [13]). Therefore, $Bi/2 = (R/2k_f)/(1/h)$ is an estimate of the ratio of internal to external (surface) resistances to heat transfer during the freezing process.

For extreme values of the Biot number, Plank's freezing time tends to the following limit:

- $Bi = \infty$ (negligible surface resistance, e.g., $h = \infty$, when the surface temperature is equal to the environment temperature at all times): the freezing time is proportional to the square of product size:

$$t_{Plank} = \frac{\rho\lambda R^2}{2k_f(T_f - T_a)} \quad [17]$$

- $Bi = 0$ (negligible internal resistance): temperature is uniform in the product at all times, and the freezing time is proportional to product size:

$$t_{Plank} = \frac{\rho\lambda R}{h(T_f - T_a)} \quad [18]$$

Knowledge of the Biot number helps in the optimization of heating and cooling processes. If it is much larger than 1 (i.e., if internal resistance is controlling heat transfer), then there is little use trying to improve heat transfer coefficient, say, by reducing the amount of wrapping or increasing air velocity, and the engineer should try to reduce the thickness $2R$ of the product (if possible). On the other hand, when $Bi \ll 1$, reducing the thickness will be less effective and efforts should be made to increase the heat transfer coefficient. Breaking up the food in smaller packages or pieces will increase the surface area to volume ratio A/V and hence reduce the freezing time, according to eqn [15].

Practical Freezing Time Calculations

Many empirical equations have been proposed for the prediction of freezing time. The most successful start from Plank's equation and apply approximate correction terms to take into account sensible heat effects and the gradual release of the latent heat. An example is Pham's approximate equation, which predicts freezing time with about 10% accuracy in most cases:

$$t_f = \frac{\rho R}{E_f h}\left(\frac{\Delta H_1}{\Delta T_1} + \frac{\Delta H_2}{\Delta T_2}\right)\left(1 + \frac{Bi}{2}\right) \quad [19]$$

where ΔH_1 and ΔT_1 are, respectively, the specific enthalpy change and temperature difference for the precooling period and ΔH_2 and ΔT_2 are those for the combined freezing–subcooling period, which may be calculated from

$$\Delta H_1 = \rho c_u(T_i - T_{fm})$$
$$\Delta T_1 = \frac{T_i + T_{fm}}{2} - T_a$$

$$\Delta H_2 = \rho[\lambda_f + c_f(T_{fm} - T_c)]$$
$$\Delta T_2 = T_{fm} - T_a$$

T_{fm} is a nominal 'mean freezing temperature,' and the following equation was proposed for most water-rich biological materials:

$$T_{fm} - T_0 = \theta_{fm} = 1.8 + 0.263\theta_c + 0.105\theta_a \quad [20]$$

where θ is temperature in °C.

In eqn [19], E_f is a shape factor (1 for slabs, 2 for infinite cylinders, and 3 for spheres). The equation is applicable to more complex shapes by using empirical shape factors. However, for more precise predictions, numerical solution of eqns [9] or [12] using methods such as finite element or finite volume is preferred.

Moisture Transfer during Freezing

Food cooling and freezing is usually accompanied by the movement of moisture. We have already seen how moisture movement may occur on the molecular scale (water molecules migrating towards crystalline surface) and on the cellular scale (molecules crossing cellular membrane by osmosis due to the growth of extracellular crystals). In this section, we consider moisture movement on the macroscopic scale.

Moisture movement is due to the difference in water potential between the product and the surrounding environment. When unwrapped wet food freezes in the air, there will be moisture transfer if the water vapor pressure in the air, p_a, is different from the equilibrium water vapor pressure at the food's surface, p_s. The latter is given by

$$p_s = a_w p^*(T_s) \quad [21]$$

where p^* is the saturation vapor pressure of pure water at surface temperature T_s and a_w is the food's water activity near the surface. The latter depends on moisture content and is usually close to unity for most fresh foods. Since the surface is warmer than the air, especially towards the beginning of the cooling–freezing process, $p^*(T_s)$, and hence p_s, is usually higher than p_a, and the product will lose moisture by evaporation or sublimation. The rate of moisture loss is much faster at the beginning, when the temperature difference and hence vapor pressure difference between surface and air are large, and rapidly falls as the surface cools down (Figure 7). Most of the moisture loss during freezing therefore takes place in the initial minutes.

Moisture loss at the surface sets up a moisture profile within the food, causing water to diffuse towards the surface to make up for lost fluid. The mechanism of moisture movement is different between dense foods and porous foods. In dense (nonporous) foods, moisture moves by molecular diffusion in the dense phase and the mass diffusion flux j_w is proportional to the moisture concentration gradient ∇w according to Fick's law:

$$j_w = -D_w \nabla w \quad [22]$$

When freezing happens, moisture movement practically stops, and there is no replenishment for the sublimated moisture. A drying front forms at or near the surface and gradually recedes into the product, leaving behind a thin desiccated layer, while there is little change in the moisture profile further inside.

In porous foods, moisture moves mainly in the pores by a process known as evaporation–condensation (or sublimation–condensation), which is driven by a temperature gradient. In this model, when a warm region of the food is connected to a colder region, moisture will evaporate or sublime from the warmer region and diffuses along the pore towards the colder region (usually near the surface), where it will condense into water or ice (Figure 11). The water vapor flux can be found from Fick's law.

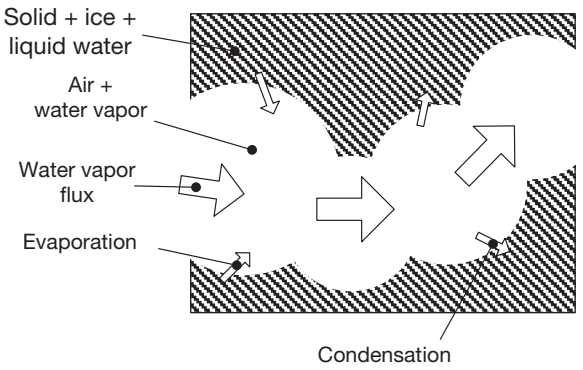

Figure 11 Evaporation–condensation in a porous food.

Evaporation–condensation causes drying of the food and is an important contributor to heat transport, accelerating the cooling rate, since water vapor carries substantial latent heat of vaporization. The contribution of this process to heat transport can be represented by an effective 'evaporation–condensation thermal conductivity' $k_{evap-con}$, given by

$$k_{eva-con} = \frac{\varphi_g}{\tau} \frac{\lambda_{vl} D_v M_w a_w}{RT} \frac{p_{atm}}{p_{atm} - a_w p^*} \frac{dp^*}{dT} \quad [23]$$

Evaporation–condensation can make a significant contribution to heat transport at above zero temperatures, but its effect becomes less at low temperatures, due to the low water vapor pressure.

Properties and Sources of Fructose

Fructose has a fruity, sweet taste, with sweetness ratings between 130% and 180% (in part dependent on the serving temperature), compared with the standard, sucrose, rated at 100%. Both sucrose and high-fructose corn syrup (HFCS) are used extensively in foods to provide sweetness, texture, and palatability. These sugars also contribute to the appearance, preservation, and energy content of the food product.

The natural sources of dietary fructose are fruits, fruit juices, some vegetables, honey, and syrups. In these foods, fructose is found as the monosaccharide and also as a component of the disaccharide, sucrose (Table 1). However, the primary dietary source of fructose is in sugars added to foods and beverages. The top four categories that contribute added sugars to the Western diet are regular soft drinks, sugar and sweets including candies, grain-based baked goods, and fruit drinks. Many of these products are sweetened with sucrose and/or HFCS. HFCS is produced by hydrolyzing the starch in corn to glucose, using α-amylase (EC 3.2.1.1) and glucoamylase (EC 3.2.1.10). This is followed by treatment with glucose isomerase (EC 5.3.1.5) to yield a mixture of glucose and fructose. The process typically produces an HFCS composed of 42% fructose, 50% glucose, and 8% other sugars (HFCS-42). By fractionation, a concentrated fructose syrup containing 90% fructose can be isolated (HFCS-90). HFCS-42 and HFCS-90 are blended to produce HFCS-55, which is 55% fructose, 41% glucose, and 4% other sugars. HFCS-55 is the preferred sweetener used by the soft drink industry in the United States and a number of other countries, although HFCS-42 is also commonly used as a sweetener in many processed food products. Concentrated fruit juices, such as apple, pear, and white grape juices, are also used to sweeten beverages. The amount of fructose in fruit juices varies, as does its proportion with glucose, but the use of concentrated apple juice or blends of apple, pear, and grape juice can provide as much or more fructose relative to glucose at a ratio of 2:1, exceeding the fructose/glucose ratio close to 1:1 found in sucrose and HFCS. Nevertheless, considering the variety of sweeteners commonly available, it is likely that fructose provides close to 50% of the energy in added sweeteners.

Patterns of Fructose and HFCS Consumption

The addition of sweeteners and sugars to so many food products led to an increase in fructose consumption from the mid-1970s to the mid-2000s. However, sugars added to the diet are difficult to quantify accurately. The 2006 USDA MyPyramid Equivalents Database allowed for better estimates of added sugar in foods and beverages. The most recent comprehensive assessment of added sugar in the US diet used this database in combination with data collected during the NHANES surveys of 2003–06. The estimated added sugar consumption for the population as a whole averaged 83 g equiv. day^{-1}, adjusted for energy intake. For the majority who consumed between 5% and 20% of energy as added sugar, the intake ranged from 45 to 92 g equiv. day^{-1}. About 12.5% of the population consumed more than 25% of energy intake as added sugars, and in this group of high-sugar consumers, the mean added sugar consumption ranged between 160 and 233 g equiv. day^{-1}, with sugar-sweetened beverages contributing 90 or more grams equivalents of sugar per day. Overall, regular soft drinks contribute about 30% of the added sugar in the Western diet, a decline from the 33% contribution in 1999 when HFCS per capita availability was at its highest level. Many beverage manufacturers have reformulated soft drink recipes using cane sugar (sucrose) as the caloric sweetener. It is not known if this reduction in the use of HFCS by beverage manufacturers has directly affected the amount of fructose consumed in the Western diet. The best estimates of total fructose consumption from added sweeteners and natural sources have been done with NHANES survey data collected in 1999–2004. The total fructose consumption was about 40–75 g day^{-1} for adult men and 30–60 g day^{-1} for adult women, providing about 8–12% of energy intake for adults. A comprehensive analysis of fructose intake using more recent survey data is not currently available.

Table 1 Sucrose, glucose, and fructose contents of fruits, vegetables, syrups, and sweeteners[a]

Food item	*Serving size*	*Sucrose (g)*	*Glucose (g)*	*Fructose (g)*
Fruits				
Apple	1 medium	2.86	3.35	8.14
Banana	1 medium	2.82	5.88	5.72
Blueberries	1 cup	0.16	7.08	7.21
Cantaloupe	1/8 melon	3.00	1.06	1.29
Cherries	1 cup	0.18	7.71	6.28
Grapes	1 cup	0.24	11.52	13.01
Oranges	1 medium	5.99	2.76	3.15
Peaches	1 medium	4.66	1.91	1.50
Pears	1 medium	1.29	4.58	10.34
Plums	1 medium	1.04	3.35	2.03
Pineapple	1 cup diced	8.48	2.70	3.18
Raspberries	1 cup	0.25	2.29	2.89
Strawberries	1 cup	0.20	3.39	4.15
Watermelon	1/16 melon	3.46	4.52	9.61
Avocado	1 fruit	0.10	0.14	0.14
Vegetables				
Broccoli	1 cup	0.09	0.43	0.60
Carrots, baby	10 small	2.70	1.00	1.00
Corn, sweet	1 ear	1.85	0.45	0.43
Cucumber	1 cup	0.00	0.75	0.89
Onions	1 slice	0.44	0.74	0.44
Peas, green	1 cup	7.24	0.17	0.57
Potatoes	1 medium	0.36	0.70	0.58
Spinach	1 cup	0.02	0.03	0.04
Sweet potato	1 medium	3.28	1.25	0.91
Tomatoes	1 medium	0.00	1.54	1.69
Sugars/sweeteners/syrups				
Sugar, turbinado	1 tsp	4.56	0.00	0.00
Sugar, granulated	1 tsp	4.19	0.00	0.00
Sugar, brown	1 tsp packed	4.35	0.06	0.05
Honey	1 tbsp	0.19	7.51	8.60
Maple syrup	1 tbsp	11.26	0.47	0.18
Molasses	1 tbsp	5.88	2.38	2.56
Agave syrup	1 tbsp	0.00	2.58	11.52

Absorption of Fructose

Dietary fructose is ingested as the simple monosaccharide and also as part of the disaccharide, sucrose. Sucrose is hydrolyzed by sucrase (EC 3.2.1.10) at the intestinal brush border to yield one molecule of glucose and one of fructose. Glucose is rapidly absorbed via a sodium-coupled cotransporter and arrives at the liver via the portal circulation. Fructose absorption occurs by facilitated diffusion, enabled by a fructose-specific hexose transporter, GLUT5. This transporter is found in the jejunum on the brush border membranes. To maintain a favorable concentration gradient for continued fructose diffusion, it has been suggested that upon entry into the enterocyte, fructose is converted to fructose-1-phosphate, but it is not known if enterocytes are capable of this initial step of fructose metabolism. It is known that fructose enters the portal circulation from the enterocytes using the basolateral transporter, GLUT2, which also transports glucose and galactose. The expression of GLUT5 increases within hours of exposure to a fructose-enriched diet, indicating that the transporter is regulated by luminal signals, specifically fructose. However, consumption of a large amount of pure fructose can exceed the capacity of intestinal fructose absorption resulting in diarrhea. This problem is more prevalent in very young children with high intakes of dietary fructose and in whom GLUT5 expression is constrained by developmental stage. Although rare, isolated fructose malabsorption is a pediatric disease related to developmental limitations of GLUT5 expression. The malabsorption of fructose in adults is thought to be related to the insufficient upregulation of GLUT5, although changes in the gene expression or activity of GLUT5 have not been ruled out. Several studies have shown that when a single dose of 50 g of fructose is consumed by healthy adults, more than half experience malabsorption, and in some studies, malabsorption is also observed with a 25 g dose. Fructose malabsorption results in abdominal bloating, flatulence, and diarrhea. However, the intestinal absorptive capacity for fructose increases when it is consumed along with glucose as typically occurs with meals containing starch, sucrose, and/or HFCS. Thus, coingesting glucose to roughly balance fructose, as occurs when most fruits or sucrose is consumed, largely alleviates problems of fructose malabsorption. In addition, fructose absorption increases during sustained fructose consumption, suggesting adaptation to increased fructose intake.

Fructose Metabolism Impacts Lipid and Glucose Metabolism

Upon delivery to the liver via the portal circulation, the metabolic fates of glucose and fructose can diverge. Hepatic glucose metabolism is regulated by phosphofructokinase (EC 2.7.1.11), which is inhibited by adenosine triphosphate (ATP) and citrate when the hepatic energy status is elevated, thereby limiting the hepatic uptake of dietary glucose. This allows much of the ingested glucose arriving via the portal vein to bypass the liver and reach the systemic circulation leading to increased circulating glucose and glucose-stimulated insulin concentrations.

In contrast, the initial phosphorylation of dietary fructose is largely catalyzed by fructokinase (EC 2.7.1.4), which is not regulated by the hepatic energy status. This leads to unregulated fructose uptake by the liver, resulting in most of the ingested fructose being metabolized in the liver (Figure 1) and very little reaching the systemic circulation. This has been demonstrated in the 24 h fructose and glucose profiles in subjects who consumed fructose- or glucose-sweetened beverages with three meals. With the consumption of glucose-sweetened beverages, postmeal glucose peaks increased over fasting levels by 4–5 mmol; with consumption of the fructose-sweetened beverages, postmeal fructose peaks increased by less than 0.4 mmol. Other tissues that take up the small quantities of fructose that bypass the liver include the kidneys, skeletal muscles, and adipose tissues. The GLUT5 transporter is expressed in these tissues, but at relatively low levels.

Postprandial increases of plasma glucose and insulin concentrations are substantially lower when subjects consume fructose compared with isocaloric amounts of refined starch or glucose. The ability of fructose to lower postmeal glucose responses compared with an isocaloric amount of complex carbohydrates would be of potential benefit for maintaining glucose control in patients with diabetes or impaired insulin sensitivity. Indeed, many studies show isocaloric fructose replacement for other carbohydrates results in improvements

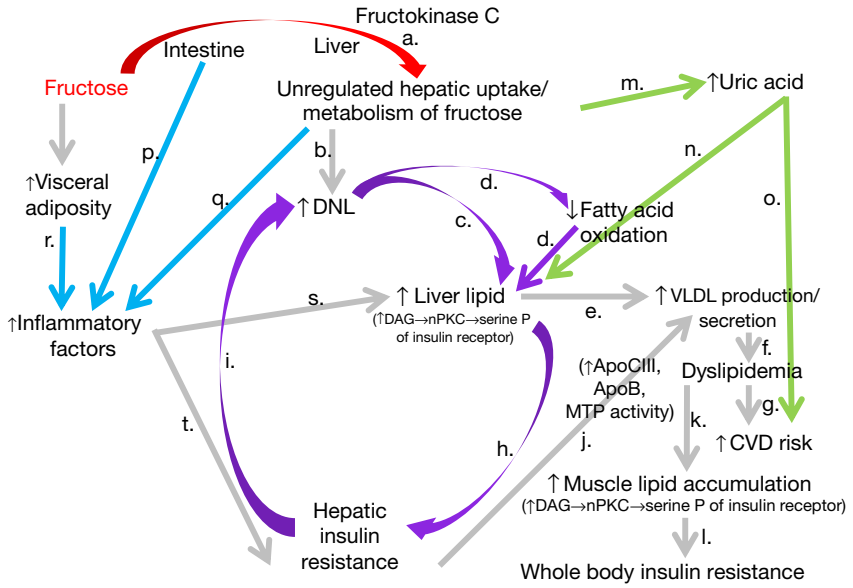

Figure 1 Potential mechanisms by which the consumption of fructose affects lipid metabolism and hepatic insulin sensitivity. Hepatic glucose metabolism is regulated by insulin and hepatic energy needs, and this allows much of the ingested glucose arriving via the portal vein to bypass the liver and reach the systemic circulation. In contrast, the initial phosphorylation of dietary fructose in the liver is largely catalyzed by fructokinase C, (a) which is not regulated by the hepatic energy status. This results in unregulated fructose uptake by the liver, with most of the ingested fructose being metabolized in the liver and very little reaching the systemic circulation. The excess substrate leads to increased *de novo* lipogenesis (DNL). (b) DNL increases the intrahepatic lipid supply directly, via synthesis of fatty acids, (c) and indirectly, by inhibiting fatty acid oxidation. (d) Increased levels of intrahepatic lipid content promote very-low-density lipoprotein (VLDL) production and secretion. (e) This leads to increased levels of circulating TG and low-density lipoprotein cholesterol (dyslipidemia (f)), risk factors for CVD. (g) Increased levels of hepatic lipids may also promote hepatic insulin resistance by increasing the levels of diacylglycerol, which activates novel protein kinase C (nPKC) and leads to serine phosphorylation (serine P) of the insulin receptor and insulin receptor substrate 1 (IRS1) and impaired insulin action. (h) Due to selective insulin resistance, DNL is even more strongly activated in the insulin-resistant liver DNL, (i) which has the potential to generate a vicious cycle (*purple arrows*). This cycle would be expected to further exacerbate VLDL production and secretion by increasing the intrahepatic lipid supply. Hepatic insulin resistance also exacerbates VLDL production/secretion (j) by increasing apoB availability and apoCIII synthesis and upregulating microsomal triglyceride transfer protein expression (MTP). This exacerbates and sustains exposure to circulating TG, leading to the accumulation of intramyocellular lipids in the skeletal muscle, (k) impaired insulin signaling, and whole-body insulin resistance. (l) Uric acid may also be involved in the metabolic dysregulation induced by fructose. The fructokinase-catalyzed phosphorylation of fructose to fructose-1-phosphate, which results in the conversion of adenosine triphosphate (ATP) to adenosine monophosphate (AMP) and a depletion of inorganic phosphate, leads to uric acid production via the purine degradation pathway. (m) High levels of uric acid are associated and may contribute to increased risk for development of fatty liver, (n) CVD, (o) and metabolic syndrome. Fructose exposure in the intestines (p) and liver (q) and fructose-induced increases of visceral adiposity (r) may promote inflammatory responses that further promote liver lipid accumulation (s) and/or impair hepatic insulin signaling (t).

in glycemic control in diabetic individuals. Also, fructose, in small quantities, increases the hepatic uptake of glucose and promotes glycogen storage, most likely by stimulating the activity of hepatic glucokinase (EC 2.7.1.2), and in individuals with type 2 diabetes mellitus, the addition of small amounts of fructose to an oral glucose tolerance test lowers the postprandial glycemic response, indicating improved glycemic control. However, given that one of the goals of maintaining tight glycemic control in diabetic patients is to lower their risk of cardiovascular disease (the major cause of death in these patients), it is extremely important to consider the potential effects of the unregulated hepatic uptake of high levels of dietary fructose beyond its benefits on short-term glycemic control.

The unregulated hepatic uptake of high doses of fructose results in increased production of lipogenic precursors, thereby leading to increased *de novo* lipogenesis (DNL) (Figure 1). DNL increases the intrahepatic lipid supply directly via synthesis of fatty acids and indirectly by inhibiting fatty acid oxidation. Increased levels of intrahepatic lipids promote increased production and secretion of very-low-density lipoprotein (VLDL), specifically VLDL1, the large VLDL particles that carry more TG than the smaller VLDL2 particles. The overproduction of VLDL1 has been proposed as the underlying defect that leads to dyslipidemia, that is, characteristic of patients with type 2 diabetes and metabolic syndrome.

Increased accumulation of intrahepatic lipids may also promote hepatic insulin resistance, possibly by increasing the levels of diacylglycerol, which activates novel protein kinase C (nPKC) and leads to serine phosphorylation (serine P) of the insulin receptor and insulin receptor substrate 1 (IRS1) and impaired insulin action. Due to selective insulin resistance, DNL is even more strongly upregulated in the insulin-resistant liver, which has the potential to generate a vicious cycle, that is, DNL increases liver lipids, which increases hepatic insulin resistance, which further increases DNL (Figure 1, purple arrows). This cycle would be expected to further exacerbate VLDL1 production and secretion by increasing the intrahepatic lipid supply. Hepatic insulin resistance may also indirectly increase VLDL production and secretion by (1) increasing apolipoprotein B (apoB) availability, the protein backbone of VLDL; (2) upregulating microsomal triglyceride transfer protein expression, which catalyzes the assembly of triglyceride and apoB into VLDL; and (3) increasing the production of apolipoprotein CIII (apoCIII), which promotes the conversion of VLDL2 into VLDL1.

Augmented VLDL secretion increases the exposure of the vasculature to triglycerides and apoB and can also lead to intramyocellular lipid accumulation. Increased intramyocellular lipid concentrations are correlated with reduced whole-body insulin sensitivity in humans. It is possible, but not definite, that this relationship is mediated by the same mechanism described for the development of hepatic insulin resistance: diacylglycerol-mediated activation of nPKC resulting in serine phosphorylation of the insulin receptor, IRS1, and other downstream phosphorylation events.

One of the most marked and significant effects of fructose consumption is increased 24 h exposure to circulating uric acid. As presented in the pathways in Figure 1, the mechanism by which fructose consumption leads to increased uric acid concentrations involves the unregulated uptake and metabolism of fructose. The first step in the metabolic pathway, the fructokinase-catalyzed phosphorylation of fructose to fructose-1-phosphate, results in the conversion of ATP to adenosine monophosphate (AMP) and a depletion of inorganic phosphate. The degradation of AMP through the purine degradation pathway leads to increased uric acid production. While the role of increased uric acid in the development of gout has been long known, more recent evidence suggests that uric acid is a potential mediator of metabolic disease, with a number of recent studies showing that it is both strongly associated and predictive of metabolic syndrome, fatty liver, and cardiovascular disease.

It is also possible that other factors such as inflammation and oxidative stress are contributors to, or possibly mediators of, the metabolic dysregulation induced by excessive fructose intake. Inflammatory responses to fructose could be mediated through its direct exposure to the intestine and/or liver. In animals, fructose consumption has been shown to increase the intestinal translocation of bacterial endotoxin, which is associated with hepatic tumor necrosis factor-α, and liver lipid accumulation. In isolated hepatocytes, fructose exposure, compared with glucose exposure, leads to the activation of c-Jun NH_2-terminal kinase (JNK), increased serine phosphorylation of IRS1, and reduced insulin-stimulated tyrosine phosphorylation of IRS1 and IRS2. In humans, the consumption of fructose, but not glucose-sweetened beverages, increases the circulating levels of some inflammatory markers including monocyte chemoattractant protein-1 (MCP-1) and platelet activator inhibitor-1 (PAI-1). Increases of visceral adiposity could also contribute to inflammation in response to the consumption of high levels of fructose.

While the roles of all the potential contributors to the adverse effects of excessive fructose consumption have yet to be determined, it is clear that the unregulated hepatic metabolism of fructose catalyzed by fructokinase, specifically fructokinase C, is essential. Fructokinase exists as two isoforms: fructokinase A, which is widely distributed and has low affinity for fructose, and fructokinase C, which is expressed primarily in the liver, intestines, and kidneys and has high affinity for fructose. It has been demonstrated that fructose-induced metabolic syndrome is prevented in knockout mice lacking both isoforms but is exacerbated in fructokinase A knockout mice compared with wild-type mice. These results demonstrate that the metabolism of fructose through fructokinase is necessary to generate adverse metabolic effects. The exacerbation of these effects in the mice lacking only fructokinase A demonstrates that fructokinase C is the key driver of the adverse effects induced by fructose. It also suggests that fructokinase A offers some protection against the adverse effects of fructose by allowing for some fructose metabolism in peripheral tissues, whereas in its absence, fructose delivery to the liver and flux through fructokinase C are increased, and the adverse metabolic effects of fructose are exacerbated.

Evidence for Metabolic Dysregulation by Excessive Fructose Intake

Providing nonhuman primates (rhesus monkeys) with a daily fructose-sweetened beverage along with ad libitum intake of a standard diet results in weight gain and increased body adiposity and produces several features of the metabolic syndrome, including dyslipidemia (increased triglycerides and

apolipoprotein CIII and decreased high-density lipoprotein concentrations) and insulin resistance. Interestingly, the adverse metabolic changes in this nonhuman primate model of diet-induced metabolic syndrome can be prevented by concurrent supplementation with a high dose of omega-3 fatty acids derived from fish oil. Direct experimental data from studies in human subjects also support many of the mechanisms described in the preceding text. Consumption of large quantities of fructose-sweetened, but not glucose-sweetened, beverages by older, overweight men and women for 10 weeks increased DNL, 24 h circulating triglycerides, LDL cholesterol, and apolipoprotein B concentrations and decreased fat oxidation and insulin sensitivity; these changes did not occur in the men and women consuming glucose-sweetened beverages. In this study, consumption of glucose-sweetened beverages with meals results in increased postprandial glucose excursions (i.e., glycemic index/load) and glucose-stimulated insulin secretion compared with a baseline high-complex-carbohydrate diet, while consumption of fructose-sweetened beverages produces lower postprandial glucose and insulin responses. Nonetheless, it was the diet with the fructose-sweetened beverages that resulted in increased visceral adiposity, produced unfavorable changes in circulating lipids, and decreased insulin sensitivity, indicating that it is the fructose, and not the glucose, component of dietary sugars that is primarily responsible for the observed adverse metabolic effects. In another study, young, healthy men who consumed moderate amounts of fructose for 3 weeks had lower hepatic insulin sensitivity (indexed by endogenous glucose production during euglycemic hyperinsulinemic clamp) than when they consumed moderate amounts of glucose. Whole-body insulin sensitivity was not affected in these men, which is consistent with the idea that fructose induces hepatic insulin resistance prior to the development of whole-body insulin resistance.

Recent studies indicate that adverse metabolic effects also occur when fructose is consumed in the form of sucrose or HFCS. Young, healthy subjects consuming 25% energy requirement as HFCS-sweetened beverages for 2 weeks exhibited significant increases of fasting LDL, non-HDL cholesterol and apoB, and postprandial triglycerides, which were comparable with those observed in subjects consuming fructose and greater than those in subjects consuming glucose. Liver lipids and cholesterol were significantly increased in overweight and obese men and women who consumed $1\,l\,day^{-1}$ of sucrose-sweetened soda (~20% energy requirements) for 6 months, compared with those consuming isocaloric amounts of low-fat milk, $1\,l\,day^{-1}$ aspartame-sweetened beverages, or $1\,l\,day^{-1}$ water. In this same study, the muscle lipid content was increased compared with the baseline only in subjects consuming sucrose. In a study in young healthy men, the total and LDL cholesterol increased after the consumption of moderate levels (~13% energy requirements) of dietary fructose or sucrose, but not glucose.

Fructose and Chronic Disease Risk

Numerous recent studies add to the considerable epidemiological evidence that increased sugar consumption is associated with metabolic disease, including cardiovascular disease, diabetes, fatty liver, hyperuricemia, and hyperlipidemia. Perhaps, the most compelling is the recent report that that there is increased risk of CVD mortality with increased intake of added sugar across quintiles. These data are of concern because the average level of added sugar consumption in the United States, 15% of daily calories, is associated with an 18% increase in risk for CVD mortality. Furthermore, recent data demonstrate that the consumption of beverages providing 0%, 10%, 17.5%, or 25% energy requirement from HFCS results in dose-dependent increases of established lipid/lipoprotein risk factors for CVD within 2 weeks in young men and women, and another study found that unfavorable changes in lipid risk factors are sustained after 6 months of sugar-sweetened beverage consumption of $1\,l\,day^{-1}$. These intervention studies provide mechanistic support for the epidemiological results.

Fructose Consumption, Body Weight, and Obesity

With the increase in fructose intake, primarily as sugar-sweetened beverages, occurring coincidently with the increase in the prevalence of being overweight and obesity at the end of the twentieth century, it is important to examine the evidence that links fructose consumption and body weight gain. In epidemiological studies, consumption of larger amounts of soft drinks and sweetened beverages is associated with greater weight gain in women and increased energy intake and higher body mass index in children. In experimental studies when fructose or sucrose-sweetened beverages are added to the diet, subjects do not compensate for the additional energy provided by these beverages by reducing energy intake from other sources, and total energy intake increases. In a controlled clinical trial, the consumption of large quantities of glucose- or fructose-sweetened beverages, along with the participants' usual diets ad libitum, led to a weight gain of about 1.5 kg after 8 weeks' exposure to either sugar. Of metabolic significance in this trial, intraabdominal (visceral) fat increased in those consuming fructose-sweetened beverages, while the increase in body fat was primarily due to an increase in subcutaneous fat in those consuming glucose-sweetened beverages.

Weight gain and the lack of caloric compensation when consuming sweetened beverages containing fructose may be explained by the lack of a significant effect of fructose ingestion on the secretion of hormones involved in the long-term regulation of food intake. Comparison of the effects of ingesting fructose- and glucose-sweetened beverages with meals indicates that fructose ingestion results in smaller increases in blood glucose and insulin concentrations following the meals. In addition, circulating leptin concentrations are lower, and the normal suppressive effect of meal consumption on ghrelin concentrations is attenuated with fructose beverages. Glucose, insulin, leptin, and ghrelin are all involved in the long-term control of food intake and body weight regulation through the central nervous system. Since these key signals are absent or reduced when fructose is consumed compared with equicaloric amounts of glucose, chronic consumption of a diet high in fructose could contribute, along with high levels of dietary fat and inactivity, to increased energy intake, weight gain, and obesity.

Inborn Errors of Fructose Metabolism

Several genetically based abnormalities in the fructose metabolism have been described in humans. Fructokinase deficiency

leads to high levels of fructose in the blood and urine. In the absence of fructokinase, fructose can be metabolized to fructose-6-phosphate by hexokinase (EC 2.7.1.1), although at a low rate. Consequently, no serious health problems are associated with this abnormality. In fact, fructokinase knockout in mice leads to attenuation of the metabolic dysregulation associated with high-fructose diets.

The aldolase A, B, and C enzymes (EC 4.1.2.13) catalyze the reversible conversion of fructose-1-diphosphate into glyceraldehyde 3-phosphate and dihydroxyacetone phosphate, and deficiencies in the A and B enzymes have been identified. Aldolase A is expressed in embryonic tissues and adult muscles. Possibly owing to the importance of this enzyme in fetal glycolysis, its deficiency results in mental retardation, short stature, hemolytic anemia, and abnormal facial appearance. There is no known treatment for aldolase A deficiency. Aldolase B is expressed in the liver, kidneys, and intestines, and a deficiency of this enzyme is more common and can be exhibited at first exposure to fructose during infancy or can have its onset in adulthood. Upon ingestion of fructose-containing foods, vomiting and failure to thrive are apparent. Hypoglycemia (in some cases severe), increased blood uric acid, and liver dysfunction also occur. While this disorder can be treated effectively by eliminating sources of fructose, sucrose, and sorbitol from the diet, completely eliminating these ubiquitous dietary components can be quite challenging. However, left untreated, severe organ damage can occur, presumably caused by the accumulation of fructose-1-phosphate, which not only is possibly toxic to liver and kidney cells but also results in the depletion of the cellular phosphate pool.

Deficiency of fructose-1,6-bisphosphatase (EC 3.1.3.11) is also considered a genetic disorder of fructose metabolism. This enzyme has a critical role in the enzyme complex regulating glycolysis and gluconeogenesis. Deficient individuals exhibit hypoglycemia, acidosis, ketonuria, hyperventilation, and often hypotonia and hepatomegaly. The urinary excretion of many organic acids is altered; notably, urinary glycerol is elevated and is useful in the diagnosis of this disease. The treatment includes avoidance of dietary fructose, sorbitol, and prolonged fasting.

D-Glyceric aciduria is caused by D-glycerate kinase (EC 2.7.1.31) deficiency. Only ten cases have been documented with symptoms ranging from none to metabolic acidosis, failure to thrive, psychomotor retardation, spastic tetraparesis, and seizures. The absence of significant symptoms in some suggests that this enzyme deficiency is essentially benign, and other associated enzyme deficiencies may underlie the more severe symptoms.

Summary

Fructose, a monosaccharide, is found in the food supply in fruits, vegetables, syrups, and sweeteners, usually paired with another monosaccharide, glucose. Consumption in Western diets is often higher than the recommended intakes. Excessive intake can lead to metabolic dysfunction and increased risk of chronic disease. The manifestation of metabolic dysfunction associated with fructose or HFCS consumption may be influenced by gender, the amount consumed, the food matrix in which it is consumed, and other dietary factors such as the energy level of the diet or nutrients or bioactives coingested with fructose. More research is needed to determine factors that exacerbate or mitigate the metabolic dysfunction associated with overconsumption of fructose or HFCS.

Fructose: Sources, Metabolism, and Health

DM Klurfeld, Agricultural Research Service, Beltsville, MD, USA

Published by Elsevier Ltd.

Sources and Production

Fructose, from the Latin meaning fruit sugar, is a six-carbon sugar made by plants and has the same chemical formula ($C_6H_{12}O_6$) as glucose but is an isomer of that compound, with fructose having two hydroxymethyl groups, while glucose has one hydroxymethyl group. Although this is often represented in molecular drawings as occurring at the end of each linear molecule, the cyclic carbon ring is the more common form of both sugars. All plants in which fructose is found also synthesize glucose in varying proportion so that sugarcane and/or beet sugar contains sucrose, which is a disaccharide formed from equimolar amounts of fructose and glucose bound by a glycosidic linkage. Sugarcane is grown in warm climates and sugar beets in temperate and cooler areas, but both are used to produce the same sucrose. Other plants contain varying ratios of fructose to glucose, ranging from 3:1 in agave nectar to 2.5:1 in grapes, 2:1 in apples or pears, and 1:1 in dates and honey (which is made by bees from nectar of flowers). Some plants also synthesize small amounts of other sugars. So, commonly consumed fruits and their juices are the major dietary sources of fructose in excess of glucose.

Industrially, fructose is produced by isomerization of glucose derived usually from cornstarch and less so from sucrose. Pure crystalline fructose is used primarily as a specialty sweetener in that it is generally used in small amounts in any product. Even when part of a mixture of sugars, fructose provides other important functional properties to foods such as browning upon heating via the Maillard reaction, depression of freezing point, or being a humectant to keep baked products moist. There is considerable misunderstanding about the fructose content of high-fructose corn syrup (HFCS), which is discussed in the succeeding text in detail. Suffice it to say here that HFCS is usually 55% or 42% fructose with most of the remainder glucose plus small amounts of other sugars. The higher fructose content corn syrup is used for beverages and the lower content mostly for processed foods and baked products.

Patterns of Consumption

Isolated sugars are a relatively recent addition to the human diet. In the distant past, sporadic availability of fruit was the main source of concentrated sugars. Some estimates of the Paleolithic diet suggest that $\sim$20 g day^{-1} of fructose were consumed, but based on ripeness of various fruits and the fact that hunter-gatherers were often hungry, seasonal intake could have been several times that amount. In industrial societies, consumption of sugar was only a few kilograms per person per year until the mid-1800s when it began to increase linearly until a peak around 2000, with slight declines in some countries since then. Generally, the countries that ate more sugar recently have cut back, while other countries that consumed less have increased their intake.

Fructose is 20–40% sweeter than sucrose and is the sweetest of caloric sweeteners. Pure fructose is rarely used as a sweetener by itself. Ironically, it is commonly used in 'health foods' such as yogurt in the United States because health-conscious consumers want less added sugar but do not purchase such foods unless they are sweetened to accustomed tastes. At one time, it was thought that fructose was better for diabetics than sucrose since it did not raise blood glucose or require insulin for its metabolism by humans and crystalline fructose was sold in supermarkets for that purpose. However, fructose is no longer recommended as a preferred sugar for diabetics even though its intake is associated with lower glycemic response because there is increased risk of lactic acidosis, and the high cost of crystalline fructose prevented its incorporation into mainstream food products. Such advice was replaced by recommendations for moderate consumption of sucrose with recent emphasis on restriction of total carbohydrates for diabetics.

In the United States and a few other countries, commercial food processors use HFCS as a replacement for sucrose in many products so that the availability of sucrose and HFCS is approximately equal in the United States. The other nations are primarily Canada, Mexico, Hungary, Slovakia, Belgium, Bulgaria, South Korea, and Japan. Among these countries, the United States consumes about 25 kg year^{-1} per capita, Hungary about 15 kg year^{-1}, and the rest between 5 and 10 kg year^{-1}. Increases in use among these countries have come at different times and in many, quite recently. Few other countries have intake of HFCS greater than 1 kg year^{-1}. Despite the name HFCS, the most commonly used form of this sweetener, for soft drinks, contains 55% fructose and 42% glucose with the remainder other sugars; another type of HFCS for use in solid foods has 42% fructose. The name was coined to distinguish HFCS from regular corn syrup, which is comprised of 100% glucose. Although when HFCS was developed in the late 1960s, it was less expensive than sucrose whose price was twice the world average in the United States and remains so, the cost difference between the two sweeteners has been negligible for a number of years. HFCS is a liquid that is easier and less expensive to handle and move around a factory via pipes than is crystalline sucrose, which is very hydroscopic, leading to caking and increased labor expenditures.

Fructose is normally consumed covalently linked with glucose as sucrose or as monosaccharides in solution as HFCS, reflecting a general pattern of excessive sugar consumption by Americans; similar levels of sugar are consumed in New Zealand, Brazil, Argentina, Australia, Mexico, and Canada. Intake was almost 120 g day^{-1} for all people ages two and over in 2009–2010 according to the US National Health and Nutrition Examination Survey. The most significant sources of fructose, and all sugars, are soft drinks; sweetened fruit drinks; fruit and fruit juices; grain-based desserts like cookies, cakes

pies, or donuts; frozen desserts such as ice cream and frozen yogurt; candy; and sweetened ready-to-eat cereals. While the Dietary Guidelines for Americans distinguish between naturally occurring and added sugars, there are no metabolic differences between them; the emphasis on reducing the amount of added sugars is to encourage consumption of high micronutrient density foods, which will, in turn, be lower in energy content.

Availability, Absorption, and Metabolism

Fructose is highly available from almost all foods in which it is found, with the possible exception of some nuts, which contain trace amounts. As a monosaccharide, fructose is absorbed directly into the bloodstream from the small intestine as are glucose and galactose. If sucrose is ingested, contact with the brush border of intestinal epithelial cells results in immediate cleavage of most sucrose into its constituent monosaccharides via sucrase. While the traditional view of gastrointestinal physiologists has been that splitting of sucrose at the membrane of the epithelium is 100% efficient, recent studies make it clear that some sucrose is absorbed intact and is excreted in the urine, making urinary sucrose a potential biomarker for sugar consumption.

Intestinal epithelial cells contain the transporters GLUT-2 and GLUT-5; the former actively transports all monosaccharides, while the latter is specific for fructose and is dependent on a concentration gradient. Ingestion of fructose and glucose in roughly equal proportions, as is the most common scenario, facilitates uptake of both sugars. This is particularly relevant for study of fructose malabsorption. It is likely that the condition is overdiagnosed because free fructose in sufficient amount and form is rarely, if ever, encountered in a typical diet. When a 25 g bolus of fructose is used in a drink to evoke breath hydrogen, about half of healthy subjects exhibit evidence of malabsorption; when a 50 g dose is administered, the prevalence rises to 80%. The use of unrealistic amounts of fructose in solution to elicit microbial fermentation to breath hydrogen (which may not correlate with symptoms) is not a logical diagnostic pathway. This is not meant to minimize the fact that there are undoubtedly a large number of individuals who have gastrointestinal symptoms after consumption of large amounts of fructose. An excess of fructose over glucose is more likely to elicit symptoms of malabsorption. Hereditary fructose intolerance, resulting from mutations in the aldolase B gene, is quite rare with a prevalence of 1 in 20 000–30 000 people. While it is unclear what the true rate of fructose intolerance is in the general population, individuals with functional gastrointestinal disorders display a high rate of intolerance to fructose with half that group reporting symptoms. Well-controlled studies have shown a higher rate of intolerance to fructose than malabsorption, suggesting that symptoms are not entirely due to passage of unabsorbed fructose into the large intestine where it is fermented by the microflora.

Once absorbed, glucose is utilized by all cells of the body and can be stored as glycogen in the liver and muscles. In contrast, fructose is metabolized primarily in the liver and its uptake there depends on GLUT-2. An often unappreciated fact is that a considerable amount of fructose is converted to glucose by hepatocytes; isotopic tracer studies indicate that 30–50% conversion occurs in the liver within a few hours of consumption. This is postulated to occur via the reversible reaction between fructose 6-phosphate and glucose 6-phosphate; the latter can be used to produce glucose or be incorporated into glycogen (Figure 1).

Fructose is phosphorylated by fructokinase as a first step in its metabolism. Fructokinase exists in two isoforms – A and C – with the A isoform found in many tissues including the liver, muscles, intestines, and kidneys, while the C isoform is exclusively in the liver. At least half the metabolism of fructose occurs in the liver but certainly not all. Fructose 1-phosphate is acted upon by aldolase B to produce dihydroxyacetone phosphate (DHAP) and glyceraldehyde. The latter is acted upon by triokinase to make glyceraldehyde 3-phosphate (G3P). DHAP and G3P derived from fructose enter the pathway for glycogen synthesis just the same as intermediate products of glucose breakdown. However, these metabolites can also enter into the pathway for synthesis of triglycerides. It is well established that high fructose consumption can result in excessive pyruvate production, which yields increased acetyl CoA, leading to enhanced lipid biosynthesis. The same intermediates can also contribute to glycogen synthesis, and there are no known sensing mechanisms that allow the body to distinguish between metabolites derived from fructose versus glucose.

One measure of metabolic efficiency is diet-induced thermogenesis (DIT), which is the increase in energy expenditure following consumption of a meal. This reflects the costs of metabolism of a nutrient and has the practical value of decreasing the amount of energy available for weight gain. Most studies found a significant ~60% increase in DIT following ingestion of a meal containing fructose compared with one having glucose as the main sugar. These studies require abnormally large doses of the sugars so it is not clear what relevance they have to normal dietary patterns, but the increased thermogenesis indicates that fructose is used less efficiently than glucose for energy-yielding processes, likely because fructose is metabolized primarily in the liver, while glucose is oxidized in most cells. While these results reflect differences in consumption of pure fructose and glucose, there is no published information on the metabolic conversion of fructose to glucose, DIT, or other relevant pathways when mixtures of the two sugars alone or as sucrose are consumed. Although storage of sugars as fat is quite inefficient compared with storage of dietary lipids as fat, the increase in total sugar consumption throughout the twentieth century was followed by a decline in physical activity and accompanied by increased energy intake from all macronutrients that was not needed for maintenance, so the carbohydrates were converted to stored fat. At the present time, there are conflicting data on whether fructose intake leads to increased de novo lipid synthesis, but the metabolic biochemistry suggests that this process should be less efficient than the same process from glucose. Although there are claims on both sides of this issue, a meta-analysis comparing controlled feeding trials of fructose versus any other carbohydrate (which was either glucose or starch metabolized to glucose) found no effect of fructose in eucaloric trials and a small but significant increase in weight in hypercaloric experiments that could not be distinguished from the general effect of excess

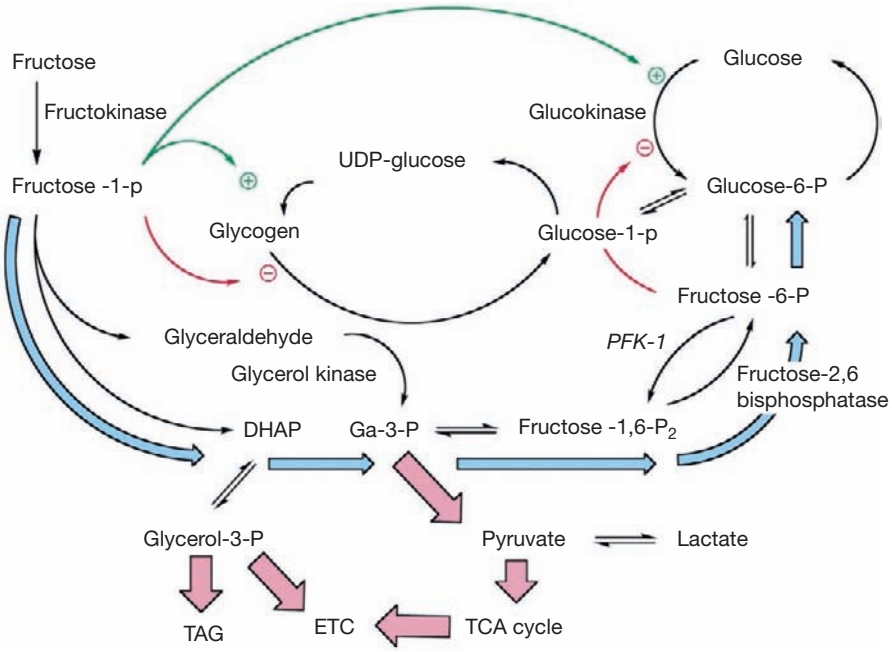

Figure 1 Overview of the major aspects of hepatic metabolism of glucose and fructose. Key points emphasized in the text of the original article: the two sugars converge at the level of the triose-phosphates (dihydroxyacetone phosphate (DHAP) and glyceraldehyde-3-P (Ga-3-P)). Conversion of fructose to the triose-phosphates is unidirectional, but fructose 1-phosphate is a positive effector of glucokinase and regulates glycogen synthesis by activating the synthase and inhibiting phosphorylase. The last effect may be different between species. Light blue arrows show the path of gluconeogenesis from fructose leading to glucose-6-P, which, in turn, can produce glucose or be incorporated into glycogen. Reproduced with permission from Feinman, R. D. and Fine, E. J. (2013). Fructose in perspective. *Nutrition & Metabolism* **10**, 45.

energy. Perhaps the most important conclusion of the meta-analysis was that the existing trials were of moderate to weak quality because they were too small and too short in time and had a number of other weaknesses in the methodology.

Health Effects

It is ironic that many research nutritionists do not know the nutrient content of many foods and many food scientists are not aware of the metabolic consequences of consuming common foods or nutrients. Since little pure fructose is consumed, there has been undue focus on HFCS, in part because of a lack of knowledge of its fructose content by nutrition researchers. As noted earlier, the name was coined to distinguish HFCS from conventional corn syrup rather than to indicate that it is unusually high in fructose in comparison with sucrose. In fact, much of the current interest in fructose is derived from the claim that the increase in obesity in the United States closely followed the increased use of HFCS. However, this claim did not take into account the fact that HFCS simply replaced sucrose in many processed foods nor was actual consumption by individuals considered so that the analysis suffered from what is termed the 'ecological fallacy' by attributing average population exposures to affected and unaffected individuals. More so, since the late 1990s, the use of HFCS has fallen in the United States, while obesity rates have plateaued for some groups and increased for others. But perhaps most importantly, obesity increased at a faster rate than in the United States in many countries of the world where virtually no HFCS is consumed, negating a causal relationship of that sweetener with weight gain.

In addition, there is also a small but vocal group of researchers who repeatedly publish comparisons of very high (greater than the 99th percentile of intake)-dose fructose with the same amount of glucose and suggest their results have important implications for what people should eat. There has also been concern expressed that the monosaccharides glucose and fructose in solution may have different effects from those of sucrose in a drink. However, particularly at acidic pH, sucrose dissociates into its constituent sugars within a few weeks so that most soft drinks actually contain more of the monosaccharides than the disaccharide when consumed. Furthermore, since almost all sucrose is rapidly split to its constituent sugars upon contact with the brush border of the intestinal epithelium, the body only sees mixtures of the two monosaccharides. There are, however, conflicting data that calories from liquids are not compensated for by reduction of other foods as is often observed with solid foods. Again, the existing controversy may have diverted researchers from studying true links to overconsumption.

Despite the information in the preceding text, researchers continue to study large doses (often $\geq$75 g or ~15% of daily energy requirement) of fructose in comparison with glucose in solution, neither one of which is consumed except under laboratory conditions. It is clear that consumption of the two sugars together has different effects, which are ameliorated in comparison with exposure to one of the monosaccharides, but a 75 g bolus of sugar in isolation is an obviously unusually heavy load that exceeds normal intake of either

monosaccharide from all sources in 1 day. Such doses of fructose or glucose result in increased endogenous lipid synthesis, increased plasma triglycerides, increased adipose tissue deposition, and weight gain. What these studies generally demonstrate is that fructose can be worse than glucose under specific conditions. However, these effects are generally not observed in a diet without excess calories and the two sugars are virtually never consumed in isolation. Adequate physical activity seems to protect against both short- and long-term effects of excessive fructose intake as does concomitant intake of fish oil, indicating the interactive effects of other dietary components and physical activity on health end points. The main issue with using such high amounts of fructose is that it violates the basic maxim of toxicology in that the dose makes the poison. Virtually all nutrients, essential or not, cause toxicity at high enough levels.

High levels of fructose feeding have been claimed to cause insulin resistance, the metabolic syndrome, and increase lipid synthesis. The main problem for interpreting such claims is the diet design in which extremely high levels of fructose are used and in which a very high-carbohydrate diet is fed. Therefore, it is difficult, if not impossible, to distinguish between a fructose-specific effect and the influence of a high-sugar or high-carbohydrate diet from the experiments in the literature. This is particularly problematic in people who are in excess energy balance, have increased baseline abdominal obesity, and/or have little habitual physical activity. All these conditions relate to the propensity to respond with appropriate levels of insulin postprandially and the insulin sensitivity of peripheral cells.

One of the shortcomings of virtually all controlled feeding studies on fructose is the relatively short time period of 4 weeks or less. If there were certainty that such time periods represented steady state for the metabolic consequence of interest, there would not be a controversy. But it is unknown if such values are in steady state or on a trajectory to worsen or toward adaptation. In other words, we have no experimental evidence to guide experimentalists in what is an adequate, let alone optimal, time frame for feeding studies of fructose. Most of the literature seems to be based on finding a statistically significant effect, rather than what is biologically meaningful.

It is well established that increasing total dietary carbohydrate results in elevated blood triglycerides, particularly when the carbohydrates are simple sugars. While some individual studies claim that fructose feeding is particularly hypertriglyceridemic, a meta-analysis of studies in diabetics indicates an effect in type 2 diabetics only, of fructose only in comparison with starch, only in studies that fed 60 or more grams per day, and in those studies of less than 4 weeks in length. Also, fluid fructose appeared to have greater negative effects than fructose from solid foods. At the same time, most of these studies reported that serum cholesterol concentrations were reduced in subjects given fructose.

Substitution of fructose for glucose or starch leads to reduced postprandial glycemic responses. The European Food Safety Authority (EFSA) currently allows a health claim in which food companies substitute fructose for sucrose or glucose because this reduces postprandial blood glucose responses even though the EFSA advisory panel acknowledged that high intakes of fructose may lead to elevated blood lipids, insulin resistance, and increased abdominal fat deposition.

A large number of animal studies have been conducted using fructose as the sole carbohydrate source, often at 65–70% by weight, particularly in rodents. These studies often report adverse health effects, including increased hepatic lipid synthesis and deposition, increased serum lipids, and increased weight gain. The rationale for such an approach is that untoward effects are magnified with this diet so that lower amounts must also be harmful. However, it should be obvious that reproducing an abnormal physiological response in an animal to an unrealistic diet means nothing for public health recommendations. The primary value of animal studies is in understanding mechanisms of developing disease, thereby providing a means to intervene in the process. In regard to fructose, there appear to be differences in hepatic metabolism of fructose between rodents and humans and between isolated hepatocytes exposed to fructose and the response of hepatic metabolism in a human fed fructose so the potential relevance of any of these studies is debatable.

Emphasis on potential adverse health effects of fructose has diverted scientific and public attention away from the real issue of excessive consumption of total sugars that usually represent excess calories, whether the sugar is added to foods or inherent in them. There is no credible evidence that obesity induced by overconsumption of sugar differs from that induced by excessive intake of fat, but it is also unclear if excessive sugar intake in weight-stable individuals has the same degree of effect as seen in overweight or obese subjects. Unfortunately, there is no information on either an optimal or maximal level of sugar that can be consumed without untoward health risks. It is clear that modern levels of sugar consumption are many times what we were exposed to for thousands of years. But simply because a lower amount of sugar was available in the distant past does not indicate that low level is what we should be eating now. The belief that humans have not evolved to metabolize the array of foods and nutrients that we have available now has support from some nutritionists and much of the general public but is clearly dismissed by evolutionary scientists who accept the fact that humans like other animals and plants continue to evolve as their environment changes.

Fruit Juices

PR Ashurst, Reachfar, Ludlow, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Industrial production of fruit juices started in the United States around 1870. Concord grapes were juiced from their vines, and the juice was filtered, bottled, and then pasteurized in a hot water bath. The European fruit juice industry began in 1896 with the publication of detailed instructions for commercial production of unfermented fruit juices. That same year, apple and grape juices were first produced commercially in Berne, Switzerland. In the United States, nationwide expansion of commercial juice production developed about 1929, when economic necessity forced American consumers into an era of home canning, which included fruit and vegetable juices. During the 1930s, the development of pasteurization techniques and availability of lined cans afforded products of superior juice quality and an era of unprecedented growth for the industry.

During the 1940s, frozen single-strength fruit juices (i.e., juices produced by direct pressing of fruit, rather than by reconstitution of concentrated juice) were introduced to consumers in the United States. Frozen concentrated fruit juices were first sold in that market during 1945–46. In the same decade, orange concentrate, hot packed into small flat glass bottles, was made available in the United Kingdom to supplement vitamin C intake for children and pregnant women.

The development of freezing technology had a dramatic effect on the industry and was responsible for most of the early growth of the citrus industry in Florida and other producing countries such as Brazil. Frozen concentrated fruit juices for reconstitution and frozen concentrated orange juice (FCOJ), in particular, have now become the principal juice products of international commerce.

Single-strength juices, now known in the industry as 'not from concentrate' (NFC) or 'direct' juices, have entered the market more recently. These have been developed in two principal forms. Freshly pressed juices that have had no further processing other than chilling and have a very short shelf life of a few days are now available. Fresh juices that have been flash pasteurized and packaged in a very clean, but not aseptic, environment to give them a chilled shelf life of several weeks are also widely sold.

Single-strength and reconstituted juices and juice drinks can be packed under aseptic conditions in laminated containers and polyethylene terephthalate (PET) bottles. These can be stored at ambient temperatures for convenience and economy for producer and consumer alike. Aseptic packaging is also used for more economical storage and transport at ambient temperatures. The process is suitable for bulk single-strength and concentrated juices although freezing at about −18 °C remains the principal means of transporting and storing concentrated bulk juices.

Brazil and the United States are the main producing countries for orange juice. Germany, eastern European countries, and, increasingly, China are the principal sources for apple juice. Smaller producers are located more widely around the globe. The main consumer markets are the United States and Europe with increasing consumption in Asian countries.

Raw Materials

The early juice industry was often a salvage operation. The principal source of raw material was misshapen, poorly colored, or skin-blemished fruit unsuitable for the fresh, canned, or frozen fruit market. For many years now, raw materials have been selected and bred especially for suitability for juice production.

Variety and maturity of fruits are important factors affecting suitability for juice production. For some juices, such as citrus or grape, only a few varieties have traditionally been used to provide a distinctive flavor or to ensure freedom from unwanted characteristics. Developments in processing technology now enable the use of a wider range of varieties. Bitterness and other unwanted characteristics can now be removed or reduced by processing. When a range of varieties is available, blends are often used to achieve uniformity of flavor or analytic characteristics. Blends are sometimes perceived as having a better flavor or commercial advantage than a single varietal juice. For example, fruit having a high sugar content may be mixed with fruit from a different variety to achieve a desired sweetness/acidity balance. This balance, known as the sugar–acid 'ratio' is based on °Brix readings, that is, %w/w sugar, obtained with a refractometer, divided by the value for total acidity (%w/w) obtained by titration.

Field staff are often employed to advise growers on agronomic aspects of fruit production. The application of sprays to the growing crops and the coordination of harvesting with factory production schedules are important. Payment for raw materials is frequently based on specifications that are either official government grades or stated market standards. There is a smaller but significant demand for fruits and juices certified as organic or fair trade. To assist in juice authentication, an independent organization has been set up in Europe to inspect, validate, and register processing factories worldwide.

Composition and Fruit Juice Authenticity

Juice composition varies widely from country to country, with fruit variety and season. Much work has now been carried out, mostly in Europe, to develop sophisticated methods for authenticating fruit juices. Commercial databases can now be used to authenticate the principal fruit juice types from almost anywhere in the world. Fruit juice standards, particularly relating to juices reconstituted from concentrates, are now published by the German Industry (The RSK system), AIJN – European Fruit Juice Association, and Codex Alimentarius.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00334-2

Adulteration of fruit juices, particularly orange and apple, has been a significant issue in the past because of relative commodity price differentials between fruit juice solids and sucrose. Natural sugars are a major constituent of most fruit juices. The partial substitution of juice solids by sucrose or other bulk sugars from a variety of different sources can be an attractive commercial proposition. This can be achieved without affecting obvious juice quality. The addition of excessive amounts of pulp wash (see section '**Citrus Processing**') to citrus juices has also been commonplace despite being prohibited in some countries. The addition of malic acid to bland apple juice concentrates with low levels of acidity has also been used. This produces the more valuable high acid juice. In the case of more expensive red fruit juices, adulteration can take many forms including dilution with less expensive juices and by the addition of sugars.

A wide range of analytic techniques is now available to detect various forms of adulteration. The German 'RSK' system largely requires a fruit juice to meet a number of analytic characteristics. In other countries, new methods have been developed. For the detection of carbohydrate addition, measurements of their stable isotopes of carbon, hydrogen, and oxygen and comparison against a wide database have proved to be a powerful tool. The detection of small amounts of oligosaccharides that are characteristic of the added carbohydrate can also be useful in identifying adulteration. Other techniques that have proved valuable for specific applications include the examination of the amino acid and anthocyanin profiles of juices and the detection of added malic acid to apple juice. Many countries now use an industry-based voluntary screening of fruit juices sold to consumers. This is supported by inspection of producer factories and an audit trail of the supply chain for products. The net result has been a significant reduction in instances of adulteration although isolated occurrences still arise.

Manufacturing

Figures 1 and 2 set out the typical steps in the generalized production of citrus and soft fruit juices. Equipment and processes vary significantly for the type of fruit to be handled. In most major processing countries, harvested fruit is transported to the adjacent plant. For the production of 'freshly pressed juices' in some countries, including the United Kingdom, fruit is imported for local and often small-scale pressing and packaging.

Citrus Processing

Fruit of appropriate quality is washed, sometimes with a detergent, to remove soil and debris. It then passes over roller brushes and is rinsed and drained. Manual or automatic graders remove unwholesome fruit as the fruit passes over roller conveyors. It is then segregated automatically by size prior to juice extraction. Several types of extractors are available. Sizing and grading of each load of fruit, based on fruit color, size, shape, and weight, is increasing. This can be carried out by computer-controlled equipment. There is potential for total electronic grading and thus complete automated process control.

In one type of extractor (e.g., FMC Technologies Inc.), the fruit is located between two cups having sharp-edged metal tubes at their base and metal fingers that intermesh. The upper cup descends and the many fingers on each cup interweave to express the juice. The tubes cut holes in the top and bottom of each fruit. On further compression, the rag, seeds, and juice sacs are compressed into the bottom tube between the two plugs of peel. A piston moves up inside the bottom tube forcing the juice through perforations in the tube wall. A simultaneous water spray washes the peel oil expressed during extraction away from the peel as an oil–water emulsion. Peel oil is recovered separately from the emulsion usually by a centrifugal process. Each extractor unit has several cups of a single size, and in a typical factory installation, banks of extractors process different fruit sizes.

In another extractor type (e.g., Automatic Machinery and Electronics Inc. (AMC)), the individual fruits are cut in half as they pass a stationary knife. The halves are oriented in a vertical plane, picked up by synthetic rubber cups, and positioned across plastic serrated reamers. These revolve in a synchronized carrier in a vertical plane. As the fruit halves progress around the extractor turntable, the rotating reamers exert increasing pressure and express the juice. Oil and pulp contents in the juice increase with greater reaming pressure. Recoverable oil is removed in a separate step prior to juice extraction. Needle-sharp spikes prick the peel of the whole fruit, releasing oil that is washed away with water and recovered from the oil–water emulsion. Although most citrus juice extraction equipment is based on these two types of extractor, other types are used. Plants similar to that originating in the United States are now made in other countries.

During extraction of citrus juices, it is desirable to have as gentle an extraction pressure as possible. There should be minimal contact time between juice and pulp to reduce the amount of bitter substances expressed from the peel into the juice. The amount of suspended solids and pulp in citrus juice is controlled in a subsequent separation. This is effected by a finisher where a screw action is used to force juice through a rotating perforated screen and separate the larger pulp particles from juice. The oil level in the juice may, if required, be adjusted by vaporizing under a vacuum. Separated pulp is washed and finished several times to produce a solution. This may then be either added back to the juice to increase juice yield or concentrated to produce the so-called pulp wash solids. This material, also called water extract of orange solids, can be used as a base for cloudy beverages. The addition of pulp wash has been the subject of much debate in the issue of juice authentication. It is now generally regarded as acceptable if added back in an 'in-line' process in small ($<5\%$) quantities. Its addition offline is not generally now acceptable for authentic juice. Empirical methods for measuring pulp wash content have been developed using UV spectrophotometry.

Orange juice from the Navel varieties containing limonin and pulp wash solids can be excessively bitter. A commercial process developed in about 1992 for debittering these liquids involves the use of an ion exchange resin.

Concentration and Aroma Recovery

Most orange and grapefruit juice sold and transported internationally is frozen as concentrate, usually at 60–65 °Brix. Citrus

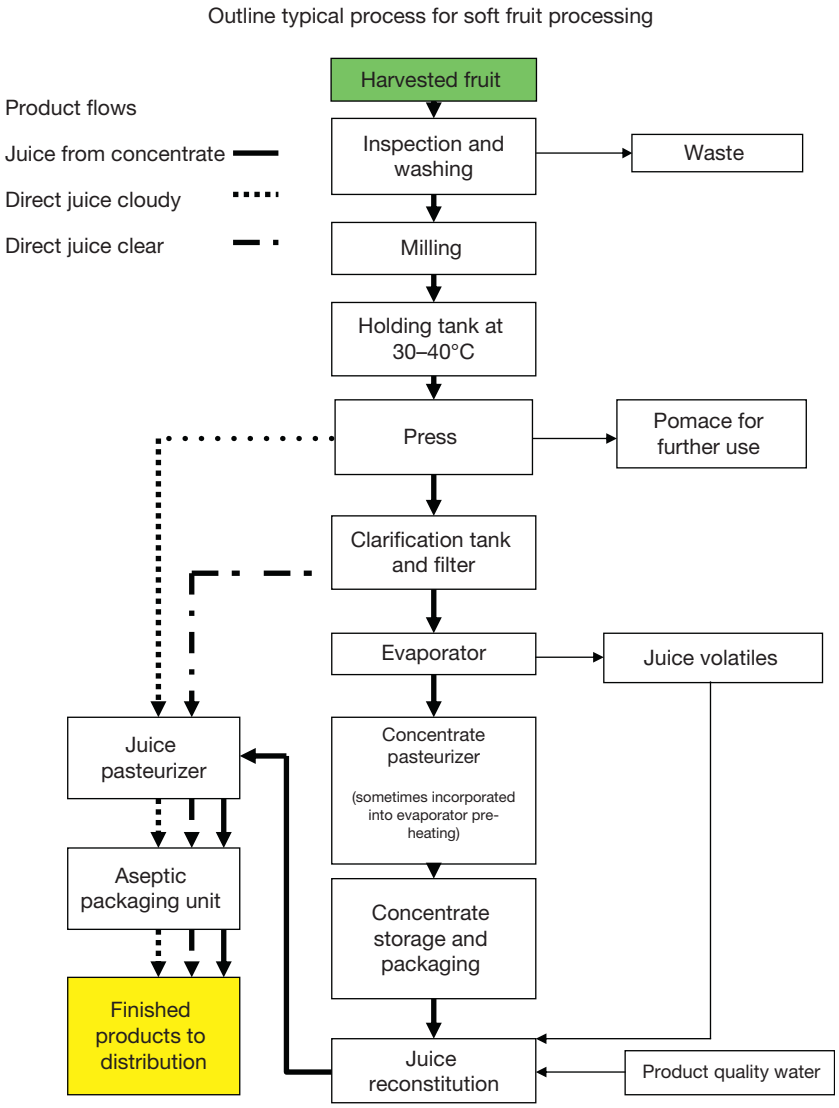

Figure 1 Outline typical process for citrus fruit processing.

juices are almost exclusively concentrated in a thermally accelerated short-time evaporator (TASTE). These evaporators are of optimized efficiency for the amount of water removed per kilogram of steam used. For example, in a seven-effect evaporator, 2.77 kg (6.1 lbs) of water is removed for each kilogram of steam used. Each effect consists of a bundle of tubes, with falling films of juice flowing inside. These are mounted inside a cylinder so that steam flowing into the first-effect cylinder can condense on the outside walls of the tube bundle. Heat transfer vaporizes a portion of the water contained in the juice. The hot water vapor thus produced is used to heat juice in the next effect and so on. This results in successively lower temperatures with each consecutive effect. The temperature will be around 98 °C in the hottest effect and reaches ~45 °C in the last effect. Concentrated juice is discharged from the last effect to a vacuum flash cooler yielding a product temperature of about 13 °C. The whole system is under vacuum with a progressively higher vacuum in each successive effect. This is sufficient to cause water evaporation.

During water removal, much of the desirable aroma characteristic of the citrus juice is carried off with the vapor, especially in the early effects. Essence recovery units are used routinely to condense the volatile flavor substances. This water-phase essence, industrially termed 'volatiles,' and an oil-phase essence oil are produced. These valuable commercial flavor fractions are saved separately. They either may be added back later to concentrated juice or may be used as separate flavor ingredients. Concentrate is cooled quickly and stored at or below −10 °C in bulk vessels. Most of the single-strength orange juice marketed worldwide is prepared by reconstitution and water-phase essence, and oil fractions may be added during this process. This restores flavor lost during concentration. Blended concentrates are reconstituted to between 11.2 and 11.8 °Brix juice. They are then pasteurized and chilled prior to packaging for the retail market. Aseptic packs of laminated material, glass, or PET bottles of 1.0 l or more are the most popular. In European markets, there is a code of practice requiring reconstituted orange juice to have a minimum of

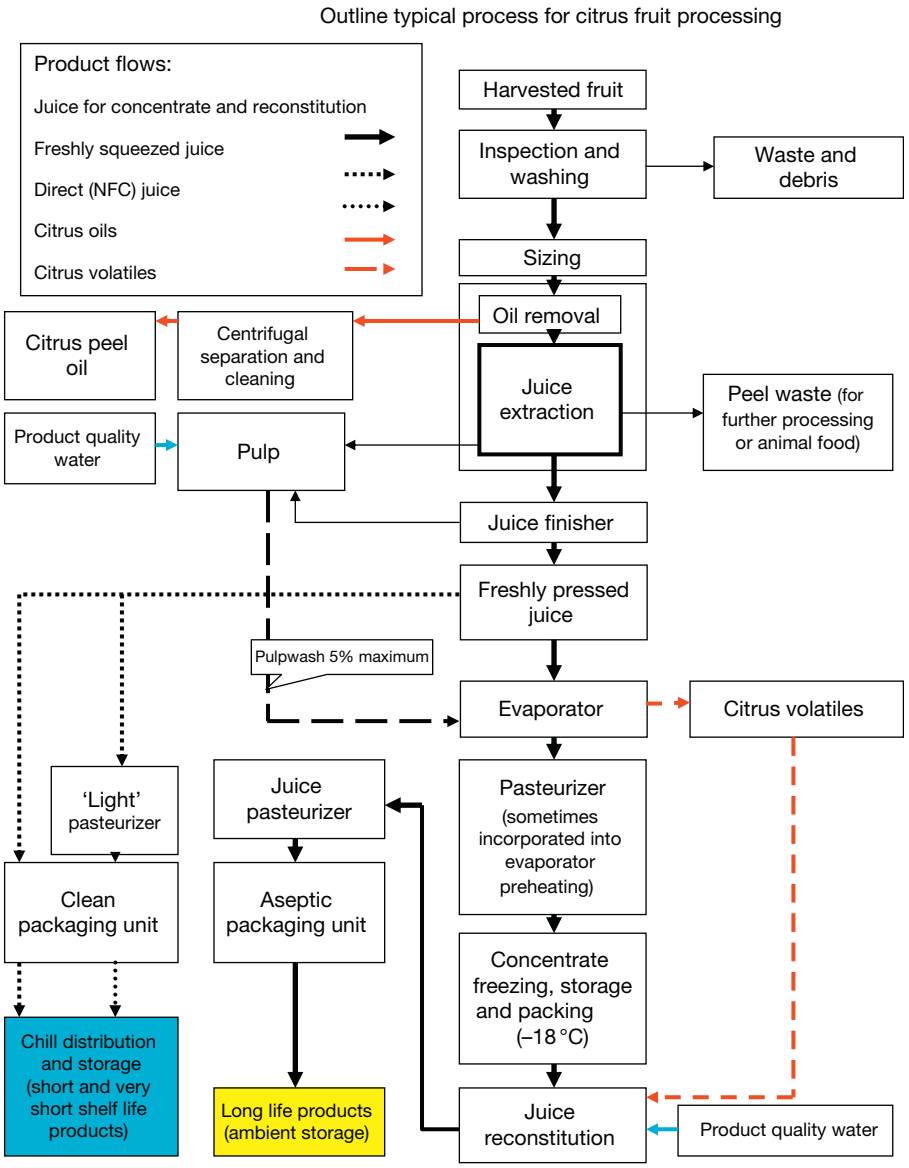

Figure 2 Outline typical process for soft fruit processing.

11.2 °Brix. In countries that follow the WHO Codex Alimentarius guidelines, the minimum must be 11.5 °Brix.

A newer citrus juice concentration process, requiring minimal heat treatment, has been applied commercially in Japan. Pulp is separated from the juice by ultrafiltration (UF) and pasteurized. Separated juice containing the volatile flavorings is concentrated at 10 °C by reverse osmosis. Concentrate and pulp are recombined to yield a product at a concentration of 42–51 °Brix. The flavor of this concentrate has been judged superior to that of commercially available concentrate and close to that of fresh juice. Clarified citrus juices (other than lemon or lime) are not regarded as acceptable to most consumers in Europe or the United States.

A further process using freeze concentration has also been developed and has been used on a very limited commercial scale. Fresh juice is cooled to below 0 °C, and the water crystals that form are removed and washed by more juice. This process is repeated four or five times until the residual juice has a concentration of around 45 °Brix. The juice is said to have flavor characteristics that resemble those of the fresh juice. The economics of the process are said not to be favorable for most markets and applications.

Pasteurized single-strength orange juice, NFC, often called premium orange juice in the United States, is increasing in sales worldwide. There has been a corresponding reduction in the retail market share of FCOJ in the United States. NFC juice requires special extraction and storage conditions to ensure high quality. Juices are expressed with extractors designed to produce juice having low oil content (<0.035%). Juice must be chilled and stored aseptically or in frozen blocks to provide a year-round supply to packers.

Unpasteurized orange and grapefruit juices also are increasingly popular products in the United States and Europe. Fruit must be processed under strict conditions of hygiene and the

juice kept just above 0 °C during its approximately 14-day shelf life. Year-round juice supply relies on the importation of fresh fruit from different growing countries according to the harvest season. It is often difficult to maintain consistency of flavor and Brix–acid ratio.

Lemon and Lime Juice

Lemons and Persian or Key limes can be extracted using similar FMC- and AMC-type extractors described earlier in the text. The juice can be concentrated in a TASTE evaporator, an APV Crepaco, Inc. evaporator, or other types of evaporators. An alternative method of manufacture for clarified lime juice to supply the UK demand for lime juice cordial is often used. Whole limes are crushed in a screw press and the resulting juice and pulp is allowed to stand for several days. This permits natural pectolytic enzyme activity to clarify the juice. Peel and pulp residues are then processed to recover lime oil. Separated juice can be concentrated in a suitable evaporator or by subjecting it to UF. This latter technique produces a six to seven times concentrate with an outstanding pale color. Lemon juice is widely produced in several European countries, notably Italy, Spain, and Greece as well as Argentina. It is generally available as either a clear or cloudy product. Lemon and lime juice concentrates are still available in Europe preserved with about 1500 mg kg^{-1} sulfur dioxide. These are typically used in making concentrated (dilute to taste) soft drinks. Clarified lime juice, made by mixing direct juice with filter aid prior to passing through a filter press, is the one clarified citrus juice that is a significant article of commerce in the United States. The pasteurized bottled juice is popular for drink mixes, punch bases, and fountain drinks.

Citrus Comminutes

In the United Kingdom in particular, there is a demand for comminuted citrus products, especially made from oranges and lemons. These are for use in the manufacture of 'whole fruit drinks' for consumption after dilution. Such products rely on the combination of juice, peel, and oil constituents to provide a much stronger flavor than can be obtained from juice alone. Early comminutes were produced by simply pulping the whole citrus fruit. Later developments take the various components from citrus processing including concentrated juices. They are then blended in required proportions, milled, and pasteurized. Citrus comminutes are often stored with added chemical preservatives for later use in the manufacture of soft drinks. UK regulations permit the limited carryover of sulfite preservatives from comminutes into appropriate end products.

Soft Fruit Processing

Fruit used for juicing must be sound, free from gross damage or contamination. The presence of mold or rot can lead to tainted juices or, especially in apples, the presence of toxic mold metabolites such as patulin. Mechanical harvesting can cause bruising and skin penetration, which may cause off-flavors or allow the growth of pathogenic bacteria such as *E. coli*. Mechanical harvesting is used extensively on apples and black currants, whereas berries are mainly picked by hand. Most temperate deciduous fruits, including apples, pears, grapes, berries, black currants, and red currants, are processed in a similar way. This typically involves milling the whole fruit and then pressing the juice from the resulting mash. Equipment for processing stone fruits such a peaches or apricots requires an additional stage to remove the stones prior to pressing. Many tropical soft fruits require specialized processing stages.

Milling

All fruit used for juicing must be thoroughly washed. A variety of methods are used to break the fruit to release juice. These methods depend on the structure of raw material, the clarity desired in the final juice, enzymatic discoloration, and breakdown of pectin.

Milling is essential for relatively hard fruit such as apples, whereas grapes and berries need only light crushing. Some soft fruits, such as raspberries and strawberries, are often received frozen and must be defrosted prior to processing. Grapes and other fruit harvested in clusters are mechanically destemmed prior to crushing. For crushing, a series of intermeshed arms mounted on two cylinders shred the grapes as they pass through to produce a mash.

The pulp from stone fruit, such as apricots, mangoes, and peaches, must be removed in a way that prevents damage to the stone or pit. These often contain components that can affect juice flavor and stability during storage. A mill for stoned fruit contains hard rubber-lobed wheels that rotate together to force the fruit down and strip most of the pulp from the intact stone. An alternative process for peaches involves halving and pitting the fruit in a Filper twist pitter. This pulps the fruit halves then heats the pulp to 82 °C in a steam cooker. A fruit disintegrator is then used to produce a puree, which is put through a finisher. Such pulpy fruit purees can be treated with sugar syrup to produce nectar drinks typically containing 25–50% juice.

Enzyme Treatment of Pulp

Because of their cell structure, some fruits are not easily juiced by milling and pressing. Commercial pectolytic enzymes are widely used to break down cell structure and degrade pectins in milled fruit to improve juice extraction efficiency. When clear products are required, enzymes may also be used to treat juice following pressing.

Press Aids

Fibrous materials are sometimes added to the fruit pulp to facilitate juice liberation or to provide a stable structure to withstand the application of pressure. Several types of press aid are used, for example, diatomaceous earth, coarse wood flour, rice hulls, and bleached or unbleached wood pulp. Diatomaceous earth and wood flour may be sprinkled over press cloths or added to the pulp before the cloths are filled for hydraulic pressing. This addition makes discharge of the spent cakes easier and also increases the yield of juice.

Pressing

There are a variety of fruit presses. Some presses are more suitable for one type of fruit than for others, but most can be used for any fruit with varying degrees of success. Some presses require the use of a press aid such as diatomaceous earth or wood chips. Total juice yield from the original fruit defines press efficiency. Additional yield can be obtained by adding a small amount of water to the press cake and pressing again. The denomination as 'pure juice' of such products is not permitted in many countries.

A simple rack-and-frame press uses heavy nylon or polypropylene woven cloth positioned in a wooden frame inside a rack. A measured amount of apple or other fruit mash is added from a hopper above the frame. The mash is leveled and the edges of the nylon cloth are folded over the mash to encase it and create a 'cheese.' The frame is removed, and a second rack is placed on top of the first cheese. This process is repeated until a stack of cheeses is prepared. A hydraulic ram then applies gradually increasing pressure on the stack and expresses the juice. A high yield of juice (~80%) can be obtained and no press aid is required. Because this process is labor-intensive, it is mostly used for small farm and pilot-plant operations.

The Bucher-Guyer horizontal rotary press is a highly automated batch process machine that requires no press aid. The press consists of a hydraulic piston inside a horizontal large rotating cylinder. Many flexible rods covered with a knitted synthetic fabric are arranged between piston face and the cylinder end. The rods have serrated surfaces to allow juice that passes through the fabric to flow to the discharge ends. Hydraulic pressure is applied to the piston for a preset time, which is retracted, and the cylinder is rotated to break up the press cake. This cycle is repeated several times before the press cake is removed from the cylinder and the press is cleaned. Juice yield for this horizontal rotary press can reach 84%; with secondary water addition, it may be increased to 92%.

The Stoll press uses a horizontal hydraulic ram and a chamber with screens on the sides that holds the mixture of fruit mash and press aid. Hydraulic pressure is applied to the mash first at 2750–3440 kPa (400–500 psi) and then at 17 200–20 600 kPa (2500–3000 psi) for preset times. Pomace is removed after each cycle. One person can operate several presses at once, each with a throughput of 4–5 ton fruit per hour.

A belt press commonly uses two belts of woven material arranged in a horizontal plane. Fruit mash is deposited on, and spread out evenly between, the two belts that converge and press the mash between them. The belts wrap around a series of successively smaller cylinders or pass between rollers (less efficient) for the pressing action. Juice yield for the wraparound belt press is typically 72% and increases up to 92% with secondary water addition.

Concentration and Aroma Recovery

Concentration of juice from soft fruit is best carried out using an evaporator that causes as little thermal degradation as possible. Equipment that permits recovery of volatile materials important to the aroma of the fresh fruit is preferred. Evaporators that use a high temperature for a short time and operate under a vacuum, such as the APV Crepaco falling film plate evaporator or the Alfa Laval centrifugal evaporator, are most commonly used. The TASTE, almost universally used for citrus, is rarely if ever used to concentrate soft fruit juices.

Multiple-effect falling film vacuum plate evaporators use a plate-and-frame heat exchanger to heat the juice to the required temperature for boiling under partial vacuum. The plate evaporator consists of multiple gasketed plates arranged in series within a compact frame. As feed juice flows in a single pass as a falling film, the water is vaporized on contact with steam-heated plates. It is discharged as a liquid–vapor mixture to a large volume separator. The concentrated juice flows out the bottom and the water vapors are used to heat the next effect or are condensed. For maximum energy efficiency, the warm concentrate stream is used to preheat feed juice. Falling film plate evaporators are especially useful for fruit juice that is heat-sensitive. This is because of short heat contact time, rapid start-up and shutdown times, and minimum juice loss from a small liquid hold up volume. Such evaporators can be used by a single processor for multiple fruit crops during the year.

Centrifugal evaporators are also suitable for concentrating fruit juices because they have very low heat contact times. The expanding flow centrifugal evaporator contains a stack of rotating, steam-filled hollow cones. As juice is sprayed onto the inside of the cones near the apex, centrifugal force spreads juice across the inner surfaces of the cones. The resulting concentrate is forced to the stationary walls of the evaporator and collected. Steam condensate on the outer surface of each cone is similarly forced out by centrifugal force. Thus, the heating surface in contact with the product is constantly heated with hot dry steam. Juice concentrate and steam condensate are continuously removed. Juice can be concentrated in one pass with a few seconds contact time.

There are two principal methods available for aroma recovery. In one method, a portion of the water is stripped from the juice prior to concentration. It is then fractionally distilled to recover a concentrated aqueous essence solution. Apple juice requires 10% water removal, peach 40%, and Concord grape 25–30% to remove volatile flavor as an essence. Fractional distillation affords an aqueous essence flavor solution of 100–200-fold strength. This means the essence is 100–200 times more concentrated in flavor than the starting juice. A second method of essence recovery is to condense the volatiles from the last effect of the evaporator; they are enriched in volatile flavor components.

Clarification

The appearance of fruit juices varies widely. Citrus and pineapple juices typically have high contents of insoluble pulpy solids and are almost always sold as cloudy juices. By contrast, cranberry, grape, and many apple juices have little or no suspended solids and are translucent. In some juices, such as citrus, many of the flavoring constituents adhere to the pulp, and the clarified juices lack flavor. Preservation of the natural pectin content by rapid heating and cooling of juice as soon after pressing as possible is necessary to inactivate the natural enzymes. This has been found to be particularly important in providing a stable cloud. The size of the suspended particles is another factor influencing flocculation. Particle size may be adjusted by screening, homogenization, colloid milling, or selective filtration.

In the production of opalescent or natural-type apple juice, ascorbic acid is often added to the fruit pulp before pressing or to the juice as it comes from the press. This is to retain more of the apple flavor. Ascorbic acid addition and pasteurization of the juice as soon as possible after pressing minimize oxidation of polyphenols, which cause browning and contribute to pulp flocculation.

In the production of clear juices, natural pectin present is degraded with added pectolytic enzymes. This facilitates filtration and minimizes subsequent precipitation or flocculation of pectic substances. Other sources of colloidal haze in filtered juices are polymerized tannins or compounds formed by the combination of tannins and proteins. Haze also may result from the denaturation of proteins. To overcome tannin precipitates, gelatin is sometimes added to the juice during enzyme digestion. The amount and type of gelatin added to form a floc must be carefully controlled because an excess of gelatin may cause a haze. Laboratory procedures are frequently conducted by adding graduated amounts of gelatin and tannin to samples of juice and noting the amounts required for greatest clarity. Such tests are frequently necessary because of the variation in the natural tannin and protein contents of the juice. The use of kieselsol, a synthetic silica sol, in combination with gelatin, or pectinase enzyme mixtures, increases the speed of the clarification process. This makes in-line clarification possible.

Treatment of juice with commercial pectolytic enzyme preparations may be carried out at low temperature for 15–18 h or at 40–50 °C for 1 or 2 h. If a higher digestion temperature is used, the juice may be clarified by rotary vacuum precoat filtration. This is followed by a small-cartridge or leaf-type filter to remove any filter aid. If juices are digested at low temperatures, sufficient time usually elapses for flocculation of the solids. Clear juice is then decanted and passed through a pressure-leaf filter. The filter aids used are diatomaceous earth of fine to medium grades depending on the clarity desired and the nature of the solids. Completeness of pectin destruction is of importance in maintaining good filtration rates and filtrate clarity.

The use of UF membranes is becoming increasingly popular for clarification of apple juice and is also used for lime juice. All particulate matter and cloud is removed, but enzymes pass through the membrane as part of the clarified juice. Thus, pasteurization before UF treatment to inactivate enzymes prevents later haze formation from enzymatic activity. Retention of flavor volatiles is lower than that using a rack-and-frame press but higher than that using rotary vacuum precoat filtration.

Natural style juices especially apple juice that contain cloudy components are increasing in popularity because these retain more fresh flavor if processed carefully. Optimum processing conditions involve chilling the fruit to 4 °C before milling. The addition of 500 ppm ascorbic acid to retard browning, pressing under nitrogen, and flash pasteurization of the juice as quickly as possible are also employed.

To avoid formation of tartrate crystals in bottled grape juice, filtered juice is stored at −2 °C, or just above the freezing point, for several weeks. This permits the deposition of potassium acid tartrate crystals. Prior to storage, juice is pasteurized at 88 °C and then cooled in storage at −2 °C before it is pumped into clean storage tanks. Unless care is taken in the sanitation of the pasteurization and cooling equipment, piping and tanks, yeast growth may cause alcohol production and/or generation of off-flavors.

Pasteurization

Fruit juices generally have pH values of 4 or less and spoilage is usually limited to yeast and mold growth with occasional bacterial contamination. Flash pasteurization minimizes flavor changes owing to heat treatment. For flash pasteurization, several methods are used. The most common is a plate heat exchanger with a separate holding tube. Typical flash pasteurization conditions for microbial stability are 85 °C for 15–30 s although a higher temperature, typically 95 °C, is usually regarded as necessary for complete enzyme inactivation. NFC juices are typically subjected to a temperature of between 90° and 95° for a few seconds. Juice treated in this way is then packed and stored cold but will normally have an extended but still limited shelf life.

An alternative, and widely used procedure, is to package juice cold in suitable containers. Pack and contents are then heated with hot water sprays in a tunnel, typically in three stages: preheating to around 40–50 °C, pasteurizing at around 70 °C for around 20 min, and then cooling.

Alternatively, filling the container with hot juice pasteurizes the package and the product, thus delivering product pasteurization. This technique carries a higher risk of spoilage of end products and is limited by the type of packaging available.

Aseptic packaging in flexible laminated multilayer plastic containers has become popular worldwide. The packaging materials used are economical and the product can be stored at ambient temperature. In such packaging, the juice must be heat-pasteurized, cooled to prevent heat damage to the package, and introduced into the package in a sterile atmosphere. The packaging material is fed from a reel and presterilized with hydrogen peroxide or other approved sterilant solution. It is then formed into the required shape and filled in the aseptic chamber. Aseptically packaged juice drinks typically have a shelf life of at least 12 months in temperate ambient conditions.

Alternative methods of pasteurization that are under development include irradiation with high-energy electrons or x-rays and the use of high-pressure pasteurization. In the latter process, batches of product in flexible packages are placed in a pressure vessel and subjected to pressures of around 600 MPa. Current processes are labor-intensive and limited by batch operation. Consequently, the process is limited to premium products where, for freshly squeezed product, shelf life can be extended by two or three times that of unprocessed juice.

Chemical Preservatives

The use of any chemical preservative in pure fruit juices is no longer permitted in most countries although labeling the product as a 'juice drink' can sometimes provide a loophole to facilitate the use of permitted chemical preservatives. Most governments require a listing of ingredients, including preservatives, on the labels of food and beverage containers. The most common preservatives used in beverages

containing fruit juice are the potassium and sodium salts of sorbic, benzoic, and sulfurous acids and also dimethyl dicarbonate ('Velcorin').

Freezing Preservation

Fruit juices can be preserved by freezing or dehydration but these processes are now little used for consumer products. Freezing is however widely used to ensure stability during transport of bulk juices.

Tropical Fruit

A wide range of tropical fruit juices are now available although blends are often more popular than individual juices. Pineapple juice has been the most popular tropical fruit juice consumed in the United States and Europe for many years. It has long been a by-product of the pineapple canning industry although now whole fruit for processing is grown in many countries including Thailand and Kenya.

Other tropical fruit juices are often considered too pulpy or are judged to have harsh or exotic flavors, which make 100% juice products unacceptable to many consumers. They are sometimes more acceptable as juice blends or nectars containing 25–50% juice or as blended fruit drinks where their strong flavors are diluted or modified. 'Smoothie' juices and drinks often based around banana pulp are also increasing in popularity.

Fruit Juice Drinks

Commonly, a juice drink contains around 5–10% of the named fruit juice, with added sugar or other sweetener, an acidulant, flavoring, and other minor ingredients as appropriate. The 1990 US Federal Nutrition and Labeling Act requires the declaration of juice content so that the consumer can make a more informed choice. Similar regulations now exist in EU countries. With cocktails and juice drinks, added sugars, acids, flavorings, colorings, and nutrients can be used to provide a wide variety of stable products of uniform quality and wide consumer appeal.

Notes

Mention of a trademark, trade name, or proprietary product is for the purposes of example or identification only and does not imply a warranty or guarantee of the product by the author or publisher. Other products may also be suitable.

Fruits of Tropical Climates: Biodiversity and Dietary Importance

Introduction

Tropical climates offer a wide array and diversity of fruits that have rich nutraceutical values and organoleptic qualities. These fruits are preferred by consumers mainly owing to their seasonal availability, traditional value, and rich mouthfeel. However, still, there are many diverse ranges of fruits that have remained underexplored for commercial utilization. The underexplored fruits are those that can be considered 'underexploited' (eaten by tribal or indigenous populations) or otherwise consumed by animals and birds in the wild. Exploring underutilized fruit crops can be opined to meet the nutritional necessities of underprivileged population and contribute towards enhancing the economic security and satiability in the developing region.

By and large, consumers prefer to eat fresh fruits to fulfill their daily requirements of energy and to gain adequate amounts of essential minerals and vitamins for a healthy living. However, available concentrations of bioactive compounds required to cater an individual's needs can depend on the fruit's maturity, harvesting stage, season, and the processing and preservation conditions adopted. Moreover, concentrations of the bioactive compounds and nutrients (amino acids, dietary fiber, and phenolic compounds) can vary within a fruit (e.g., in pulp, seeds, and pericarp), too. Recent years have witnessed a rapid expansion of ongoing research on fruit consumption, and it is a well-accepted fact that regular intake of fresh fruits can lower various risks associated with chronic diseases (cancer and cardiovascular diseases) and aging.

The climate in tropical countries is always warm and humid throughout the year. There are more than 100 tropical countries in the world, which have their own unique biodiversity encompassing a rich arena of fruits and vegetables. Some of the tropical countries like India, Malaysia, Australia, Thailand, Brazil, Vietnam, Cambodia, Kenya, Chile, Egypt, and Indonesia have already tried to tap the potential market of tropical fruits and have gained significant foreign exchequer, too. These countries have set up appropriate strategies to gain high exporting potential. The global production market of tropical fruits varies depending on the demand of consumers.

Tropical fruits can be categorized either as major or minor fruits. Some examples of major tropical fruits include mango, papaya, jackfruit, pineapple, dates, sapota, jambu, guava, and melons, while that of minor fruits include the exotic ones such as dragon fruit, durian, rambutan, passion fruit, star fruits, lychee, breadfruit, longan, noni, pulasan, and ackee. Most of these fruits are either consumed directly or converted into food products such as juice, jams, and jellies. Of late, fruit powders are also gaining wide popularity among consumers and manufacturers owing to the retention of natural flavor, color, and nutrition. An overview on the potential use of underutilized tropical fruits is depicted in Figure 1.

Agreeably, majority of the underexplored tropical fruits do not have much scientific information, and there is a major gap in scientific knowledge. Based on this, in the preceding text, we have attempted to highlight some of the most popular and exotic 'minor fruits,' which have some scientific evidence and information pertaining to their source, production, consumption patterns, and potential health-promoting effects.

Berberis (Family: Berberidaceae; *Berberis vulgaris*, *B. microphylla*, and *B. heterophylla*)

Berberis are a group of small berries, sweet and sour in taste. They are widely distributed in tropical regions (Asia, South America, and Africa) and scantly in temperate regions (Europe) of the world. There are several species of berberis; however, only a few of them are known to have food value. Commercially, these fruits are not popular but are consumed by some indigenous people in the growing regions. Ripe fruits are highly acidic (owing to vitamin C content) and impart a tingling sensation upon consumption. In the Indian subcontinent, fruits are used for culinary purposes (as a substitute for tamarind), while in Iran, they are used as flavoring agents during meat preparation. Some species (*B. heterophylla*, *B. microphylla*, and *B. darwinii*) are popular in Chile and Argentina, wherein they are used in the preparation of jellies and jams.

Most of the *Berberis* species have been used in traditional folk medicine, especially in the Afro-Asian regions. Phytochemicals such as isoquinoline alkaloid berberine (useful in treating a wide array of diseases including that of cancer) have been isolated from berberis. The nutritional and antinutritional qualities of the pulp and seed portions of edible berberis (*B. asiatica*; *B. aristata*; *B. lycium*; *B. jaeschkeana*; *B. pseudumbellata*) from the western Himalayas (India) have been reported to contain high fiber, protein, fat, tannins, and phytic acid.

Breadfruit (Family: Moraceae; *Artocarpus altilis* Parkinson Fosberg)

The breadfruit plant is a small evergreen tree with large leaves, widely distributed in the tropical and pantropical regions. The fruit has gained popularity in New Guinea, Indonesia, the Philippines, Taiwan, Hawaii, Malaysia, and India for its multiple culinary uses. A mature tree can yield more than 200 fruits in a season. Fruits are oval or oblong in shape (size 3–6 in., weighing ~1.5–2 kg) and covered with a thick pericarp (spines) and have latex exudates upon maturity. Fruit latex has medicinal value. Unripe fruits are green-colored while ripe are with yellow tinge (yellow color is due to the presence of papayotin and artocarpin enzymes). Consumers prefer to

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00337-8

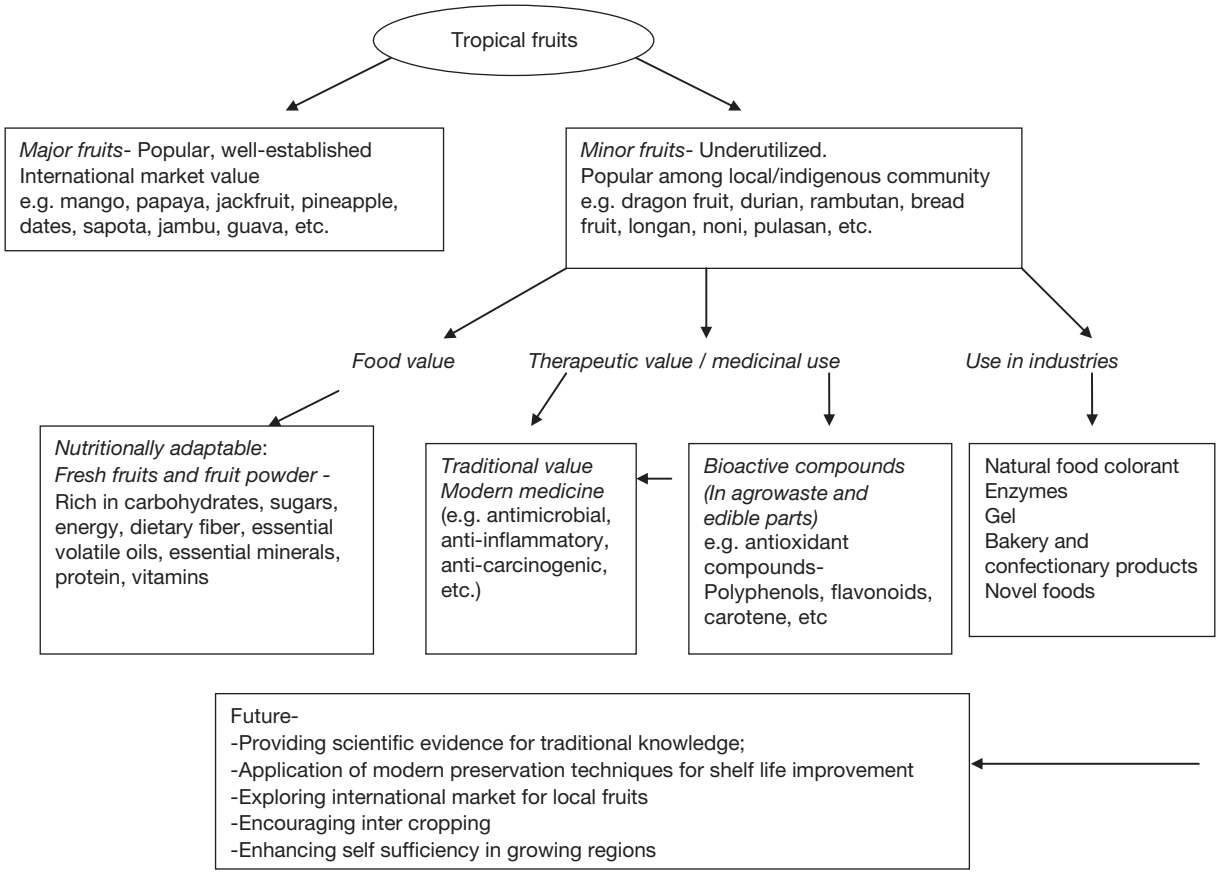

Figure 1 An overview on the potential uses of underutilized tropical fruits.

eat green and raw breadfruit flesh as vegetable. Seeds, though big, are less preferred to be eaten.

Fruits are rich in starch (~25%), and many starch-based food products are prepared by boiling, roasting, or baking. Raw breadfruits are prepared as curries, fermented and mashed with coconut milk, followed by baking in banana leaves. Nutritionally, breadfruits are rich in carbohydrates, fiber, protein, and essential minerals such as calcium and iron and ascorbic acid. Scientific reports on the medicinal value are scarce on this fruit. However, some traditional knowledge is available wherein breadfruit latex is used to treat sprains and broken bones; toasted flowers are used to treat toothaches (https://ntbg.org/breadfruit/uses/tree1.php; asses date: 18 February 2014).

Cashew Apple (Family: Anacardiaceae, *Anacardium occidentale* L.)

A small evergreen tropical tree (growing to 25–30 ft) produces highly valuable cashew nuts and the cashew apple. This tree has its origin in Brazil but is cultivated extensively in India and Vietnam. In fact, the cashew apple is botanically considered to be a false fruit (pseudocarp). The fruits are oblong-shaped (5–10 cm long) and brightly colored (yellow to orange and red, depending on the cultivar). Ripe cashew fruits are juicy with a unique taste (astringent) and a sweet and strong aroma. The cashew apple is consumed directly or is used to prepare alcoholic drinks (or rather country liquor such as that of feni).

Nutritionally, cashew apple juice is believed to be rich in vitamin C, carotenoids, and phenolic compounds. Traditionally (in Brazil), fruit juice is used as a remedy to treat sore throat and chronic dysentery. Alcohol produced from the ripe fruit is believed to reduce rheumatic pains. Cashew apple juice is reported to exhibit antioxidant, antimicrobial (antibacterial and antifungal), and antimutagenic and antitumor activities. High levels of carotenoids and ascorbic acid content in cashew apple products from Brazil have been reported. Besides, different varieties of cashew apples collected from different regions in Brazil showed them to be rich in β-carotene, β-cryptoxanthin, α-carotene, and 9-*cis*-+13-*cis*-β-carotene. Essential volatile oils from fruits of red and yellow cashew varieties showed oil from the red variety to be dominated by palmitic and oleic acids, while oil of yellow cashew was dominated by palmitic acid, furfural, 4-hydroxydodecanoic acid lactone, (*E*)-hex-2-enal, (*Z*)-hex-3-enol, and hexadecanol.

Durian (Family: Bombacaceae; *Durio* species; *Durio zibethinus*)

The durian plant is a native of the Malay Peninsula but is widely cultivated in Thailand, the Philippines, and Indonesia,

too. Durian fruits are seasonal and are popular as the 'king of fruits.' A matured tree bears fruit after 5–7 years of planting the seed, and fruits hung on a peduncle, which is firmly attached to the trunk and branch. The fruit is oblong to round-shaped, with the outer skin being light-green to brown in color (weighs between 1 and 3 kg, 15–16 cm in diameter, and 30–32 cm long). The yield per tree of durian is in the range of 15–800 fruits/season.

The fruit skin is covered with 1–2 cm long thick hexagonal spines and is very hard (55–66%). The edible part or aril is 22–30% encompassing big seeds (12–15%). Owing to a short shelf life, efforts are being made to commercialize durian flesh to convert into fruit powder. Even though farm varieties are popular, some of the wild cultivars (e.g., *D. kesudinarum* and *D. grandiflorus*) are also known to produce edible fruits, but these are less preferred owing to poor quality and taste. The durian fruit gets its popularity based on the distinctive odor, aroma, and taste.

Durian fruits are high in nutrition and bioactive compounds. The fruit pulp is a good source of protein, lipids, ash, fiber, and carbohydrates/sugars. Fatty acids contain the methyl esters of myristic acid, linoleic acid, oleic acid, 10-octadecenoic acid, palmitoleic acid, palmitic acid, and stearic acid.

Today, attempts are being made to prepare bakery products with durian flavor using the fruit powder. Novel bakery products such as jam, candy, ice cream, juice, and fruit shake are also being attempted. The fruit pulp is consumed directly or eaten with sticky rice. In order to retain the characteristic organoleptic qualities, in some countries, overripened fruits are fermented with salt or sugar to produce 'tempoyak' (acid-fermented durian) or 'lempok.' Dodol, a traditional sweet dish, is also prepared by cooking durian pulp with sugar. Some of the other traditional products like 'kuan' (pulp cooked with flour and sugar) are also prepared using durian fruit.

With regard to unripe or partially ripe fruits, they are boiled and consumed as vegetable, used to prepare soup, and converted into fruit bars or leathers. Reports are available wherein durian fruits have shown antiproliferative activities. Water-soluble polysaccharides from rinds of durian have been reported to have pharmaceutical value. The use of the durian fruit as a therapeutic agent to reduce cholesterol, in treatment of cardiovascular diseases, and as an antioxidant to prevent oxidative stress, obesity, and diabetic mellitus is also reported.

Rambutan (Family: Sapindaceae: *Nephelium lappaceum* L.)

This is a popular exotic fruit originated in Southeast Asia, extensively consumed and cultivated in Malaysia, Indonesia, Vietnam, the Philippines, India, Australia, and Thailand. There are several native and wild cultivars (more than 200) of rambutan. Fruits are oval in shape and possess smooth, hairy skin coverings, which are rather considered as soft spines. When raw (unripe), the hair color is green, but when ripe, they are bright red to maroon. However, depending on the cultivar, the color can be pink or yellow. The edible portion (flesh or aril part) is inside the skin (or hairy pericarp), which is juicy and sweet to acidic. This in turn encompasses a white translucent fleshy seed coat that covers an oblong-shaped seed. A single female plant (up to 20 m in height and 5–8 years old) can produce approximately 40–50 kg of fruit. As of today, Thailand is the leading exporter of rambutan (production rate: 6–7 lakh ton per annum), with earnings of more than 15 million US dollars.

Rambutan is consumed directly by opening up the peel. However, owing to huge amount of production, the fruits are processed into juice, jelly, and jam or are canned along with pineapple slices in a sweet syrup base. The seeds are poisonous but are consumed after roasting to treat diabetic patients, treat fever, and treat stomach upsets. In Malaysia, rind residues of the fruit are dried and used in local traditional medicine to treat common fever, flu, and dysentery. With regard to health-promoting activities and bioactive compounds, the pulp portion contained a significant amount of polyphenols. However, the rind is reported to have high antioxidant activity.

Rambutan seeds are reported to be rich in crude protein, fat, fiber, and ash. Seeds are rich in fatty acids such as oleic, arachidic, stearic, and palmitic acids. The presence of high amounts of arachidic acid is ought to contribute immensely to food and cosmetic applications.

Pulasan (Family: Sapindaceae; *Nephelium mutabile* Blume)

Pulasan is a tropical ornamental, drought-resistant fruit-yielding tree, encountered in regions of Southeast Asia (Malaysia, Thailand, the Philippines, and Indonesia). The fruits are seasonal and harvested twice annually. This fruit is confused with rambutan owing to its look-alike physical features (dark-red color, oval shape, and occurring in clusters). People prefer to eat the fruit directly, though fruit juice is also popular. The fruits are used as a flavoring agent in the preparation of ice creams, puddings, jellies, and jams. Traditional claims on body fat reduction upon consumption of this fruit and seeds do not have any scientific basis. The production rate and marketing statistics still remain undocumented. The flesh part is edible and is sweet and juicy. The seeds are edible and are eaten after roasting (tastes like almonds). A cocoa-like beverage is also prepared by the roasting of seeds.

Nutritionally, the fruits are documented to contain carbohydrate (16.6), fiber (0.5), ash (0.7), protein (0.9), and fat (0.1) (all in g/100 g) and vitamin C (10.80 mg/100 g) (http://www.nutriweb.org.my/cgi-bin/dbrecords.cgi?comp=Proximateandsubmit_do-=Viewandfood_no=106081andpart1=Raw+and+Processedandfname=Pulasanandgroup=Fruitsandmname=Pulasan, assessed date; 22 February 2014). Volatile constituents of the fruit contain aliphatic hydrocarbons such as pentadecane and aliphatic alcohols.

Mangosteen (Family: Clusiaceae; *Garcinia mangostana* L.)

Mangosteen, a native plant of Indonesia, is popular as the 'queen of fruits.' This is widely cultivated in Cambodia, India, Thailand, Malaysia, Sri Lanka, Vietnam, the Philippines, and Africa. The fruit contains maroon- to purple-colored thick skin

(pericarp or rind) with gummy latex. The edible portion (aril) consists of white flesh with tiny nonedible seeds. The edible portion of the fruit is sweet to sour in taste, juicy, and fibrous.

In traditional medicine, the fruits are recommended to be used to treat stomach ulcers and acidity. In addition, the rind portion is recommended to treat abdominal pain, diarrhea, inflammation, skin infection, and common wounds. Details of the processing of this fruit into food products are scarce. However, in local markets, mangosteen juice in a syrup pack is available. The mangosteen fruit encompasses rich amounts of phytochemicals and has high polyphenolic contents (phenolic acids, anthocyanin, proanthocyanidin, and xanthone) and cyanidin-3-sophoroside and cyanidin-3-glucoside. The rind portion of this fruit possesses antimicrobial, antioxidant, and antitumoral activities.

Nutritionally, the fruits contain 0.41 of protein, 17.91 of carbohydrates, and 1.8 of total dietary fiber (g/100 g of sample) and 2.9 mg/100 g of vitamin C (http://ndb.nal.usda.gov/ndb/foods/show/2348?qlookup=mangosteenandfg=andformat=andman=andlfacet=andmax=25andnew=1asses date: 23rd February 2014).

Identical to mangosteen, there is one more popular evergreen tree fruit referred to as the 'wild mangosteen.' This tree species is common in India, Sri Lanka, and other South Asian regions. The fruits are round to ovoid in shape (weighing 50–60 g) and are red- to maroon-(dark violet)colored when ripe, the pulp being sweet to sour in taste and astringent. Traditionally, juice prepared from fruit rind is believed to be of high medicinal value and is effective to treat digestive disorders, acidity, rheumatic pains, and constipation in humans. The rinds are sun-dried and are used in traditional food preparation (as acidulants) in parts of India to prepare sour curries and in the preparation of refreshing drinks.

Nutritionally, the rind portion contains 4% total sugars, 1.4% fat, 1% protein, and 1.7% tannins. The rind has a high antioxidant potential and contains anthocyanins such as cyanidin-3-glucoside and cyanidin-3-sambubioside. Dried rind is also reported to possess antibacterial and antifungal activities. Some of the bioactive compounds such as garcinol and isogarcinol have been isolated from the fruit. Fruit consumption is also linked with the prevention of leukemia cell lines (in humans) and possesses anticholinesterase and antiobesity activities.

Longan (Family: Sapindaceae; *Dimocarpus longan* Lour.)

The longan fruit is extensively cultivated in China, Indonesia, Malaysia, Vietnam, and Taiwan. The fruit is comparable with lychee fruits. The edible part (flesh) is inside a soft skin (pericarp) that is semitranslucent, juicy, sweet, and succulent with a pleasant aroma. The small, oval-shaped seeds are enclosed within the fruit flesh. The flesh portion contains polysaccharides such as D-galactopyranose, L-arabinofuranose, D-glucopyranose, and D-galacturonic acid. Phenolic compounds such as gallic acid, corilagin, flavone glycosides, and glycosides of quercetin and ellagic acids have been isolated from the pericarp. The pericarp, aril, and seeds exhibited antityrosinase, antioxidant, anticancer, and antiglycated activities. The pericarp portion also possesses antimicrobial (antibacterial and antiviral), anti-inflammatory, and anticarcinogenic properties.

Longan seeds though are nonedible (17%, w/w of fresh fruit); they are reported to be rich in polyphenols like gallic acid, grevifolin, corilagin, methyl brevifolin carboxylate, ethyl gallate 1-β-O-galloyl-D-glucopyranose, and 4-O-α-L-rhamnopyranosyl-ellagic acid and ellagic acid. Consumption of this fruit is reported to provide the benefits of antioxidant, antityrosinase, and immunomodulation activities. Longan fruit extract is also known to inhibit linoleic acid oxidation and free-radical scavenging activities against DPPH and hydroxyl radicals and superoxide anions.

Langsat (Family: Meliaceae; *Lansium domesticum* Corr. Ser.)

Langsat is a tropical, medium-sized, fruiting tree originated in Southeast Asia (Indonesia, the Philippines, Vietnam, and Malaysia). The fruits occur in clusters, are oval in shape (2–5 cm), and have a thin, golden-yellow-colored skin that can be peeled easily. The edible part is the inner juicy flesh (sweet and sour taste) that encompasses minute, flat, nonedible seeds (5–6 mm). The fruits are eaten raw without much processing. However, in local markets, fruit syrup is also popular, which is used to prepare refreshing juice. The actual production and marketing statistics of this fruit remain undocumented.

The outer skin part contains oleoresin, which is traditionally used in selected tropical regions to treat diarrhea. Seed extracts have insecticidal and antimalarial activities. Fruit extracts exhibited antityrosinase and antioxidant activity, too. The isolation of tetranortriterpenoids and triterpenoids from seeds has been linked with antimalarial activity against *Plasmodium falciparum*. The edible portion of the pulp is rich in carbohydrates, protein, fiber, and ascorbic acid.

Litchi (Family: Sapindaceae; *Litchi chinensis* Sonn.)

The litchi (or lychee) fruit is native to China and is extensively cultivated in warm tropical climates of Malaysia, Brazil, India, Bangladesh, Taiwan, and Japan. The fruits are similar to longan, with the edible part being the translucent aril, which are juicy and sweet to sour in taste. The pericarp is green when unripe and pink when ripe. The fruits are rich in phytochemicals, minerals, and dietary fiber. Litchi fruits are used by Chinese as a traditional remedy for a healthier heart, liver, and spleen.

Antioxidant activities in seeds are also reported. The seeds of litchi (*semen litchi*) are used to treat neuralgic pain. The pulp of litchi contains antioxidant compounds such as glycosides of quercetin and kaempferol. The pericarp encompasses antioxidant compounds (phenolic compounds, tannins, and anthocyanins) that exhibited high free-radical scavenging activity against DPPH radicals, superoxide anions, and hydroxyl radicals. In addition, the pericarp is reported to strongly hinder linoleic acid oxidation and show activity against hepatocellular

Table 1 Some reports highlighting the bioconstituents in selected tropical fruits

Fruit type	*Observations*	*Reference*
Berberis (*B. asiatica*; *B. aristata*; *B. lycium*; *B. jaeschkeana*; *B. pseudumbellata*)	High in fiber (pulp 7.0–8.1%; seeds 4.4–5.3%), protein (pulp 4.7–7.2%; seeds 5.9–8.5%), and fat (pulp 2.6–4.0%; seeds 4.6–5.3%) In seeds, tannin content varies between 1.4 in *B. jaeschkeana* and 2.4 mg/100 g in *B. asiatica* and phytic acid 2.2 in *B. lycium* and 9.9 mg/100 g in *B. pseudumbellata* In pulp, tannins ranged between 0.39 in *B. aristata* and 1.2 mg/100 g in *B. jaeschkeana* and phytic acid 0.37 (*B. asiatica*) and 6.0 mg/100 g (*B. pseudumbellata*)	Chandra et al.
Breadfruit (*Artocarpus altilis*)	Nutritionally, breadfruit contains carbohydrates (21.5–29.5%), fiber (1.08–5.5%), proteins (1.3–2.2%), lipids (0.2–0.86%), and ash (0.56–1.2%) and minerals such as calcium (0.05 mg/100 g), iron (2.4 mg/100 g), with ascorbic acid ranging between 15 and 30 mg/100 g	Morton
Cashew apple (*Anacardium occidentale* L.)	Cashew apple products such as concentrated juice, frozen pulp, nectar, ready-to-drink, and sweetened concentrated juice were found to contain ascorbic acid that ranged between 13.7 and 121.7 mg/100 g and total carotenoids that ranged from 8.2 to 197.8 μg/100 g	Assunção and Mercadante
	In: Different varieties of cashew apples collected from diverse regions in Brazil Identified compounds included β-carotene (16.6–67.9 μg/100 g), β-cryptoxanthin (7.7–64.4 μg/100 g), α-carotene (5.9–51.9 μg/100 g), and 9-*cis*-+13-*cis*-β-carotene (3.3–15.6 μg/100 g)	Assunção and Mercadante
	In: Red and yellow cashew varieties, the essential volatile oil in the red variety was dominated by palmitic (19.6%) and oleic (19.6%) acids, while oil of yellow cashew varieties was dominated by palmitic acid (11.4%), furfural (10.0%), 4-hydroxydodecanoic acid lactone (8.2%), (*E*)-hex-2-enal (7.2%), (*Z*)-hex-3-enol (6.2%), and hexadecanol (6.2%)	Maia et al.
Durian (*Durio* species: *Durio zibethinus*)	Durian fruits are high in nutrition and bioactive compounds. The fruit pulp is a good source of protein (1.47%), lipids (5.33%), ash (1.12%), fiber (3.08%), and carbohydrates (27.09%). The pulp contains methyl esters of myristic acid (2.52%), linoleic acid (2.20%), oleic acid (4.68%), 10-octadecenoic acid (4.86%), palmitoleic acid (9.50%), palmitic acid (32.91%), and stearic acid (35.93%)	Devalaraja et al. and Ho and Bhat
Rambutan (*Nephelium lappaceum* L.)	Fruit contains high polyphenols. However, the rind is reported to have a high antioxidant activity	Palanisamy et al.
	Rambutan seeds are reported to be rich in crude protein (7.80%), fat (40%), fiber (11.6%), and ash (1.22%). The seeds are rich in fatty acids such as oleic acid (40.3%), arachidic acid (34.5%), stearic acid (7.1%), and palmitic acid (6.1%). The presence of high amounts of arachidic acid is ought to contribute immensely to food and cosmetic applications	Zee
Pulasan (*Nephelium mutabile*)	Volatile constituents of the fruit contain aliphatic hydrocarbons (70.2%) such as pentadecane (61.4%) and aliphatic alcohols (19.4%)	Wong et al.
Mangosteen/Garcinia sp. family	Rind portion contains 4% total sugars, 1.4% fat, 1% protein, and 1.7% tannins. However, the seeds are good in triglycerides. The rind has a high antioxidant potential and is reported to have high anthocyanins (2.4%), mainly cyanidin-3-glucoside and cyanidin-3-sambubioside	Nayak et al.
Longan (*Dimocarpus longan*)	The flesh portion contains polysaccharides such as D-galactopyranose (33.7%), L-arabinofuranose (32.8%), D-glucopyranose (17.6%), and D-galacturonic acid (15.9%). Phenolic compounds such as gallic acid, corilagin, flavone glycosides, and glycosides of quercetin and ellagic acids have been isolated from the pericarp	Shi et al.
Langsat (*Lansium domesticum* Corr. Ser.)	The isolation of five tetranortriterpenoids and 11 triterpenoids from seeds exhibited antimalarial activity against *Plasmodium falciparum* (IC_{50} = 2.4–9.7 μg ml^{-1}) Besides, 1 g of edible portion of the pulp contains 9.5 g carbohydrates, 0.8 g protein, 2.3 g fiber, and 1 mg ascorbic acid. Fruit extracts exhibited antityrosinase and antioxidant activity, too	Saewan et al. and Morton
Litchi (*Litchi chinensis* Sonn.)	The presence of free, bound, and total phenols (range of 66.17–226.03, 11.18–40.54, and 101.51–259.18 mg of gallic acid equivalents/100 g, respectively) and the presence of free, bound, and total flavonoids in the range of 16.68–110.33, 10.48–22.75, and 39.43–129.86 mg of catechin equivalents/100 g, respectively, are reported	Zhang et al.

carcinoma and fat oxidation. The presence of free, bound, and total phenolics and total flavonoids has been reported.

In Table 1, some reports highlighting the bioconstituents identified in selected tropical fruits are depicted.

Future Perspectives

Majority of the edible tropical fruits possess rich nutraceutical value. Exploring these fruit crops can be opined to meet the nutritional requirements of the underprivileged population and contribute towards enhancing the economic security in the region. Besides, still, there are major gaps in the available database on the health benefits incurred on regular consumption of these fruits. Of late, fruit powders are also gaining wide popularity among consumers and manufacturers owing to the retention of natural flavor, color, and nutrition. This can be explored further to be used as a nutritional supplement, too. In addition, as the nonedible portions such as peels and seeds are also known to encompass rich nutraceutical value, further research studies are warranted in this direction.

Introduction

Fresh fruits are an integral component of a balanced human diet in the tropical region. Though majority of the exotic tropical fruits are seasonal, their regular consumption is considered to provide rich health benefits. Traditional knowledge is available on the health-promoting effects on consuming certain fruits, thus supporting the need for enhanced intake of fruits. Scientific evidences and database information provide details of the traditional knowledge and clarify the claims made for the nutritional and therapeutic effects of the exotic fruits. Majority of the exotic fruits or their wastes have been reported to exhibit rich antioxidant, antitumor, and antimicrobial activities. Exotic fruits encompass rich amounts of phytochemicals such as carotenoids, polyphenolic compounds, vitamins, essential minerals, and fatty acids, which can efficiently reduce the incidence of chronic diseases and protect the human body against free radical-induced damages. Providing adequate information on bioactive compound composition in an exotic fruit not only is vital for research purpose but also can also be of use for local governments to recommend regular intake of a fruit as an additional supplement along with the normal food.

This article is in continuation with our earlier article and highlights more on the popular exotic fruits of the tropical and pantropical regions of the world. Focus is also laid on the biodiversity of the plant species, their composition, and the potential benefits incurred on regular consumption. Major challenges faced by the agro-based food industries with regard to production, marketing, and preservation of good-quality fruits are also discussed. In the following text of this article, we are highlighting on the remaining popular and exotic tropical fruits with relevance to their biodiversity and health-promoting effects.

Wolf Apple (Family Solanaceae, *Solanum lycocarpum*)

Wolf apples are smooth, globular berries (average 10 cm diameter) and are edible by both livestock and humans. Edible part is the flesh or pulp having several embedded seeds. Matured fruits are soft, aromatic, and sweet with skin and pulp being yellow in color (with red tinge when overripe). Generally, the fruit pulp is processed into jams.

With regard to nutritive value, these fruits are rich in carbohydrates, proteins, lipid, and ash with the absence of any dietary fiber. Fruits possess high antioxidant activities and are effectively used to treat hypoglycemia and dyslipidemia. Green fruits are rich in the steroid precursor 'solasodine,' and the fruit powder/flour is used to treat diabetic patients.

Rose Apple (Family Myrtaceae, *Syzygium malaccense* or *Syzygium samarangense*)

Rose apple is a common inhabitant of the Malaysian Peninsula and Indian subcontinent and parts of North Africa. Fruits are edible and bell-shaped (5–7 cm long, weighing around 35–36 g) with a unique flavor. Upon maturity, a single plant yields more than 700 fruits. Fruit skin (peel) is thin and occurs in different colors such as white, pink, pale green, red, mixture of green and red, and purple to red. The whole fruit is edible and the inner flesh (mesocarp and endocarp) are succulent and white in color, without any seeds.

Rose apple fruits are used in salads or as a snack food. *Rojak, a Malaysian salad delicacy of mixed fruits, is prepared using* pineapple, rose apple, fresh cucumber, mango, sugar, chili, lime bean curd, and paste of cuttlefish (or shrimp) in different proportions. Most of the people rely on eating rose apple when thirsty, owing to its high water content. Fruits are eaten raw, and owing to short shelf life, majority of the harvest is wasted.

There is a major gap in technological knowledge of utilizing this fruit for commercial purposes. Rose apple contains carbohydrates (6.5%), fiber (5.1%), protein (0.9%), lipids (0.1), and ash (0.5%). In Ayurvedic system of Indian medicine, the fruit is believed to improve brain and liver functioning. In addition, seeds are recommended to treat stomach cramps, dysentery, and diarrhea.

Sweetsop (Family Annonaceae, *Annona squamosal* L.)

Sweetsop (or custard apple) plant is a semideciduous tree, which is predominantly drought-resistant. Fruits are mainly preferred for their sweet taste and fragrance. Fruits are ovoid to conical (8–10 cm in diameter and length, weighing 1–2 kg), are pale green to yellow in color, and are thick-skinned (rind) with knobby, hexagonal sections. Pulp portion of matured, ripe fruits are eaten fresh. Unripe fruit are inedible and are astringent.

Pulp portion encloses thick inedible seeds. In some of the pantropical regions, leaves and seeds are used for their insecticidal properties. Sweetsop fruit are rich in carbohydrates/sugars, fiber, proteins, ash, and vitamin C. Fruits are also traditionally used as flavoring agent during preparation of ice cream in the Philippines, where marketing of sugar apple wine is popular.

Soursop (Family; *Annona muricata* L.)

Soursop is a tropical fruit, native to South American countries (Mexico, Brazil, Cuba, Peru, and Venezuela). However, this

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00338-X

plant is widely cultivated in South East Asia, Pacific regions, and North Africa. Matured fruits are 20–25 cm long and weigh an average of 5–6 kg. Skin color is green and has prickles or soft thorns. The edible portion is the flesh, which is white-colored and encompasses inedible black seeds. Once mature, the fruits are harvested and allowed to ripe. However, fruits harvested when unripe and without reaching physiological maturity are of low quality and bitter in taste. Harvesting stage is determined when the skin color changes from dark green to dull yellow/green with their pulp being firm (firmness checked by thumb pressing).

Soursop fruits are either consumed directly or prepared into various food stuffs. This fruit is considered rich in dietary fiber and vitamins C, B_1, and B_2. The pulp portion is used to prepare juice, smoothies, nectar, candies, and fruit bars and as flavorings. In Malaysia and Indonesia, the fruits are used as an ingredient to prepare traditional foods like 'ais kacang' (shaved ice), 'dodol' (a sweet flavored dish), and refreshing fruit juice.

Nutritionally, the fruits contain carbohydrates (16.84 g/100 g), protein (1 g/100 g), total sugars (13.54 g/100 g), and total dietary fiber content (3.3 g/100 g; USDA, http://ndb.nal.usda.gov/ndb/foods/show/2459?qlookup=09315andformat=Fullandmax=25andman=andlfacet=andnew=1, assessed date 20 February 2014). Nearly 86% of the fruit is pulp with 3% being receptacle. Taste of soursop is attributed to the presence of sugars and organic acids (malic and citric acids) (0.65–0.85%). Studies have shown ripening stages to increase the total soluble sugars, ascorbic acid by 11-fold, malic acid by 7-fold, and citric acid by 3-fold. Fruit juice is rich in minerals like zinc, copper, and phosphorus. Besides, nearly 59 compounds were identified in the oil obtained from peel, leaves, and pulp.

Fruits have high polyphenol content, and regular consumption is linked with beneficial properties such as anticancer, anti-leishmanial, and antidiabetic activities. Contradictorily, consumption of soursop fruit is correlated with the development of neurodegenerative disease (Parkinson disease), which is attributed to the presence of annonacin in the seeds.

Gandaria (Family Anacardiaceae, *Bouea macrophylla* Griffith)

Gandaria or the plum mango (or kundangan fruit), a tropical, ornamental, evergreen fruit-bearing tree, is widely distributed in Malaysia, Thailand, Burma, the Philippines, and Indonesia. Both unripe and ripe fruits (approx. size: 3–5 cm, round to globose) are edible and are consumed directly or used for cooking purpose. Ripe fruit pulp is yellow to orange in color, sweet, aromatic, and juicy and has an orange-colored peel. Ripe fruits have been used by indigenous people to prepare thirst-quenching drinks or are converted to jam, syrup, and stewed. Unripe fruits have a green- to white-colored pulp and are sour with green skin. These are used in preparing curries or salads, and some of the traditional snack food like 'rojak' (fruit and vegetable mixed salad) and 'asinan' (fermented pickles).

Nutritionally, ripe fruits are high in protein, fat, carbohydrate, fiber, vitamin C, and lutein contents. However, no reports are available on the medicinal value of this fruit.

Pomelo [Family; Rutaceae; *Citrus maxima* (Burm.) Merr. or *Citrus grandis* L.)

Pomelo is a citrus plant grown in tropical regions of Asia. The fruits are large (up to 25 cm, weighing 2–3 kgs) with the skin being green- to yellow-colored when ripe. The inner edible flesh is pink-, white-, or cream-colored and sweet to sour in taste. In some cases, bitter and acidic fruits are also encountered. Pomelo fruits are rich in dietary fiber, sugars, and organic acids. Volatile fractions and flavor profile of different cultivars have shown the presence of nearly 50 aroma compounds comprising esters, terpene alcohols, unsaturated aliphatic aldehydes, terpene aldehydes, and nootkatone (a sesquiterpene ketone, a characteristic grapefruit flavor component) identified to impart flavor. Methanol extracts of fruit tissues are reported to exhibit antioxidant and antimicrobial properties. Coumarins, furanocoumarins, sitosterols, limonoids, and other volatile and nonvolatile compounds and limonin and nomilin, *p*-coumaric acid, oils, and caffeic acids have been detected. Isolated compounds have revealed inhibitory antimicrobial effects against *Escherichia coli*, *Bacillus subtilis*, *B. cereus*, *Salmonella enteritidis*, and *Staphylococcus aureus*. Additionally, antioxidant potential of the fruit peel and pulp and its fermented products is also reported. In addition, antidiabetic activity of the fruit extracts is known.

Kasturi Lime (Family Rutaceae, *Citrus microcarpa*)

Fruits of kasturi lime are oval in shape (1–2 in. diameter) with a thin, green skin and orange-colored flesh. Fruits look like a miniature of a lime fruit and are sour-sweet and aromatic. Kasturi lime is cultivated in Malaysia, Thailand, the Philippines, and Indonesia. This plant is an evergreen tropical columnar shrub (2–7.5 m tall) bearing few hundreds of fruits on maturity. *Citrus microcarpa* is reported to be a natural hybrid of mandarin and oval kumquat (*Citrus reticulate* × *Citrus japonica*) plants.

Fruit juice is used as a flavoring agent in selected local dishes and drinks (herbal tea), in marinades and beverages, and in salad dressings. Traditionally, fruits are used to treat coughs and minimize skin irritations and as a laxative. Kasturi lime is rich in bioactive and antioxidant compounds. Narirutin, a flavonoid, is found in abundance. Volatile components in fruit peel are dominated by limonene, β-myrcene, α- and β-pinene, β-phellandrene, and sabinene. Fruits contain ample amounts of volatile oil with the rind portion containing several aldehydes, beta-pinene, sesquiterpenes, linalool, tannins, and glucosides. Recently, 60 different types of volatile compounds have been identified in this fruit. As well, the presence of high levels of citric acids is reported. Antioxidant and hepatoprotective activities of the fruit (peel and extract) are also reported.

Identical to kasturi lime, there is one more fruit – calamondins (*Citrus madurensis*), a native to China. These fruits are

acidic, juicy, and orange-colored and are considered to be miniature of the popular tangerines. Fruits juice is used to prepare refreshing beverage and as flavoring agent during preparation of soups. In traditional Chinese medicine, fruit juice of calamondin is used to treat cough and also makes an excellent hair conditioner. However, scientific work reported on this fruit is still scarce.

Star Fruit (Family Oxalidaceae, *Averrhoa carambola* L.)

Star fruit is a popular tropical fruit considered to be native to India, Malaysia, China, Indonesia, Taiwan, the Philippines, Australia, and Florida. Fruits are oblong and angled (dissected longitudinally into 5–6 ridges) and are between 5 and 15 cm long, weighing 50–100 g. Fruits have a thin, waxy skin that is either green or orange to yellow in color. The whole fruit is edible and juicy. When sliced in cross section, fruits have the form of a 'star' and hence the name. The fruits are harvested when they are either light green, dark green, or yellow in color. In fact, two distinct classes of star fruits are cultivated: Small type that is light green is very sour but with high oxalic acids, and big type is sweet, mild-flavored, and with less oxalic acid.

In Ayurvedic medicine, fruit juice is recommended to aid in digestion and reduce high body temperatures and as a natural eye drop to improve vision. According to 'Yunani' medicine, ripe fruits reduce thirst and inhibit diarrhea and vomiting during food poisoning. Traditionally, in India, ripe fruits are used to stop blood hemorrhages. In Vietnam, fruit juice is used as an eye salve and for the amelioration of high blood pressure. In some countries, intake of juice is considered useful to relieve from excessive intake of alcohol. In Brazil, fruit juice is recommended as a diuretic and as a treatment for eczema.

Star fruits are used in fruit salads, jam preparations, clarified juices, jellies, and preserves. Local population in Malaysia cook star fruits with seafood or meat. In addition, salads prepared by mixing and stewing star fruits with apples, sugar, and cloves are also popular. However, in most of the growing regions, fruits are eaten raw with common salt and chili.

Star fruits are a major source of vitamins A and C and contain ample amount of calcium, folate, calcium, potassium, and oxalic acids. Star fruits are low in sugar and have phenol compounds such as epicatechin and proanthocyanidins. High levels of oxalic acids in star fruits (0.08–0.73 g/100 g) are also reported. However, reports are also available on intoxication and fatality on consumption of fresh star fruit juice.

Pitaya (Family Cactaceae, *Hylocereus undatus* Haw.)

Pitaya or the dragon fruit is believed to be an origin of Mexico and Central and South America. Today, this fruit is widely cultivated and has gained popularity in Thailand, Malaysia, Indonesia, China, Vietnam, Taiwan, Bangladesh, and Australia. Typical to a cactus plant, pitaya is an evergreen annual plant with cladode (as stem). Fruits are categorized with the presence of unique bracts on the thin skin of bright red (pink to purple)-colored fruits. Flowers and fruits of the plant are edible. Depending on the cultivar, the edible pulp portion can be either red (pink) (*H. polyrhizus*), white (*H. undatus*), or yellow (*H. megalanthus*) with small tiny black edible seeds. Overall, average weight of a fruit is approximately 300–350 g, and a single plant is estimated to produce up to six cycles of fruits annually.

Pitaya fruit is preferred by consumers owing to their unique taste, shape, and flesh color. Though pitaya is preferred to be eaten directly, intake as fresh juice is more popular in the growing regions. Pitaya-based products like jams and candy are commercially available in Malaysia and Indonesia. Wine preparation from red pitaya is also reported in Guangxi province of China. Pitaya fruit (both skin and flesh portions) is reported to contain water-soluble betacyanins, which are responsible for the intense red (dark pink/purple) color and its antioxidant activities. In addition, lycopene, vitamin E, and beta-carotene are reported in the pulp portion.

Fruits are high in total polyphenols, tannins, betalains, nonbetalainic compounds, and antioxidant compounds. Oligosaccharides from pitaya fruit are linked with prebiotic properties. Pitaya peel contains high amount of pectin and insoluble to soluble fiber. In addition, powder prepared from the fruit has potential to be used as natural food colorant. Significant amount of betacyanin pigment is reported from peel. Inhibition in the growth of melanoma cells is also reported from peel extracts of red pitaya. Intake of pitaya fruit is also linked with the reduction of dyslipidemia and promotion of wound healing capacity in diabetic rats. Seeds encompass essential fatty acids dominated by linoleic and linolenic acids.

Snake Fruit (Family Palmaceae, *Salacca edulis* Reinw)

Snake fruits are common in Malaysia, Indonesia, Brunei, and Thailand. The tree looks like palm tree, bearing fruits in bunch, which are ovoid in shape having a stretched (pointed) end. The outer skin of the fruit is red- to brown-colored and is covered by smooth, flexible scales. Snake fruit pulp is edible, sweet, and sour giving a tingling sensation in the mouth. The pulp of the fruit occurs in three lobes, enclosing a inedible seed.

Snake fruit are rich in total, soluble and insoluble dietary fibers; minerals such as sodium, potassium, magnesium, calcium, iron, manganese, zinc, and copper; and bioactive compounds such as polyphenols, flavonoids, flavanols, anthocyanins, vitamin C, total carotenoids, and β-carotenoids. Besides, nearly 46 volatile compounds have been identified in the fruit, dominated by 25% of methyl 3-hydroxy-3-methylpentanoate and 23.4% of methyl (E)-3-methylpent-2-enoate.

Persimmon (Family Ebenaceae, *Diospyros kaki* L. or *Diospyros* sp.)

Persimmon has an origin in China and Japan but is widely cultivated and marketed in Korea, Malaysia, and Thailand. Fruits are seasonal, round or spherical in shape (2–10 cm), and are borne on a small tree in few hundreds. The fruit pulp is edible, fibrous, and soft and is sweet. Ripe fruits are orange- to yellow-colored or red- to orange-colored. As the fruits are seasonal, using this fruit in dried form is traditionally recommended. The ripe fruits are mainly preferred to be eaten directly or are

cooked (after removal of skin) to produce various ethnic, traditional foods. A wide array of products are prepared using the fruits, which include pudding, jams, jellies, cookies, fruit salads, and ice creams. Unripe fruits also have culinary use.

Nutritionally, fruits contain high fiber and minerals like potassium, sodium, calcium, magnesium, iron, and manganese found in adequate quantities. Japanese persimmon is reported to contain 18.59% carbohydrates, 12.53 g/100 g total sugars, 3.6% dietary fiber, 0.19 g/100 g fat, 0.58 g/100 g protein, 0.33 g/100 g ash, and 7.5 mg/100 g vitamin C (USDA, http://ndb.nal.usda.gov/ndb/foods/show/2412?qlookup=09263andformat=Fullandmax=25andman=andlfacet=andnew=1; assessed date; 22 February 2014).

The presence of high amounts of polyphenols and antioxidant compounds is reported from the fruit. The major polyphenols include catechin, epicatechin, epigallocatechin, condensed proanthocyanidins, and *p*-coumaric acid. Reports available have also indicated the potential of this fruit to exhibit hypolipidemic or the cholesterol-lowering activity in rat models.

Passion Fruit (Family Passifloraceae, *Passiflora edulis*)

Passion fruit plant is a climber (vine) originated in South America and North African countries. They are abundant in Argentina, Australia, Brazil, India, Indonesia, Vietnam, and others. Fruits are seasonal; unripe fruits are green, while ripe fruits are cream to yellow to dark purple, with a thin and soft and firm skin with the pulp being sweet, aromatic, and juicy, having tiny seeds covered with mucilage.

Ripe fruits are used to prepare juice or are consumed directly with addition of little sugar. However, passion fruit has wide market applications and is used as flavoring agent in preparation of cake, ice cream, jam, deserts, smoothies, etc. Nutritionally, the fruits are rich source of dietary fiber, vitamin C, and lycopene. The subfractions and flavonoid constituents of the fruit are known to exhibit anxiolytic (antianxiety) properties. Administration of fruit peel extract is reported to reduce blood pressure in female spontaneously hypertensive rats and in humans without any adverse affects. Oral intake of peel extract of purple passion fruit is reported to reduce pain and stiffness along with improving physical function in people suffering from knee osteoarthritis.

Passion fruit extract is used in South American folk medicine to treat asthma, bronchitis, anxiety, and insomnia. Fruit peel extract has significant amounts of antioxidant compounds such as edulilic acid, cyanidin-3-*O*-glucoside, and quercetin-3-*O*-glucoside. Peel extract of purple passion fruit is reported to be beneficial to reduce asthmatic symptoms.

Tarap (Family Moraceae; *Artocarpus odoratissimus* Blanco)

Tarap fruits (green pedalai or marang) are a native of Borneo (Sabah) region in Malaysia but widely distributed in Brunei, the Philippines, Myanmar, Thailand, and Hawaii. The tree is identical to bread fruit tree and grows between 25 and 30 m tall. Fruits occur singly, weigh approximately 1–1.5 kg, and are 15–16 cm in length and 12–13 cm in diameter. Just like jackfruit, this fruit too has short, green- to yellow-colored spines, which are soft and brittle. Ripe fruits have strong odor, and the inner part of the fruit (flesh/pulp) is edible that is very sweet to sour and juicy. The pulp is divided into several segments (bulbs) enclosing seed.

In some households, young fruits are also cooked as vegetables. Just like jackfruit, this fruit is consumed directly. However, seeds are also edible and can be eaten after roasting or boiling. Traditional preparation includes mixing the flesh (with seeds intact) with corn flour and egg batter followed by deep frying. The flesh is also used as a flavoring agent of ice creams and cakes and fermented to obtain vinegar.

Tarap fruit flour contains high amount of carbohydrates with average levels of protein, ash, crude fiber, fat, and essential minerals such as potassium, calcium, sodium, and iron. Fructose is dominant in the flesh. In addition, antioxidant activities, cytotoxicity, and polyphenol content of different fruit parts are also reported by various researchers (**Table 1**).

Influence of Modern Food Processing Methods

Owing to short shelf life and being seasonal, tropical fruits require to be consumed fresh to retain their original taste, aroma, and flavor. However, exporting to regions where they are not cultivated is a task. Hence, application of modern processing and preservation techniques assumes high importance. If not fresh, then at least these fruits need to be processed (e.g., canning, syrup base, and jam) into edible forms to be used for marketing, especially during off-seasons. In tropical countries, a huge number of popular and underexplored tropical fruits need to be preserved for dietary use as they possess several health beneficial properties. Emerging and well-established technologies such as active packaging and combination of atmospheric packaging with natural botanicals could be explored for shelf life improvement of tropical fruits. Nonthermal food processing technologies like application of ultraviolet radiation (UV), electron beams, pulsed electric field, high-pressure processing, use of ultrasound, ozone, and minimal processing can be considered for preservation of fresh tropical fruits and their products.

Future

More research needs to be focused toward generating suitable statistical database on the exact production rate, and convertibility factor of the excess fruits harvested into a shelf stable product. Providing more scientific evidence on the nutraceutical value to health conscious consumers on lesser known fruits is a necessity to enhance the marketability and to attain self-sufficiency in the growing regions. Identifying novel bioactive compounds with potential therapeutic value can be explored. The by-products or waste generated from the inedible portions can be explored to generate some economical use. Developing low-cost postharvest techniques for preserving and improving shelf life of fresh produce needs to be explored.

Table 1 Bioconstituents of some selected tropical fruits

Fruits	*Observation*	*References*
Fruit of wolf (*Solanum lycocarpum*)	With regard to nutritive value, the fruits contains carbohydrates (5.74%), proteins (1.6%), lipids (1.6%), and ash (0.63%) with the absence of any dietary fiber Fruits exhibit high antioxidant activities (162.97 EC 50 μg DPPH/mL) with total polyphenols content being 35.58 g gallic acid equivalents/kg	Roesler et al. (2010) Silva et al. (1994)
Sweet sop (*Annona squamosa*)	Sweetsop fruit contains 12.78% carbohydrates, 4.72% fiber, 1.22% proteins, 3.88% lipids, and 1.37% of ash with an ascorbic acid level ranging between 15 and 44.4 mg AA/100 g	Silva et al. (1994)
Soursop (*Annona muricata*)	Fruits contain high polyphenol content (72 trolox equivalent antioxidant capacity and 42 gallic acid equivalents mg/100 g, respectively). Among the various compounds, aliphatic acids, esters (51%), and terpenes such as mono- and sesquiterpenes (β-caryophyllene 12.7%, 1,8-cineole 9.9%, linalool 7.8%, α-terpineol 2.8%, linalyl propionate 2.2%, and calarene 2.2%) were isolated from the essential oil of fruits	Lako et al. (2007)
Gandaria (*Bouea macrophylla* Griffith)	Nutritionally, ripe fruits have high protein (40–112 mg/100 g), fat (20–120 mg/100 g), carbohydrates (11–140 mg/100 g), fiber (600–140 mg/100 g), vitamin C (20–100 mg/100 g), and lutein (457 mg/100 g) contents	Morton (1987) Tee et al. (1997)
Pomelo (*Citrus maxima* or *Citrus grandis*)	In Malaysian (pink and white type) pomelo, juice contained sugars (mg ml^{-1}): fructose (11.02 and 13.41), glucose (13.13 and 10.43), and sucrose (49.91 and 56.51) in pink and white juices, respectively Besides, organic acids (mg ml^{-1}) detected were ascorbic (0.22 and 0.39), citric (14.15 and 0.14), malic (0.75 and 1.94), and succinic (0.05 and 0.39) acids and were in appreciable amounts in pink and white juice, respectively Volatile fractions and flavor profile of different cultivars have shown the presence of nearly 50 aroma compounds comprising esters, terpene alcohols, unsaturated aliphatic aldehydes, terpene aldehydes, and nootkatone that were identified to impart flavor in pomelo Methanol extracts of fruit tissues exhibited antioxidant and antimicrobial properties. Coumarins, furanocoumarins, sitosterols, limonoids, and other volatile and nonvolatile compounds were detected. The extract concentration providing 50% inhibition was dominated by mixture of limonin and nomilin (135 μg ml^{-1}), *p*-coumaric acid (105 μg ml^{-1}), oil (95 μg ml^{-1}), and caffeic acids (45 μg ml^{-1}). Isolated compounds revealed inhibitory antimicrobial effects against *E. coli*, *Bacillus subtilis*, *B. cereus*, *Salmonella enteritidis*, and *Staphylococcus aureus* Antioxidant potential of the fruit peel and pulp and its fermented products is also reported. Essential oil from peel had high amounts of total phenolic (214 mM) and flavonoid (134 mg QE/g of d.w.) contents compared to fruit pulp Antidiabetic activity of *C. grandis* extract treated with *Aspergillus saitoi* is reported. Studies conducted indicated hydroxylated products from fruit extract (after enzymatic and microbial treatments) to be useful toward developing pharmaceutical foods focused toward controlling blood glucose level in diabetic patients	González-Mas et al. (2011) Cheong et al. (2011) Mokbel and Suganuma (2006) Jang et al. (2010) Kim et al. (2009)
Kasturi lime (*Citrus microcarpa*)	Narirutin, a flavonoid, is found in abundance in *C. microcarpa* (2.89–4.60 mg g^{-1} dry weight) Volatile components in fruit peel contain limonene, β-myrcene, α- and β-pinene, β-phellandrene, and sabinene. Volatile oil constitutes between 0.9% and 1.06% of the components, with the rind portion containing several aldehydes, beta-pinene, sesquiterpenes, linalool, tannins, and glucosides. Recently, 60 volatile compounds and high levels of citric acid (5.0–5.52%) are reported in the fruit. Antioxidant and hepatoprotective activities of fruits are also reported	Bhat et al. (2011a) Cheong et al. (2012) Kawaii et al. (1999)
Pitaya (*Hylocereus undatus* Haw.)	Total phenolics (9.2–13.3 mg/100 ml), betalains (76.1–88.1%), nonbetalainic compounds (11.9–23.9%), and antioxidant capacity (TEAC) (24.5–36.1 ascorbic acid equivalents in mg/100 ml) in different genotypes are reported Whole fruit is also reported to contain high polyphenols (86.10 mg GAE/0.5 g) and tannins (2.30 mg CE/g) with EC50 (for DPPH) value of 2.90 mM ascorbic acid equivalents/g (all on d.w.) Seeds encompass essential fatty acids dominated by linoleic acid (48%) and linolenic acid (1.5%)	Esquivel et al. (2007b) Rebecca et al. (2010)
Snake fruit (*Salacca edulis* Reinw)	Snake fruit contains 3.0, 1.2, and 1.8 g/100 g (f.w.) of total, soluble, and insoluble dietary fibers, respectively. The fruits are reported to contain minerals such as sodium (254.3), potassium (12.473), magnesium (668.0), calcium (242.8), iron (13.22), manganese (11.44), zinc (11.41), and copper (3.71) mg kg^{-1} (d.w.) Snake fruits also contain polyphenols (8.46 mg gallic acid equivalent/g), flavonoids (0.313 mg catechin equivalent/g), flavanols (3.14 μg catechin equivalent/g), anthocyanins (9.74 mg cyanidin-3-glucoside equivalent/g), vitamin C (13.28 mg ascorbic acid/g), total carotenoids (2.2 μg g^{-1}), and β-carotenoids (1.17 μg g^{-1}) By using GC–MS and 1H NMR, nearly 46 volatile compounds have been identified in the fruit,	Gorinstein et al. (2011) Wong and Tie (1993)

(*Continued*)

Table 1 (Continued)

Fruits	*Observation*	*References*
	dominated by 25% of methyl 3-hydroxy-3-methylpentanoate and 23.4% of methyl (E)-3-methylpent-2-enoate	
Tarap (*Artocarpus odoratissimus*)	Fruit flour contains 75.75% carbohydrate, protein (6.58%), ash (2.84%), crude fiber (2.65%), and fat (1.89%). In addition, the flour is rich in minerals such as potassium (1.820 mg/100 g), calcium (6.00 mg/100 g), sodium (4.68 mg/100 g), and iron (0.68 mg/100 g) Fructose sugars are dominant in the flesh (5.8–13.7 g/100 g)	Masri et al. (2012) Tang et al. (2013)

Fumigants

EM Thoms, Gainesville, FL, USA
JD Busacca, Indianapolis, IN, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Fumigants are critical components in pest management programs because of their unique ability to diffuse throughout a common airspace in a commodity, substrate, or structure to eliminate a wide range of pests. Fumigation is especially useful for the treatment of soil prior to planting, raw and fresh agricultural commodities, processed food, and structures, which process, store, and transport these commodities, which are difficult to thoroughly and reliably disinfest by other means.

What Are Fumigants?

Fumigants are pesticides, which are in a gaseous state upon contact with the target pest. They differ from all other forms of pesticides, which are liquids, such as aerosols, emulsifiable concentrates, and solutions, or solids, such as wettable powders, suspension concentrates, dusts, and granules, upon contact with the pest. The size of a fumigant gas molecule is more than 1000 times smaller than that of an aerosol droplet or a dust particle. In addition, fumigants have high vapor pressure, often 10 000-fold greater than that of naphthalene (moth balls). The minute size of gas molecules and their high vapor pressure result in fumigants penetrating throughout the treated commodity, substrate, and structure to kill pests in areas inaccessible to liquid and solid formulations of pesticides. Commonly used fumigants and their major use patterns are described in Table 1.

Advantages of Fumigation

In addition to the penetrating capabilities described earlier, fumigation has other advantages. Fumigants can have broad toxicity, controlling a wide range of invertebrate and vertebrate pests. The appropriate fumigant may control all the pests infesting a commodity, substrate, or structure with one treatment. Therefore, fumigation can provide reliable elimination of pests where there is no tolerance for infestation, such as in quarantine treatments. Fumigation can also be the most rapid treatment to control pests.

Table 1 Commonly used fumigants and their uses

Fumigant	*Soil fumigation*	*Quarantine and preshipment*	*Commodity fumigation*	*Structural fumigation*[a]
Methyl bromide	X[b]	X	X[b]	X[b]
1,3-Dichloropropene	X			
Chloropicrin	X			
Metam sodium/potassium	X			
Dazomet	X			
Dimethyl disulfide	X			
Phosphine		X	X	X
Sulfuryl fluoride		X	X	X

[a]Includes mills, food processing facilities, and warehouses.
[b]Most uses phased out due to Montreal Protocol restrictions.

Fumigant Dosage

Fumigants are considered nonresidual treatments in that they do not leave residues to prevent future pest infestations. The commodity, substrate, or structural space to be fumigated is sealed prior to fumigant introduction to sufficiently confine the fumigant. The fumigant is confined for the planned exposure period to achieve the lethal dosage required to control the target pests, prior to the fumigant being actively or passively aerated. Therefore, the dosage of a typical fumigant is the product of its concentration (C) and exposure time (t). A Ct dosage can be achieved by varying either C or t to produce a toxic effect on the target pest. The model $C^n t = k$, where n is the toxicity index and k the dosage rate to produce a specific mortality level for a given species, describes the relationship of fumigant dosage to mortality. For fumigants like methyl bromide and sulfuryl fluoride, 'n' generally approximates one for typical exposure periods, such as 2–72 h. This means that concentration and time contribute equally to achieving a lethal dosage. Fumigant exposure period can be shortened if the concentration of fumigant is increased, or conversely, fumigant concentration can be decreased if the fumigant exposure period is increased.

Phosphine toxicity deviates from this model and the relationship between dosage and resulting toxicity in insects is not linear. Generally, longer exposures of insects to low concentrations of phosphine tend to produce greater toxicity than shorter exposures to high concentrations. Phosphine requires extended exposures, at least 1 day for phosphine gas and at least 2 days for metallic phosphides, to produce toxicity in target organisms. Research has documented in insects that after a minimum exposure period has elapsed, mortality for a given species become constant for a Ct dosage.

The dosage for a fumigant is based on numerous factors, including target species and life stage, temperature at the site of the target pest, fumigant formulation, atmospheric pressure, insect diapause, and selected insect resistance to fumigants. The initial concentration of fumigant to obtain this dosage is dependent upon the exposure period and the confinement of the fumigant during that exposure period. The confinement of the fumigant can be determined by measuring the fumigant concentrations in the fumigated space at two or more time intervals. These measurements determine if fumigant confinement is sufficient or if more fumigant needs to be added to achieve the required dosage. Tables listing required fumigant concentrations at sequential time intervals, based on target pest and temperature, are used for quarantine treatments when

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00339-1

target pest eradication is essential. Calculation devices, such as handheld calculators or computer programs, are available with sulfuryl fluoride to calculate dosages, dosage accumulation, and amount of fumigant to apply.

Fumigant concentration measurements represent the target pest exposure to the fumigant, since fumigants disperse throughout the confined space. This is a unique attribute of fumigants, compared to other pesticides, that exposure of the target pests to the fumigant can be reliably measured to confirm that the required dosage has been achieved for control.

Mode of Action of Fumigants

The general toxicity of fumigants to a wide range of organisms indicates adverse effects on fundamental life processes at the cellular level. Methyl bromide is an active alkylating agent. The methylation and incapacitation of enzymes, involved in regulating cellular metabolism, and other bioorganic molecules may explain the broad toxicity of methyl bromide. Sulfuryl fluoride is metabolized into fluoride in animals. Low concentrations of fluoride are readily excreted; high concentrations of fluoride can be toxic. Excessive fluoride can interfere with various metabolic processes, such as inhibiting enzymes utilizing magnesium in the glycolysis cycle. Phosphine can act as a reducing agent that can interact with transition metals and therefore has the potential to disrupt the enzymatic activity of cellular proteins. Phosphine is known to disrupt mitochondrial energy metabolism leading to a decrease in ATP synthesis.

Safety in Use of Fumigants

Because fumigants are toxic to a wide range of organisms, including humans, stringent safety procedures are required for their use. Inhalation is the primary route of potential overexposure to fumigants. When handling fumigants, workers are required to wear respiratory protection when exposure to fumigant concentrations may occur that are unknown or are above permissible exposure limits. Additional personal protective equipment required to protect the applicator's eyes and/or skin during fumigant application is dependent upon the fumigant and its formulation. Equipment, capable detecting low fumigant concentrations, is used to monitor potential worker exposure and verify aeration of commodities or a structure following fumigation. Fumigated spaces are posted with warning signs during the fumigation. Regulatory authorities may require an exclusion zone be established around the fumigation site where unauthorized personnel are not permitted to enter. The size of the exclusion zone may vary based on the fumigant, concentration applied, application method, and confinement of the fumigant. Due to their toxicity, fumigants receive ongoing, intense regulatory review and oversight. The safety procedures and equipment used with fumigants have been extensively tested to validate that they provide the required protection for workers and the public.

Limitations on Development of New Fumigants

There are very few molecules that can fulfill the exacting requirements to be used as a fumigant. These requirements include being toxic to target pests under all typical temperature and exposure conditions, easily dispersed and aerated, rapidly penetrative into infested materials, essentially nonreactive to treated materials, leaving nontoxic or no residue, nonexplosive, nonflammable, and noncarcinogenic, mutagenic, or teratogenic for humans and having no adverse environmental effects. Many of the fumigants used in the first half of the twentieth century, such as acrylonitrile, hydrogen cyanide, and ethylene dibromide, subsequently lost their registrations in many countries due to their residues or extreme danger to people.

Methyl bromide was once the most widely used fumigant. Compared to other currently used fumigants, methyl bromide is toxic to the broadest spectrum of pest species and their life stages, typically delivering the desired control in 2–24 h. Methyl bromide does not corrode metal and is considered safe for food products due to minimal chemical reaction or residues. Methyl bromide has been commonly used in soil fumigations against pests such as nematodes, fungi, soil insects, and seeds of weed plants that affect the establishment and production of many crops. Methyl bromide's rapid, broad-spectrum efficacy is why it is used globally for quarantine and preshipment treatment of perishable commodities, including fruits, vegetables, and cut flowers, and durable commodities, including grain, legumes, and timber. Methyl bromide was also used to fumigate mills, food processing facilities, and structures that store and transport commodities.

Unfortunately, methyl bromide was identified as a chemical substance that contributes to the degradation of the stratospheric ozone layer in the Earth's atmosphere. In 1992, the fourth meeting of the 'Parties to the Montreal Protocol on Substances that Deplete the Ozone Layer' placed methyl bromide on the list of ozone-depleting substances that require regulation and an eventual worldwide ban on production, use, and emission, beginning in 2005 in developed countries and in 2015 in developing countries. The Montreal Protocol exempted quarantine and preshipment applications of methyl bromide due to the impact on international trade. Since 2005, critical use exemptions have been granted in developed countries where suitable alternative treatments did not exist; however, the amount of methyl bromide and number of exemptions granted have steadily decreased. The search for alternatives for methyl bromide has been a lesson that a myriad of other treatments are required to replace the versatility, reliable efficacy, ease of use, and economy offered by this fumigant. The characteristics of fumigants that make them effective (i.e., highly volatile, broad spectrum, high use rates, and toxicity) are basically the opposite of the characteristics most global regulatory agencies are looking for in new pesticides. These characteristics, plus the time and expense of developing a new pesticide, make it unlikely that a new fumigant with broad-spectrum efficacy similar to methyl bromide will be developed and registered with currently known technology.

Soil Fumigation

Preplant fumigation of soil has been a critical management tool for the production of many high-value crops. These crops include vegetables, fruit, potatoes, tobacco, and nursery stock that are grown in high production areas of the United States,

Spain, Italy, France, Australia, and Japan for domestic use as well as for export. In many cases, these crops could not be produced economically without managing multiple soil-borne pests such as nematodes, pathogens, and weeds that can devastate crop production if left unchecked. For example, nematode and disease populations can be so destructive that strawberries cannot be grown economically without fumigants in some areas of the United Sates (e.g., Florida and California) and Spain. The advantage of fumigants over traditional nonfumigant pesticides is that they provide extremely high levels of control throughout the critical root zone area of the developing crop. This fosters better root development during the early stages of crop growth and often results in higher yield production.

Prior to the Montreal Protocol, methyl bromide was the most effective and widely used soil fumigant for high-value crops. It was highly effective against a broad spectrum of soil pests including nematodes, insects, soil fungi, and seeds of weed species and enabled farmers to plant or transplant crops after a relatively short postfumigation interval. During the phase-out period of the Montreal Protocol, extensive research was conducted by many government and nongovernment organizations to find suitable alternatives. Initially, alternatives were available that provided solutions to control certain types of soil pests, but there was no single fumigant that had the efficacy, broad-spectrum control, or convenient use properties that methyl bromide provided. Solutions required combinations of fumigants that effectively controlled a broader spectrum of pests when used together. For example, 1, 3-dichloropropene and chloropicrin provided excellent nematode and disease control, respectively, when used individually. However, as methyl bromide was phased out, they were often used together to control a wide spectrum of nematode and pathogen pests. Metam sodium/potassium and Dazomet degrade in soil to form pesticidally active methyl isothiocyanate (MITC). The efficacy of MITC can be further enhanced by combination with other soil fumigants, such as applying metam sodium with 1,3-dichloropropene and/or chloropicrin. In the near term, viable solutions to methyl bromide will include combination products.

There were many novel alternatives tested during the phase-out period of methyl bromide. Some of these alternatives included steam heating, solarization, plant extracts, biologicals, crop rotation, and resistant cultivars. These alternatives had various levels of success, but none proved to be as effective and reliable against a broad spectrum of soil pests as methyl bromide.

One of the more productive areas of research during this phase-out period was in application technology. Application of soil fumigations often utilized plastic tarps. This reduced the emissions of fumigants and also made them more effective. New plastic films were developed that significantly reduced emissions and improved the performance of the fumigation. In addition, preplant applications of fumigants through drip irrigation systems were refined, which further reduced emissions and improved efficacy of fumigants.

Fumigation for Quarantine and Preshipment

One of the most important uses of fumigants is for disinfestation of commodities for quarantine and preshipment. Fumigants can offer rapid, reliable, measurable, and effective control of a broad range of target pests without adverse effects on the fumigated commodities. Disinfestation of exported commodities is essential to thwart the introduction of nonindigenous pest species into importing countries. The cost of damage and control associated with nonindigenous species introduced in the United States alone was estimated to be $137 billion per year in 2000.

Most countries have legislation restricting the importation of infested commodities. The International Plant Protection Convention (IPPC) is part of the Food and Agriculture Organization (FAO) and helps to communicate and standardize phytosanitary certification by different countries. More than 200 parties and their territories participate in the IPPC. They are required to establish, update, and make available lists of regulated pests. Fumigants have been an essential tool in preventing further dissemination of key regulated quarantine pests.

The Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann), is one of the world's most destructive fruit pests. Its larvae can feed on over 300 plant species, including deciduous, subtropical, and tropical fruits and some vegetables. Larval feeding in fruit creates an inedible mass. Many countries, such as the mainland United States and Japan, forbid the import of susceptible fruit without strict postharvest treatment having been applied by the exporter. Historically, susceptible fruits have been fumigated with methyl bromide. The probit-9 standard for quarantine efficacy (99.99683%) was developed using methyl bromide for treating tropical fruits with heavy infestations of fruit flies. Some countries have prohibited any use of methyl bromide, even though the quarantine and preshipment uses are exempted from the Montreal Protocol. Alternative treatments have been implemented. These include heat treatment (vapor heat, hot water, or forced hot air), cold treatments, insecticidal dipping, or irradiation. Heat treatment tends to reduce the shelf life of many fruits. Cold treatment can require up to 22 days depending upon the temperature and commodity. Irradiation is not accepted in many countries. Therefore, without the use of methyl bromide, imports may be restricted from areas where the fly occurs, potentially reducing trade opportunities for these countries.

There are relatively few stored-product insects which are quarantine pests, due to centuries of colonization and trade in which these pests were globally disseminated from food stores on ships. One exception is the khapra beetle, *Trogoderma granarium* Everts, which is a global quarantine pest that infests more than 96 commodities. Larvae of the khapra beetle can readily penetrate food packaging to contaminate and render food unfit for human consumption. The larvae can survive a wide range of environmental conditions and long periods without food, during which they enter diapause or retrogressively molt to survive. The establishment of the khapra beetle can create accessibility problems for commodities. Due to a high number of interceptions of khapra beetles early in 2011, the United States restricted rice imports to permitted commercial shipments in order to reduce potential number of introductions. Methyl bromide has been the fumigant of choice for treating infested commodities and subsequently infested warehouses, storage facilities, and even residences to eradicate incipient infestations of khapra beetle in the United States, Mexico, Australia, and other countries. Phosphine and sulfuryl

fluoride are being evaluated as replacement fumigants for control of khapra beetle.

An advantage of fumigation for treatment of infested commodities is that the equipment used for fumigant confinement, introduction, monitoring, aeration, and clearance testing is mobile and readily implemented in a suitable, secure location. Fumigation does not require extensive infrastructure setup, such as for irradiation facilities. This is demonstrated by the situation with the brown marmorated stink bug (BMSB), *Halyomorpha halys* (Stal), a pest in Asia, which was introduced into the United States in the mid-1990s. The BMSB has more than 300 host plants including tree fruit, small fruit, grapes, vegetables, legumes, and ornamentals. Loss of value of commodities damaged by BMSB can be 80–90%. In 2010, this insect caused $37 million in damage to apple farmers throughout the Mid-Atlantic region of the United States. The BMSB is also is a structural nuisance, seeking harborage in buildings, vehicles, and other structures to overwinter as adults. Since December 2014, BMSB adults have been intercepted in shipments of vehicles, machinery, and equipment from the eastern United States to Australia, New Zealand, and the European Union. Treatment by heat or fogging agents was found unsatisfactory to eliminate BMSB in these items. A fumigation schedule using sulfuryl fluoride was implemented and found to be effective in eradicating the infestations. Prior to fumigation, items were sealed by a variety of configurations at port or at nearby locations to meet export schedules: tarping and/or tape-and-sealing the items to confine the fumigant, fumigating the items in sealed structures such as warehouses or shipping containers, or a combination of these methods.

It is important that any treatment applied to vehicles, machinery, and equipment has no adverse effects on these items. When applied according to label directions, sulfuryl fluoride will not affect electronics, including electronic control units, switches, relays, sensors, and touch screens, found in vehicles, machinery, and equipment. Sulfuryl fluoride is used to fumigate research laboratories, medical and manufacturing facilities, and mills and food processing facilities, which contain extensive state-of-the art electronics, and sensing and analytic equipment. Laboratory tests have documented no adverse effects on electronic equipment, including computers, when fumigated repeatedly with sulfuryl fluoride at dosages far exceeding the maximum allowed by labeling, at high temperatures (50 °C), and with equipment left operating during the fumigation. Qualitative assessments conducted by automotive engineers evaluating sulfuryl fluoride for fumigation of luxury automobiles for BMSB control determined that fumigation did not impart any odors or affect the appearance or texture of vehicle surfaces, including leather upholstery. Fumigation of vehicles, machinery, and equipment with methyl bromide for control of BMSB is an option but is not preferred due to the potential reactivity of methyl bromide with some materials containing sulfur, such as types of foam rubber, vinyl, and leather, to create persistent odors.

The rapid speed of treatment of commodities by fumigation to meet preshipment requirements is exemplified by the California walnut industry in the United States. The demand for in-shell walnuts is highest in European markets before St. Nicholas Holiday, December 6. Steamship delivery from California to Europe normally takes 30 days. Therefore, vessels shipping walnuts must set sail from California no later than November 6. The preferred variety for European in-shell walnut market is not ready for harvest until mid-October. This provides just a 3-week window for harvesting, processing, and shipping the walnuts. Walnut processors use vacuum fumigation chambers to expedite the disinfestation process of the Navel orangeworm, *Amyelois transitella*, and other field pests that could tunnel into walnuts to consume the nut meat. Sulfuryl fluoride is now used for this fumigation process and provides similar exposure time (4 h or less) and efficacy as methyl bromide. Other treatments do not penetrate the shell to control the target pests or may affect the flavor of the nut meat. Rapid heat treatment to control the in-shell pests causes rancidity in the fatty acids. The walnut industry is very important to the California economy, representing the fourth largest export from California in 2010, generating farm gate revenue of over $1 billion in 2011, involving 4000 growers and 82 processors, and employing 60 000 individuals directly and indirectly. Fumigation enables this industry to meet tight shipping schedules to offer a high-quality product in a competitive global market.

Commodity Fumigation

Fumigation can be the most effective method for disinfesting commodities when placed into storage after harvesting, which have been in storage for long periods of time, and prior to shipment for processing or export. Fumigation should be considered one tool in managing pest infestations in stored commodities. Other methods to control pest infestations include sanitation and application of approved insecticide surface treatments to storage containers prior to refilling, proper drying of commodities prior to storage, maintaining the required temperature and moisture content of commodities by aeration or other methods to prevent mold and insect growth, monitoring of pest presence through inspection and trapping, and then determining the best control strategy when pest activity reaches actionable thresholds.

Phosphine, or hydrogen phosphide, is one of the most commonly used fumigants globally for disinfestation of cereal grains, legumes, seeds, dried fruit and tree nuts, other durable food commodities, and many processed foods. Phosphine has the unusual property that it can be generated from solid formulations of metallic salts of aluminum phosphide and magnesium phosphide. These metallic phosphides react with water vapor in the treatment environment to generate phosphine. Metallic phosphides can be applied as pellets or tablets, which can be mixed with the commodity as it is loaded for storage, probed into or placed on the commodity, or placed on trays or paper adjacent to the commodity. Metallic phosphides can be applied in a diversity of sites to treat commodities in all types of storages, railcars, shipping containers, stationary truck cargo containers, and other vehicles, and in ship holds to treat grain during transit. Metallic phosphides are the fumigant of choice for treating commodities stored on farms. These solid formulations are simpler to apply compared to fumigants packaged as liquids under pressure in cylinders (methyl bromide, sulfuryl fluoride, or phosphine gas). The solid formulations, phosphine detection equipment, and respiratory protection

(cartridge mask for low phosphine concentrations) are inexpensive compared to the cost of other fumigants and cylinderized phosphine, the respiratory protection (self-contained breathing apparatus) required for methyl bromide and sulfuryl fluoride, and the detection equipment required for sulfuryl fluoride.

Metallic phosphides leave a solid residue of either aluminum or magnesium hydroxide and other inert ingredients. In bulk grains, this residue is inconsequential due to dilution during subsequent grain moving, handing, and processing. Metallic phosphides are available in a variety of formulations, such as permeable bags or blister packs, which allow for faster application of a premeasured dose and retrieval of spent material. These prepackaged, retrievable formulations can be applied to processed or ready-to-eat commodities where solid residues are not permitted and for countries that do not permit solid residues in raw commodities.

Phosphine can also be applied directly to a commodity as a gas from metal gas cylinders or phosphine generators. Dosage accumulation occurs more quickly because there is no delay in availability of phosphine as in the metallic phosphides. Phosphine gas can be applied at lower temperatures (0 °C) and to fresh commodities, such as certain fruit and vegetables. Current research is evaluating reducing the fumigant exposure time required for phosphine by combination with other gases, such as oxygen.

Globally, widespread and repeated fumigation of poorly sealed commodities has resulted in sublethal exposure and selection of resistance to phosphine. Phosphine resistance has been detected in key stored-product insects in more than 45 countries. For more than three decades, a monitoring and management program for phosphine resistance, funded and executed by a coalition of industry and government agencies, has been conducted in Australia. This program has demonstrated that phosphine resistance can be effectively managed by various methods, including intensive sanitation, use of grain protectants, better sealing and monitoring of fumigations, and increasing the phosphine dosage. Sulfuryl fluoride is used to treat commodities infested by insects known or suspected to have high levels of resistance to phosphine. Sulfuryl fluoride and phosphine have different modes of action, and phosphine-resistant insects are not cross-resistant to sulfuryl fluoride. The previously mentioned practices minimize insect infestation and damage to stored commodities, resulting in high-quality product available for use nationally and for international trade.

Sulfuryl fluoride was developed in the 1950s as an alternative to methyl bromide for control of drywood termites and other structure-infesting insects. Due to the phaseout of methyl bromide part of the Montreal Protocol, sulfuryl fluoride was further developed beginning in the late 1990s as a fumigant for durable commodities, including cereal grains, dried legumes, seeds, dried fruit and tree nuts, spices, and cocoa. Extensive research was required to indentify dosages for control of stored products pests, assess trace residues in fumigated commodities and develop residue tolerance thresholds, and verify that fumigation did not affect the taste of high-value commodities (dried fruit, tree nuts, and cocoa) or wheat kernel quality, milling quality, or properties of dough and baked goods (cookies, bread, and spaghetti). Sulfuryl fluoride received its first registration for commodity fumigation in 2004. Sulfuryl fluoride can be applied to similar sites as phosphine, except it is not permitted to treat railcars or ships that are in transit.

Other fumigants, such as ammonia, ozone, methyl iodide, carbonyl sulfide, propylene oxide (PPO), and ethyl formate, have been investigated as commodity fumigants as part of the phaseout of methyl bromide. These fumigants are effective in certain situations and have limitations. For example, PPO is used as a microbial sterilant for spices, cocoa powder, and processed nut meats. Due to its flammability, PPO is applied in special chamber or diluted with a propellant like carbon dioxide. PPO is generally effective in controlling the egg stage of insects, which can require higher dosages for control by other fumigants, such as sulfuryl fluoride. Ethyl formate occurs naturally in some foods and is designated as generally recognized as safe. Ethyl formate is also flammable and like PPO can be formulated with carbon dioxide to reduce flammability. This fumigant has poor penetration capabilities to control target insects feeding inside grain and other commodities. It also decomposes in water in commodities at a rate that is temperature-dependent.

Modified atmospheres are another method for control of commodity pests. Airtight or hermetic storage is used to create an environment in which insects die due to a decrease in oxygen through methods that are passive (insect respiration) or active (such as the use of a vacuum treatment or addition of carbon dioxide or nitrogen). The advantages of these treatments are that they do not create residues in commodities and do not have adverse environmental effects. The challenges are the cost of hermetic storage, maintaining the airtight capacity of the storage, and the time for treatment requiring one or more weeks.

Structural Fumigation

Fumigation should be considered one tool in managing pest infestations in mills, food processing facilities, and warehouses. Nonpesticidal methods to prevent infestations are extensive and include exterior and interior sanitation to remove food debris and pest harborage, a vegetation-free zone around the building exterior perimeters, and pest exclusion by sealing cracks and crevices, screening vents, and using air curtains to blow flying insects away from open entrances and loading docks. Monitoring of pest presence through inspection and traps (using lights, pheromones, or food lures) can determine when and where pest activity reaches actionable thresholds. The activity often can be controlled by additional sanitation or use of localized insecticide treatment.

Nonetheless, mills, food processing facilities, and warehouses are complex environments with many refugia for pests. Fumigation can provide whole structure control to treat areas not accessible for inspection, cleaning, or treatment with other insecticides. Sulfuryl fluoride was developed for this use pattern as a replacement for methyl bromide. As previously discussed, sulfuryl fluoride gas does not adversely affect electronics. Laboratory testing has confirmed that sulfuryl fluoride leaves no detectable residues on inert surfaces, such as metal, glass, and ceramic. Compared to methyl bromide, higher dosages of sulfuryl fluoride are required to control the egg stage of insects. Extensive field trials were conducted to validate the

efficacy of sulfuryl fluoride in these structures for control of target pests, and the sealing, fumigant introduction, and aeration methods provide required protection for workers and the public.

Phosphine is also registered for fumigation of mills, food processing facilities, and warehouses; however, metals including certain copper, brass, other copper alloy, gold, and silver are susceptible to corrosion by phosphine, especially at higher temperatures or relative humidity. In mills and food processing facilities with sophisticated electronics including sensors and computer monitoring systems, phosphine tends to be used as a spot treatment for selected equipment rather than as a whole structure treatment.

Other area-wide treatments commonly used in mills, food processing facilities, and warehouses for insect control include fogging (aerosols), mating disruption pheromones, and heat treatment. Fogging agents are liquids that are atomized and dispersed as fine particles, which look like a cloud. Fogging can offer inexpensive suppression of key stored-product insect pests. These treatments are rapid, requiring as little as 30 min to apply. Common active ingredients in fogging agents include dichlorvos and pyrethrins or pyrethroids that are used alone or in combination with insect growth regulators. Unlike fumigants, aerosol droplet size prevents distribution into obstructed harborages such as equipment or penetration into bulk commodities. The efficacy of this treatment varies by insect species, life stage, and insecticide active ingredient. Some fogging treatments are not permitted to contact food. Sanitation is a very important component of fogging, because food present during or after treatment can increase the survival of flour beetles (*Tribolium* spp.), a common stored-product pest.

Mating disruption pheromones can effectively suppress pest populations of selected species by interfering with their mating and thereby disrupting their life cycle. The pheromone must be dispensed for weeks before and during peak adult fight activity of the target pests. The penetration into commodities of these pheromones is unknown, and they do not kill active infestations of insects. Both mating disruption pheromones and fogging do not require the preparation and shutdown of facility operations as required with whole structure treatment by fumigation or heat.

Heat has been used for many decades for insect control. Heat has the benefit of no pesticide residues, no adverse environmental effects, and control of a wide range of insect pests if lethal temperatures can be obtained. Heat can require significant capital investment in heating equipment and facility modifications to withstand high temperatures for the required exposure period. High heat can cause raw and finished commodities to dry out, become rancid, degrade, and have affected handling characteristics. When possible, these commodities need to be removed or protected from exposure to high heat. High heat also can damage structural components, belts, electronics, lubricants, wood, plastics, lights, fire suppression systems, batteries, magnets, packaging, pressurized cans, and other heat-sensitive materials. When possible, these items need to be protected from high heat, removed prior to heating, replaced more often due to heat damage, or replaced with heat-resistant components. Heat does not distribute like fumigants and can stratify and sorb into concrete and other heat sinks. Temperatures need to be monitored throughout the heated space, and heat ducts and fans moved as needed to try to obtain homogenous heating. Heat also does not penetrate deeply into food residues, so sanitation prior to heating is important.

Importance of Pest Control for Food Safety

Postharvest pests such as cockroaches, mites, stored-product beetles, and moths can contaminate food with their body parts, cast skins, and feces. These contaminants contain allergenic materials that upon consumption cause IgE-mediated reactions ranging from dermal or respiratory reactions such as dermatitis and asthma to life-threatening anaphylaxis on sensitized individuals. These allergens are considered 'reasonably likely hazards' based on clinical reports proving allergenicity, evidence of ingestive effects, and recognition by medical authorities as an allergy hazard. Food products contaminated with these allergens may be subjected to a heating step in the manufacturing process; however, some of this allergenic material is heat-stable and can remain a threat to the consumer. All the earlier mentioned pests can be controlled by fumigation.

Cockroaches, including the American cockroach, *Periplaneta americana* (L.), and the German cockroach, *Blattella germanica* (L.), which can occur in food processing facilities and warehouses, have been shown to be capable of spreading foodborne pathogens. These pathogens include *Escherichia coli*, *Salmonella* spp., *Shigella* spp., and *Staphylococcus* spp. Cockroaches can harbor pathogens in their bodies, especially in the lower digestive tract, for 14–16 days, and continue to excrete pathogens in their feces during that time. Postmortem survival of *Salmonella* in cockroach carcasses may last 60 days.

Conclusions

Fumigants are critical components in pest management programs because of their unique ability to diffuse throughout a common airspace in a commodity, substrate, or structure to eliminate a wide range of pests. The appropriate fumigant achieves this with no adverse effects to the treated commodity or structure. No other treatments provide such a broad spectrum of reliable control. Fumigants enable global trade of high-quality, pest-free commodities and are used to prevent food contamination by controlling pests that can transfer allergens and pathogens. Due to the toxicity of fumigants, fumigants will continue to receive intense regulatory scrutiny. Manufacturers and food industries will continue to work with regulators to validate that equipment and methods used for fumigant application meet required safety standards for workers, the public, and nontarget organisms.

Functional Foods

Introduction

During the last decades, the demand for health-improving foods and beverages has increased in parallel with the rising costs of health care, the increase in life expectancy, and the desire for higher life quality. In this context, functional foods offer a new kind of health message, promising specific effects by means of particular food components. A large number of definitions exist worldwide for 'functional foods,' referring to (processed) foods containing ingredients that beneficially influence specific body functions, in addition to being nutritious. However, we are dealing with a concept rather than a well-defined group of food products and a universally accepted definition is lacking.

Functional Foods: Origins and Definitions

The first written evidence of the existence of functional foods traces back to 1000 BC in China. Asia has a long tradition of attributing curative or therapeutic properties to foods and herbs, but such beliefs have been considered anecdotal and based on popular traditions. The term 'medical food' was frequently used in the literature of the Eastern Han Dynasty, about 100 BC. Another similar term, 'special foods,' was used in medical works of the Song Dynasty in AD 1000. With respect to the Western traditions, Hippocrates, the Greek physician who lived in VIth–Vth centuries BC, left a well-known phrase in his legacy: "Let food be your medicine and medicine your food." Even nowadays, this philosophy of food as a medicine is the basis of the paradigm of functional foods (see Figure 1).

Specific cases of functional foods were introduced in Japan in the 1980s. Three research programs were then funded by the Japanese government, consisting of the analysis and development of food functions, the analysis of physiological regulations of the food function, and the analysis of functional foods and molecular design. Those were national efforts to decrease the growing costs of health care. Consequently, Food for Specified Health Use (FOSHU) was established in 1991, as those foods were expected to have specific effects on health by addition of relevant constituents or removal of allergens. These effects were scientifically evaluated, and permission was granted to make claims regarding specific beneficial effects on health after their consumption, but only in the form of ordinary foods.

In the United States, the history of functional foods began in 1989 when 'designed foods' were formulated as foods that contained natural or enriched chemicals and biologically active nonnutrients from plants (phytochemicals) that were effective in reducing the risk of cancer. In 1989, the terminology of 'nutraceuticals' appeared, which were defined as substances that can be considered as food or part of a food and that provide medical or health benefits, including the prevention or treatment of a disease. Next, in 1991, 'functional foods' were defined as foods containing substances (natural or otherwise) for which there is evidence that, upon ingestion, a positive effect on health is provided. Since then, several exotic terms were launched, such as genetically designed food, pharmafoods, phytofoods, phytonutrients, phytogenic substances, performance foods, smart foods, therapeutic foods, foods with added value, genomic foods, phytochemical sources, superior foods, hypernutritive foods, and real foods.

In the European Union, the Concerted Action on Functional Food Science in Europe (FUFOSE) was coordinated by the International Life Science Institute through several meetings: France 1996, Helsinki 1997, and Madrid 1998. Finally, a consensus was reached in 1999, involving three major steps: (1) a critical assessment of the science base required to provide evidence that specific nutrients and food components positively affect target functions (biological responses) in the body, (2) an examination of the available science from a function-driven rather than a product-driven perspective, and (3) an elaboration of a consensus on targeted modifications of food and food constituents and on options for their applications.

According to the FUFOSE consensus document, a food can be regarded as 'functional' if it is satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects, in a way that is relevant to either an improved state of health and well-being or a reduction of risk of disease. Functional foods must remain foods and they must demonstrate their effects in amounts that can normally be expected to be consumed in the diet. Hence, they are not pills or capsules, but part of a normal food pattern. The beneficial effects could be either maintenance or promotion of a state of well-being or health or a reduction of the risk of a pathologic process or a disease.

A functional food can be a natural food or it can contain one or more specific components, which have functional influence on the health and well-being of the consumer. Such components can be added to food (e.g., omega-3 fatty acids), removed from food (e.g., fat from milk), naturally enhanced through special conditions (e.g., selenium-enriched garlic), or modified to provide health benefits (e.g., phytosterol-added probiotics). Importantly, functional foods do not necessarily induce a health benefit in all members of the population.

Overall, functional foods are often confused with the following related concepts:

(1) *Nutraceuticals*: products made from a food but sold as pill, powder, or other dosage forms not usually associated with food and shown to have beneficial or protective physiological properties against chronic diseases.
(2) *Pharmafoods*: a universally accepted term to designate products on the food–medicine borderline, which first emerged in Japan; they are also called 'border foods' as they claim drug-like preventive and therapeutic qualities.

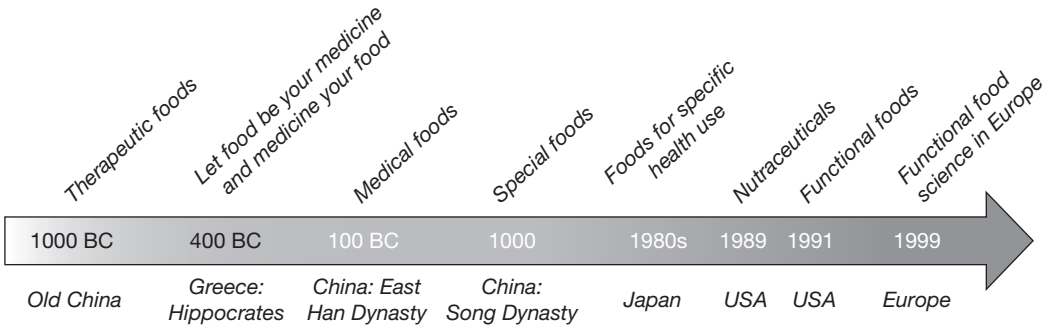

Figure 1 A historical picture of functional foods.

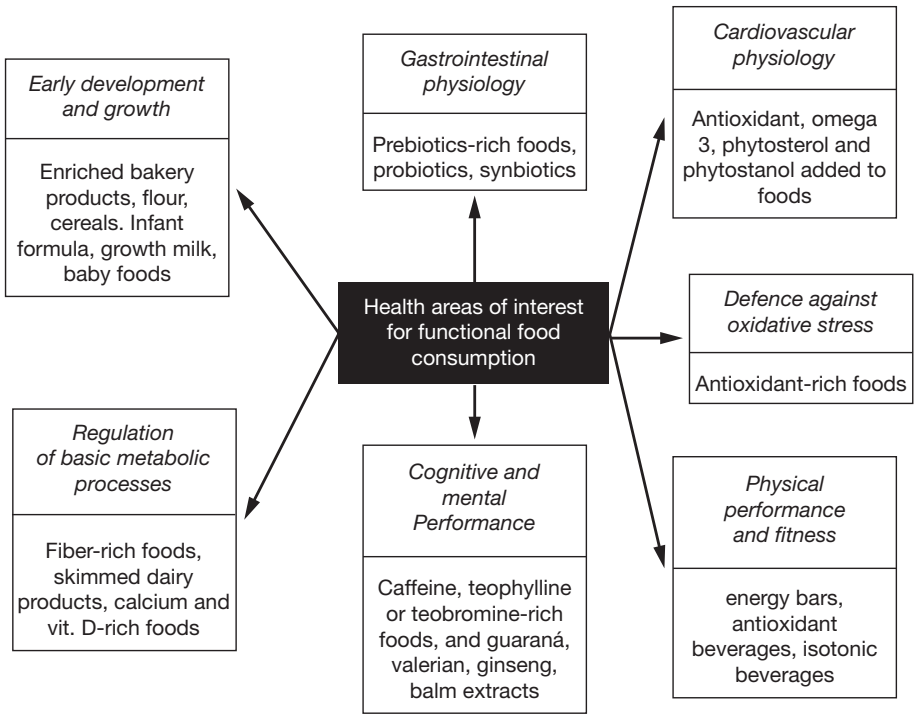

Figure 2 Health areas of interest for functional food consumption.

There are very few scientific publications on pharmafoods and even less about the possible interactions with drugs consumed by certain population sectors, such as children, pregnant women, and elderly people.

Potential Health Areas of Interest for Functional Food Consumption

Areas of human physiology that are relevant to functional foods are the following: early development and growth, regulation of basic metabolic processes, defense against oxidative stress, cardiovascular physiology, gastrointestinal physiology, cognitive and mental performance, and physical performance and fitness (Figure 2).

Early Development and Growth

Nutrition during early development has short-term effects on growth, body composition, and functions, as well as long-term effects. The course of pregnancy and childbirth and the composition of breast milk are influenced by the food intake. Pregnancy and the first postnatal months are a critical period for the development of the nervous system and sensory and cognitive abilities, as well as for the development of immune responses, bone mass, and intestinal growth and maturation. Therefore, several functional foods have been designed to provide an appropriate intake of nutrients to both mother and child, such as the addition of folic acid to bakery products, flour, and cereals to reduce neural tube defects in newborn infants. In addition, infant formula, growth milk, or baby foods are functional foods enclosed in this area.

Regulation of Basic Metabolic Processes

The control of glycemia and of food glycemic indexes and the control of the contents of starch, fiber, and fat are aspects of interest to prevent nontransmittable chronic illnesses as obesity, diabetes, dyslipidemia, and metabolic syndrome. Fiber-enriched foods or skimmed dairy products are functional foods enclosed in this area, but so is the fortification of foods with calcium and vitamin D as a strategy to improve bone mineral density.

Defense Against Oxidative Stress

Although oxygen is essential for human life, variable proportions of oxygen are daily converted in reactive oxygen species (ROS) in the mitochondria. ROS can alter the body structures through oxidative damage, that is, oxidizing proteins, peroxidizing lipids, modifying nucleic acids, and altering cell membranes. As such, they may be at the origin of illnesses as cardiovascular diseases (CVD), metabolic syndrome, anemia, several cancers, cataracts, decline of immune system, and degenerative diseases of the nervous system, as well as aging. The human body defends itself against ROS not only by means of endogenous antioxidants, such as superoxide dismutase, catalase, glutathione peroxidase, or glutathione reductase, but also by means of exogenous antioxidants, such as vitamins C and E, retinol and carotenoids, polyphenols, and minerals like selenium and zinc that are constituent of antioxidant metalloproteins. Antioxidant-rich foods can be consumed to enhance the body's antioxidant defenses and prevent or minimize several illnesses. Yet, an increase in the dietary antioxidant concentrations does not always lead to a decrease in illness and sometimes even to worrying pro-oxidative effects and cancer.

Cardiovascular Physiology

CVD are a major health concern in most countries. Major events are myocardial infarction, angina, stroke, and atherosclerosis. Most of the functional foods that promote cardiovascular health are designed to decrease fat contents from the original foods, mainly by decreasing saturated fatty acid or *trans* unsaturated fatty acid contents, as well as by adding omega-3 fatty acids, decreasing cholesterol contents, increasing phytosterol or phytostanol contents, or substituting cholesterol contents by phytosterols. Antioxidant-rich foods, including plant flavonoids, are also to be situated in this context of potential cardiovascular protection as they may inhibit LDL oxidation, modify the activities of immune-competent cells, and inhibit the formation of cell-to-cell adhesion factors. Recently, the use of vitamin K is being explored.

Gastrointestinal Physiology

The gut is an obvious target for the development of functional foods, because it is an interface between the diet and the body. The gut microbiota, together with the gastrointestinal immune system, provide the basis for a gut barrier that prevents pathogenic bacteria from invading the digestive tract and eventually the blood and the entire organism. Thus, preservation of the number and composition of the intestinal microbiota will be essential. Three strategies of functional foods have been addressed to promote healthier microbiota: prebiotics, probiotics, and synbiotics. Prebiotics are nondigestible food ingredients, mainly oligosaccharides, which stimulate growth and/or modify the metabolic activity of one or several bacterial species in the colon that potentially improve the gut health. They must not be hydrolyzed or absorbed in the upper part of the digestive tract, must be significantly transferred to the colon, and must be a selective substrate of probiotic microorganisms. Probiotics are live microbial food ingredients, mainly *Lactobacillus* and *Bifidobacterium*, combined or not, that, when ingested in sufficient quantities, have health benefits on the consumers by acting either directly or indirectly via interactions with the gut microbiota. Their major health benefits are alleviation of lactose intolerance and immune stimulation to reduce the incidence of digestive infections and also to reduce the incidence of precancerous lesions. Probiotics are only transient in the gut and do not become part of the gut microbiota. Therefore, regular consumption is necessary to maintain favorable effects. Synbiotics are mixtures of prebiotics plus probiotics addressed to increase survival of health-promoting bacteria in the gut. Probiotics are mainly – but not exclusively – applied in dairy foods, whereas prebiotics can be found in dairy products, breads and baked foods, salad dressings, and meat products.

Cognitive and Mental Performance

Some foods or food components could have effects on mood, cognition, or mental state, and these effects are characterized by a high degree of subjectivity, with large differences in response among people, mainly due to age and gender. Two types of effects can be distinguished: immediate effects (attention span, appetite, and satiety) and longer effects (changes in memory and mental processes). Carbohydrate-rich foods, through an elevation of glycemia, may influence mental performance by improvements in memory and decision time; however, high-carbohydrate meals could produce drowsiness. Generally, carbohydrates with a high glycemic index may lead to hypoglycemia due to excessive insulin responses. Yet, sucrose – the base of most of sweets – may also relieve distress and activate endogenous opioids, reducing pain perception. Tryptophan may decrease sleep latency and increase drowsiness and fatigue, likely due to its connection with serotonin metabolism. Alcohol affects most of the psychological and behavioral functions (stress, cognition, mood, and appetite), and its effects are dependent on the dose. Also, several food components, such as caffeine, theophylline, and theobromine, and plants, such as guarana, valerian, ginseng, and balm, show well-known effects on cognitive and mental performance.

Physical Performance and Fitness

Physical activity demands a high intake not only of energy but also of water, glucose, proteins, electrolytes, vitamins, and antioxidants. It is also well known that gastric emptying, and hence intestinal absorption, is influenced by physicochemical characteristics and temperature of foods. After a physical performance, it is necessary to replace glycogen reservoirs, enhance damaged muscular fibers, replace electrolytes and

water losses by sweating, and avoid oxidative stress and its subsequent mild hemolysis and immune cell depression that usually appear during and after the exercise. These changes are the rationale behind the development of functional foods such as energy bars, antioxidant beverages, or isotonic beverages.

Functional Food Consumption Worldwide

The biggest functional food markets are in Japan, Korea, and the United States, followed by Europe (see Figure 3). In the European Union, Spain, Finland, Cyprus, the Netherlands, and Sweden show high consumption of functional foods (see Figure 4). Obviously, consumer's acceptance and attitude toward functional foods determine the market size and success. While Americans accept and consume functional foods more easily, Europeans often seem to be more critical in their questioning of functional foods. It has been reported that Danish consumers have more negative attitudes toward functional foods than American and Finnish consumers. By contrast, Finnish consumers have the most positive attitudes toward functional foods. In addition, awareness of functional foods among French consumers seems to be lower than among Americans and Canadians.

Functional food consumption shows differences according to the age and gender of consumers. Functional foods like low-fat/skimmed milk, fruit juice, cereals, and probiotics are consumed by all age groups; however, cholesterol-lowering products and soy products are mostly consumed by adults and elders. Females are generally more interested in functional foods, but several products may be attractive for one or the other gender. Education has been pointed out as a factor contributing to healthy eating, and functional food users are usually more educated than the nonusers.

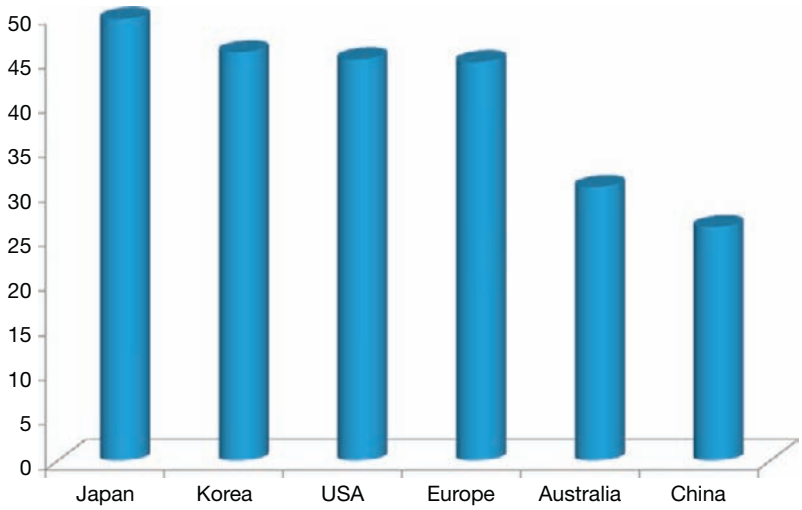

Figure 3 Proportion of functional food consumers worldwide.

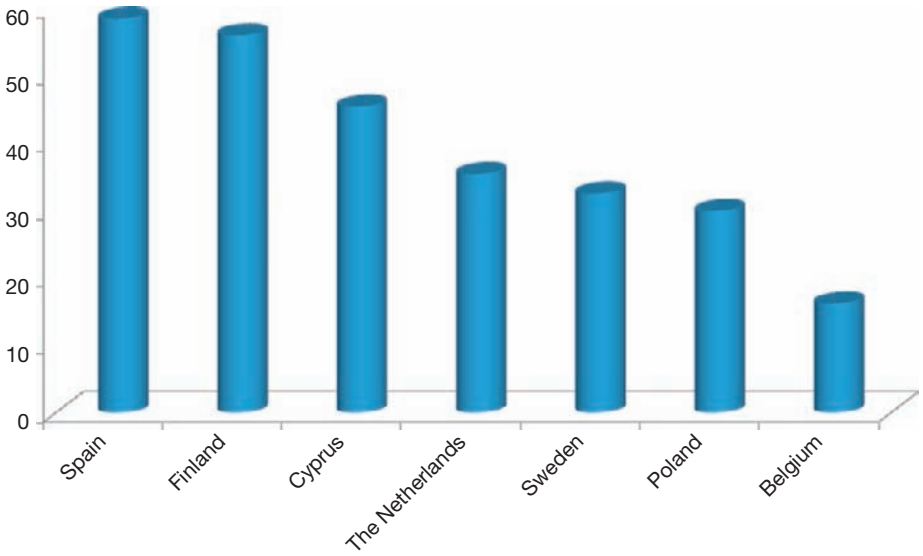

Figure 4 Proportion of functional food consumers in Europe.

Health status also may affect functional food uptake. Diet-related problems like high cholesterol, high blood pressure, and diabetes cause an increase in the consumption of cholesterol-lowering products. In several European countries, up to half of the consumers use functional foods to obtain a cholesterol-lowering effect. People with diet-related problems consumed cholesterol-lowering products in a higher proportion than those who did not have such problems; those with CVD consumed cholesterol-lowering products more frequently. Other main interests relate to blood sugar control and weight reduction.

Conclusions: Guide for Functional Food Consumption

Functional foods do not cure or prevent illnesses by themselves and are not essential to the diet. Functional foods must be viewed in the context of a healthy diet to exert their potential interest. Their inclusion in the diet may meet the following criteria:

- To incorporate functional foods in the diet, which add benefits according to the individual physiological state (pregnancy, lactation, physical activity, etc.).
- To consume functional foods in case of exclusion of certain foods by intolerance (e.g., fish, nuts, and milk), suboptimal intakes (e.g., vegetables and fruits), or low intakes (e.g., milk and dairy products and fish). In these cases, the inclusion of omega-3 fatty acid-enriched foods, vitamins or calcium-enriched milk and dairy products, or probiotics could help to lever the individual nutritional requirements.
- In chronic diseases (osteoporosis, CVD, obesity, diabetes, metabolic syndrome, etc.), the need of some nutrients may increase, and some bioactive substances contained in functional foods could exert some beneficial effects on health.
- The last consideration would refer to the preventive or health-promoting role of functional foods that, when included within a healthy diet, could help to get closer to optimal nutrition. Yet, this would require a considerable amount of further research using well-controlled methodology.

Fungi

A Moretti, Institute of Sciences of Food Production, Research National Council, Bari, Italy

Introduction to the Fifth Kingdom

In 2000, Bryce Kendrick introduced his book *The Fifth Kingdom*, inviting readers to "Imagine the picnic of your dreams. You and your loved one flat across the flower-filled meadow, coming to rest under the shade of a giant white pine. There you spread out the magic ingredients – the champagne (or wine, or beer if you prefer), the fresh crusty bread, the paté au truffle, the creamy camembert (or brie or roquefort) cheese. You may add other ingredients – many spring to mind – but up to this point your tryst is a tribute to the beneficial influence of fungi on our diet and our scenery."

Fungi make an enormous contribution to our daily lives. They represent a heterogeneous assemblage of eukaryotic organisms and are considered as a particularly versatile group with respect to their biotechnological applications in the areas of medicine, food production, pollution control, and agriculture. Recent studies on fungal biochemistry, plant pathology, medical mycology, and systematics are supported by progresses in genetics and molecular biology. Beginning from the end of the last century, an increased utilization of fungi as producers of recombinant proteins with therapeutic potential is seen. Due to their basic characteristics, fungi represent a special model for genetic investigations. These organisms can be easily cultured thanks to their ability to grow on a relatively simple medium. Also, their stable haploid phase can mutate and, in the presence of a sexual phase, mutants can be combined. Finally, due to their eukaryotic nature, they show many of the characteristics of human cells and can thus be used as a more useful model for cellular processes than bacteria.

From an ecological and environmental point of view, fungi play an important role as organic matter decomposers, but they can also cause disease in plants. Moreover, they can be used as beneficial fungi for agricultural purposes, in both organic or integrated crop protection approaches. Additionally, some harmful fungi such as *Candida* and *Aspergillus* are frequently associated with infections affecting immune-compromised patients, whereas other genera are known as environmental contaminants.

Once considered as primitive members of the plant kingdom, true fungi actually belong to the Fifth Kingdom that includes the subkingdom Dikarya (containing the phyla Ascomycota and Basidiomycota, i.e., fungi in which part of the life cycle is characterized by cells with paired nuclei), as well as the phyla Chytridiomycota and Zygomycota, which previously included the Glomeromycota, a group of fungi that forms an association with the roots of most plants. A group of parasitic organisms called Microsporidia, living inside animal cells, are now also included in the fungal kingdom, being considered a phylum basal to all fungi. Other fungi traditionally placed within the Zygomycota are distributed among several subphyla *incertae sedis* including Mucoromycotina, Entomophthoromycotina, Kickxellomycotina, and Zoopagomycotina. However, the classification system is still under modification as scientists increasingly rely on new methods. For example, Cryptomycota were described as a potentially new phylum within the kingdom.

Most fungi are filamentous, many grow as unicellular yeasts, and some primitive fungi as the Chytridiomycetes grow as individual rounded cells or dichotomous branched chains of cells. Dimorphic fungi can switch between the filamentous phase and the yeast phase in response to environmental conditions. The cells of filamentous fungi grow as an interconnected network of tubular, elongated, and threadlike structures called hyphae. The hyphae of higher fungi extend via tip (or apical) growth, which supports the invasive growth of saprobes and pathogens, facilitates long-distance transport in symbiotic mycorrhizal fungi, and, through aggregation, forms the basis for the development of multicellular reproductive structures.

The hyphal cell wall, composed by a combination of glucans and chitin, is a sort of exoskeleton that defines the shape and growth and protects the fungal protoplasts from the external environment. Some fungal species can grow as unicellular yeasts reproducing by budding or binary fission. In yeasts, the cell wall structure comprises polysaccharides such as β-glucans and proteins, mainly mannoproteins.

Fungi and yeasts have relatively simple nutritional needs and are metabolically heterotrophic. They can assimilate organic carbon and nonelemental sources of nitrogen. Sugars, from the simplest glucose to complex polysaccharides such as cellulose and lignin, are widely utilized for growth. Fungi cannot fix nitrogen and need to be supplied with nitrogen-containing compounds, either in inorganic form (e.g., ammonium) or in organic form (e.g., amino acids). In addition to urea that can be assimilated by some basidiomycetic yeasts, many fungi can grow on nitrate and nitrite being equipped with nitrate and nitrite reductases that allow conversion to ammonium.

Fungal cells characteristically display external digestion due to the release of many different enzymes and imbibe, rather than relying on the ingestion of nutrients. Their ability to absorb and grow on many substrates and to convert them in important secondary metabolites is noteworthy. Such versatile metabolic capability has attracted much interest towards fungi in view of their potential application in natural product chemistry and in the production of antibiotics and other bioactive metabolites. In addition, many fungi are currently used in several fermentation processes that lead to products of agro-food interest such as wine, beer, soy sauce, and several other food commodities.

Fungi are mostly haploid and can reproduce sexually and asexually through spores. Asexual spores, representing the end of vegetative growth, are produced by mitosis, whereas sexual spores, produced at the end of the meiotic division, can be produced upon or within specialized structures, sometimes closed in fruit bodies. Forms, details, method of production,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00341-X

release, and dispersal of spores represent valid tools used to describe most fungal taxa.

For further information about detailed taxonomic, physiological, and metabolic aspects of these organisms, we refer to the series *The Mycota*, a comprehensive treatise on fungi as experimental systems for basic and applied research.

Fungal Plant Pathogens

Losses due to plant diseases have a dramatic impact on both the economical conditions of growers and the availability of food in areas where people's survival depends on plant production. Plant diseases are caused by both abiotic and biotic factors. Among the biotic factors, fungi are an important group of plant pathogens, since more than 10 000 fungal species have been identified as causing agents of plant diseases. They include obligate parasites (biotrophs) that need to live on their host plants for their whole life and nonobligate parasites that require a host plant for part of their life cycle but can complete their cycle on dead organic matter. Most biotrophs are generally specialized in the targeting of a limited number of plant hosts, while necrotrophic fungi can either grow on a wide range of host species or be specialized on a restricted range of hosts. Moreover, some fungi, defined as endophytes, are hidden inside their plant hosts in symbiotic association. They do not show any symptom of disease and confer tolerances to several kinds of biotic and abiotic stresses to their host plant. Other fungal plant pathogens can affect the level of growth of their hosts by inducing them to produce higher amounts of regulators or producing growth regulators themselves. The effects on plants of this overproduction include the development of cankers, galls, witches' broom, leaf curl, and stunting.

Fungal plant pathogens can also be distinguished based on the stage and part of the plant host that is attacked: seeds, seedlings, or adult plants and roots, leaves, shoots, stems, woody tissues, fruits, or flowers, respectively. Some fungi that kill seedlings can often also infect the roots of mature plants, mainly through wounds, and can cause lesions or death of a part or all of the root system and crown. Vascular wilt pathogens kill their host by infecting the plant through the roots or through wounds and growing into the xylem. The first symptoms of vascular wilt are a loss of turgidity in the plant leaves, often on one side of the plant or on a single branch, and vascular discoloration.

Leaf spot pathogens infect through natural plant openings such as stomates or by penetrating directly through the host cuticle and epidermal cell wall. In order to penetrate, fungi produce hydrolytic enzymes such as cutinases, cellulases, pectinases, and proteases, thus breaking down the host tissue. Specialized structures called appressoria, formed at the end of germ tubes, are used by other fungi as an alternative way to penetrate cell walls. Once inside the plant leaf, the fungus must obtain nutrients from the cells, which is often accomplished by killing host cells in case of necrotrophs. Many leaf-spotting fungi produce toxins that kill host cells, and this often produces a lesion surrounded by a yellow halo. If enough of the leaf surface is killed, or if the infected leaves drop prematurely, the photosynthesis activity of plants can be dramatically affected.

Other diseases, such as cankers, develop when the pathogen kills the phloem and vascular cambium in a woody host, causing death of the plant part that is encircled.

Rust fungi, so named because of the abundant orange spores formed on plants infected, are biotrophic pathogens that can infect, grow, and sporulate in living plant tissues. They can be devastating pathogens by reducing the photosynthetic surface and increasing water losses in the host plant. Rust fungi attack a wide range of plants and often require two different hosts in order to complete their life cycles. Finally, some diseases caused by fungi make plant products unfit for human and animal consumption since they produce toxic metabolites (mycotoxins) that contaminate field products, especially grains. These fungi are called mycotoxigenic fungi and will be discussed later.

Mycotoxigenic Fungi

The need of ensuring food safety to consumers is considered a main issue at worldwide level. Problems related to several kinds of food contamination harmful for human and animal health have been increasing in the recent years. Globalization and the development of an exchange-based worldwide economy have deeply influenced and enlarged the food market. However, at the same time, the increased marketing of food products increased the exposure to natural and chemical contaminants.

Among the emerging issues in food safety, the increase of plant diseases associated to the occurrence of mycotoxigenic fungal species is of major importance. As a result of their secondary metabolism, these fungi can produce mycotoxins, which are low-molecular-weight toxic compounds that represent a serious risk for human and animal health worldwide. They occur naturally and are the most prevalent source of food-related health risks in field crops, where approximately 25% of the global food and feed crop output is affected. Due to their broad range of biological activities, the consumption of mycotoxin-contaminated foods is a main issue in food safety worldwide. This is particularly so since a large proportion of the world's population consumes cereals as a staple food, which are the main targets for colonization by toxigenic fungi. The mycotoxin contamination of crops is generally regulated by two main factors: susceptibility of the host plant, on the one hand, and the geographic and climatic conditions, on the other hand. Mycotoxins are produced on the plants before the harvest due to toxigenic fungal contamination in the field and also at the postharvest stage, encompassing stages of the food chain (i.e., storage, processing, and transportation). Moreover, mycotoxins can also be accumulated in animal by-products, due to a carryover effect, as a consequence of the use of highly contaminated feed.

Main mycotoxin-producing genera are *Alternaria*, *Aspergillus*, *Fusarium*, and *Penicillium*. Most of the mycotoxigenic species can produce more than a single mycotoxin, but a given mycotoxin can be produced by species that belong to different genera (Table 1). Factors that increase the stress status in plants, such as a lack of water and an unbalanced absorption of nutrients, and therefore reduce their immune system, can lead to a higher exposure to mycotoxin contamination. In addition, specific climatic conditions and environmental

Table 1 Main mycotoxigenic fungal species and genera contaminating food

Genus/species	*Main host plants*	*Mycotoxins*	*Food*
Alternaria			
A. arborescens	Wheat, tomato	AOH, AME, ALT, AAL toxin	Wheat by-products, tomato juice, and puree
A. tenuissima	Wheat	TeA, ATX-I, AOH, AME	Wheat by-products
A. alternata	Wheat, tomato	AOH, AME, ATX-I, ATX-II, ATX-III	Wheat by-products, tomato juice, and puree
A. infectoria	Wheat	Dibenzo-α-pyrones	Wheat by-products
Aspergillus			
A. carbonarius	Grape	OTA	Wine and grape by-products
A. ochraceus	Coffee	OTA	Coffee
A. flavus	Maize, nuts	AFB_1, AFB_2	Maize by-products, dried fruits
A. niger complex	Grape	FB_2, OTA	Wine and grape by-products
A. parasiticus	Maize	AFB_1, AFB_2, AFG_1, AFG_2	Maize by-products
Fusarium			
F. culmorum, *F. graminearum* complex	Wheat	DON	Wheat by-products
F. equiseti/*F. incarnatum* complex	Wheat	ZEA	Wheat by-products
F. poae	Wheat	NIV	Wheat by-products
F. sporotrichioides, *F. langsethiae*	Wheat	T-2, HT-2	Wheat by-products
F. verticillioides, *F. proliferatum* (*F. moniliforme*)	Maize	FB_1, FB_2	Maize by-products
Penicillium			
P. expansum	Apple	PAT	Apple juice
P. verrucosum	Wheat	OTA	Wheat by-products

AOH, alternariol; AME, alternariol monomethyl ether; ALT, altenuene; TeA, tenuazonic acid; ATX, altertoxin I, II, III; OTA, ochratoxin A; AFB, aflatoxin B (B_1 and B_2); AFG, aflatoxin G (G1 and G_2); DON, deoxynivalenol; ZEA, zearalenone; NIV, nivalenol; T-2, T-2 toxin; HT-2, HT-2 toxin; FB_1, fumonisin B (B_1 and B_2); PAT, patulin.

factors, as temperature and humidity, can influence the growth of mycotoxigenic fungi and eventually stimulate their ability to produce mycotoxins.

The *Alternaria* Genus

The *Alternaria* genus (*Pleosporales*, *Pleosporaceae*) includes species that are diffused worldwide, mainly as soil saprotrophs, and that can also survive on plant residues. Among different crops (e.g., oleaginous plants, vegetables, and fruits), *Alternaria* species can colonize the kernels of several minor cereals, especially wheat, barley, and sorghum, and release a number of toxic metabolites. *Alternaria* species cause postharvest decay of many vegetable products along the whole value chain, from the field, transportation, intermediate storage and processing, to the final (chilled) storage. Indeed, these organisms withstand low temperatures and can be responsible for the rot of several products during storage in refrigerators. Taxonomy of *Alternaria* spp. is not completely clear yet even though different types of molecular analysis have been used to support morphology. *Alternaria* species produce 71 known mycotoxins and phytotoxins, but only few occur naturally in food. They are divided in three main chemical groups: the dibenzo-α-pyrones, which include alternariol (AOH), alternariol monomethyl ether (AME), and altenuene (ALT); the tetramic acid group, including tenuazonic acid (TeA); and the altertoxin (ATX) group, of which the main members are ATX-I, ATX-II, and ATX-III. Moreover, other important relevant *Alternaria* mycotoxins are the AAL toxins and stemphyltoxin III, which are toxins produced in large amounts at the preharvest crop stage. Several of these *Alternaria* mycotoxins can have adverse effects on humans such as salivation, vomiting, erythema, convulsions, and gastrointestinal hemorrhage. However, due to a poor knowledge of the extent of their occurrence in food commodities, regulatory limits are still lacking.

The *Aspergillus* Genus

The genus *Aspergillus* (*Eurotiales*, *Trichocomaceae*) includes ubiquitous fungi that colonize a wide spectrum of habitats and are very common on stored grains and a wide range of foodstuffs. *Aspergillus* species have been taxonomically divided in sections that group closely related species. In particular, the sections *Flavi* and *Nigri* include species that colonize a wide range of plants of agrofood interest, where they can produce highly harmful mycotoxins such as aflatoxins, ochratoxins, and, to a very limited extent, fumonisins.

Aflatoxins (AFLs), including B_1, B_2, G_1, and G_2, are potent carcinogenic mycotoxins produced in a wide range of agricultural commodities such as maize, peanuts, and dried figs. The International Agency for Research on Cancer (IARC) classified aflatoxin B_1 as a group 1 carcinogen to humans. In addition to hepatocellular carcinoma, AFLs are associated with occasional outbreaks of acute aflatoxicosis leading to death shortly after exposure. The main species of concern for AFL contamination are *A. flavus* and *A. parasiticus*. The ability to produce AFL is highly conserved in some species but is highly variable in others. Almost all *A. parasiticus* strains produce AFLs, with only 3–6% of nonaflatoxigenic strains. In contrast, toxigenicity in populations of *A. flavus* is reported to be extremely diverse in terms of morphology and toxigenicity, and incidence of nontoxigenic strains depends on the strain, substrate, and geographic origin.

Ochratoxin A (OTA) is produced mainly by black aspergilli and *A. ochraceus* (occurring mainly on cereals and coffee beans) and acts as a potent nephrotoxin. It may be involved in the etiology of the human disease called Balkan endemic nephropathy and in the development of urinary tract tumors in humans. In 1993, IARC classified OTA as a possible human carcinogen (group 2B) and has been found in several commodities such as wine, grape juice, dried figs, rice, and coffee beans. The *Nigri* section, including species as *A. carbonarius* and *A. niger*, can often occur on grapes (Figure 1) and grape products where they can produce OTA. However, while *A. carbonarius* is a high and consistent producer (around 100% of the strains), only a limited percentage of strains of *A. niger* produce OTA.

Finally, fumonisins are also of health concern because they disrupt sphingolipid metabolism, can cause multiple diseases in experimental rodents and livestock, and are epidemiologically associated with several human diseases, including esophageal cancer. Some black aspergilli were recently shown to produce fumonisins, in particular species belonging to the *A. niger* aggregate. Therefore, the high occurrence of black aspergilli on raisins and grape must raise food safety concerns, because of the potential contamination of wines and grape by-products.

The *Fusarium* Genus

The genus *Fusarium* (*Ascomycetes*, *Hypocreales*) comprises a high number of plant-pathogenic species causing diseases in several agriculturally important crops, including cereals. Many of them produce a wide range of mycotoxins with an extraordinary chemical diversity. The ability of various *Fusarium* species to produce different classes of secondary metabolites combined with their ability to coexist in the same host and/or occur in quick succession has allowed these complexes to become 'invincible armadas.' Plant infections by *Fusarium* can occur at all developmental stages, from germinating seeds to mature vegetative tissues, depending on the host plant and *Fusarium* species involved.

Among the mycotoxins produced by *Fusarium* species, only a small number are considered important for human and animal health, including the trichothecenes and fumonisins that are under strict legislative control worldwide. Readers are referred to the excellent book *Fusarium Mycotoxins: Chemistry, Genetics and Biology*, compiled by Desjardins, for a complete review of *Fusarium* mycotoxins.

The trichothecenes are a family of epoxysesquiterpene metabolites, conveniently subdivided in two classes, based on their chemical structures: type A and type B, of which T-2 toxin and deoxynivalenol (DON) are the most common mycotoxins, respectively. The T-2 toxin is one of most acutely poisonous ones, produced mainly by *F. sporotrichioides* and *F. langsethiae*, two pathogens commonly occurring on minor cereals (e.g., barley and wheat). The illness associated with the consumption of cereals highly contaminated by T-2 includes nausea, vomiting, necrotic lesions, severe hemorrhagic diarrhea, and hemorrhagia in many of the body organs. The T-2 toxin is also a potent immunosuppressant because it causes irreversible damage to the bone marrow, leading to a characteristic reduction in white blood cells (aleukia). DON, which is the most important type B trichothecene, is much more common than the T-2 toxin in cereals such as wheat, barley, oat, and maize. It is produced primarily by *F. graminearum* and *F. culmorum*, the causal agents of *Fusarium* red ear rot in maize and *Fusarium* head blight (FHB) in wheat. DON is also known as vomitoxin because of its potent emetic properties and its action as a feed refusal factor and may still have a biological effect at very low concentrations. The acute phytotoxicity of trichothecenes and their occurrence in plant tissues suggest that these mycotoxins play a role in the pathogenesis of *Fusarium* in plants.

Fumonisins are a family of mycotoxins produced mainly by *F. verticillioides* and *F. proliferatum*, which are both very important pathogens of maize, where they cause the so-called *Fusarium* pink ear rot (Figure 2), and colonize a wide range of

Figure 1 Rotted grape berries colonized by black *Aspergilli*.

Figure 2 Rotted maize ear colonized by *Fusarium* spp.

agriculturally important plants worldwide. Fumonisins can cause the death of horses by massive necrosis of brain tissue, that of pigs by chronic accumulation of fluid in the lungs, and that of rats by necrosis of the liver. Moreover, they may also be the etiologic agents of esophageal carcinoma in humans. In 1993, the IARC evaluated these toxins as group 2B carcinogens. The role of fumonisins in phytotoxicity, pathogenesis, and other aspects of *Fusarium* ecology is still unclear.

The *Penicillium* Genus

The genus *Penicillium* (*Eurotiales*, *Trichocomaceae*) is maybe the most spread fungal genus in nature. Many of its species are ubiquitous and colonize a wide range of habitats. Generally, *Penicillium* species are considered saprotrophic fungi living on plant parts, soil, decaying organic substances, and plant residues. Moreover, many of the most common *Penicillium* species are associated not only with stored food and feed but also with animal dung and building materials, indoor air, and several other habitats. With respect to other mycotoxigenic genera, *Penicillium* species are less adapted to high temperatures. Many *Penicillium* show psychrophilic behavior and can therefore contaminate food stored at low temperatures, being able to grow at temperature around 0 °C. Some *Penicillium* species are plant pathogens acting on several fruit trees and producing harmful mycotoxins that can accumulate on several food products.

The taxonomy of this genus is difficult, mainly because of the enormous variability within the genus. Therefore, a polyphasic approach based on phenotypic characteristics (morphology and physiology), phylogeny, and secondary metabolite profiles (extrolites) is currently applied to create sections, which are useful taxonomic tools for the ecological and phylogenetic grouping of consistently related species. The genus *Penicillium* includes around 100 toxigenic species, and the range of known mycotoxins produced is wider than those of other toxigenic fungal genera such as *Aspergillus* and *Fusarium*. The *Penicillium* subgenus *Penicillium* includes the highest number of toxigenic species able to produce a large number of bioactive extrolites, including several mycotoxins. OTA is produced only by *P. verrucosum* and *P. nordicum*, with the first species being very common on cereals, mostly in cold environments, and the second species being a known contaminant of protein-rich foods, primarily found on dry-cured meat products.

Patulin, another important mycotoxin produced by *Penicillium* species, is a water-soluble polyketide lactone that occurs most often in apples spoiled by *P. expansum* or in products made from spoiled apples, such as apple juice, pies, and conserves. It has also been found in other fruits, including pears and grapes, and in vegetables, cereals, and cheese. Most of the information on the toxicity of patulin is derived from animal studies. At relatively high doses, patulin is acutely toxic in mice and rats, causing gastrointestinal lesions, distension, and hemorrhagia in the stomach and small intestine. It has been suggested that patulin is carcinogenic at low levels in the diet, but IARC has stated that there is insufficient evidence of carcinogenicity in animals or humans, other than at extremely high doses. Many other mycotoxins are produced by species of *Penicillium*. The most common are citrinin, considered nephrotoxic, penicillic acid, cyclopiazonic acid, citreoviridin, and PR toxin.

Beneficial Fungi

The consequences of the widespread and repeated use of chemical products in crop protection to control pests, plant pathogens, and weeds have become clear in recent years. It is generally recognized that some chemical pesticides contaminate groundwater and enter food chains, with an impact on a wide range of organisms. To make matters worse, fungicide-resistant plant pathogens have been developed as a result of the exasperated use of chemicals. Regardless of these problems, there is an urgent and pressing demand for food production in order to reply to an increasing world population. Consumers constantly require food and feed of high quality, cultivated according to an environmentally friendly framework and without chemical residues. All of this cannot be separated from the implications of new legislation on organic farming or the enforcement of improved integrated pest management strategies. The EU, for instance, has set rules for the sustainable use of pesticides to reduce the risks and impact of pesticide use on people's health and the environment.

From this point of view, exploitation of fungi as beneficial organisms is of increasing interest and trendsetting. Biological control via fungi is an exciting and rapidly developing research area with implications for plant productivity, animal and human health, and food production.

Many fungi can be used as biocontrol agents for plant disease management. The most extensively studied ones are *Trichoderma* spp., together with the more recently described *Sebacinales* genus. These fungi can control many different foliar, root, and fruit pathogens and dangerous organisms such as nematodes. Due to their excellent adaptability, broad spectrum, diversified mechanisms, fast growth, and simple nutritional requirements, *Trichoderma* spp. actually represent one of the most common active principles of many globally used commercial products. In addition to classical mechanisms, such as the production of inhibitory and lytic substances, mycoparasitism (Figure 3), and competition for nutrients and sites of infection, the most appealing aspect of these fungi is the ability to act as inducers of resistance in the host plants against biotic and abiotic stresses, in addition to physiological stresses such as seed aging. Many other positive effects of *Trichoderma* spp. on plants, such as the improvement of photosynthetic and respiratory efficiency, the enhancement of nutrient uptake, and the increase of nitrogen use efficiency, are considered as important as the disease-controlling aspect.

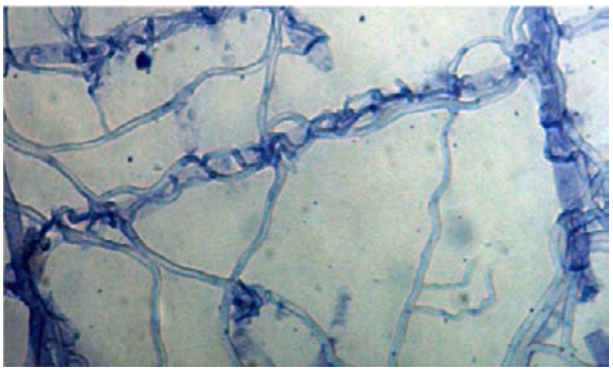

Figure 3 Coiling by *Trichoderma* spp. around hyphae of *Rhizoctonia solani*.

The most studied species within the *Sebacinales* is *Piriformospora indica*, able to promote plant growth due to the capability of colonizing host roots. This species is also able to induce resistance by upregulating some defense-related genes.

One of the most fascinating and important properties of fungi is the ability to produce a wide variety of secondary metabolites displaying a wide range of biological activities. Fungi commonly live in competitive environments, and it is generally accepted that their secondary metabolites play an important role in their ecology, with the most straightforward effect appearing in the regulation of the competitive and/or antagonistic interactions among fungal species. With their antifungal activity, many of these secondary metabolites have attracted great attention in order to satisfy the increasing need for new antifungal agents, not only in medicine but also in agriculture where new useful fungicides are being continuously sought for.

In this perspective, coprophilous fungi, a large group of saprotrophic fungi including more than 1200 species, mostly recorded from herbivorous dungs, receive increasing interest from both an ecological point of view and a biotechnological point of view. Taxonomy of these fungi is continuously being updated and unusual new species continue to be discovered: these fungi represent a productive reservoir of antibiotics, mostly of unknown structure and activity. Next-generation sequencing and automated gene prediction can preview the biosynthetic repertoire of these fungi, anticipating pathways for known and unknown antibiotics.

Beneficial Fungi and Food Safety

Mycotoxigenic fungi, such as *Aspergillus*, *Fusarium*, and *Penicillium*, pose serious problems and toxicological risks at preharvest and postharvest stage as well as in processed food products. Biological control using beneficial fungi (filamentous and yeasts) allows managing contamination by mycotoxins at both pre- and postharvest levels and can contribute to decontamination and/or detoxification of these dangerous compounds from food and feeds.

For instance, atoxigenic isolates of *Aspergillus* are widely used to prevent aflatoxin contamination of crops, such as nuts and maize, in several parts of the world. Field experiments have demonstrated that *Trichoderma gamsii* and *Fusarium equiseti* can reduce FHB incidence and DON contamination on wheat. The yeastlike *Aureobasidium pullulans* or the yeast *Metschnikowia fructicola* are able to reduce OTA contamination by *Aspergillus* sp. on grape and can degrade OTA to a less toxic compound *in vitro*.

Finally, patulin- and OTA-producing fungi on apples and pears can be controlled by the application of *Aureobasidium pullulans* or *Candida sake*, resulting also in a reduction of mycotoxin contamination.

Beneficial Fungi and Food Quality

Additional positive effect deriving from the application of beneficial fungi in plants concerns the improvement of nutritional factors in derived foods. An example is provided by the arbuscular mycorrhizal fungi (AMFs, Glomeromycota), able to establish a symbiotic relationship with the roots of most terrestrial plants. Interaction between plants and mycorrhizal fungi increases the crop yield and the disease resistance and also improves the intake of minerals and compounds with antioxidant properties. In lettuce, AMFs improve growth and nutritional quality (mineral nutrients, total soluble sugars, ascorbate contents, and quantities of anthocyanins, carotenoids, and phenolics). In tomato, this symbiosis enhances the nutritional and nutraceutical value of fruits by modifications of plant secondary metabolism that lead to increased levels of lycopene.

Bioactive fungal polysaccharides represent potential ingredients in food and nutraceuticals. Fungal polysaccharides comprise a large group of biopolymers mostly derived from edible mushrooms (maitake or shiitake) or yeasts. These polysaccharides are characterized by potential immune-modulating, anticancer, antimicrobial, hypocholesterolemic, hypoglycemic, and health-promoting properties. The fact they are obtained by edible mushrooms and yeasts makes them good candidates for the formulation of novel functional foods and nutraceuticals without serious safety concerns.

Conclusion

The fungal kingdom represents an impressive example of genetic biodiversity including organisms that can, from a human perspective, be either beneficial or harmful to human beings. Fungi can be considered as a perfect example of organisms that keep ecological balance and help to preserve the Earth from certain destructive human interventions.

Introduction

Crop production is vulnerable to different pests and plant diseases and most of them are related to pathogenic fungal diseases. Fruits and vegetables are highly susceptible to fungal spoilage, both in the field and during postharvest storage. Significant fungi genera include *Pythium*, *Phytophthora*, *Fusarium*, *Penicillium*, *Alternaria*, *Botrytis*, *Geotrichum*, *Sclerotinia*, and *Rhizoctonia* spp. Important agricultural commodities, such as grain crops, are also venerable to fungal contamination particularly by *Aspergillus*, *Penicillium*, *Fusarium*, and *Alternaria* spp. In grains, molds are responsible for off-flavor formation and contribute to loss in dry matter through the utilization of carbohydrates as an energy source, degradation of lipids and proteins, and production of volatile metabolites and of allergenic compounds. Infection by *Botrytis cinerea*, *Plasmopara viticola*, and *Uncinula necator* is a significant problem in grape production worldwide.

Fungicides have been used for over 200 years to protect plants against diseases caused by fungi attack. From the remote beginnings, mainly to protect cereals and grapes, the number of crops and crop diseases treated, the chemicals available, the area and frequency of their use, and the effectiveness of treatments have increased enormously. Curiously, two of the first established products, copper-based formulations and sulfur, are still used widely and effectively, while several chemical families, such as phthalimides, dithiocarbamates (DTCs), dinitrophenols, and chlorophenyls, have been successfully used for more than 40 years. In the late 1960s and 1070s, a large number of more potent fungicides, of novel structure and mostly with systemic activity, were introduced, including 2-amino-pyrimidines, benzimidazoles, carboxanilides, phosphorothiolates, morpholines, dicarboximides, phenylamides, and sterol demethylation inhibitors (DMIs). Systemic fungicides have gradually replaced the older nonsystemic products, establishing higher levels of disease control.

In the 1980s, mostly analogs of existing fungicides were introduced, particularly DMIs, with improved properties. Since then, however, a number of novel compounds have been introduced commercially, including phenylpyrroles, anilinopyrimidines, quinone outside inhibitors (QoIs, including strobilurin analogs), benzamides, carboxylic acid amides (CAAs), phenoxyquinolines, oxazolidinediones, spiroketalamines, and scytalone dehydratase inhibitors, among others. Some recently developed products – unique in that they do not directly affect the pathogen itself – elicit a response from the host plant known as 'systemic acquired resistance' (SAR). These compounds basically mimic chemical signals in plants, activating plant defense mechanisms such as the production of thicker cell walls and antifungal proteins. The utility of SAR inducers has been limited so far, as many pathogens are capable of overcoming such defenses.

Fungicides remain vital for the effective control of plant diseases, which are estimated to cause yield reductions of almost 20% in the major food and cash crops worldwide. In this article, some of the most important issues related to fungicides, such as fungicide classification, environmental fate, reduction of fungicide residues in food, effects on health, maximum residue levels, and analytic methods for their determination, are discussed, from the viewpoint of analytical chemists.

Fungicide Classes

Fungicides can be classified according to different criteria but perhaps the most usually employed are the mode of action and the chemical group. Fungicides can also be classified according to where in the disease cycle they are active: (1) protectant or preventive, if they are effective prior to infection and the initiation of the disease cycle; (2) curative, fungicides that are effective against the fungus growing in the leaf tissue post the infecting spore germination; or (3) eradicant or antisporulant, that is, fungicides that are capable of stopping sporulation by the pathogen.

Fungicides kill fungi by damaging their cell membranes, inactivating critical enzymes or proteins, or by interfering with key processes such as energy production or respiration. Others impact specific metabolic pathways such as the production of sterols or chitin. When low concentrations of fungicides damage the cell, activation of one or more stress response pathways allows the cell to respond to the damage and survive. However, higher concentrations generally overwhelm the fungal stress response system leading to inhibition of growth or cell death.

A list of fungicides organized by the mode of action that also includes data on the target site, chemical group and name, and resistance risk of each compound is maintained by the Fungicide Resistance Action Committee (FRAC). All fungicides within a chemical group share a common mode of action and resistance mechanism, even though their chemical structures may be different. Two exceptions in the FRAC classification scheme are the 'multisite activity' fungicide class and the 'unknown' class of fungicides with unknown modes of action.

In this section, some of the most important fungicide chemical families are briefly discussed, given that from the food safety perspective, namely, in the development of analytic methods, this is one of the most pertinent classifications used.

Inorganic Compounds

Sulfur is a widely used fungicide by both conventional and organic farmers. It is one of the top pesticides in terms of quantities used accounting for more than 25%, both within the European Union (EU) and in California.

Copper-based fungicides, such as the Bordeaux mixture, $CuSO_4 + Ca(OH)_2$, have been intensively used in Europe since the end of the nineteenth century to control vine (*Vitis vinifera* L.) fungal diseases, such as downy mildew caused by *P. viticola*. Additionally, other copper compounds have been introduced including copper oxychloride ($3Cu(OH)_2 \cdot CuCl_2$), among others. Besides vineyards, copper-based fungicides have also been extensively used in hop fields and coffee, apple, and avocado orchards and in the cultivation of vegetables (e.g., tomatoes and potatoes).

Copper used to be one of the most applied pesticides, but it is currently used to a much lesser extent than sulfur. Sulfur is generally considered to be of low risk to humans, animals, and the environment, while copper is considered to have potentially toxic properties for certain nontarget organisms.

Dithiocarbamates

DTCs are a group of organosulfur fungicides characterized by a broad spectrum of activity against various plant pathogens, low acute mammal toxicity, and low production costs. Thus, DTCs are widely used in agriculture especially in combination with modern systemic fungicides to control resistances and to expand the spectrum of activity. As a consequence, DTCs are some of the most frequently detected pesticides in the EU, and this group also showed one of the highest frequencies in exceeding maximum residue limits (MRLs) in food commodities sampled during 2010 in the 27 EU member states, Iceland, and Norway.

DTCs can be classified into three subclasses depending upon their carbon skeleton: (1) dimethyldithiocarbamates (DMDCs) such as ziram, thiram, and ferbam; (2) ethylenebis (dithiocarbamates) (EBDCs) such as mancozeb, maneb, zineb, and metiram; and (3) propylenebis(dithiocarbamates) such as propineb. This distinction is important because many countries are restricting the use of EBDCs due to their toxicity.

Benzimidazoles

Benzimidazoles are a group of specific fungicides, introduced around 1970, that includes carbendazim, benomyl, and thiophanate-methyl as representatives. They inhibit β-tubulin assembly during mitosis and were first used to control gray mold (*B. cinerea*) and apple scab (*Venturia inaequalis*), but the pathogens rapidly developed field resistance, and they are now widely used in their relative crop segments because of their broad spectrum. Aside from their application in agriculture, benzimidazoles are used in animal and human health as anthelmintic and antiulcer drugs.

Though benomyl sales have decreased since registration was canceled in the EU and the United States, thiophanate-methyl meets the strict criteria for registration in Japan, the EU, and the United States, and its use has been increasing to control *Sclerotinia* rot of soybean in Brazil and deoxynivalenol levels on cereal grains in the EU.

Dicarboximides

The broad-spectrum dicarboximide fungicides, including procymidone, iprodione, and vinclozolin, were commonly used to control *Botrytis* on vines, fruits, and vegetables in the 1980s. Fungicides of this class have been used since the mid-1970s mainly to control fungi of the related genera *Botrytis*, *Sclerotinia*, and *Monilinia*.

Dicarboximides largely replaced benzimidazole fungicides, which in many situations were no longer effective due to resistance. Dicarboximide-resistant variants appear frequently in laboratory, and after about 3 years of intensive use, resistant strains were detected in the field. Vinclozolin was used worldwide on oilseed crops, vines, fruits, and vegetables. It was widely used in Europe until 2007 when a ban was implemented. The United States remains a major use area although uses were restricted in 2000 and is currently limited to canola and turf.

Concern about the toxicity of vinclozolin and/or its metabolites is related to its antiandrogenic activity and its ability to act as a competitive antagonist at the androgen receptor. Its terminal metabolite, 3,5-dichloroaniline, is also considered a potential carcinogen.

Triazoles

Modern systemic fungicides are typified by the triazoles. This group of fungicides is still the basis of cereal disease management strategies worldwide, particularly in Europe, North America, Australia, and New Zealand, where they are primarily mixed with strobilurins and with the new-generation pyrazole carboxamide SDHIs (succinate dehydrogenase inhibitors), introduced in 2010.

Azole fungicides are widely used in agriculture and in the treatment of human mycosis. Their antifungal activity is based on their ability to inhibit CYP51 (lanosterol 14-demethylase), a key enzyme for sterol biosynthesis in fungi. Several azole fungicides have been found to possess a common teratogenic potential to induce facial, axial skeleton, and limb defects, in laboratory animals tests. The inhibitory potency of triazoles is not limited to fungi and has been observed in several mammalian cytochrome P450-dependent activities, such as hepatic microsomial enzymes, accounting for the possible interference of azoles with the metabolism of other drugs.

Phthalimides

The phthalimides represented a major improvement over the previously used inorganic fungicides since they were more active, less phytotoxic, and easier to prepare by the user. The phthalimides captan and folpet are fungicides largely used in agriculture, namely, in grape production, and still provide very good powdery mildew control if properly applied. They have similar chemical structures, except that folpet has an aromatic ring unlike captan. Their half-lives in several matrices are very short, since they are readily broken down to tetrahydrophthalimide and phthalimide, respectively.

Phenylamides

Phenylamides (benalaxyl, metalaxyl, and metalaxyl M) were first introduced in 1977. They act specifically against oomycete pathogens and have no effect on other classes of fungi. The first cases of resistance occurred in 1980, against metalaxyl applied to cucumbers for the control of *Pseudoperonospora cubensis* in

Israel and applied to potatoes in several European countries for the control of late blight (*Phytophthora infestans*).

Anilinopyrimidines

After resistance to dicarboximides developed, the anilinopyrimidines (pyrimethanil, cyprodinil, and mepanipyrim) were introduced in the 1990s and have been used to control strains with multiple resistances to dicarboximides and benzimidazoles.

Pyrimethanil and mepanipyrim are particularly active against gray mold and apple and pear scab, whereas cyprodinil provides effective control of a wide range of cereal pathogens. Cyprodinil has been commercialized alone for cereals and as a mixture with fludioxonil against *B. cinerea* on grapes and vegetables.

Anilinopyrimidines inhibit elongation of germ tubes at low concentrations. Several amino acids, particularly methionine, reverse the fungitoxicity of the anilinopyrimidines. Biochemical studies suggest that pyrimethanil inhibits the biosynthesis of methionine, affecting cystathionine β-lyase.

Phenoxyquinolines

Quinoxyfen was introduced for the control of powdery mildew of cereals (*Erysiphe graminis*) and grapevine. In the EU, quinoxyfen was approved for use as a fungicide in 2004. Quinoxyfen inhibits spore germination and appressorium development and thus exhibits a preventive action toward powdery mildew pathogens. Because of its vapor redistribution and possibly its systemicity, quinoxyfen shows long-term protection.

Phenylpyrroles

Phenylpyrrole fungicides are derived from the antibiotic pyrrolnitrin, a secondary metabolite of *Pseudomonas pyrrocinia*. Fludioxonil is used in seed treatments and foliar sprays for the prevention of infection by *B. cinerea*.

Fludioxonil shows improved photostability and has very good activity against *B. cinerea*, *Monilinia* spp., and *Sclerotinia* spp. For use against foliar diseases, fludioxonil is commercialized alone or as a mixture with cyprodinil. Both fungicides play an important role in some biocontrol systems, particularly in the control of strawberry gray mold.

QoI-Fungicides (QoI, 'Strobilurins')

This class comprises fungicides from several different, but related, chemical groups (e.g., methoxyacrylates, methoxyacetamides, oximino acetates, and methoxycarbamates), which have a common antifungal mode of action, inhibiting electron transfer at the Qo site in mitochondrial complex III. Within 2 years after their introduction, marked loss of action against powdery mildew, associated with development of highly resistant populations, was observed in some European countries. Important resistant problems were subsequently observed in several target pathogens in wheat, apple, and bananas.

Strobilurins are natural substances isolated mainly from mushrooms (basidiomycetes). Strobilurin-A was isolated from the liquid cultures of *Strobilurus tenacellus*. These products are biosynthesized in fungus from phenylalanine via the shikimic acid cycle, and their discovery opened the door for new chemistry of synthetic fungicides. By applying quantitative structural activity relationship on the structures of natural strobilurins, many pesticide companies were able to synthetize analogs that are more efficacious and more stable fungicides.

The strobilurins were first commercialized in 1996 with the launch of azoxystrobin and kresoxim-methyl, and within only a few years, they were registered and sold in over 80 crops in 70 different countries. In 2008, sales of azoxystrobin alone were approximately US$ 900 million, making it the world's biggest selling fungicide.

Field application of the natural strobilurins was not possible because of difficulties in their large-scale production and their relative volatility and photochemical instability. Thus, efforts were directed at chemical optimization. Azoxystrobin, kresoxim-methyl, metominostrobin, and trifloxystrobin, some of the presently commercialized strobilurins, altogether have a wide spectrum of activity. This class of compounds possesses a unique spectrum of activity. Although the simultaneous control of pathogens belonging to different classes, such as powdery mildews (ascomycetes) and rusts (basidiomycetes), was already known for triazoles, strobilurins were able to control simultaneously powdery and downy mildews for the first time, which is particularly useful for crops such as grapevine as well as many others.

Other Chemical Families

Over the years, industrial research programs have resulted in the development of valuable crop protection compounds with many desirable properties including specificity, systemicity, curative and eradicant action, and high activity at low use rates.

As an example, SDHIs inhibit succinate dehydrogenase in complex II of the mitochondrial respiratory chain. Development of SDHIs can be traced back to three generations. The first generation (e.g., carboxin) was developed in the 1960s and used as a seed treatment against *Rhizoctonia* spp. Mepronil and flutolanil are representative of the second generation and were introduced in the 1980s. They are also active against basidiomycetes, particularly *Rhizoctonia* spp., and are used to control rice sheath blight in rice. The leading products of the third generation of SDHIs are boscalid and penthiopyrad, whose spectrum of efficacy has broadened to include ascomycetes.

At present, the CAA fungicides used commercially include dimethomorph, flumorph, pyrimorph, benthiavalicarb, iprovalicarb, valifenalate, and mandipropamid. They specifically act against oomycete pathogens and probably have a common mode of action. Soon after dimethomorph was introduced in 1993, and despite recommendations to always use in combination with multisite fungicides, less sensitive populations of *P. viticola* were observed in a number of vineyards in France and Germany.

Representative compounds of some of the most important fungicide chemical families are presented in Table 1.

Environmental Fate

Synthetic organic fungicides belong to different chemical classes, and it is thus difficult to generalize their behavior in

Table 1 Physical–chemical properties of representative compounds of some of the most important fungicide chemical families

Chemical family	*Example*	*Mode of action*	*pK_a*	*Water solubility ($mg\ l^{-1}$, 20–25 °C)*	*Octanol/water partition coefficient log P (K_{OW})*	*Normalized soil organic carbon–water partition coefficient (K_{OC})*	*Aerobic soil half-life (days)*
Ethylenebis (dithiocarbamate)	Mancozeb 	Multisite action (M3)	10.3	6.2	1.80	2000	6–15
Benzimidazole	Benomyl 	β-Tubulin assembly in mitosis (B1)	4.48	2.9	1.37	1900	0.79
N-Trihalomethylthio (phthalimide)	Folpet 	Multisite action (M4)	-3.34 ± 0.20	0.8	3.11	143.9–304	8–14
Dicarboximide	Vinclozolin 	Osmotic signal transduction – MAP/histidine kinase (*os-1*, *Daf1*) (E3)	n.a.	2.6	3	100–735	3–21
Triazole	Penconazole 	C14-demethylase in sterol biosynthesis (*erg11/cyp51*) (G1)	1.51	73	3.72	2205	133–343

Phenylamide (acylalanine)	Metalaxyl 	Nucleic synthesis (RNA polymerase I (A1))	$\ll 0$	8400	1.75	30–300	10–40
Anilinopyrimidine	Cyprodinil 	Amino acid and protein synthesis (methionine biosynthesis (D1))	4.44	13	4.0	1706	20–60
Phenylpyrrole	Fludioxonil 	Signal transduction (MAP/histidine kinase, *Os-2*, *HOG1* (E2))	pK_a 1 < 0	1.8	4.12	75 000	140–350
Strobilurin	Kresoxim-methyl 	Target site and code: complex III, cytochrome bc1 (ubiquinol oxidase) at Qo site (cyt b gene) (C3)	< 0	2.0	3.4	219–372	<3

Data from Bermúdez-Couso et al. (2007); FRAC Code List 2014 (Fungicides sorted by mode of action); Komárek et al. (2010); Tomlin (1997); n.a. – not available.

the environmental compartments. In soils, fungicide fate is also significantly influenced by soil properties. Some fungicides have been detected in surface waters at concentrations higher than the EU regulatory limit, and it can be assumed that their extensive use poses a potential risk for the environment and human health. Therefore, the choice of fungicides should be performed carefully in accordance with good agriculture practices, physical–chemical characteristics of the soils, and climatic and hydrogeological regimes.

The fate of fungicides in soil is governed by processes that affect their persistence, such as chemical and microbial degradation, and processes that affect mobility, which involve adsorption, diffusion, absorption by plants, runoff, wind erosion, volatilization, leaching, and assimilation by microorganisms. The adsorption process is essential in the fate of pesticide in soils. The most common quantitative measurement of the sorption of organic pollutants by soils from aqueous solution is the soil organic carbon–water partitioning coefficient, K_{OC}. Thus, compounds with higher K_{OC} values will be less mobile than those with lower values.

Nearly 25% of the agrochemicals used in the world are chiral and this property can influence all aspects due to the possible different activities of stereoisomers. Despite having exactly the same physical and chemical characteristics, when exposed to a chiral environment, stereoisomers generally behave differently and this can lead to diverse activities, toxicologies, or degradation patterns.

Reduction of Fungicide Levels in Food

Pesticide residues are traces of pesticide active ingredients and metabolites that remain on food after being applied on the farm or in postharvest handling, including any specified derivatives, such as degradation and conversion products, metabolites, reaction products, and impurities considered to be of toxicological significance.

Pesticide degradation rates depend upon many factors, including characteristics of the compound and processing conditions. At high levels, pesticide residues can cause poisonings when ingested, but these types of poisonings are relatively rare. Cumulative effects of low-level exposures through pesticide residues in food have created concern and scientific and political debate for more than a century. Producing definitive answers on the effects of lifelong, low-level exposure to pesticides is extremely difficult and tests the limits of toxicology and epidemiology.

The common food processing operations along with the degree of pesticide residue removal, including fungicides, in each process have been reviewed. These processes included baking, bread making, dairy product manufacture, drying, thermal processing, fermentation, freezing, infusion, juicing, malting, milling, parboiling, peeling, peeling and cooking, storage, storage and milling, washing, washing and cooking, washing and drying, washing and peeling, washing peeling and juicing, and winemaking. Extensive literature review demonstrates that in most cases, processing leads to large reductions in residue levels in the prepared food, particularly through washing, peeling, and cooking operations.

Fermentation processes also influence pesticide residues in food. In most cases, fermentation leads to large reductions in original residue levels, with the formation of new pesticide by-products. The behavior of residues depends on the physical–chemical properties of the pesticide and the nature of the process. The presence of pesticides may decrease the growth rate of fermentative microbiota (yeasts and bacteria), which may cause stuck and sluggish fermentations. The observed changes have repercussions on several aspects of food sensory quality (physical–chemical properties, polyphenolic content, and aromatic profile) of fermented food.

The misuse of pesticides, including fungicides, may leave harmful residues in grapes after harvest that may pass to the must and eventually to the wine during fermentation, which involves a possible health risk. The proper use of pesticides does not cause a contravention of MRLs in grapes, and numerous studies have provided data on the dissipation rates of some pesticides in wine grapes and during winemaking. Azoxystrobin, cyprodinil, fludioxonil, and tebuconazole showed different disappearance rates, whereas pyrimethanil residues remained constant up to harvest. The residues of fenhexamid in grapes decreased rapidly to one-third of the initial concentrations after almost 1 week after the application. The order of dissipation rates in grapes for some fungicides widely used in vineyards was found to be vinclozolin > fenarimol > metalaxyl > penconazole > mancozeb.

Residues of boscalid, cyprodinil, dimethomorph, fenhexamid, metalaxyl, procymidone, and tebuconazole have been found in wine samples, being boscalid, cyprodinil, dimethomorph, and fenhexamid frequently determined pesticides in wine samples. Since some pesticides are less soluble, much higher residue concentrations were detected in cake than in crushed grapes and must (procymidone > cyprodinil > dimethomorph > boscalid > fenhexamid > metalaxyl > tebuconazole > azoxystrobin > quinoxyfen). The main processes that significantly reduced pesticide residues in the vinification of grapes are pressing and separation of lees from wine after alcoholic fermentation. In the processing of white grapes, the clarification of must is also an important factor in significantly reducing pesticide residues.

The influence of ten new-generation fungicides (ametoctradin, benthiavalicarb-isopropyl, boscalid, cyazofamid, dimethomorph, fenhexamid, kresoxim-methyl, mepanipyrim, metrafenone, and pyraclostrobin) on the fermentative activity of *Saccharomyces cerevisiae* yeast was evaluated in pasteurized red must. The presence of ametoctradin, dimethomorph, and mepanipyrim seemed to affect sugar-to-ethanol yield in the stationary phase. Additional experiments were carried out for these three fungicides in ecological red must from *V. vinifera* cv. *Tempranillo*. When the must was unfiltered, the fermentative activity of yeasts was unaffected by the presence of these fungicides. However, when the must was previously filtered, slight decreases of biomass and ethanol production, as well as in fruity aroma, were registered.

In the EU, some of the most frequently detected fungicide residues in food monitoring programs were propamocarb, thiabendazole, boscalid, DTCs, and imazalil. Together with chlorpyrifos (an insecticide), these substances were found in 5–25% of the samples analyzed.

In field experiments, enantioselective dissipation of penconazole occurred in head cabbage and pak choi, with the preferential degradation of (−)-penconazole, and resulted in an enrichment of the (+)-penconazole residue in the two

vegetables. However, the enantioselective behavior was not observed in cucumber and tomato. This was the first report of enantioselective behavior of penconazole.

Effects on Health

Regarding pesticides, which include fungicides, many health impact assessment studies have been carried out in the United States, Europe, and elsewhere in the past 15–20 years. In Europe, significant studies are also currently in progress to assess health effects caused by different types of environmental contaminants, including plant protection products. The large number and the chemical diversity of active substances and their different toxicity characteristics are of utmost importance. Although significant data gaps exist for a large part of the approved active substances, it has been found that many are positive for at least one health effect, after chronic and/or acute exposure, including carcinogenicity, reproductive, and neurodevelopmental disorders, as well as endocrine disruption.

Although not sufficiently in many cases, negative effects of some pesticides on human health, such as neurological dysfunctions and diseases, hypospadias, endocrine disruption, and increases in the incidence of cancers, have been reported.

Some fungicides can affect the endocrine system and interfere with important developmental processes in humans and wildlife. Endocrine-disrupting compounds represent a challenge, as their effects depend on both the level and timing of exposure, being especially critical when exposure occurs during development. In rat studies, fetal exposure to various chemicals with androgen receptor antagonist properties (e.g., the fungicides vinclozolin, procymidone, and prochloraz) causes disturbances of testosterone production and results in hypospadias, cryptorchidism, impaired fertility, and dysgenetic testicular histology. Studies with vinclozolin have suggested that this fungicide could be a potential comutagenic compound in human beings.

Some triazoles, including epoxiconazole and propiconazole, are also used as pharmaceuticals for treatment of fungal infections. Azole fungicides act by inhibition of enzymes necessary for the fungal cell membrane. Several members of this family have a number of toxicological risks, including carcinogenicity and reproductive toxicity. In mice, epoxiconazole and propiconazole have been reported as hepatocarcinogenic. Tebuconazole and epoxiconazole have shown antiandrogenic activity.

Exposure to pesticide residues, particularly during periods of rapid growth such as fetal life and infancy, may affect a child's health and development by increasing the risk of congenital malformations, cancer, malabsorption, immunologic dysfunction, endocrine disease, and neurobehavioral deficiencies.

Ethylenebis(dithiocarbamate) fungicides affect the thyroid gland and the lymphocyte genome, enhance the production of the thyroid-stimulating hormone, and probably cause higher prevalence of solitary nodules of workers. Mancozeb is also probably hormonally active as an estrous cycle-disrupting fungicide. Studies have suggested that seasonal application of mancozeb may cause changes of some immune parameters, but does not pose a significant immunotoxic risk for vineyard workers. After the exposure of workers to quinoxyfen, red, itchy rash with blistering was noticed.

The fungicides for which there has been evidence for endocrine disruption in humans and wildlife include fenbuconazole, pentachlorophenol, prochloraz, procymidone, pyrimethanil, tributyltin, trichlorophenate, triphenyltin, and vinclozolin.

In Europe, extensive legislation outlines global principles for including parent compounds and their metabolites in residue definition for risk assessment based on their significant contribution to the dietary risk (irrespective of their source) considering potential exposure from diet (abundance in food/feed items and drinking water and their relative amount) and relative toxicity.

Human health risks resulting from exposure to fungicides and mycotoxins via food have been compared, since they may be regarded as counteracting agents – fungicides are applied to protect crops from being infected by fungi and thus prevent the growth of mycotoxin-producing organisms but potentially lead to residues of the applied fungicides on or in the crop. An integrated probabilistic risk assessment model was used by the authors to compare the estimated health impacts on humans caused by crops contaminated with the fungicides spiroxamine and tebuconazole or with the mycotoxins deoxynivalenol and zearalenone. Based on the available data and the assumptions made, none of the four compounds was found to have impact on human health in the addressed scenarios.

Maximum Residue Levels

For food samples, pesticide residues have been regulated by several legislative authorities throughout the world, basically concerned with the quality, efficacy, and safety in the use of pesticides; however, there is not a global harmonized legislation. EU has set MRLs that are in general in the range of 0.01–10 mg kg^{-1}, depending on the combination commodity/pesticide. The lowest value is characteristic of banned compounds because it is considered as the minimum limit of detection (LOD) achievable. A value of zero is considered below the LOD because of the inaccuracies in the measurement methods available.

The more stringent regulations established for pesticides in food are those applied in food intended for infant consumption. Children and infants represent a vulnerable risk group of the population in terms of pesticide toxicity, and rigorous regulations have been set to protect them from dietary exposure to these chemicals. The EU specified the general MRL of 10 μg kg^{-1} for any individual pesticide residue in baby food.

Nevertheless, for most of the studied fungicides, MRLs have not been established in transformed products such as wine. For wines elaborated in the EU from September 2008, MRLs were established for boscalid (5000 mg l^{-1}), captan (20 mg l^{-1}), and pyraclostrobin (1000 mg l^{-1}). Other countries, such as Italy and Switzerland, have also established MRLs for some of the fungicides (vinclozolin, dichlofluanid, and boscalid in Switzerland at 1000 mg l^{-1} in all cases and quinoxyfen, boscalid, and pyraclostrobin in Italy at 10, 1000, and 50 mg l^{-1}, respectively).

In the United States, the Federal Food, Drug, and Cosmetic Act (FFDCA) authorizes EPA to set maximum residue levels,

or tolerances, for pesticides used in or on foods or animal feed.

Analytical Methods

The analysis of pesticide residues represents a basic instrument for the protection of human health and for trade and official control purposes. Despite pesticide trace analysis is being carried out since the 1970s, it still remains a challenge because different chemical classes may be present at low concentrations in complex matrices. Therefore, the development of multiresidue analytical methods with higher recoveries and lower limits of detection is an ongoing process, as well as incorporating the ultimate innovations.

Liquid chromatography coupled to mass spectrometry (LC-MS) and tandem mass spectrometry (LC-MS/MS) is increasingly applied for measuring pesticide residues, because the metabolites involved in residue definition are generally more polar than the parent pesticides, making LC-MS ideal for their detection. In addition, researchers are increasingly using ultra-high-resolution liquid chromatography (UHPLC) to enable simultaneous analysis of larger groups of pesticides and their degradation products as well as time-of-flight mass spectrometry (TOF-MS) and quadrupole time-of-flight mass spectrometry (QqTOF-MS) to identify new active substances, degradation products, and metabolites.

Analytical methods for determining fungicide residues involve several extraction and purification steps to remove the potentially interfering compounds that are generally present at higher concentrations than the pesticide residues. Solid-phase extraction (SPE); solid-phase microextraction (SPME); stir bar sorptive extraction (SBSE); the quick, easy, cheap, effective, rugged, and safe (QuEChERS) method; hollow fiber liquid phase microextraction; matrix solid-phase dispersion (MSPD); and single-drop microextraction, among others, have been proposed for the extraction of fungicides as alternative to liquid–liquid extraction.

The trends in recent years have been toward the use of smaller sample sizes, more environmentally friendly and safer approaches, and faster and less laborious methods aiming at high recoveries and good precision.

Final Remarks

Chemical control will continue to play a central role in optimizing yields from the world's crops for the future, and fungicides are expected to remain as essential tools for plant disease management. The availability of compounds developed by exploring novel chemistry, the activation of plants' natural resistance mechanisms, and the use of natural products are expected to contribute to sustainable agriculture, providing benefits to users, environment, and society as a whole, not forgetting the continuation of studies on fungicide impacts on the environment and human health.

Game Meat

In a global sense, game refers to wild animals and birds, with the term 'game' being used for culinary purposes to describe all birds and animals that are hunted for food. In the European Union (EU), wild game is defined in the EU Regulation (EC) No. 853/2004 as being "wild ungulates and lagomorphs, as well as other land mammals that are hunted for human consumption and are considered to be wild game under the applicable law in the Member State concerned, including mammals living in enclosed territory under conditions of freedom similar to those of wild game, and wild birds that are hunted for human consumption." The same legislation also defines 'small wild game' as being wild game birds and lagomorphs (rabbits and hares) living free in the wild and 'large wild animals' as land mammals, living free in the wild that do not fall within the small wild game definition. In the United States, wild game refers to wild land mammals (including those living within an enclosed area under conditions of freedom) that are hunted and wild birds. Large native game animals in the United States include antelope, buffalo, caribou, deer, elk, moose, and reindeer, while game birds include wild turkeys, wild geese, wild ducks, grouse, quail, pheasant, and other nondomesticated species of fowl.

Around the world, a vast number of wild animals are harvested for several reasons including for food purposes and sport hunting, with the type and range of animals hunted depending on climate, animal diversity, tradition, local taste, legislation, and local perception on what can or cannot be legitimately hunted. For example, in Europe, the most frequent big game species include red deer, roe deer, fallow deer, mouflon, and wild boar, while in South Africa, the hunted game species are mainly several African ungulates including springbok (*Antidorcas marsupialis*), blesbok (*Damaliscus pygargus phillipsi*), and kudu (*Tragelaphus strepsiceros*), among other antelopes. Game meat consumption is also related to the consumers' acceptability, which is influenced by several factors including cultural, religious, and ethnic aspects, organoleptic characteristics, price, and availability, among others.

Nowadays, besides being hunted as free-running animals in the wild, originally, wild species of animals are being raised, domestically or semidomestically, for sale. Farmed game is used not only for meat production but also for animal breeding, aiming at their subsequent release into the wild for restocking the game population in private and community hunting areas. According to the EU Regulation (EC) No. 853/2004, farmed game is defined as being farmed ratites (such as ostrich) and farmed land mammals other than domestic bovine, porcine, ovine, and caprine animals and domestic solipeds (single-hoofed, e.g., horse). With the exception of farmed rabbits, which are often produced in intensive systems, most of the other farm-raised game (such as deer, reindeer, and wild boar) is generally farmed using extensive systems. In the United States, species such as the American elk, wild boar, pheasant, and antelope (blackbuck (*Antilope cervicapra*) and nilgai (*Boselaphus tragocamelus*)) are being farm-raised, while in Europe, in particular in northern countries, the most common farmed-raised animals are deer (including several different species such as red deer (*Cervus elaphus*) and fallow deer (*Dama dama*)) and reindeer (*Rangifer tarandus*). Deer production is also a well-established industry in New Zealand. To distinguish farmed-raised game from wild free-running animals, some authors proposed to designate the first as venison, associating the second as being African game antelope. However, the designation 'venison' is most frequently used as a culinary term referring to meat not only from deer but also from other cervids such as reindeer, elk, and moose.

Although production and consumption data for farmed game are scarce, according to the Food and Agriculture Organization (FAO) Statistics Division, game meat production has been steadily increasing during the last decade (from approximately 1.59 million tons in 2000 to more than 1.99 million tons in 2012), which can possibly be related to a general increased consumption of game meat.

In fact, in the last years, game meat is increasingly perceived as a delicacy product; thus, its consumption in restaurants and at home dinners has also been increasing. This can be explained by several different motivations including the perception that game meat is healthier, its particular taste and flavor, the idea that game meat can be considered as a biological product (free-running animals without the use of anabolic steroids and other drugs), and the attraction for new experiences such as tasting exotic meats.

Game Meat: Sources and Production

Hunting has been practiced since ancestral times being one of man's main sources of food in prehistoric ages. Over millennia

of civilization, with the development of agriculture and domestication of animals, the importance of hunting and game meat as a means of survival radically decreased in most parts of the world. Nevertheless, in the present time and particularly in developing countries, a variety of different wildlife species is still sought as food as they inevitably remain a cheap source of protein for many population groups. In Africa and other regions of the globe, such as the Amazon in South America, bushmeat (according to the Convention on Biological Diversity, bushmeat is a term used to describe any terrestrial wild animal in tropical and subtropical countries harvested for subsistence or commercial purposes) remains of major importance either for consumption or to obtain revenue from trade. Although some recent data have been published on the bushmeat consumption in some parts of the world, such as in South America where consumption in indigenous communities can attain values of 35.8 to 191.6 kg per capita year, the level of consumption is very difficult to estimate due to several factors, such as unreported data concerning harvested animals, direct sales, trade in hidden markets, and illegal poaching. However, it is generally accepted that in rural African areas, bushmeat continues to represent a vital dietary item for a vast number of people although high variations across the continent exist. Apart from being consumed by local populations, game meat is also frequently tasted by tourists who visit those regions, although this represents a minor percentage of the total game meat consumed.

During the last decades, the potential of African ungulates for meat production is also being taken into account for meat exportation, with different wild animals that roam in large enclosures being harvested for this purpose. In 2005, it was estimated that South Africa exported the deboned meat from 160 000 game carcasses, with commercially harvested antelope being predominately the springbok (*Antidorcas marsupialis*, >80%), blesbok (*Damaliscus pygargus phillipsi*), and kudu (*Tragelaphus strepsiceros*), while other species such as blue wildebeest (*Connochaetes taurinus*), impala (*Aepyceros melampus*), and gemsbok (*Oryx gazella*) were exported in smaller numbers. Nowadays, most of the game meat harvested in Africa for exportation is obtained from game ranches with the promotion of legal wild meat production through game ranching being advocated as a way to conciliate wildlife conservation, rural food security, and community livelihood improvement. With the evolution of wildlife management, recurrent droughts, and the rising demand for tourism and safari hunts, wildlife ranching industry has been increasing in countries such as Zambia, Zimbabwe, Botswana, and Namibia, being most developed in southern Africa. In game ranching, wild animals roam free and are managed on natural vegetation although they are generally maintained in defined fenced areas. The incomes of game ranching arise mostly from sport/trophy hunting and ecotourism, though animal culling for meat production also generates relevant revenue, being also important to simultaneously control animal surpluses.

In the past 50 years, the farming of different game species has grown considerably worldwide possibly related to a higher consumption of game meat as it is generally perceived as a healthy food with distinctive and appreciated organoleptic qualities. To respond to an increasing consumer's demand for venison, in some countries such as New Zealand, farmed deer production has advanced to a level where typical livestock farming is applied, thus assuring a regular supply of quality meat. In New Zealand, red deer is the major farmed species, accounting for about 85% of the total farmed deer, which nowadays corresponds to approximately 1.1 million animals. According to the European Food Safety Agency (EFSA) data, among the cervids, the fallow deer and the red deer are the most common species farmed in Europe, with approximately 280 000 animals farm-raised in 2010, although less than half of these are slaughtered annually. In some European countries (Sweden, Norway, and Finland) and in Alaska, venison production is dominated by traditional reindeer farming, which is generally performed in a less-intensive system when compared to red deer farming since the animals are free-ranging in the forests/mountains instead of being enclosed in fenced areas. The animals that pasture extensively in herds may belong to different owners, being recognized by specific cut marks on their ears. In the United States and Canada, different cervid species are being farm-raised including the elk (*Cervus canadensis*), the fallow deer, the sika deer (*Cervus nippon*), the axis deer (*Axis axis*), and the white-tailed deer (*Odocoileus virginianus*).

Regarding small game animals, as referred, rabbits are generally farmed-raised mostly using intensive systems, while hares are hunted in the wild. Several game bird species, including migratory birds such as geese and ducks, are also frequently hunted worldwide, with a small number of species, such as pheasants, also being breed in captivity for restocking hunting areas or for boosting natural populations.

Chemical Composition of Game Meat and Nutritional Considerations

Nowadays, consumers are increasingly demanding for healthy and safe products as they are concerned about the food they eat. In general, consumers associate game to a healthier, thinner, and tasty meat arising from animals that are supposed to be free of hormones and drugs, such as antibiotics. In fact, game meat can generally be considered to be highly nutritious, as it is a valuable source of protein, minerals, and vitamins. Table 1 shows a compilation of data published on the proximate composition of different game meat. The values presented in Table 1 show that, considering the evaluated animals, protein contents are generally higher than 20%, with some species presenting levels around 25% protein. On the contrary, total fat content can be considered as being low, as it is generally inferior to 5%, with some species including different ungulates, lagomorphs, and game birds presenting levels less than 0.5% fat (Table 1).

Currently, it is of general agreement that total fat intake is certainly related to health risks; however, it is also accepted that concerning fat, both quantitative and qualitative aspects are important. Thus, the type of consumed fat or fatty acids is of critical importance. According to the 2010 FAO recommended dietary intakes for total fat and fatty acids, dietary fat should provide 20–35% of total energy and saturated fatty acids (SFA) should not exceed 10%. Individual SFA have different biological effects, with lauric, myristic, and palmitic acids increasing LDL cholesterol, while stearic acid is not considered to have such effect. Thus, the replacement of SFA (C12:0–C16:0) with polyunsaturated fatty acids (PUFA), whose consumption is

Table 1 Proximate composition of meats from different game species (g/100 g; mean values are given)

Animal species			*Proximate composition (g per 100 g)*			
		Samples	*Moisture*	*Protein*	*Fat*	*Ash*
Ungulates						
Kudu[a]	*Tragelaphus strepsiceros*	Longissimus dorsi muscle; males and females, total $n=18$	74.14–74.49	23.60–24.30	1.56–1.58	1.23–1.29

associated with health benefits, has been recommended for decreasing the LDL cholesterol and total/HDL cholesterol ratio and decreasing the risk of coronary heart disease. A similar but lesser effect could be achieved by replacing SFA with monounsaturated fatty acids (MUFA). Although the 2010 FAO recommended dietary intakes do not mention a specific n-6/n-3 PUFA ratio, a daily intake ratio of 4:1 and a ratio of PUFA to SFA above 0.4 have been suggested by different authors.

Table 2 presents the fatty acid composition reported for different game species, including ungulates (African ungulates and cervids), lagomorphs, and game birds. As can be observed, in general, game meat presents a favorable fatty acid profile, with some game meats presenting low levels of SFA and/or considerably high levels of PUFA. Total SFA ranged from 22.2% in duiker to 51.12% in impala, with several large game animals presenting higher levels of stearic acid than

those of palmitic acid (the last considered as being potentially atherogenic while the former having neutral effects on health). In general, a high proportion of PUFA was reported for the species presented in Table 2, in particular for kudu, springbok, common duiker, and quail. Pheasant, pigeon, and wild boar were reported to present a higher level of MUFA than of SFA. In general, data reported for the different game meats evidenced desirable ratios of PUFA/SFA and n-6/n-3 PUFA. Ratios of PUFA/SFA ranged from 0.25 to 1.81, with all meats presenting ratios above the recommended value of 0.4, with the exception of some samples of pigeon. The high variability of values reported for some species could possibly be related to, not only different factors, such as diet, but also genetic origin, age, sex, region, and climate. A high proportion of n-3 PUFA is also evidenced by the ratios n-6/n-3 PUFA, which were below the recommended ratio of 4:1, with the exception of game birds and some wild boar samples (Table 2). For ungulates, high levels of the essential α-linolenic acid (ALA, C18:3n3) were reported, ranging from 1.92 to 4.85%. According to FAO recommendations, the minimum dietary requirement of ALA for adults to prevent deficiency symptoms is >0.5% of total energy, while a dietary intake of 0.250 g–2.0 g per day of n-3 long-chain PUFA eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) is recommended as part of a healthy diet.

Other Health Considerations

Microbiological Issues

The microbiological conditions of game carcasses and meat can vary widely. Carcasses from farmed game slaughtered and dressed at suitable abattoirs can present microbiological conditions comparable to that of carcasses from livestock, while those obtained from hunted animals will depend on several factors that can influence the possibility of carcass contamination and the potential growth of contaminating bacteria. These factors include the health of the animal, the types of microorganisms carried by each species (mainly on the hide and gastrointestinal tract), the circumstances in which the animal is killed, the conditions during evisceration in the field, the time before cooling, and the conditions under which the carcasses are transported, stored, and processed, among others. Currently, the vast majority of game, either hunted or farmed, is killed with a rifle or shotgun; thus, another important factor is the skill of the hunter as the anatomical shooting location is of critical influence for the carcass hygiene. For large game animals, such as deer, the hunters, generally, target the chest so the shot passes through the heart and lungs, though in deer culling, the animal is frequently shot in the head or neck to minimize the carcass damage. However, due to several reasons, such as the hunters' inexperience, the animal can be killed by shooting the abdominal area that can damage the gut, causing bacteria contamination. The skill of the hunter is also very important in the evisceration process to avoid damaging the gut.

Despite the increasing quality of hygiene standards in game meat harvesting and handling, human cases of infection can still occur. The relevant biohazards related to game meat, including parasites, bacteria, and viruses, can vary among countries according to the epidemiology and food consumption habits of each region. According to the EFSA Panel on Biological Hazards, *Salmonella* spp. in farmed wild boar and *Toxoplasma gondii* in farmed deer and farmed wild boar were recently ranked as a high priority for farmed game meat inspection, while *Trichinella* spp. in wild boar was ranked as low priority due to current controls, which should be continued.

Besides being a possible source of human infection due to foodborne diseases, wild game animals can also represent important reservoirs of zoonotic infections. In particular, due to wildlife contacts with domestic animals, there is an increasing concern regarding the possibility of disease transmissions.

Exposure to Lead from Gunshot

The majority of game animals are killed by gunshot, with hunters generally using lead-based bullet or shot ammunition, especially for large game animals. Lead is a nonessential and toxic metal that adversely affects a wide range of systems in the human body, with some effects being observed at very low levels of lead in the blood (PbB), such as neurocognitive and neurodevelopmental deficits in children and elevated systolic blood pressure and chronic kidney disease in adults. Thus, game meat obtained from animals shot with this type of ammunition can be a potential source of dietary lead for humans, representing a potential hazard. Previously, there was a general belief that the dietary lead exposure from game meat would be low because the mass of the projectile(s) remained in one large piece that either passed through the carcass or was easily removed, the meat around the wound channel is generally removed and if fragments of ammunition were visible in the meat, they are also discarded during food preparation or, at the most, consumers avoid swallowing them. However, recent studies showed that game meat can contain small and numerous bullet fragments, visible in radiographs, which can be widely dispersed relative to the wound channel, with this being particularly noticed if bullets impact with the animal's bones. Hence, several authors have been suggesting that lead exposure from game meat can pose a potential health risk, in particular for high-level consumers, such as subsistence hunting communities and the hunters' families.

Following the request of the European Commission, EFSA recently produced a scientific opinion on the risks to human health related to the presence of lead in foodstuffs. In this report, the Panel on Contaminants in the Food Chain concluded that the provisional tolerable weekly intake (PTWI) of 25 $\mu g\ kg^{-1}$ b.w. dietary lead, previously set by the Joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives (JECFA), was no longer appropriate as there was no evidence for a threshold for critical lead-induced effects. Based on data from different foods, game meat was among those that presented the highest levels of lead; thus, frequent consumers of game meat were included in the group with higher lead exposure levels. However, the impact of a specific diet, assuming a weekly meal of 200 g of game meat, did not appear to cause a greater risk regarding systolic blood pressure compared to other adult consumers. In general, the panel concluded that the risk of clinically important effects on either the cardiovascular system or kidneys of European adult consumers, at current levels of lead exposure, is low to

negligible, but for infants, children, and pregnant women, there is a potential concern for effects on neurodevelopment. However, it should be highlighted that the panel also referred that the possibility of effects on some consumers having a diet rich in game meat could not be excluded. In fact, different studies have been pointing out an association between game consumption and lead levels in the blood, although a lack of correlation was observed in some cases.

Adulteration of Game Meat and Processed Products

As referred, the consumption of game meat has been increasing in the last years. In general, game meat and products thereof are considered delicacy products and command higher prices compared to other meat products, thus being susceptible targets for frauds. Adulteration due to the fraudulent substitution of game by other lower-value meat species occurs mainly for economic reasons, with processed products being particularly prone to this type of unscrupulous practices. Therefore, the authentication of game meat and game meat products can contribute to avoid unfair competition among producers and to provide accurate information for consumers, being also important for safety and public health reasons, that is, in what concerns possible zoonoses affecting game animals and birds. So far, different methodologies, mainly relying on protein or DNA analysis, have been proposed for meat species identification purposes. However, in the last years, DNA-based methods have been elected for species identification as they present several advantages when compared to protein-based techniques, namely, the ubiquity of DNA in every type of cells, the higher stability of DNA molecules, and high specificity. Moreover, when evaluating processed meat products, protein-based methods present limitations, such as the possibility of protein denaturation and modification of specific epitopes associated with processing. Among DNA-based methods, polymerase chain reaction (PCR) is the most commonly used molecular technique due to its simplicity, fastness, specificity, and sensitivity. Until now, several different techniques have been proposed for verifying game meat and product authenticity, including species-specific PCR and real-time PCR, random amplified polymorphic DNA (RAPD) analysis, PCR–restriction fragment length polymorphism (PCR-RFLP) analysis, PCR sequencing, and DNA barcoding.

In RAPD, a DNA band pattern or fingerprinting is obtained by amplification using short arbitrary primers. The advantage is that species-specific patterns are generated without amplifying information about the gene fragments. However, it is difficult to obtain reproducible results and this technique is not suited for the identification of a targeted species in admixed meats or processed products. In PCR-RFLP, sequence variations within defined DNA regions are exploited to obtain characteristic restriction patterns. This technique has been proposed for the identification of different game meats with the successful identification of meats from closely related species, such as pork and wild boar meats. However, similarly to RAPD, this technique might not be applicable in complex and processed matrices since results may show a combination of miscellaneous restriction patterns that are difficult to understand.

Among the referred techniques, species-specific PCR is being increasingly used due to its simplicity, high specificity, and high sensitivity, being suitable for meat authentication studies, even in complex and processed foods. In this technique, a primary aspect consists of primer design targeting specific DNA fragments, which allows the specific identification of a target species in complex matrices containing a pool of heterogeneous DNA sequences. Even though the use of both nuclear and mitochondrial genes has already been described for the identification of game meat species, the latter offer the advantage of being several folds more abundant than nuclear DNA, thus improving sensitivity. More recently, quantitative analysis has been achieved by the use of real-time PCR since the target amplification is directly monitored along each amplification cycle. Data collection is performed by using fluorescent molecules able to provide a strong correlation and to measure minute amounts of DNA. Fluorescent compounds used in real-time PCR approaches for game meat identification include general dyes that intercalate DNA molecules, such as SYBR Green and EvaGreen, and different probe-based systems such as hydrolysis TaqMan probes. The use of dyes offers a suitable and less expensive alternative, while the use of probes that specifically bind within the target sequence adds specificity to the reaction and generally permits the use of smaller amplicons, which is especially useful for processed foods.

Although still few works report its application, DNA barcoding has emerged in the last years as a promising tool for the authentication of meats and meat products including game. In the near future, it is expected that newly and advanced technologies for high-throughput sequencing, namely, next-generation sequencing (NGS), coupled with DNA barcoding, can be applied to meat species identification, allowing the simultaneous identification of multiple species in complex matrices.

In spite of the utility of DNA-based methods in species identification for authenticity purposes, the majority of published works are devoted to the development of techniques with fewer referring to its application. Although some studies reported that several commercial processed meat products evaluated for authenticity purposes were in good agreement with the labeled game species, recently, other works reported a high incidence of species substitution and mislabeling in game meat products sold in different countries. These recent results suggest the existence of fraudulent practices, thus evidencing the importance of control and inspection programs and the need for systematically verifying labeling statements.

Garlic

CS Charron, JA Milner[†], and JA Novotny, US Department of Agriculture, Beltsville, MD, USA

2016 Published by Elsevier Ltd.

Garlic (*Allium sativum* L.) has been used as a food and medicinal herb for thousands of years. Ancient references to the use of garlic date to at least the third millennium BCE. Early records include recipes from Mesopotamian cuneiform tablets and medical remedies detailed in the Egyptian Ebers Papyrus. Garlic is, in a sense, a controversial plant. While praised by many for its unique culinary roles and possible health benefits, garlic has been reviled by others for its pungency. These opposing perceptions ultimately are grounded in the underlying biochemistry of garlic. The characteristic aroma and flavor of crushed fresh garlic arise from a number of relatively simple sulfur compounds. With cooking or processing, additional sulfur compounds are generated, which in turn modify not only aroma and flavor but also potential health effects. The many forms in which garlic is ingested, and their corresponding diverse chemical profiles, make the study of garlic-related health benefits an interesting and challenging field. The widespread consumption of garlic and the long history of its use in folk medicine drive the research attention it has received.

Garlic: Sources and Production

Although garlic is thought to have originated in Central Asia and the majority of production occurs in Asia, garlic is currently cultivated throughout the world. As of 2011, over 20 million metric tons of garlic was harvested globally (Table 1). About 80% of the world's garlic production was in China, with India, Egypt, Korea, Russia, Myanmar, Bangladesh, the United States, Argentina, and the Ukraine accounting for approximately another 12% of the total. Garlic production has increased significantly in recent years. Over the 10 years from 2001 to 2011, the global garlic harvest has more than doubled with over 90% of this increase accounted for by China (Figure 1). Common subspecies of garlic are the softneck (*A. sativum* L. var. *sativum*) and hardneck (*A. sativum* L. var. *ophioscorodon*) types. Softneck garlic is typically grown for sale in large supermarkets because it is better adapted for mechanized planting and harvesting and stores longer than hardneck garlic. Softneck garlic bulbs generally have more but smaller cloves than bulbs of the hardneck type. Hardneck garlic grows well in cooler climates and is preferred by some for what they perceive as stronger, more complex flavors. Elephant garlic (*A. ampeloprasum* L. var. *ampeloprasum*) resembles true garlic but is biochemically different and botanically is more closely related to leeks.

Composition of Garlic and Garlic Preparations

One key to understanding the possibilities of garlic for human health and the sometimes divergent results of scientific studies exploring the biological effects of garlic intake is to understand the various ways that garlic is processed and consumed, and to recognize that the biochemical compositions of various garlic products often differ significantly. Generally, garlic is consumed either as a whole food as part of a meal or as a dietary supplement consisting of distinctive garlic-derived organosulfur compounds, often produced by extraction and concentration processes. As a food, garlic is prepared in multiple ways. Dehydrated garlic is used as a condiment and is commonly incorporated into many processed foods as a flavoring agent. Fresh garlic is most frequently sliced, chopped, or crushed and may be incorporated into recipes in its raw form or cooked by boiling, sautéing, baking, or roasting. Other culinary techniques for preparing garlic include aging in vegetable oil and pickling. As dietary supplements, garlic and garlic-derived products may be formulated as tablets, capsules, or liquid extracts. Many garlic-derived dietary supplements have undergone an extraction process that significantly alters the chemical compositions of the products, with the notable exception of dried garlic powder that is biochemically similar to raw intact garlic. Extracted formulations include aged garlic extract, steam-distilled garlic oil, and oil-extracted garlic macerate.

Intact or Dehydrated Garlic

Garlic bulbs not only are well known for their unique sulfur compounds but also contain nonsulfur compounds not ubiquitously found in plants. Among these are fructans, steroid saponins, and selenium. Fructans are fructose polymers and comprise over 90% of the nonstructural carbohydrates in garlic. In contrast, garlic does not contain monosaccharides or starch (glucose polymers). Steroid saponins are a kind of natural detergent consisting of a hydrophilic glycoside moiety attached to a lipophilic steroidal group. Saponins may have a cholesterol-lowering effect. Garlic is a selenium accumulator, and as such, selenium levels in garlic are highly responsive to selenium fertilization. Organoselenium compound in garlic includes Se-methylselenocysteine, which metabolizes to methylselenol and thereby exhibits anticarcinogenic and antioxidant activities. Other nonsulfur garlic constituents occurring at appreciable levels include arginine, γ-glutamylphenylalanine, and allixin (3-hydroxy-5-methoxy-6-methyl-2-penthyl-4*H*-pyran-4-one), a phytoalexin that accumulates with long-term storage of garlic bulbs.

Much of the research into the bioactive compounds of garlic has centered on its sulfur compounds. The total sulfur content in garlic is about 0.35% of its fresh weight. Predominant sulfur compounds in raw intact or dehydrated garlic are alliin (*S*-allylcysteine sulfoxide), γ-glutamyl-*S*-*trans*-1-propenylcysteine, and γ-glutamyl-*S*-allylcysteine (Figure 2). In whole garlic, these compounds constitute about 0.5–1.4%, 0.3–0.9%, and 0.2–0.6% of the bulb, respectively. Sulfur compounds occurring at lesser concentrations include isoalliin (*S*-*trans*-1-propenylcysteine sulfoxide), methiin (*S*-methylcysteine

sulfoxide), γ-glutamyl-*S*-methylcysteine, and γ-glutamyl-*S*-*cis*-1-propenylcysteine. *S*-Alkylcysteine sulfoxides such as alliin can be transformed to thiosulfinates when in the presence of water and the enzyme alliinase but are relatively stable in intact and dehydrated garlic.

Crushed or Cut Garlic

In intact garlic, alliinase is localized in vascular bundle sheath cells, whereas alliin is compartmentalized in mesophyll cells. Upon tissue disruption, the exposure of alliin to alliinase leads to the synthesis of allicin (diallyl thiosulfinate) in a matter of seconds. A similar enzymatic process occurs in the case of addition of water to garlic powder in which alliinase has been preserved. Allicin itself is moderately stable at room temperature. Allicin in undiluted crushed garlic has a half-life of about 2.4 days. Incubating crushed garlic in water extends the half-life of allicin, indicating the presence of garlic compounds that destabilize allicin in macerated cloves. In a process that is accelerated with increased temperatures, allicin decomposes through a series of steps resulting in polysulfides including diallyl disulfide and diallyl trisulfide, as well as allyl alcohol, propene, and sulfur dioxide. However, polysulfides are not present at significant levels in freshly crushed, room-temperature garlic.

Although γ-glutamyl-*S*-*trans*-1-propenylcysteine and γ-glutamyl-*S*-allylcysteine are far more stable than alliin under conditions of tissue rupture, they are metabolized as well, having a half-life of about 1 week. By the enzymatic activity of γ-glutamyl transpeptidase, they are quantitatively transformed to *S*-allylcysteine and *S*-1-propenylcysteine.

Aged Garlic Extract

This garlic formulation is produced by extraction of fresh chopped garlic in aqueous ethanol over the course of several months, after which the solution is filtered and concentrated. This process favors the generation of water-soluble compounds such as *S*-allylcysteine, *S*-*trans*-1-propenylcysteine, and *S*-allylmercaptocysteine with a concomitant decrease in the γ-glutamyl-*S*-alkenylcysteines. The aging process also yields smaller amounts of lipid-soluble diallyl sulfide, triallyl sulfide, diallyl disulfide, and other polysulfides. Allicin levels decrease rapidly although levels of alliin, which diffuses into the extract away from matrix-bound alliinase, change little for up to 2 years. Aged garlic extract is available in tablets and capsules as well as a liquid.

Steam-Distilled Garlic Oil

Steam treatment of crushed garlic causes allicin to react with itself, leading to a product high in mono- and polysulfides, in particular diallyl disulfide, diallyl trisulfide, allyl methyl disulfide, and allyl methyl trisulfide. In addition to allyl and methyl sulfides, 1-propenyl sulfides are also found in steam-distilled garlic oil. Allicin and other thiosulfinates as well as the γ-glutamyl-*S*-alkenylcysteines found in raw crushed garlic are not contained in garlic oil. Typically steam-distilled garlic oil is diluted in vegetable oil about 100–200-fold and is available in capsules.

Oil-Extracted Garlic Macerate

The extraction of homogenized garlic in soybean or other vegetable oils results in the decomposition of allicin to the oxygenated ajoenes and the ring-structured vinyldithiins. 2-Vinyl-4-*H*-1,3-dithiin constitutes about half of the sulfur

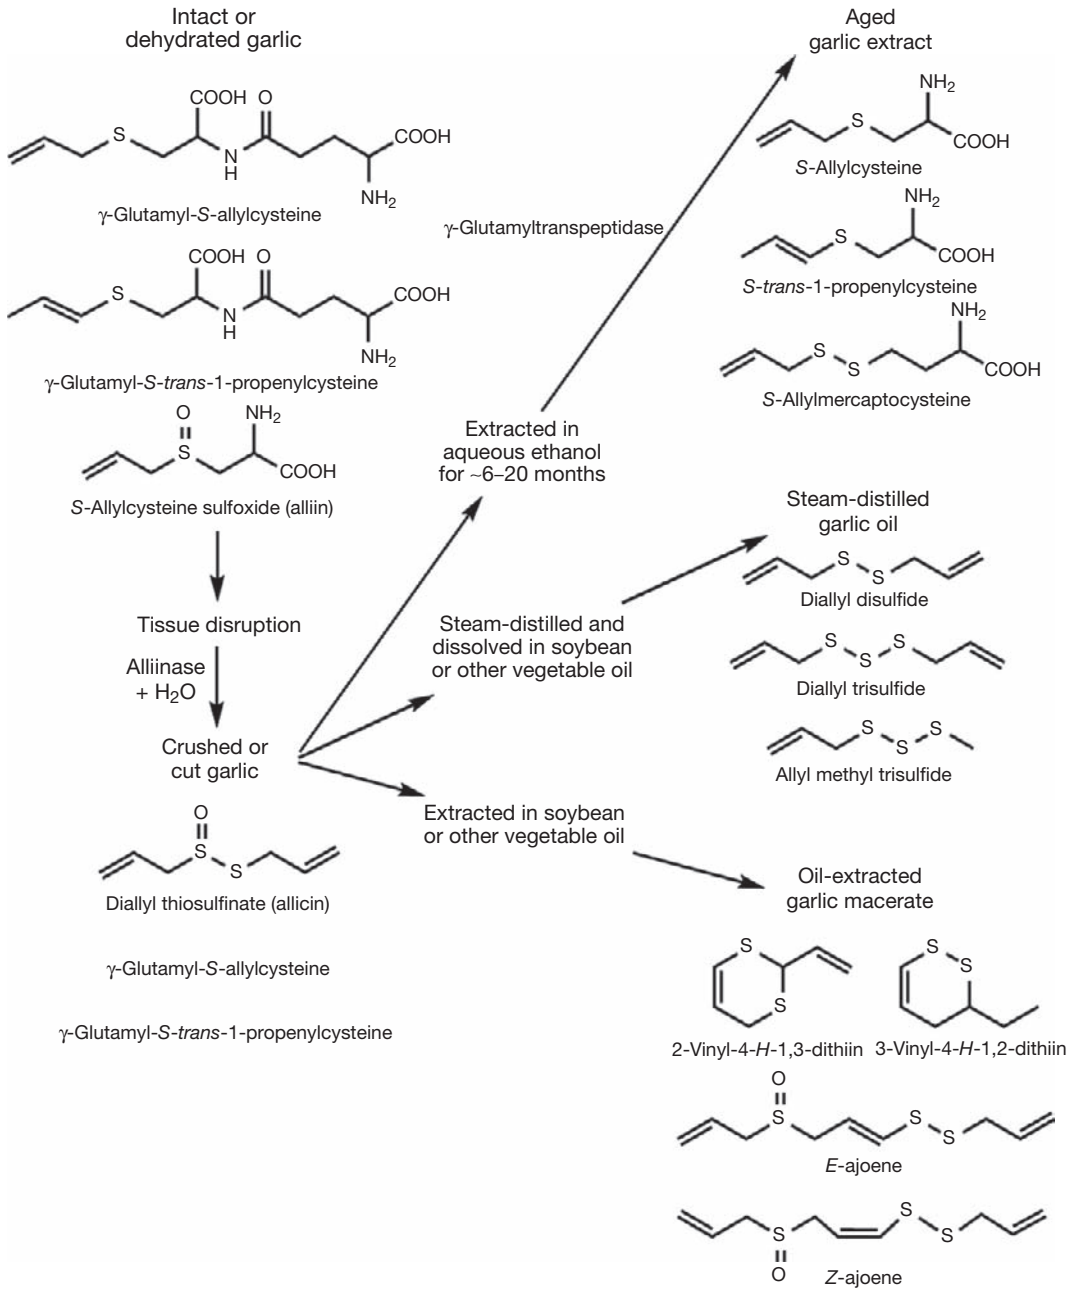

Figure 2 Major sulfur-based compounds present in garlic and in preparations derived from garlic.

compounds on a weight basis, whereas 3-vinyl-4-*H*-1,2-dithiin constitutes less than a quarter. Diallyl disulfide, diallyl trisulfide, and allyl methyl trisulfide are found at low levels in oil-extracted garlic macerate. Thiosulfinates and γ-glutamyl-*S*-alkenylcysteines do not occur in this product. This formulation also is generally sold as capsules.

Bioavailability, Absorption, and Metabolism

Most studies of the bioavailability and metabolism of garlic constituents have focussed on garlic's sulfur compounds. Although garlic and garlic formulations have been chemically well-characterized, current understanding of the fate of ingested potentially bioactive garlic compounds is far less complete. Allicin was once thought to be the principal sulfur-based compound responsible for the biological effects of garlic, but this is no longer the case. Despite considerable effort, no one has detected allicin or alliin or any of their metabolites *in vivo* in human blood, even following the consumption of 25 g of chopped raw garlic. Allyl methyl sulfide occurs in alveolar (lung) air after consuming allicin, strongly suggesting that allyl methyl sulfide is a metabolite of allicin present in the circulatory system. When incubated in heparinized human

blood, allicin disappears within five minutes and results in the generation of diallyl disulfide, which is stable for about an hour. Diallyl disulfide has not been observed *in vivo*.

The lack of bioavailability of allicin has been explained in a couple ways. One explanation is that allicin binds to protein and fatty acids in plasma membranes and is thus prevented from entering the circulation. A second explanation is that allicin may react with plasma glutathione to form allyl mercaptan (2-propanethiol), which is then rapidly converted via a methyltransferase and *S*-adenosylmethionine to allyl methyl sulfide. Alternatively, dithioallyl compounds such as allicin, diallyl trisulfide, diallyl disulfide, and ajoene also may react with free and protein-bound cysteines in the gut to form *S*-allylmercaptocysteine, with subsequent conversion in erythrocytes and epithelial cells to allyl mercaptan and then to allyl methyl sulfide. In rats given diallyl disulfide by gavage, allyl mercaptan, allyl methyl sulfide, allyl methyl sulfoxide, and allyl methyl sulfone were found in the stomach, liver, plasma, and urine. Allyl methyl sulfoxide and allyl methyl sulfone have not been reported in humans following garlic consumption.

Allicin is stable under gastrointestinal conditions but most likely does not reach target organs due to its binding to proteins and fatty acids and/or its rapid metabolism in blood. Nonetheless, the presence of allicin in the gastrointestinal tract is of interest because its metabolite allyl methyl sulfide may exert biological effects. Furthermore, the identities and bioactive properties of allyl methyl sulfide metabolites have not been elucidated, so the apparent absence of allicin in human blood does not in and of itself discount possible health benefits of consuming fresh garlic or allicin-producing garlic dietary supplements. Additionally, allicin exhibits antimicrobial effects and thus would be expected to modify intestinal microbial populations that in turn impact food digestion and human health. Generally, when raw garlic has been crushed and time allowed ($\sim$10–15 min) for alliinase to catalyze the hydrolysis of alliin to allicin prior to cooking and/or eating, allicin can be delivered intact to the gastrointestinal tract. However, in the case of dried garlic powder capsules in which alliinase is preserved during dehydration, the inhibition of alliinase by stomach acid may limit the conversion of alliin to allicin. Similarly in the case of enteric-coated garlic powders designed to pass through the stomach unmetabolized, simulated intestinal fluids have been shown to inhibit the production of allicin.

Allyl methyl sulfide is found in breath following consumption of garlic and garlic formulations, along with methanethiol and allyl mercaptan. However, only allyl methyl sulfide originates from the gut, whereas other metabolites result from oral metabolic processes. Measurement of allyl methyl sulfide in breath has been used as an indicator of allicin metabolism. The maximum concentration of breath allyl methyl sulfide following consumption of raw garlic occurs at about two hours and declines to undetectable levels by 30 h. Intake of ajoene, diallyl disulfide, diallyl trisulfide, and steam-distilled garlic oil also produces breath allyl methyl sulfide. In contrast, vinyldithiins, diallyl sulfide, and *S*-allylcysteine do not result in detectable breath allyl methyl sulfide. None of these latter compounds contains a dithio (S–S) group, which is thought to be necessary to generate allyl methyl sulfide. Allyl mercaptan, the immediate precursor to allyl methyl sulfide, is an exception.

S-Allylcysteine is found in plasma following intake of aged garlic extract, which is rich in *S*-allylcysteine. *N*-Acetyl allylcysteine has been found in urine following consumption of a garlic extract that was not chemically characterized. It was not described as aged garlic extract, however, and therefore probably was not high in *S*-allylcysteine. The precursor to *N*-acetyl allylcysteine may be γ-glutamyl-*S*-allylcysteine, which by the action of γ-glutamyl transpeptidase could be hydrolyzed to *S*-allylcysteine. *S*-Allylcysteine may be metabolized by two pathways. In one pathway, *S*-allylcysteine is acetylated by *N*-acetyl transferase, resulting in *N*-acetyl allylcysteine. Hepatic flavin-containing monooxygenases then oxidize *N*-acetyl allylcysteine to *N*-acetyl allylcysteine sulfoxide. In the second pathway, the flavin-containing monooxygenases act first upon *S*-allylcysteine, transforming it to *S*-allylcysteine sulfoxide (alliin), and *N*-acetyl transferase catalyzes the conversion of *S*-allylcysteine sulfoxide to *N*-acetyl allylcysteine sulfoxide. Other garlic γ-glutamylcysteines, which are abundant in intact, crushed, and dried garlic, may undergo similar metabolic processes.

Garlic: Health Effects

There is a rich history of garlic being used to prevent and treat health conditions as varied as asthma, cholera, and fever. With the rapid advancement of biological and medical science over the last half century, hundreds of studies have reported on the biological effects of garlic and garlic-related metabolites. Although the sheer number of studies devoted to garlic is impressive, there is a remarkable lack of clarity as to the roles of garlic in human health. The vast majority of studies have been conducted using cell culture (*in vitro*) or animals and signal that garlic intake may provide protection against cancer and cardiovascular disease. The results from cell and animal studies have not been consistently duplicated in human studies. Although all of the reasons for this are not known, often dose levels of garlic and garlic-related compounds used in cell and animal experiments do not mirror what is realistically achievable in humans. Moreover, the physiology of animals does not always well model human physiology, thus preventing the simple translation of results from animal studies to humans.

Results from human studies have been inconsistent with each other, suggesting the need to elucidate specific mechanisms of action induced by garlic and the specific garlic components that drive these mechanisms. The inconsistency of results from human studies may derive in part from the use of differing garlic formulations, doses, the durations of the studies, and outcome variables. Another important factor that may explain the inconsistencies of the effects of garlic and garlic formulations on health in humans is the variety and quality of experimental study designs. Epidemiological studies include prospective cohort and case–control (retrospective) studies. In prospective cohort studies, subjects are selected based on their garlic intake, and their disease status is monitored over a period of time that may extend to several years. In case–control studies, subjects are selected based on their disease status and attempts are made to correlate this status with prior garlic intake. In both prospective and case–control

studies, garlic intake is often self-reported and may not be accurate. Additionally, data interpretation may be confounded by the many forms of garlic and garlic formulations, the ways in which garlic is cooked, the varieties that are consumed, and the field and storage conditions to which cultivated garlic is exposed.

In contrast to epidemiological studies that are observational in nature, randomized controlled dietary intervention studies (randomized controlled trials) typically provide a known amount of garlic, garlic formulation, or specific garlic-derived compounds to control and intervention groups. Depending on the length and objectives of the study, the treatment response measured may be disease status or, alternatively, biomarkers that do not necessarily indicate the presence of a disease, but may otherwise reflect health status. The best-designed randomized controlled dietary intervention studies randomize to reduce baseline between-group variation, thoroughly characterize and report the dietary treatment, include an appropriate control group, administer a placebo to the control group in place of the dietary intervention of interest, and are double-blinded. In studies involving garlic and garlic formulations, the strong odor of the treatment often cannot be reproduced in a placebo and thus placebos are not always possible and subjects cannot always be blinded to the treatment they are receiving. Randomized controlled dietary intervention studies are particularly useful for determining the efficacy of a dietary intervention to affect a health outcome variable in a particular subject population. Epidemiological studies are valuable for hypothesis generation and often provide the foundation and impetus for designing and conducting randomized controlled studies.

Cancer Prevention and Treatment

There is a significant body of preclinical research aimed at understanding the roles of garlic and garlic formulations in the prevention and treatment of cancer. Preclinical studies have provided a means of elucidating the mechanisms by which garlic and garlic formulations may have anticancer effects. Xenobiotic metabolism may be affected by garlic compounds. Cytochrome P450 2E1, one of many phase 1 enzymes, which activate procarcinogens, is inhibited in culture by diallyl sulfide and its putative metabolites diallyl sulfoxide and diallyl sulfone. In rats, however, the phase 1 enzymes cytochromes P450 1A1, 2B1, and 3A1 were increased by garlic oil, diallyl sulfide, diallyl disulfide, and diallyl trisulfide, although P450 2E1 was decreased. Phase 2 enzymes modify activated carcinogenic intermediates to reduce toxicity and facilitate excretion. One type of phase 2 enzyme, the glutathione transferases, is upregulated in the livers of rodents provided diallyl disulfide or *S*-allylcysteine. These effects on phase 2 enzymes along with the inhibition of P450 2E1 are suggestive of an anticancer effect although the upregulation of P450 1A1, 2B1, and 3A1 (other phase 1 enzymes) by garlic polysulfides may not be desirable.

Besides influencing xenobiotic enzymes, garlic compounds may exert anticancer effects by arresting cell cycle progression, inducing apoptosis, inhibiting angiogenesis, or modifying histones. Treatment with diallyl disulfide, diallyl trisulfide, allicin, *S*-allylmercaptocysteine, or ajoene induces G2/M phase cell cycle arrest in a number of neoplastic cell lines. Garlic polysulfides induce apoptosis in several cancer cell lines but seem not to affect normal cells. The mechanisms for inducing apoptosis may include the regulation of the apoptotic Bcl-2 protein family and generation of reactive oxygen species. The inhibition of angiogenesis by diallyl sulfide and diallyl trisulfide seems to occur in part by suppressing vascular endothelial growth factor. Histone modification modifies gene expression by regulating access of transcription factors to DNA and may be protective against cancer. Modification of histones and associated inhibition of cultured neoplastic cells in response to allicin, allyl mercaptan, allyl methyl sulfide, diallyl disulfide, *S*-allylmercaptocysteine, and *S*-allylcysteine have been reported and involve hyperacetylation of histones H3 and H4. Other possible anticancer mechanisms resulting from garlic consumption include increased free radical scavenging and antioxidant activity.

In comparison to the abundance of preclinical studies, there are far fewer human studies investigating the effects of garlic and garlic formulations in cancer prevention and treatment. Many of the human studies are epidemiological studies. In the Iowa Women's Health Study, a prospective cohort study, 41 837 women of ages 55–69 were monitored for colon cancer incidence for 5 years. When the uppermost and lowermost consumption levels were compared, cancer incidence was inversely correlated with garlic intake, with an age- and energy-adjusted relative risk of 0.68. In the European Prospective Investigation into Cancer and Nutrition involving 368 010 women and 153 447 men, results after an average 6.5-year follow-up suggested that garlic and onion consumption reduced intestinal cancer, corresponding to a hazard ratio of 0.70 per 10 g per day increase. When 477 312 of these participants were followed up after 11 years, the decreased risk of intestinal cancer associated with garlic and onion intake was no longer present. An expert review panel organized by the World Cancer Research Fund and the American Institute for Cancer Research published a report in 2007 in which they judged that *Allium* vegetables, which include garlic, probably protect against stomach cancer. This conclusion was based on two cohort studies, 27 case–control studies, two ecological studies, and an intervention study utilizing allitridum (diallyl trisulfide) and selenium. Based on two cohort and six case–control studies investigating garlic consumption, the reviewers also concluded that garlic probably protects against colorectal cancer. Recent epidemiological studies have produced inconsistent results. An analysis of prospective data from the American Cancer Society Cancer Prevention Study (CPS) II Nutrition Cohort including 42 824 men and 56 876 women weakly supported a reduced risk of colorectal cancer in women, whereas in men, there was a slight increase in risk of colorectal cancer associated with past use of garlic supplements. In a prospective study encompassing cohorts of the Nurses' Health Study (121 700 women) and the Health Professionals Follow-up Study (51 529 men) followed for up to 24 years, garlic intake was not associated with the risk of colorectal cancer. The accumulation of both positive and null results suggests the need to identify groups most likely to benefit from garlic intake and the forms and doses of garlic that are most effective.

As with epidemiological studies investigating the effects of garlic on cancer, results from randomized controlled trials have

not always been consistent. In a double-blind randomized clinical trial, aged garlic extract increased natural killer cell number and activity in patients with liver, pancreatic, or colon cancer but did not increase their quality of life. In a different trial, after 12 months, aged garlic extract suppressed the emergence of colorectal adenomas, which are precancerous lesions of the large bowel. Another randomized double-blind trial tested the ability of a combination of aged garlic extract and steam-distilled garlic oil to reduce the incidence of precancerous gastric lesions. The study had 3365 participants and lasted for 7.3 years. Garlic supplementation did not affect the prevalence of precancerous gastric lesions or gastric cancer incidence compared to the control treatment. Synthetic allitridum in combination with selenium, however, decreased the risk of gastric cancer compared to placebo in an experimental population at high risk for gastric cancer. The garlic/selenium treatment was administered every other day for 1 month for each of three consecutive years to the intervention group of 2526, whereas members of the placebo group of 2507 received a corn oil capsule and starch tablet. Follow-up was at 10 years. In a trial to test the topical application of an ajoene-containing cream to basal cell carcinoma lesions, it was found that most tumors were reduced in size and Bcl-2 expression was decreased after twice daily treatment for 6 months. This response was attributed to the induction of apoptosis in the tumor cells.

Cardiovascular Effects

Investigation of the effects of garlic and garlic formulations on cardiovascular health has been another principal focus of garlic research. Numerous preclinical and clinical studies have investigated parameters such as plasma lipids, blood pressure, and platelet aggregation. A wide range of garlic preparations have been tested under varying experimental conditions. Several meta-analyses have been published that attempt to view and interpret the accumulated evidence and highlight significant trends.

Studies conducted in animals suggest that garlic and garlic preparations favorably modify total cholesterol, high-density lipoprotein (HDL), and low-density lipoprotein (LDL). Garlic formulations tested include allicin, dried garlic, boiled garlic, and garlic oil and, in most cases, have been provided at doses ranging from 2% to 5% of the total diet. Studies have been undertaken to determine possible mechanisms of lipid regulation. Activity of a key enzyme involved in cholesterol synthesis, 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase, was decreased in hens that had been given solvent-extracted garlic macerate or garlic oil for 24 days. In cultured hepatoma cells, garlic extract, diallyl sulfide, diallyl trisulfide, and allyl mercaptan inhibited cholesterol synthesis, perhaps by means of a mechanism in which inhibition of 4α-methyl oxidase led to feedback inhibition of HMG-CoA reductase.

Clinical trials investigating the effects of garlic and garlic formulations on lipid parameters have produced mixed results. In a particularly well-designed randomized controlled trial conducted through Stanford University, raw garlic, a commercial dried garlic powder product, a commercial aged garlic extract product, and a placebo were given to treatment groups each with 47–49 moderately hypercholesterolemic (LDL cholesterol of 130–190 mg dl^{-1}) subjects. Each of the treatments was extensively chemically characterized. The daily dose of the raw garlic was 4.0 g and the dried garlic product was provided in a similar quantity based on allicin generation. The provided dose of the aged garlic extract was 1.5–3 times the manufacturer's recommended amount. Subjects were randomly selected and assigned to treatment groups. The protocol entailed consumption of the dietary treatment 6 days per week for a total of 6 months, and lipid parameters were measured monthly. There were no significant treatment effects on total cholesterol, LDL cholesterol, HDL cholesterol, the total cholesterol/HDL cholesterol ratio, or triglycerides.

The results of the Stanford University trial do not necessarily extrapolate to other subject populations or to all garlic doses and formulations. It is possible that populations with higher LDL concentrations would respond favorably to the tested garlic treatments or to treatments consisting of higher doses. In a recent meta-analysis that included 39 randomized, placebo-controlled human trials investigating the effect of garlic on lipid parameters, it was concluded that when consumed for at least 2 months, garlic effectively reduced cholesterol by 17 ± 6 mg dl^{-1} and LDL cholesterol by 9 ± 6 mg dl^{-1} in humans with baseline total cholesterol levels >200 mg dl^{-1}, which is a higher baseline than that of the Stanford University trial. Twenty-four of the trials included in the meta-analysis used garlic powder, six used garlic oil, five used garlic extract, and two used raw garlic. This ~8% reduction in serum total cholesterol was deemed to be clinically relevant and associated with a 38% reduction in coronary events at age 50.

Garlic has also been studied as a means to regulate blood pressure. A meta-analysis that encompassed 11 randomized controlled trials assessed the efficacy of garlic to modulate blood pressure in normotensive and hypertensive subjects. Garlic treatments significantly reduced systolic blood pressure more than placebo by 4.6 mm Hg (95% CI: −7.36, −1.77) but diastolic blood pressure did not differ significantly. When stratified into normotensive and hypertensive groups, systolic blood pressure and diastolic blood pressure did not change in normotensive subjects but decreased significantly by 8.38 mm Hg and 7.27 mm Hg, respectively, in the hypertensive group. Dried garlic powder was used in nine of these studies, and aged garlic extract and distilled garlic oil were each used in the remaining two studies. A recent dose–response double-blind randomized placebo-controlled trial seemed to verify that at least in hypertensive populations, aged garlic extract reduces blood pressure over a 12-week period.

Evidence for an effect of garlic on platelet aggregation is conflicting. Although some *in vitro* studies have indicated an antithrombotic effect of garlic, this result has not been consistently observed in clinical trials. Several clinical studies conducted prior to 2002 reported inhibition of platelet aggregation, whereas more recent studies have reported no effect of consumption of garlic or garlic supplements. Raw garlic, boiled garlic, garlic powder, garlic oil, and aged garlic extract have been tested. When the equivalent of 8 g of raw garlic was provided daily for 4 weeks, platelet-rich plasma aggregation decreased less than 10% but collagen-induced whole blood aggregation increased 10–13%. Given that this dose of garlic is unusually high, the investigators who conducted this study concluded that normal levels of garlic likely would not have an

antithrombotic effect in healthy individuals. Additional carefully designed randomized controlled trials may be needed to clarify whether garlic or garlic formulations affect humans and particularly what subpopulations may be most likely to respond to the intervention.

Antiglycemic Effects

Several animal studies indicate that garlic preparations improve oral glucose tolerance. Nevertheless, evidence for antiglycemic effects in humans is scant. Most human studies conducted prior to 2000 do not support a role for garlic or garlic formulations in glucose control. Two recent studies report a positive effect of garlic supplements. A randomized double-blind placebo-controlled trial was conducted in 60 type 2 diabetic patients to test the antiglycemic effects of a 300 mg time-released garlic powder tablet taken twice daily. After 1 week, fasting blood glucose was lower compared to baseline in the garlic group, but this effect did not occur at 2, 3, or 4 weeks. Serum fructosamine, a measure of long-term compensation of metabolic control, was decreased compared to baseline and the placebo group at 3 and 4 weeks. In an open-label, prospective, comparative study conducted in a different population of 60 type 2 diabetic patients all receiving metformin for glucose regulation, an uncharacterized garlic supplement was provided to half of the patients. Fasting blood glucose and postprandial blood glucose were reduced at weeks 2, 4, 6, 8, and 12 in the garlic supplement group compared to the control group. In light of the inconsistent data, additional large-scale randomized controlled trials with well-characterized interventions are required to determine whether garlic or garlic preparations are useful as antidiabetic agents.

Conclusions

Garlic has been used as a food and as a medicinal herb for thousands of years. Based on current trends, garlic use can be expected to continue to expand. The unique flavor and aroma of garlic have inspired countless culinary dishes and remedies for treating numerous medical conditions. Garlic's sensory attributes are based on its remarkable sulfur chemistry, a biochemical system that is activated upon cellular disruption and that offers an expanding array of sulfur compounds with further processing. With the advent of modern science, the utility of garlic and garlic preparations for treating human diseases is under investigation. Based on preclinical studies, there is reason to be hopeful that garlic compounds may ameliorate certain human conditions, particularly as related to cancer and cardiovascular disease. Epidemiological studies and randomized controlled trials have lent mixed evidence for the efficacy of garlic and garlic preparations in humans. The inconsistent findings likely are related to the use of different garlic treatments, doses, durations of testing, subject populations, and outcome variables. Our understanding of the roles of garlic and garlic preparations in human health will benefit from additional well-designed human studies that carefully characterize the garlic interventions used and that investigate possible differential effects in various human subpopulations.

Gelatin

Gelatin or gelatine, which mainly composed of 50.5% carbon, followed by 6.8% hydrogen, 17% nitrogen, and 25.2% oxygen, is a type of insoluble protein produced by hydrolysis of collagen extracted from a variety of animal sources such as the skin, bones, and connective tissues. These sources are normally generated as a by-product following animal slaughter by the muscle food processing industry (meat, poultry, and seafood). Collagen is part of the basic structure of animal bodies (including humans) and constitutes the skin, tendon, bone, membrane, and connective tissues. It consists of rigid bar-like molecules arranged in fibers and linked by covalent bonds. The molecules have three polypeptide chains stabilized by hydrogen and hydrophobic bonds and arranged in a triple helix structure due to the repeating sequence glycine–proline–hydroxyproline (Gly-X-Y).

There are a number of collagen types that can be classified based on their distribution within the tissues. However, most collagen consists of types I, II, and III. Type I collagen is distributed as loose or dense connective tissue and can be found in the skin, bones, tendons, and blood vessels. Type II collagen consists of tissues derived from the cartilage and vitreous humor and type III collagen is found in loose connective tissue and also in the muscle, where it has an association with type I collagen. These collagen types are also different in terms of molecular composition.

The amino acid content of gelatin is almost identical in composition with the original collagen from which it was derived. It also has repeating sequences of Gly-X-Y, with Gly representing proline and Y representing hydroxyproline. Gelatin possesses all the essential amino acids, with the exception of tryptophan. It contains a high amount of glycine, proline, and hydroxyproline but is low in cysteine, methionine, and tyrosine. Proline and hydroxyproline are very important with respect to gelling properties.

Properties Associated with Gelatin

Gelatin is translucent, almost tasteless and odorless, brittle, easy to digest, and a nonallergenic protein. Dry gelatin has a moisture content of about 10%. Generally, gelatin is processed into powder or granulated form. The color of the powder depends on the gelatin source. For example, gelatins derived from cows and pigs possess a yellowish color compared with gelatins derived from fish. Gelatin derived from pork skin also has less color than gelatin derived from bone or hide. However, color generally does not influence the properties of gelatin.

Gelatin is a relatively low-priced food ingredient since it is normally generated as waste. It is abundant (from a wide variety of land and marine sources) and has great functional properties. The properties of gelatin are dependent on a number of factors, such as collagen type, gelatin source, age of the animal at slaughter, and processes used to generate gelatin. Differences in amino acid composition, such as content of α-, β-, or γ-chain components and degree of molecular weight, can be affected by these factors.

Gelatin is pure, natural, and not chemically modified. It has a high amino acid content. Unlike collagen, gelatin is soluble in hot water. It is unique since it is a thermoreversible gel, possesses a unique melt-in-the-mouth property (melts at lower temperature compared to other forms of hydrocolloids), and has a wide application range within the food industry. Gelatin has also been widely used in pharmaceutical, cosmetic, and photographic industries.

Protein Structure of Gelatin

Proteins (from Greek 'prota,' which means 'of primary importance') are polymers that are composed of many amino acids joined together, as a linear chain, by amide bonds. Such proteins are called polypeptides. Proteins contain more than 100 amino acid residues from 20 proteinogenic amino acids. Amino acid residues occur when amino acids combine together (e.g., glycine and alanine) and release a water molecule as a consequence of this interaction. Proteins can differ in terms of form and function and the differences observed can be explained by overall protein structure, origin of proteins, and the amino acid composition comprising the protein.

There are four basic protein structures: primary, secondary, tertiary, and quaternary forms. A primary protein structure is one where the amino acid sequence is arranged linearly. Meanwhile, a secondary protein structure is one where the shape of the protein molecules exists in either α-helix or β-sheet (folding and coiling), which is caused by hydrogen bonding between –C═O and –NH groups within the chain and the primary amino acid building blocks. The tertiary protein structure results when folding and bending of the protein molecules occur due to interactions with the R groups on individual amino acids. This interaction may occur as a result of hydrogen bonding, dipole–dipole interactions, covalent bonding, or ionic bonding (salt bridges) depending on the polarity of the R groups. Meanwhile, a quaternary protein structure results as a consequence of noncovalent interactions that bind multiple polypeptides into a large macromolecular complex.

A basic amino acid contains a central carbon (α-carbon) bonded to hydrogen, an amino group (NH_2), a carboxyl group (COOH) and R group, and a unique amino acid side chain that distinguishes one amino acid from another. The 20 amino acids available in nature are listed in **Table 1**. Amino acids can be divided into nonpolar (hydrophobic), polar (hydrophilic), and electrically charged (positive or negative hydrophilic) groupings. Polar amino acids may be involved in hydrogen bonds due to its tendency to contact with water,

Table 1 20 different of amino acids

Amino acid	*Three-letter code*	*Properties*
Glycine	Gly	Hydrophobic
Alanine	Ala	Hydrophobic
Valine	Val	Hydrophobic
Leucine	Leu	Hydrophobic
Isoleucine	Ile	Hydrophobic
Methionine	Met	Hydrophobic
Phenylalanine	Phe	Hydrophobic
Tryptophan	Trp	Hydrophobic
Proline	Pro	Hydrophobic
Serine	Ser	Hydrophilic
Threonine	Thr	Hydrophilic
Cysteine	Cys	Hydrophilic
Tyrosine	Tyr	Hydrophilic
Asparagine	Asn	Hydrophilic
Glutamine	Gln	Hydrophilic
Aspartic acid	Asp	Negatively charged (hydrophilic)
Glutamic acid	Glu	Negatively charged (hydrophilic)
Lysine	Lys	Positively charged (hydrophilic)
Arginine	Arg	Positively charged (hydrophilic)
Histidine	His	Positively charged (hydrophilic)

whereas hydrophobic amino acids are normally located inside the core of protein. Meanwhile, an imino acid is a molecule that contains both imino (CNH) and carboxyl functional groups and, consequently, is related to amino acids. Proline is formally classified as an imino acid, although it is sometimes called an amino acid.

Gelatin is a mixture of different polypeptide chains, α-chains, β-chains (dimers of α-chain), and γ-chains (trimmers of α-chain). An α-chain has one peptide chain, a β-chain consists of two peptide chains that are still connected, and a γ-chain is composed of three connected peptide chains. Gelatin that contains higher quantities of α-chains exhibits higher gel strengths.

Types and Bloom of Gelatin

Gelatin can be classified into two types and this is determined by gelatin pretreatment during the gelatin manufacturing process. Type A gelatin with an isoionic point of 6–9 is obtained from acid-treated collagen, whereas type B gelatin (isoionic point of 5) is derived from an alkali-treated precursor. Gelatin derived from pig skin is normally referred to as type A gelatin and gelatin derived from beef skin is referred to as type B gelatin.

Gel strength and viscosity are the most important physical properties of gelatin. Gel strength, also known as 'bloom' value, is a measure of the strength and stiffness of the gelatin, reflecting the average molecular weight of its constituents, and is usually between 30 and 300 bloom (<150 is considered to be a low bloom, 150–220 a medium bloom, and 220–300 a high bloom). Higher bloom value indicates greater gelatin strength. Based on the type of product required and its function, a different bloom value for gelatin is applied.

Gelatin Manufacturing

Gelatin is commercially manufactured from collagen using a series of processing steps, including conditioning, extraction, filtration or purification, concentration, drying, and grinding. However, the process used may vary depending on the type of collagen source used, porcine or bovine sources, and skin or bone or hide origin. During the conditioning process, the material is cut and washed to cleanse and degrease the collagen before it is used to manufacture gelatin using either a type A (acid) or type B (alkaline) process. This is followed by the extraction process, whereby the material is mixed with clean and warm water before producing gelatin solution. The next process is filtration or purification in which few processes like centrifuging, ion exchange, and ultrafiltration may be applied to remove any salts or inorganic material. Concentration is the process of removing water from liquor gelatin by vacuum evaporators in a gentle process. At this stage, gelatin is highly viscous. The solution is filtered again through polishing filters to ensure the finest particles are removed. After gelatin solution is heat-sterilized, the solution is then dried on stainless steel conveyor belt using warm and dry air steam. Finally, after some physical, chemical, and bacteriological testing, gelatin will be ground, milled, sieved, and blended according to customer specifications. Some manufacturers set gelatin for quality assurance testing before delivering the products to their customers.

Sources of Gelatin

As previously stated, commercial gelatins have traditionally been obtained from pigs (porcine) and cattle (bovine) sources and derived from the skin, bone, and hide. However, gelatin derived from these sources are limited in some respects as they cannot be used or consumed by Muslims, Jews, or Hindus on various grounds.

Alternatively, gelatin is derived from marine sources. Gelatins from fish sources are obtained as a by-product from fish processing or from fish waste. About 30% of fish waste is in the form of bone and skin, which consist of a high collagen content. These types of gelatins have never been associated with prions, are religiously acceptable, and may possess unique functional properties. Nowadays, research and development of gelatin sources derived from fish are rapidly growing. This includes gelatin obtained from skins, bones, fins, heads, scales, or swim bladder.

There are a few factors that need to be considered when choosing gelatin from fish such as water-type species, fish types, and fish components used. The origin of fish, either warm-water (e.g., tuna, catfish, tilapia, Nile perch, shark, and megrim) fish or cold-water (e.g., cod, hake, Alaska pollock, and salmon) fish, may affect the physical properties of gelatin. Skin gelatins from warm-water fish have similar melting temperatures with skin gelatin obtained from warm-blooded animals. However, skin gelatins derived from warm-water fish have lower melting temperatures due to differences of imino acid content and degree of proline hydroxylation. Different extraction processes, temperatures, preservation methods, etc., also

influence the properties of fish gelatin. Despite there being an issue with allergic reactions related to fish gelatin, the wide variations of fish gelatin sources bring high prospect as important commercial gelatin sources in the future as commercial demand for gelatin continues to increase.

Apart from fish, the development of gelatin from other marine sources is ongoing, for example, from squid. Squid skins have a high degree of cross-linking and are obtained from a few species such as splendid squid (*Loligo formosana*) and giant squid (*Dosidicus gigas*). They are discarded as protein waste with low value and normally used as animal feed. However, the hurdle for gelatin extraction from squid skin is that color problems ensue due to pigments present in their skins. To overcome this problem, some researchers have used H_2O_2 as a bleaching agent to improve whiteness or brightness in extracted gelatin.

Recently, poultry sources like chicken skin, feet, meat residue, and bones are also being developed to obtain gelatin. Gel strength of chicken-derived gelatins may give higher bloom values than that of beef gelatins, the differences again being attributed to intrinsic characteristics such as amino acid content (higher imino acid, which is essential for gelling effect), molecular weight distribution, type of extraction treatment, and properties of collagen. The market for poultry gelatin is still niche and the global demand is not overwhelming as of yet. This is due to the higher price of poultry gelatin sources, lower production of raw materials compared to mammalian gelatins, and uncertainty on quality of gelatin.

In certain countries, gelatin derived from insects is also being considered as additional sources of gelatin. Melon bugs (*Aspongopus viduatus*) and sorghum bugs (*Agonoscelis pubescens*) are processed to produce oil that is utilized for medicine and cooking purposes. Gelatin can also be extracted. This type of gelatin has all of the essential amino acids, yet the quantity of the insect protein produced is only in the moderate range. Potential sources of collagen from alligator bones and giant red sea cucumber are also being studied. Alligator bones are identified as possessing collagen type I with imino acid contents, which are very similar to subtropical fish species and lower than that obtained from bovine skin. Figure 1 illustrates the sources of gelatin.

Gelatin Applications

Gelatin has been introduced in pharmaceuticals since early nineteenth century. Due to its film-forming, adhesive, and thermoreversible gelling properties, it is utilized as capsule in either two-piece hard capsules or soft elastic gelatin capsules, tablet coating, and encapsulation. It is also has been applied in surgical sponges, ointments, emulsions, syrups, wound dressing, health supplements, etc.

In terms of cosmetic application, this material is being used in lipsticks and hair care products (shampoos and conditioners) and as 'hydrolyzed animal protein.' Today, many cosmetic products such as creams, lotions, and masks utilize collagen as a moisture retainer as it has been proven to increase hydration and suitable for all skin types.

Gelatin has been used in photography since 1871 for many applications. Gelatin has been used by this industry as a coating layer, subcoating layer, noncurl layer, and antihalogen layer in a host of photographic products. Today, gelatin is widely used as the shell material in the outdoor paintball game as it is safe and nontoxic. Gelatin derived from pork skins and beef bones/hides is used in the manufacture of the paintball shell, a capsule with different size and shape that contains water-soluble dye. The broad applications of gelatin in the food industry will be discussed subsequently.

Application of Gelatin in Food

Gelatin is generally recognized as safe food ingredient and easy to use. Therefore, this material is utilized in many food products owing to the versatility of the ingredient, which can deliver the following functions: gelation, binding, water binding, emulsifying, foaming, film forming, elasticity, and viscosity. Adding gelatin to food products does not affect the flavor of original food products because it has a neutral flavor and odor. The variation of applications and its functions are influenced by the processing condition, bloom value, type of gelatin, viscosity, and percentage used. For example, texture and hardness of low-fat products can be altered by adjusting the gel

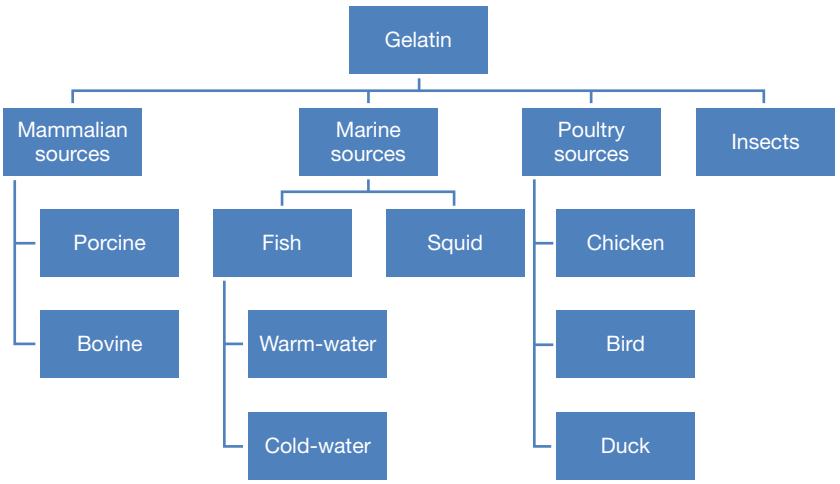

Figure 1 Gelatin sources.

Table 2 Some gelatin applications in foods

Product category	*Function*	*Food products*
Meat	Binding and glazing agent, casings, coatings	Canned meats, jellied meats, sausages, meat
Bakery and confectionary	Stabilizer, binding and gelling agent, emulsifier, elasticity and chewability improver, coating	Icing, glazes, creamy fillings, marshmallows, toppings, mousses, chiffons, gummy bears, gelatin and wine gums, toffees, chewing gums, compressed tablets, nougats, licorice, chocolate, and sugar-filling products
Dairy	Stabilizer, emulsifier, texture improver, water binder, increasing viscosity, fat replacement	Yogurts, creams, buttermilks, margarines, cheeses
Desserts	Stabilizer, gelling agent, coating	Pudding, custard, ice creams, milk ices, syrups, gravies, fruits
Wines and juices	Clarifying agent	Wines, beers, fruit juices, vinegar

strength or changing the concentration of gelatins. Table 2 summarizes some gelatin applications in foods.

Meat Products

Gelatin has been used as a binder and glazing agent in meat products and used to help set meat shape in canning applications. High bloom strength gelatin has also been used to gel the fluids of jellied meats allowing the pieces of meat to form certain shape. For sausage manufacture, collagen/gelatin has been used as edible casings as collagen/gelatin offers good uniformity of appearance and strength.

Bakery and Confectionary Products

Gelatin can also act as a stabilizer and can help to maintain crystal structure of sugar for bakery products such as icing, glazes, creamy fillings, and marshmallows. Additionally, because of its whipping and stabilizing properties, gelatin has been added to topping, mousse, and chiffon-type products. Gelatin is used in confectionary for its gummy properties, for example, in candy such as gummy bears and wine gums. Depending on the gelatin type, bloom strength, and concentration, the texture of gummy products can vary from soft to hard or from short to long. Gelatin is also compatible with other materials or gelling agents such as starch, pectin, and gum Arabic. Therefore, they can be mixed together and increase texture ranges in foods. Other confectionary products that may contain gelatin are toffees and chewing gums (improving elasticity), compressed tablets (as binder), nougat (enhancing chewability), and licorice (improving moisture retention, extending shelf life, and for binding properties). For chocolate or sugar-filled products, gelatin is used as a coating material before filling processes commence in order to prevent oil and moisture migration occurring from inside the product to the external product surfaces.

Dairy Products

In dairy products, gelatin is widely used due to its compatibility with milk proteins. It acts as an excellent stabilizer due to its gelling and water-binding actions, particularly for yogurts (including low and nonfat yogurts). It helps to improve yogurt texture by assisting in the development of smooth, creamy, and delicate mouthfeel properties while at the same time prolonging product shelf life. These properties also led gelatin to be used in concentrated cream or thickened cream by increasing cream viscosity. Small amounts of gelatin are frequently added to buttermilk and margarine to avoid separation and again promote smooth product textures. Gelatin also helps to stabilize the emulsion during spreading and storage. Additionally, high demands for low and nonfat dairy products give rise to the opportunity for gelatin use since it has unique 'fat-like melting characteristics' that mimic full-fat products. For cheese products like cottage cheese and cream cheese, gelatin acts as water binder and fat replacer. It also assists in the enhancement of smooth and creamy textures due to its unique melting point (close to dairy fats).

Dessert Products

Gelatin also has been used as one of the main ingredients in desserts, such as puddings, custards, ice cream, and milk ices as again it provides a unique texture, is a good stabilizer, possesses excellent gelling properties, and provides melt-in-the-mouth and unique mouthfeel properties.

Wine and Juice Products

Gelatin is being used in beverage products to clarify wines, beers, unfermented juices, and vinegar. These beverages normally contain insoluble matter that creates a haze or cloudiness and is impractical to remove. Therefore, gelatin has been applied for the clarification process or fining.

Basics of Gelatin Usage as Packaging Film Material

Gelatin also has high potential as biodegradable and/or edible films particularly for food packaging. Gelatin as packaging materials has high resistant to solvents and has excellent levels of flexibility. The uniqueness of gelatin as films in their physical properties is also influenced by intrinsic factors and physical parameters including sources of gelatin, concentration, gel strength or bloom value, film manufacturing process, temperature, drying time, and plasticizer type associated with molecular weight distribution and amino acid composition.

Gelatin is also being developed as active packaging material by incorporating antimicrobial and antioxidant agents to obtain films with good antioxidant and/or antimicrobial properties. These agents are normally derived from natural sources (plant extracts) such as essential oils (lemon, lime, kaffir lime, bergamot, ginger, turmeric, and plai), green tea extract (GTE), grape seed extract, ginger extract, and gingko leaf extract. There are also claims stating that gelatin itself also possess antioxidant activity. However, this finding is still not clearly demonstrated and still underway.

To date, gelatin (as either coatings or films) has been applied as 'food wrapper' mainly in meat-based products such as sea bass slices, rainbow trout, and cod fillets. Chicken meat powder and crackers are some dry food products that utilize gelatin as packaging materials. The application of this hydrocolloid as food packaging material is still constraint, but the research is evolving.

Conclusions

Higher demand of gelatin nowadays led to the exploration of alternative gelatins. Gelatin sources, ages of animals, processing conditions, etc., caused gelatin to exhibit diverse properties and characteristics attributed to differences of molecular weight distribution and amino acid contents. This scenario caused gelatin to have multifunctional properties and therefore catering for a broad range of applications. Numerous researches are ongoing to develop high yield and better quality of gelatin for commercialization purposes.

Genetically Modified Foods

A Moglia and E Portis, University of Torino, Torino, Italy

© 2016 Elsevier Ltd. All rights reserved.

What Is GM Food?

Genetically modified (GM) food is manufactured from ingredients derived from a plant, animal, or microbe (fungus, bacterium, or yeast) in which a segment of nonnative DNA has been introduced using recombinant DNA technology. An alternative term used for these products is 'bioengineered' or 'genetically engineered' food. Currently, several GM crops have entered the human food chain either directly as food or indirectly via animal feed. Recombinant DNA technology (see Box 1), originally designed for manipulating bacterial DNA, has been adjusted to allow the incorporation of a gene(s) encoding a specific trait in a manner that is in principle highly predictable. Unlike conventional plant breeding, GM technology offers the possibility of producing phenotypes, which could never occur in nature, since the species origin of the introduced gene(s) (termed 'transgene') may well be far away from the recipient plant species. In a variant of the GM approach, the intention is not to introduce an exotic gene, but rather to suppress or enhance the expression of a native one. So far, the major investment in GM crops has been focussed on improving levels of resistance to insect damage, inducing resistance to herbicide, enhancing the nutritional quality of the end product, promoting the expression of resistance to pathogenic viruses, and prolonging the shelf life of the product. The next wave of GM crops is expected to widen the search to achieve the production of biomedical and industrial products, such as monoclonal antibodies, vaccines, plastics, and biofuels.

Three Generations of GM Crops: Purposes and Commonly Modified Traits

According to the FAO, global demand for food is predicted to increase by 40% by 2030. Whether this demand can be met without the deployment of GM crops is controversial. To successfully market a GM food, there must be some perceived advantage to either the producer or the consumer. The advantage to the former translates as a lower production cost and to the latter as a lower product price and/or improved end-use quality. The first generation of GM crops was targeted largely to producer traits, such as tolerance to environmental stresses (drought, salinity, etc.), enhanced disease/pest resistance, and tolerance to herbicide application. The second generation has begun to address consumer traits such as improved nutritional content, while the third-generation GM crops are largely directed at nonfood/feed applications, for example, the production *in planta* of pharmaceutically active molecules. The major GM food crops, their purposes, and potential benefits are discussed in the succeeding text.

Increasing Food Production

GM crops currently on the market have been designed to enhance crop production by bolstering the plants' resistance against disease, by protecting them against insect damage, or by introducing herbicide tolerance in order to control weeds more effectively. Such crops, initially focussed on maize and soybean in the United States, have been widely cultivated, and have arguably enhanced the profit margins of large-scale producers in the Americas, but are increasingly now being also deployed in smaller-scale production situations in Asia and Africa as a means of both increasing farmers' profitability and reducing exposure to pesticides.

Herbicide tolerance

Many of the first-generation herbicidal agents were nonselective and environmentally damaging. More recent products have addressed both of these drawbacks. Glyphosate, for example, is quite rapidly degraded by soil biota and so avoids the problem of persistence in the soil. Modern herbicides target plant-specific enzymes and so are generally nontoxic to animals (including humans) or insects. Two approaches have been taken to create herbicide-tolerant (HT) crops via genetic modification: one is to reduce the sensitivity of a host enzyme and the other is to engineer a herbicide detoxification pathway into the host. An example of the former approach is a gene isolated from a herbicide-resistant strain of *Agrobacterium tumefaciens*; it encodes an EPSPS enzyme not compromised by glyphosate. The gene was incorporated by Monsanto first into soybean and subsequently into a range of other crops. Transgenic plants tolerant to the herbicide acifluorfen, which inhibits chlorophyll synthesis, have been produced by overexpressing an enzyme involved in this process. In contrast, resistance to the herbicides glufosinate and bromoxynil is based on the latter approach, specifically by introducing a transgene that directs the conversion of the herbicide into a nontoxic product. In the case of glufosinate, the key bar gene is *Streptomyces hygroscopicus*, while for glyphosate, the gene, obtained from *Ochrobactrum anthropi*, encodes glyphosate oxidase. The availability of transgenic HT crops has promoted a significant switch from conventional to zero or low-tillage production systems, which implies energy savings and a reduction in both CO_2 emission and soil erosion. Herbicide tolerance has been commercialized in soybean, maize, canola (oilseed rape), and cotton, has been approved for sugar beet and alfalfa in several countries, and has been incorporated (but not yet approved) in both rice and wheat.

Insecticidal activity and disease resistance

The most widely exploited transgene conferring insecticidal activity is *Bt*, isolated from the bacterium *Bacillus thuringiensis*. GM-derived virus resistance crop has also been deployed. At the laboratory level, resistance has been engineered to several bacterial and fungal plant pathogens. The incorporation of *Bt* has been one of the most successful applications of GM technology. The Bt toxin is a potent natural crystal protein endotoxin, and *Bacillus thuringiensis* spores and preparations of

Box 1 Plant Transformation Techniques: Established Methods and New Frontiers

Two established methods for plant transformation are recognized. The first exploits the natural ability of the soil bacterium *A. tumefaciens* to introduce a segment of its DNA into the host's genome; the second relies on the mechanical delivery of purified DNA into a temporarily receptive host cell. Both methods result in a rather random mode of insertion, which can have unpredictable effects. The cutting edge of plant transformation is predicated on achieving multigene transfer, site-specific transgene integration, and gene transfer between sexually compatible species.

Agrobacterium-*Mediated Transformation*

Agrobacterium-mediated transformation is the plant transformation method in most common use. Its cornerstone is the bacterium's transferred DNA (or T-DNA for short), which is carried on a plant tumor-inducing plasmid and is transferred upon infection into a host cell. In a successful infection, the T-DNA is integrated into the host's genome, leading to the host cell expressing certain bacterial genes. The T-DNA sequence has been adapted for genetic modification by replacing the bacterium's genes with the desired transgene(s), maintaining the left and right border sequences, which are needed to effect transfer and incorporation. Although the natural hosts for *Agrobacterium* are dicotyledonous species, it can be induced under laboratory conditions to effectively transform a wide range of higher plant species, including the monocotyledonous cereals.

Direct Gene Transfer

Particle bombardment (biolistic transfer): The earliest successes in plant transformation relied on a process whereby tiny tungsten or gold particles were coated with the transgene DNA sequence and then were propelled into cultured plant tissue by means of an electric discharge or a pressurized stream of helium gas. It remains effective as a transgene delivery method, especially in species that are easily not infectible by *Agrobacterium*.

Polyethylene glycol (PEG)-mediated transformation: In this method, the cell walls need first to be stripped from the host cells to leave a porous protoplast. When exposed to a mixture of polyethylene glycol and certain divalent cations, the protoplasts readily absorb DNA from the surrounding medium in a similar way to bacterial cells. Once within the protoplasts, some of this DNA becomes stably integrated into the plant chromosomes.

Electroporation: Originally developed to transform bacterial cells, this technique is also able to deliver DNA into plant protoplasts. The protoplasts are rendered porous by subjecting them to electrical pulses. DNA present in the surrounding medium can then migrate into the protoplast, where it can be incorporated as in the PEG method in the preceding text.

Silicon carbide whisker-mediated transformation: Silicon carbide whiskers are fine enough to physically puncture intact plant cells. The technique involves the violent stirring of a suspension of plant cells in the presence of the transgene DNA and the silicon carbide whiskers. The DNA enters the plant cells through the ensuing punctures, after which it can be incorporated as in the preceding text.

Microinjection: The concept is based on delivering the DNA in solution directly into a plant cell by means of a glass microcapillary injection pipette, in the same way as human in vitro fertilization is carried out. Few examples of the successful transformation of plants have ever been reported.

Bioactive beads-mediated gene transfer: The vector of the transgene DNA is represented in this application by a bead made of calcium alginate. The beads are introduced into protoplasts either via electroporation or via polyethylene glycol treatment.

Organelle-Mediated Transformation

Homologous recombination-mediated organelle transformation offers the possibility of transferring the transgene into a preselected position in the host genome. Chloroplast transformation vectors exploit two plastid sequences, which flank the transgene; the function of the flanking DNA is to promote homologous recombination at a predetermined locus in the chloroplast genome, once the vector has been delivered into the host protoplast either via particle bombardment or following PEG treatment. Plastid-transformed plants have been shown to express transgenes at a high level thanks to the high copy number of plastids present in the plant cells.

Cisgenesis and Intragenesis

The term 'cisgenesis' refers to the transfer of one of more genes originating either from the host species itself or from a close relative. A typical cisgene comprises the target gene itself along with its native promoter and terminator region. 'Intragenesis' refers to where the target gene (again isolated from the host species or a close relative) is attached to a host (or close relative) regulatory element, but not necessarily derived (as is the case for a cisgene) from the same locus as the gene sequence itself was.

Genome Editing with Sequence-Specific Nucleases

Genome editing using site-specific integration, deletion, and mutation is expected to have a profound impact on plant transformation in the near future. The technology is based on the use of chimeric nucleases, which induce targeted DNA double-strand breaks (DSBs). DSBs in nature are repaired either by homologous recombination or by error-prone nonhomologous end joining. The target genomic site can be repaired by inserting a transgene into the DSB. A number of engineered nucleases can in principle be designed to generate DSBs at almost any chosen genomic location.

Zinc-finger nucleases (ZFNs) are synthetic restriction endonucleases that combine a zinc-finger domain recognizing a specific DNA sequence with a nuclease domain (usually based on the *FokI* restriction enzyme). The sequence of the zinc-finger domain directs the ZFN to a specific genomic site.

TALENs are artificial endonucleases built by fusing the DNA binding domain present in a TAL protein to the *Fok*I cleavage domain. The DNA binding domain comprises a repetitive array of 33–35 amino acid residues, which determines the specificity of the TALEN's binding.

Homing endonucleases (or meganucleases) are highly specific DNA cleaving enzymes, ubiquitously found in microbes and in eukaryotic mitochondria and chloroplasts. They are encoded by genes that display genetic mobility, such as introns and inteins. A number of these enzymes have been completely redesigned for them to serve as tools for genome engineering. They are typically homodimeric but can be developed to form heterodimers of differently engineered monomers, targeting a large genomic recognition site (20–30 bp).

CRISPR/Cas, which represents 'clustered regularly interspaced short palindromic repeat-associated nucleases,' has recently emerged as a potential tool for genome editing in plants. The system is based on a Cas9 nuclease and an engineered single-guide RNA (sgRNA), which specifies the target nucleic acid sequence. sgRNA is a chimera created by fusing two short molecules called CRISPR RNA (crRNA) and transactivating crRNA (tracrRNA). The canonical length of the guide RNA is 20 nt.

crystalline Bt toxin have been used to control insect pests since the 1920s. This remains one of the few insecticides acceptable to organic or 'ecological' agricultural systems. The first Bt toxin gene was cloned in 1981, and the first field trial of transgenic tobacco expressing a Bt toxin gene was performed in 1986. The first GM rice involved *Bt* as the transgene (produced in 1988). Current *Bt* maize cultivars, which have been commercialized in the United States, contain several *Bt* genes to give a range of insect specificities, often in combination with herbicide tolerance. Other insecticidal proteins have in the meantime

been discovered, including lectins, protease inhibitors, antibodies, wasp and spider toxins, microbial insecticides, and insect peptide hormones.

China was the first country to commercialize virus-resistant GM crops in the form of virus-resistant tobacco in 1992, and this was followed by virus-resistant tomato, zucchini, squash, and watermelon. Commercially available transgenic papaya germplasms engineered to express the coat protein of papaya ringspot virus have shown a high level of resistance: 80% of the Hawaiian papaya crop is currently GM.

Abiotic stress tolerance

Abiotic stress, particularly soil salinity, drought, and extreme temperature, is a leading cause of crop loss. As water resources decline and desertification intensifies in response to climate change, such losses are likely to worsen. The expected increase in the area and extent of arable land salinization will require new technologies to ensure crop survival. Despite an enormous and continuing research effort, few genes able to enhance abiotic stress tolerance have been convincingly demonstrated as able to perform as promised under field conditions. The sequestration of solutes into the vacuole is a physiological strategy commonly adopted by plants as a response to drought and salinity stress. Enhancing the production of osmolytes such as mannitol and proline has been attempted in various plant species as a means of improving the level of abiotic stress tolerance. Upping the level of expression of the gene encoding choline oxidase (*codA*) is known to enhance the production of glycine betaine, a small molecule used by plants to achieve osmotic adjustment. In rice, expressing *codA* in the chloroplast has been shown to represent an effective means of enhancing the plant's tolerance against abiotic stress. The most remarkable example to date of a successfully commercialized GM crop improved with respect to abiotic stress tolerance is represented by Monsanto's DroughtGard™ maize, released in 2013 in the United States. The transgene introduced into this maize encodes cold shock protein B (CSPB) and was isolated from the bacterium *Bacillus subtilis*. CSPB acts as an RNA chaperone, helping to maintain physiological performance during a stress episode by binding to and then unfolding RNA molecules in a way that allows them to function normally. DroughtGard™ materials have been shown to maintain grain yield better than wild-type maize under a regime of water stress.

Improvement in Product Quality

Product quality is taken to include nutritional value, organoleptic quality, the prevention of, or at least the delay in, the postharvest degradation or even loss of nutrients; and the removal of compounds having a deleterious effect. This second generation of GM plants has yet to live up to expectations, and no commercial crops having these properties are currently on the market.

Improved shelf life

The Flavr Savr™ tomato was the first GM crop and whole food approved by the US government Food and Drug Administration. The product reached the market in 1994. It was engineered to exhibit prolonged shelf life, which was achieved by delaying its postharvest ripening, softening, and rotting. The technology involved was the introduction in the antisense orientation, of a gene encoding polygalacturonase. The Flavr Savr™ tomato was abandoned in 1999, in part due to consumer resistance to GM technology and in part to the fact that the trait had been introduced into a background that prevented the crop from performing well in a commercial situation. Delayed ripening is a trait that should be useful for a number of soft fruits, in particular raspberry and strawberry. Extending a product's shelf life not only benefits the producer and retailer but also enables the consumer to keep the product longer before it spoils.

Improved nutritional content

While in developed economies, the regular inclusion of fresh vegetables and fruit in the diet avoids micronutrient deficiency; this is more difficult in situations where the diet relies over heavily on cereals that lack key vitamins, minerals, and essential amino acids. Rice and maize, for example, are both low in lysine, vitamin A, iron, zinc, and selenium, all of which are essential for normal growth and metabolism. GM technology can in principle engineer cereals to produce higher amounts of these micronutrients in the grain. A leading example is 'golden rice,' the history of which illustrates not only how GM technology could help alleviate malnutrition in developing countries but also how intellectual property rights and patents owned by multinational corporations can complicate matters, even when the humanitarian case is strong. Vitamin A deficiency is widespread in the developing world; it is estimated to account for the deaths of some two million children per year and is a major cause of blindness. Humans can synthesize vitamin A from its precursor β-carotene, a common compound in plants but absent from the cereal grain. The golden rice concept succeeded in engineering the rice endosperm to produce β-carotene by introducing a set of three transgenes obtained from *Narcissus* and *Erwinia*. Some of the transgenic lines were able to accumulate enough provitamin A to impart a distinct yellow color to the endosperm (hence the name 'golden' rice). Further development has led to the production of 'Golden Rice 2,' in which the *psy* gene from maize has been combined with the *Erwinia uredovora* carotene desaturase gene *crtI*. Compared with the original golden rice, this version produces 23 times the amount of carotenoid (a maximum 37 $\mu g\, g^{-1}$) and an improved accumulation of β-carotene. It has been estimated that 72 g of Golden Rice 2 grain should provide 50% of the recommended daily allowance of vitamin A for a 1–3-year-old child. The intention of the golden rice project was to provide the technology free of charge to the developing world, which required the negotiation of more than 100 intellectual and technical property licenses. For more information, including technical, historical, and humanitarian aspects, the reader is referred to the web page of the golden rice project.

Rice is also a poor source of vitamin B9 (folate). The fortification of rice grain with folate has been achieved by heterologously expressing various genes from *Arabidopsis thaliana*, which are involved in the folate pathway. The best of the transgenic lines currently available accumulate 100-fold the wild-type level of folate, such that a 100 g portion of transgenic grain contains as much as four times the adult daily folate requirement. Iron deficiency, which leads to the development of anemia, is also being tackled by the biofortification of rice; the strategy being followed here focuses on a gene for ferritin,

driven by an endosperm-specific promoter. Similar successes have been recorded for increasing the lysine content of canola, soybean, and maize.

Fatty acids represent another potential target for GM-based improvement crop, because certain of these molecules have important effects on human metabolism and health. One of the most promising approaches has targeted the transgenic production of very-long-chain polyunsaturated fatty acids. The production of stearidonic acid by the removal of Δ^{12} desaturase activity has attracted much attention from various biotechnology companies, and a transgenic soybean, which produces 15% stearidonic acid and 5–8% GLA (gamma-linolenic acid), is reportedly close to commercialization. Increasing the accumulation of secondary metabolites in tomatoes is being attempted by inducing the overexpression of certain key structural or regulatory genes; for example, manipulating the expression of a certain transcription factor has proved to be particularly effective in enhancing the accumulation of anthocyanin up to a level of 3 mg g^{-1} fresh weight, of flavonols up to a level of 10 mg g^{-1} fresh weight, and of resveratrol. Importantly, a pilot experiment has shown that when cancer-susceptible mice were provided with a diet supplemented with high-anthocyanin tomatoes, their life span was significantly extended.

Production of Pharmaceuticals

A third generation of transgenic crops is represented by the engineering of plants to produce high-value products such as vaccines or industrially important molecules. The use of plants for this purpose (sometimes referred to as 'pharming') has some advantages over microbial platforms, particularly concerning scalability, production cost, and the use of a eukaryotic organism. A range of plant species have been experimented with as carriers. Potato, tomato, and carrot have all been transformed to express certain vaccines, with the potato and banana in particular seen as favorable as a source of orally administered vaccine. Lettuce, cabbage, and cauliflower have tended to be relatively inefficient as expressors of vaccines. Tobacco, as a nonfood crop, represents an ideal choice for the production of vaccine antigens. The species is very simple to transform (it was the first plant species to be transformed) and has been extensively bred to produce high quantities of biomass, and its management as a commercial crop is well developed. Grain crops have the advantage that proteins accumulated in the seed tend to be stable at ambient temperatures.

Currently, three pharmaceutically attractive proteins have been approved for manufacture, namely, an antibody to combat caries; a vaccine against the Newcastle virus (a pathogen of poultry) glucocerebrosidase, used for the treatment of Gaucher's disease; and anti-Ebola agent ZMapp produced in tobacco.

Food Derived from GM Crops

Most current GM crops involve a species in the human food chain, where the product is consumed either directly as food (e.g., rice) or indirectly as the raw material for a processed product (e.g., canola). The major nonfood GM crop is cotton. Table 1 lists examples of GM foods. GM food has been categorized for regulatory purposes into (i) GM food (potato, tomato, soya, maize, sunflower, rice, pumpkin, melon, etc.), (ii) food containing ingredients derived from GM plants (starch, oil, sugar, amino acids, vitamins, etc.), and (iii) food containing GM organisms (such as yogurts made with transgenic *Lactobacillus*).

Table 1 Examples of GM foods obtained from GM crops

GM crops	*Appear on ingredient list as*	*Examples of food*
Maize	Glucose, glucose syrup, dextrose, fructose, maltodextrin, starch modifier/thickener	Cakes, biscuits, muffins, muesli bars, breakfast cereals, simmer sauces, snacks, peanut butter
Soybean	Soy oil/vegetable oil, soy protein/vegetable protein, soy lecithin/ emulsifier	Mayonnaise, bread, cakes, biscuits, snack foods, chocolate, margarine-type spreads, sauces
Canola	Vegetable oil, canola oil	Cooking oil, margarine-type spreads, mayonnaise, bread, cakes, biscuits, snacks (such as potato chips)
Cotton	Vegetable oil/cottonseed oil	Cooking oil, margarine-type spreads, mayonnaise, snacks (such as potato chips), simmer sauces

Maize Products

Ground and dried maize constitutes a staple food in many parts of the developing world. GM versions of maize have been commercialized carrying transgenes endowing herbicide tolerance and insecticidal activity. In the developed world, a large proportion of the maize crop is used as livestock feed, while most of the rest is processed into high-fructose syrup and starch or cooking oil or is converted into biofuel (ethanol). A small proportion enters the human food chain directly in the form of grits, meal, and flour. Maize oil is sold directly without further processing as cooking oil or is used to make margarine.

Soybean Products

In addition to HT and *Bt* soybean, GM technology has also been used to alter the composition of its oil. The fatty acid profile of wild-type oil encourages its rapid oxidation, and the rancid flavor this generates has limited its usefulness to the food industry. GM versions of soybean have been derived in which the amount of oleic and stearic acids has been boosted, while that of linolenic acid has been reduced. Oil represents about 20% of soybean seed dry matter, with the remainder being used for the manufacture of a wide range of food and beverage products. A substantial proportion of the harvested seed supplies the poultry and animal feed market.

Fruits and Vegetables

GM versions of a number of fruit and vegetable species have been generated; the following lists just some of the more

significant ones. Papaya has been engineered to resist ringspot virus, which in the early 1990s was a major priority for Hawaiian growers. The resistance effectively saved the state's papaya industry. The NewLeaf™ potato, which harbors the *Bt* gene, was intended to provide protection from damage caused by the Colorado potato beetle. The product was released by Monsanto in the late 1990s but was withdrawn in 2001 due to resistance from the large fast-food retailers. Currently, no transgenic potatoes are on the market, although there is an application from BASF for approval to release 'Fortuna potato,' a cultivar resistant to late blight thanks to the presence of the two genes *blb1* and *blb2*, isolated from the wild related species *Solanum bulbocastanum*. A second GM potato produced by BASF was 'Amflora,' the starch content of which had been manipulated; this cultivar was grown in Germany and Sweden in 2011, but was no longer commercially available once BASF had decided to cease its involvement in GM crops in the EU in 2012. GM zucchini selected to be resistant against three viruses are currently grown in North America. The 'nonbrowning Arctic' apple, created by Okanagan Specialty Fruits, is currently being marketed in the United States and is expected to be released shortly in Canada, pending regulatory approval. Browning is caused by the action of polyphenol oxidase (PPO) enzymes, so a nonbrowning type requires the silencing of all of the active *PPO* genes present. Bangladesh (but not India) has approved the commercial cultivation of eggplant carrying Bt. Following a human trial of provitamin A-enriched banana in the United States, the aim is to growing the crop commercially in Uganda by 2020. The flesh of this GM banana is orange (rather than the normal cream color) as a direct result of the accumulation of provitamin A.

Processed Derivatives

Vegetable oil enters the human food chain in the form of both cooking oil and margarine and is used in the manufacture of many prepared foods. The GM crops contributing currently to commercial vegetable oil are predominantly not only maize and soybean but also canola and cotton. The refining process removes nearly all nontriglyceride ingredients, but both protein and DNA residues can still be detected in the oil. Canola is the source of the third most widely consumed vegetable oil; the product also has a range of nonfood uses, for example, in the cosmetics industry. Oil derived from cottonseed is largely used for culinary purposes. Both maize and soybean oil are used as a source of lecithin, a compound widely used as an emulsifier by the food processing industry. Glyphosate-resistant sugar beet has been extensively adopted in the United States and has been approved for cultivation in many countries. Sugar beet represents a major source of refined sugar and molasses, and the residues are used as an ingredient of animal feed. The refining process is highly effective, and there are no confirmed reports of the presence of residual DNA or protein in commercially produced sugar.

Global GM Production

Commercialized GM Crops

The first transgenic food to be commercialized was the Flavr Savr™ tomato, which was released in 1994, and other GM crops followed shortly thereafter. By 1996, 1.66 Mha of land was under cultivation by GM crops, largely maize and soybean. In spite of a widening international acceptance of GM technology, the portfolio of crop–trait combinations remains rather limited. By 2012, HT soybean accounted for 47% of the global area sown to GM crops and 79% of the traded volume in soybean. The second most widely exploited GM crop is maize, accounting for 35% of the global area sown to GM crops and 32% of the traded volume (2012 figures). The transgenes present in GM maize confer either HT- or *Bt*-mediated insecticidal activity; increasingly, these two traits are being combined into a single cultivar. The other two widely grown GM crops are cotton and canola. The resistance against bollworm and budworm conferred to cotton by the *Bt* gene is very attractive to developing country producers who often lack the infrastructure and financial resources to resort to control based on chemical insecticides; in the United States, combined Bt and HT cotton is commonly grown. HT canola is currently restricted to Canada, the United States, and Australia. The remaining GM crops (HT alfalfa and sugar beet, virus-resistant papaya, squash, eggplant, and zucchini) cover only relatively small areas.

An example of a multitransgene ('stacked') GM crop is SmartStax maize, produced by Monsanto and Dow AgroSciences. The line carries a total of eight transgenes (including *Bt*). The outcome of the GM intervention is to provide protection against both surface insects, such as the corn earworm (*Helicoverpa zea*), the European corn borer (*Ostrinia nubilalis*), and the southwestern corn borer (*Diatraea grandiosella*), and subsurface pests, such as western, northern, and Mexican corn rootworms (*Diabrotica virgifera virgifera*, *Diabrotica virgifera zeae*, and *Diabrotica barberi*), while incorporating HT crops to facilitate broad-spectrum weed control. The variety was approved for cultivation in the United States (and elsewhere) in 2009. A more recent innovation is Genuity® DroughtGard™ maize, which is the first GM intervention to address drought tolerance.

The Geographic Spread of GM Crop Production

The area and production of GM crops are documented by the International Service for the Acquisition of Agri-biotech Applications (Figure 1). By November 2013, regulatory approval for the cultivation of GM crops had been granted by 26 countries. Since 1996, the global area under cultivation by GM crops has increased 100-fold: no other agricultural technology has spread so quickly and on such a large scale. The 2013 area was 175.2 Mha, representing an increase over the 2012 area of 3% (5 Mha). The estimated value of the GM seed market reached US$14.84 billion in 2012, with maize taking 56% and soybean 32% of the sales. GM crops are grown throughout the Americas and a large part of Asia but to only a limited extent in Europe and Africa (Figure 1). The number of countries growing GM crops increased from six in 1996 to 12 in 1999, 17 in 2004, 21 in 2005, 25 in 2009, and 27 in 2013. More than half of the world's population live in the 27 countries currently growing GM crops; 19 of these are developing countries and contribute over half of the global production. The acreage in the developing world exceeded that in the industrialized countries for the first time in 2012. An estimated

Figure 1 World map showing which countries and mega-countries* grew GM crops in 2013. ISAAA Report 2013.

18 million farmers grow GM crops, 90% of whom are small and relatively resource-poor farmers in India, China, South Africa, and the Philippines. The most prominent GM crop in the developing world is *Bt* cotton, which cultivated by over seven million farmers in each of China and India. Some 400,000 Filipino farmers have chosen to grow GM maize. The expectation is that further diffusion of the technology will be more rapid in the developing than in the developed world, fueled by regulatory acceptance by more countries and the development of GM versions of crops, which are concentrated in developing countries, such as rice, cassava, and cowpea.

The United States remains the lead producer of GM crops; the level of adoption of GM maize is 88%, of GM soybean 93%, and of GM cotton 94%. Brazil is the second largest grower of GM crops (23% of the global acreage); its area sown reached 3.7 Mha in 2013, a 10% increase over the 2012 area, consisting largely of soybean, maize, and cotton – 40.3 out of the 46.2 Mha planted to these three crops is covered by GM cultivars. The third largest producer is Argentina, where 14% of the cropping area is sown to GM crops, mainly soybean. India ranks fourth (11 Mha); there, the leading GM crop is *Bt* cotton, which covers 95% of the total cotton acreage – an area that has increased 220-fold since 2002 – and involves an estimated 45 million small farmers. Canada grew 10.8 Mha of GM crops in 2013, with a 96% adoption rate of HT and/or *Bt* canola. China is the sixth largest producer: 4.2 Mha of GM crops, most of which is represented by *Bt* cotton, which enjoys a 90% adoption rate. In Europe, the only significant site of GM crop production is in Spain, where about 0.14 Mha of *Bt* maize was grown during 2013 (up to 15% from 2012). There remains a strong level of consumer resistance to GM technology in Europe. In Africa, currently, three countries have given regulatory approval for particular GM crops – these are South Africa, Sudan, and Burkina Faso – and the current area of GM crop production is estimated to be around 3.5 Mha. Seven other countries (Cameroon, Egypt, Ghana, Kenya, Malawi, Nigeria, and Uganda) have already, or are in the midst of conducting confined field trials, the penultimate step prior to regulatory approval. The public–private partnership 'Water Efficient Maize for Africa' aims to develop drought-tolerant and insect-protected maize using conventional breeding, marker-assisted breeding, and GM technology, with the goal of making such varieties available royalty-free to smallholder farmers in Sub-Saharan Africa; a time line of 2017 is expected for the first varietal releases. The African Agricultural Technology Foundation (AATF) is working towards making pod borer-resistant cowpea and bacterial wilt-resistant banana available to small farmers in Africa. The International Rice Research Institute has successfully bred the golden rice trait into its widely adapted breeding line IR64 and other Asian varieties to test whether the agronomic performance of the new varieties will be acceptable to farmers.

Public and Scientific Concerns Surrounding GM Crop Production and Consumption

Antibiotic Resistance Genes

Since the successful transformation of a plant cell is a rather low-frequency event, a means of positively selecting for transformed cells is highly desirable. Among the most common such selective agents are antibiotics, incorporated into the cell culture medium in order to kill cells (those that have not been transformed) that have not taken up the antibiotic resistance gene associated with the transgene. The deployment of antibiotic resistance genes for this purpose has proved to be a major barrier to the consumer acceptance of GM crops. The fear is that the incorporation of such resistance genes in a transgenic plant risks its horizontal transfer to pathogenic gut microorganisms when GM food is consumed. This scenario is possible, but highly unlikely. Firstly, the antibiotic resistance genes used to create GM plants originate from natural populations of bacteria, so there is as much, if not more, chance of horizontal transfer between natural bacteria in the environment and gut flora, especially as the gene is typically present in bacteria in a highly mobile structure called a plasmid. Secondly, the antibiotic resistance genes used in plant transformation confer resistance to antibiotics, which are longer used in human or animal medicine, because they have long since lost their effectiveness after many years of intensive use. Some progress has been made to sidestep the requirement for antibiotic resistance genes by adjusting the form of sugar made available to the in vitro cultured plant cells. Other more recently developed strategies have sought to exploit site-specific recombination systems (see **Box 1**).

The Problem of Super Weeds

A potential problem associated with the use of HT crops is the selection intensity, in which their use puts on weed populations to develop resistance, whereby rendering the weeds difficult to control. A way in which such resistance could readily develop is the transfer of the trait from the crop to a wild weedy relative through cross-pollination. Such an event has been documented already, as 24 glyphosate-resistant weed species have been identified over the period since the introduction in 1996 of Roundup Ready GM crops. Glyphosate-resistant weed species have now been found in 18 countries worldwide, with a significant impact on the economics of crop production in Brazil, Australia, and Argentina. It needs to be borne in mind, however, that herbicide tolerance can arise spontaneously by mutation among weed populations subjected to herbicide use quite independently of the GM situation, since 64 weed species have been shown to have developed resistance to atrazine, even though no atrazine resistance transgene has ever been deployed. The transfer of herbicide resistance to weeds is a live issue nonetheless, although at present it is regarded more as an issue for agricultural management than as a public hazard. The development of local populations of HT weeds needs to be dealt with by the use of alternative herbicides and/or a directed program of mechanical weed removal. Over the next few years, it is likely that GM products will be developed incorporating herbicide tolerance based on herbicides other than glyphosate, to give farmers more flexibility in managing weeds; one such product already available is the Bayer CropScience Liberty series of GM cotton, soybean, canola, and maize, which all carry resistance to the herbicide glufosinate.

'Genetic Pollution': Gene Flow from GM Crops into Landraces

In 2000, an attempt by a group of farmers in Oaxaca (Mexico) to gain organic certification for their maize landrace failed because it carried both the *Bt* and HT genes used in Monsanto GM material. Since GM crops were at the time not approved for commercial production in Mexico, it was assumed that the transgenes must have been transferred via cross-pollination from GM plants. Since this time, a number of scientifically rigorous studies have been made to characterize the extent of transgene flow into Mexican maize; some of these have failed to show any introgression of transgenes. The scientific community remains divided over whether transgenes have really entered the gene pool of Mexican landrace materials; some critics worry that the diffusion of these GM traits into local material may compromise plant fitness.

Health Risks Associated with the Consumption of GM Food

The possible health risks associated with the consumption of GM food center on the introduction of toxins and allergens. The argument is that the insertion of a transgene(s) can lead to unforeseen pleiotropic effects when it is expressed or that the insertion process per se causes changes to native genes. The risk that food may contain allergens is not confined to that produced from GM crops, since, for example, according to the US NIH National Institute of Allergy and Infectious Diseases, the prevalence rate of peanut allergy is 0.6%, while a substantial number of people cannot tolerate wheat gluten. Even conventional plant breeding can sometimes throw up unexpected toxicities. There are examples of GM products that were discarded prior to release because of this problem: An example is the attempt to improve the resistance of the pea to pea weevil attack by inserting a gene isolated from the kidney bean; the product was never marketed because test feeding to mice identified a potential negative immune response. A second, celebrated example involved a soybean GM bred as a nutrition-enhanced poultry feed that was discontinued when the transgenic protein tested positive in a serum assay. The industry has had to learn to pay due attention when foods may contain plant ingredients derived from GM crops engineered with genes encoding known allergenic materials, such as milk, eggs, nuts, wheat, legumes, fish, mollusks, and crustaceans. Part of the regulatory process for GM crops involves a demonstration that no unforeseen products are present ('substantial equivalence') in the comestible part of the proposed crop cultivar.

A 2012 publication, which attained wide notoriety, described a two-year feeding study of rats given grain of a GM HT maize cultivar. The study claimed that the GM material induced deleterious effects on the health of the rats. After a year-long investigation, the paper was withdrawn by the journal on the grounds that it was not sufficiently scientifically rigorous. The European Food Safety Authority later issued a statement confirming that the study's design and methodology

were both defective and that there was insufficient evidence to reopen the safety evaluation of this GM maize cultivar. Despite a nearly 20-year exposure of the US population to massive quantities of GM maize in their diet, there is still no convincing evidence that GM technology per se is associated with any specific health risk.

Business Related to GM Crops

Estimates of the economic benefits flowing from crop biotechnology lie in the billion dollar range, shared between consumers, producers, and the companies that have developed the GM crop varieties. Some concerns have been voiced regarding the risks of monopoly control of GM crops by a handful of powerful multinational corporations. Current regulatory requirements to bring a GM crop variety to the market are both time-consuming and expensive and constitute a major barrier to market entry and exclude public sector involvement. Nevertheless, the present generation of GM crops has rested largely on discoveries made in the public sector, so the public perception that crop biotechnology is the exclusive domain of multinational corporations is illusory. The so-called terminator technology has been promoted in some quarters as an example of big business imposing its wishes on farmers and consumers. This GM application attracted adverse publicity because cultivars engineered in this way would produce sterile offspring and thus prohibit the use of farm-saved seed. At the same time, the opponents of the technology have chosen to ignore a potential benefit of the technology in preventing the escape of transgenes into wild plants. Terminator technology has not been used in any GM crops to date.

Introduction

Genetically modified (GM) foods have been the main focus of academic and management practitioner's debate for the past 20 years. Consumer concerns over the safety of GM food products and the cultivation of GM crops are channeled through applied research results. The current economic turbulence and the food crisis, during which food prices are increasing, while income and consumer confidence plummets, bring the consumer audience over the hard choice to cut spending, and in the center of this debate, GM food is found to be promoted as both a solution and a problem to the current consumer food needs and wants. With the current unveiled scandal of horse meat contamination in products labeled as beef in Europe, consumers are losing trust to the food production chain, and the impact of this mistrust escapes the realms of the United Kingdom affecting the continental markets. Despite the scandalous turbulence in the media in both the United Kingdom and the EU, the rising prices on food are bringing GM food back in the center of the debate.

During the 2007–08 global food crisis, the alleged agribiotechnology solution was purely a resourceful spin of the agribiotechnology companies trying to exploit the media outburst on the food prices during that period. This trend has been pointed out by many studies. The debate in the area of the food crisis and GM food seems to circulate around the allegations that GM food is 'forced' into the food market or that the food crisis inevitably leads to the GM food adoption. This high polarization finds its roots in the global sentiment on international resources and the cost of living around the world midst one of the hardest economic downturns that the developed world has faced so far.

In the area of political discussion, scholars have been equally evolving the debate further. It has been observed that there is a political myth construct around GM food and genetically modified organisms (GMOs), attempting to present GM produce as 'Frankenfoods,' drawing an image to the public in this way of the mad scientist developing catastrophic recipes that will ultimately bring the Armageddon on earth. It sounds as an overstretched remark, and someone has to look twice to notice that these points are raised by an academic and not a reporter.

Many scholars focus on the EU reluctance in introducing or adopting GM food. This part of the debate appears to be split into two equal divisions: those that favor the introduction of GM foods in the EU and those that strongly oppose it.

Those that oppose it refer to possible risks of environmentally damaging effects, and others refer to ethical concerns on corporations setting patents and prohibiting farmers to reuse GM seeds, while the most prominent argument appears to be the insufficient test trials and the absence of evidence on long-term health effects through trials. On the other hand, there is an abundance of authors in support of the introduction of GM food, bringing forward the benefits of GM food technology and debating the prospect of GM food being an important remedy on world hunger and the current food crisis while insisting on the applications of GM food technology on a variety of commercial sectors that mostly help improve the human effect on the environment. These views have been portrayed as a form of 'anti-GMF' hysteria, and popular concerns on the issue have been discussed, offering evidence against these concerns.

GMOs can be defined as organisms in which the genetic material (DNA) has been altered in a way that does not occur naturally. GM foods are derived from GMOs.

Currently, ~50 GM plants and derived products are approved for commercial use in the EU (http://ec.europa.eu/food/dyna/gm_register/index_en.cfm).

GM plant applications cover seven crops; mostly maize, followed by cotton and soybean, and – to a lesser extent – oilseed rape, potato, sugar beet, and rice.

The predominant traits include not only resistance to insect pests and tolerance against certain herbicidal active substances but also modified composition (e.g., altered fatty acid profile), tolerance to drought, and reduced amylose content. Many GM plant applications deal with 'stacked' events where two or more single transformation events have been combined by conventional crossing to introduce several traits into one plant.

In the economic arena, the arguments for the GM food outweigh those that are against. The positive impact of GM crops in developing countries on income, poverty, and nutrition has been defended by many authors. The positive developments of the applications of GM crops in China and India, with reference to Bt cotton and beta-carotene golden rice, have been discussed.

As the discussion on GM food continues, evidence suggests that there is a great rift in the production and adoption of GMCs (GM crops). It has been indicated that the 11 countries that grew one or more million hectares in 2012 are led by the United States that grew 69.5 million hectares, Brazil with 36.6 million hectares, Argentina with 23.9 million hectares, Canada with 11.6 million hectares, India with 10.8 million hectares, and China with 4.0 million hectares. Of the top 11 countries, each growing 1.0 million hectares or more of biotech crops, the majority are industrialized countries. Over 1 million hectares are grown also in Pakistan and Uruguay and about one million in Bolivia.

Legislation Issues

According to the Council Directive 90/220/EEC, "'genetically modified organism' (GMO) means an organism, with the exception of human beings, in which the genetic material has

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00348-2

been altered in a way that does not occur naturally by mating and/or natural recombination." In the Council Directive 98/81/EC, "'microorganism' shall mean any microbiological entity, cellular or non-cellular, capable of replication or of transferring genetic material, including viruses, viroids, animal and plant cells in culture." Also in the Council Directive 98/81/EC, "'genetically modified micro-organism' (GMM) shall mean a micro-organism in which the genetic material has been altered in a way that does not occur naturally by mating and/or natural recombination." "*Biotechnology* is the use of living systems and organisms to develop or make useful products, or 'any technological application that uses biological systems, living organisms or derivatives thereof, to make or modify products or processes for specific use.'"

The Regulation (EC 1829/2003, Articles 12 and 13) imposes the labeling of GMOs in the words 'GM' and 'produced from GM (name of the ingredient)' in the following cases:

- In case of an accidental or technically unavoidable quantity of approved GMOs in conventional foods, the lowest detection concentration is specified at 0.9% for every isolated food ingredient included.
- In case there is an accidental or technically unavoidable quantity of GMOs in foods or cattle feed and there has been a positive scientific evaluation by the official European Community authorities, but its circulation has not yet been typically approved, the percentage is specified at 0.5%.

Moreover, Regulation (EC) No. 1830/2003 "concerns the traceability and labeling of genetically modified organism and the traceability of food and feed products produced from genetically modified organisms and amending Directive 2001/18/EC." According to the previously mentioned community legislations, the process of assessment of environmental hazards from GMOs aims at determining and evaluating, in every case separately, the potentially unfavorable consequences (direct, indirect, short-term, and long-term) that their release may have on people's health. In parallel, the cumulative consequences are taken into account over a long time span.

The strict regulations that the EU imposes for the presence of GMOs in food and feed have been discussed thoroughly. The strict labeling laws allow the EU to effectively filter GM food imports and accept only those products that contain GM food ingredients that are in line with the EU food safety regulations (currently representing 0.9% of the total GMF varieties).

Moreover, it is discussed that where the EU is reliant on imports (particularly soybean for animal feed) from North and South America, these imports are allowed to enter the EU market despite the ban of those products that could contain unsafe GM foods or GM ingredients.

The US Food and Drug Administration (FDA) does not currently require genetically engineered organisms (GEOs) to be identified because it has determined that genetically engineered foods are substantially equivalent to conventional crops and as such they are safe.

Genetically engineered foods would require labeling only if modifications altered food composition significantly, changed the nutritional value, or introduced an allergen.

According to the Genetically Engineered Food Safety Act (2003), the Congress defines 'genetically engineered organism' as (A)

> "an organism that has been altered at the molecular or cellular level by means that are not possible under natural conditions or processes (including but not limited to recombinant DNA and RNA techniques, cell fusion, micro- and macroencapsulation, gene deletion and doubling, introducing a foreign gene, and changing the positions of genes), other than a means consisting exclusively of breeding, conjugation, fermentation, hybridization, *in vitro* fertilization, tissue culture or mutagenesis, and (B) an organism made through sexual or asexual reproduction (or both) involving an organism described in subparagraph (A), if possessing any of the altered molecular or cellular characteristics of the organism so described."

According to the Genetically Engineered Pharmaceutical and Industrial Crop Safety Act (2003), "'pharmaceutical crop' means a genetically engineered plant that is designed to produce medical products, including human and veterinary drugs and biologics. The term includes a crop intentionally treated with genetically engineered material that, in turn, produces a medical substance." "Pharmaceutical crops and industrial crops also pose substantial liability and other economic risks to farmers, grain handlers, food companies, and other persons in the food and feed supply chain."

Canada and the United States opted to regulate all plants or products with new traits developed through either genetic engineering or any other plant breeding techniques under the same, yet existing, regulatory system. The transformation techniques were not considered inherently risky. Therefore, the focus of product-based regulatory systems is on the risks of products and new traits or attributes introduced into a plant, rather than the method of production.

Argentina, Brazil, the EU, and many other countries have put new process-based regulatory systems in place to regulate the use of GMOs, as the techniques used for their production were thought to raise specific safety concerns. In these jurisdictions, a GMO is mainly characterized by the transformation techniques used in its production. "Techniques of genetic engineering/modification include, but are not limited to: recombinant DNA, cell fusion, micro- and macro injection, encapsulation, gene deletion and doubling. Genetically engineered organisms will not include organisms resulting from techniques such as conjugation, transduction and hybridization."

Moratoriums on GMO release and impacts on investment in GMO research are the cases for Australia. Technology assessment (TA) is a process that considers the societal implications of technological change in order to influence policy to improve technology governance. TA formally emerged with the US Office of TA, which began in 1974 to serve the US Congress. A formal TA agency is due to be formed in Australia, which would build capacity in TA to deal proactively with technology controversies and contribute to more socially aware technological development and provide the foresight, oversight, and community dialogue that informs technology governance in other countries, notably in Europe.

Risk Assessment of GM Food/Feed

According to WHO (1995), risk assessment is the scientific evaluation of known and potential adverse health effects resulting from human exposure to foodborne hazards.

Recently, the EU Standing Committee on the Food Chain and Animal Health (SCoFCAH) adopted the implementation of a Commission Regulation on the applications for authorization of GM food and feed in the European Union. The Regulation follows guidance developed by the European Food Safety Authority (EFSA) for the safety assessment of the foods/feed derived from GM plants. The new regulation demands a 90-day feeding trial in rodents for every single transformation event and, in specific cases, the same trial for plants containing transformation events stacked by conventional crossing. EFSA guidance recommends this type of experimentation only under certain conditions.

The risk assessment strategy for GM plants and derived food and feed is focussed on the comparison between GM plants and derived food and feed and their respective comparators. This comparative approach is based on the fact that traditionally cultivated crops have gained a history of safe use for consumers and/or domesticated animals. The concept of substantial equivalence applies here.

Risk assessment includes "(i) the molecular characterization, (ii) comparative agronomic, phenotypic and compositional analysis of the GM plant and derived food/feed and its traditional counterpart, (iii) toxicological assessment of newly expressed compounds and of constituent compounds the levels of which may have changed as a result of the genetic modification, (iv) the assessment of potential allergenicity of the novel protein(s) as well as of the whole food derived from the GM plant and (v) the nutritional assessment of the food/feed derived from a GM plant."

Toxicological testing must be proportionate to the potential source(s) of new hazards in order to be robust and efficacious. These hazards for GM products may be derived from the transformation process, that is, from newly expressed substance(s) or via some alteration of the plant composition.

Specific toxicity tests such as repeated dose–toxicity studies using laboratory test animals may be needed for the characterization of single substances (e.g., newly expressed compounds including proteins) and for the assessment of the consequences of any compositional alterations (e.g., in the content of micro- and macronutrients and natural toxins/antinutrients).

"Given the limitations of animal feeding trials with whole GM food/feed, these experiments should only be performed where necessary and EFSA (2011a) has indicated examples of conditions where such studies may be useful. These include (i) when the genetic modification has resulted in multiple and complex compositional alterations, (ii) when there is uncertainty and safety concerns on the possible occurrence of unintended (off target) effects (e.g., where new open reading frames (ORFs) are produced with similarities to toxins/allergens, or where metabolic pathways of the plant have been perturbed) or (iii) when there are indications for interactions between single events that have been stacked. This list of conditions is not exhaustive, and decisions should be made on a case-by-case basis, taking into account developments in our understanding of the potential impacts of genomic perturbations."

The updated guidelines for the risk assessment of GM plants and derived food and feed were used by the European Commission (EC) and EU member states as a basis for the preparation of the *Commission Implementing Regulation (EU) on applications for authorisation of genetically modified food and feed in accordance with Regulation (EC) No 1829/2003 of the European Parliament and of the Council and amending Regulations (EC) No 641/2004 and (EC) No 1981/2006*. This Regulation has been adopted in February 2013 by EU member states and came into force 6 months after its publication.

The landscape of GMOs is changing quickly including the development of GM plants targeted toward major compositional changes such as the development of crops with modified metabolism and physiology to provide improved quality and enhanced nutritional profiles.

However, a comprehensive safety assessment of the GM plant per se is advocated in cases where appropriate comparators are not available. GM plants with stress-tolerant phenotypes are now being widely tested in field trials around the world, with the first and most advanced drought-tolerant maize being launched commercially in the United States in 2013. These plants may raise specific issues for the environmental risk assessment that will be more challenging to resolve compared with the first generation of GM plants.

Besides new traits, the next generation of GMOs will consist of new types of organisms that have not been previously assessed by EFSA, such as GM trees, GM animals, and GM algae. Regarding GM trees, some risk assessment guidelines are already available from international discussions (OECD).

The EFSA GMO Panel concluded that cisgenic and conventionally bred plants represent similar hazards, whereas intragenic and transgenic plants could raise new hazards. The EFSA GMO Panel considered that its existing risk assessment guidelines for plants and products developed through transgenesis would generally apply to cisgenic and intragenic plants but that it would require less event-specific data, depending on the specific case. In addition, the EC has commissioned several reports on specific aspects of new biotechnological plant breeding techniques. In the United States, the Environmental Protection Agency has opened up a debate on a draft rule that would exempt certain cisgenic organisms from registration as GMOs. Another challenge is the development of regulatory frameworks for novel plant products that allow international harmonization.

The US Department of Agriculture, for example, announced that it does not have the authority to oversee cisgenic plants created without the help of a plant pathogen, whereas the Australian Office of the Gene Technology Regulator considered that certain cisgenic plants might not be regulated. Finally, the need to avoid disparities in risk assessment practices between products with equal potential to cause harm should be addressed. Several authors have argued that process-based regulatory approaches lack consistency because conventionally bred products can raise safety concerns similar to those for their transgenic counterparts. The European Policy Evaluation Consortium, commissioned by the EC to evaluate the EU GMO legislation, came to a similar conclusion. Only the Canadian legislative approach enables consistent evaluation of plants with similar new traits, irrespective of the techniques used.

The assessment of unintended effects caused by the genetic modification plays a key role in the safety/nutritional evaluation of GM foods/feed, which may lead to compositional alterations with potential toxicological effects on humans/animals. Perturbations in the plant's physiology and biochemistry will likely be detected by phenotypic, agronomic, or targeted compositional analyses.

The unintentional contamination can be due to accidental factors, such as cross contamination over the transfer of raw materials/ingredients in containers that have remains of GMOs. The unintentional contamination is mainly caused by the supply of ingredient or raw material contaminated with GMOs or any of its derivatives.

The unintentional contamination can be dealt with the application of preventive or corrective actions, after the risk for unintentional contamination in every ingredient or raw material has been determined. A promising and robust tool for the implementation of risk assessment is the Failure Mode and Effects Analysis, which requires a good knowledge of the system and its elements.

Prevalent Trends Toward GM Foods in Consumer Behavior Studies to Date

The disparity and uneven balance skewed toward a negative stance for GMF in the EU and the United Kingdom have been heavily analyzed by the academia. After 15 years of academic debate, still the future of GM food technology is continuously disputed and by no means concluded. In the field of consumer behavior, GM food has been equally debated.

Some authors have described GM food debate as a worldwide issue that has concluded negatively. The generally positive perception toward GMFs in developing nations stems from more urgent needs in terms of food availability and nutritional content.

By looking in the literature to date, there are three main inquiry paths in the field of GM food and consumer behavior research:

- Attitudinal surveys
- 'Willingness to pay (WTP)'
- Experimental auction markets

The aforementioned trends are linking each research path, with the chosen data collection and analysis approach, and they are indicative of their relationship with the marketing mix (price, place, promotion, and product).

Attitudinal Surveys

There are many in-depth attitudinal studies carried out by various academics, government agencies, and organizations and up-to-the-minute polls carried out by the media. Usually employed with a cross-sectional time horizon, they investigate popular opinions on GM food in various times (relevant to the time each survey was conducted). As a result, the opinions expressed vary considerably and the results rely on how the questions are structured and designed, the demographic design of the sample investigated (e.g., size, demographics, location, and cultural bias), and the time the survey was conducted.

Results show that Europeans have been seeing GM food as a negative approach to food production relative to other biotechnology developments, for example, medical or ecological ones. Equally, the public attitudes toward GM foods are also appearing to be more negative in Europe than in North America and elsewhere. Within the European market, attitudes have varied from country to country and over time.

A good example of the variation over time and by country is that of southern European countries before and after 2008, and earlier before and after 1997. For instance, southern European countries were more accepting GM foods than northern countries up until 1997. After 1999, Italy and Greece revealed the most negative attitudes toward GM foods in Europe. The responses changed again with the 2008 financial crisis, when southern European countries were seeking a more cost-effective approach toward agriculture, thus tending to be more interested in what GM food technology had to offer. According to some forum discussions, Greek farmers are now happier to discuss a possible introduction for GM crops, if that means that their production costs will be reduced.

Equally, consumers would be more willing to consider the benefits that GM food technology has to offer, if GM foods would be introduced as a cheaper and more nutritious solution. Evidently, the current economic hurdles of southern Europe had an impact on consumer attitudes and the recent trends are evident on other countries of southern Europe, such as Spain, Italy, Malta, and Portugal. So this particular category of studies can capture the 'public feeling' toward GM foods and biotechnologies and find trends of such sentiment and other associations with regard to GM food technology. Attitude surveys are relatively easy to run, a 'cheaper alternative' when compared to other inquiry tools and are generalizable to a population. While they can quantify and discuss briefly consumer views and sentiments toward 'softer' variables such as consumer preferences and acceptance, they are counterproductive when used to study price and income effects on consumer-stated preferences. One of the most important criticisms of the attitudinal surveys is their 'hypothetical structure' limitations. Attitude surveys have the capacity to view their subjects as citizens rather than consumers, allowing in this way a survey to be both a public opinion inquiry and a consumer attitude survey. Respondents may consider information and beliefs to reveal their views to the survey.

However, consumer attitudes may or may not be effective proxies of consumer market behavior. Attitude surveys many times appear to present significant biases. The structure of questions, how the information is presented to each subject, and the degree of knowledge and understanding of the respondent on the issue are only some of the areas where bias may form during the design and data collection stage. Another issue in this category of studies is the factor of comparability. Attitudes are known to be variable. Thus, differences in food culture, for example, could make results and trends coming out of a study as nontransferable and therefore not comparable. In any case, biases can be minimized but not eliminated through careful design and statistical analysis.

'WTP' Studies

As majority of the studies focussing on GM food attitudes employ attitudinal surveys, some authors have demonstrated that the model of 'WTP' can successfully encapsulate consumer response toward GM foods, by challenging respondents with realistic food choices. Studies have shown that consumers may be willing to pay more for GM foods, when considering

desirable properties of the food product, or alternatively to pay more to avoid them. These studies employ contingent valuation, which to date is the most popular 'WTP' method. This model develops measures that are projected from consumer responses to a set of hypothetical questions. A hypothetical scenario is presented to the subject who in turn has to make a choice based on the hypothetical attributes presented. Socioeconomic data about the respondents can be collected by using socioeconomic information from each subject, insert additional altitudinal questions, or employ a chain of questions linked with one or more variables in order to confirm that the subject understood the scenario offered.

Using WTP surveys, some authors concluded that many European consumers would need a discount to consume foods with GM ingredients. Some other authors also identified a mean price that consumers are willing to pay for GM food and also linked this price to socioeconomic characteristics.

Evidently, WTP surveys can offer important clues about individual consumer-stated preferences and offer an insight to consumer decision-making on GM food products. The model allows for sociodemographic data to be associated with consumer attitudes. One of the major limitations of WTP surveys is their theoretical design, which does not allow an in-depth insight to GM food products.

The roots of this criticism are founded on the notion that a theoretical question can only receive a theoretical answer. Equally, responses on theoretical scenarios could result in unreliable results to be given. This weakness in particular is a very important event, especially when in GM food attitudinal study, there are high levels of unaware respondents on the issues inquired for the technology. Therefore, the level of information of the participant on the issue is an important factor that combined with the hypothetical nature of WTP survey results into the noted weakness.

This method of inquiry is also vulnerable to two other types of bias: strategic bias and hypothetical bias. Strategic bias can be defined as the event when a respondent overestimates a price, for example, if they intend to affect the outcome of the inquiry. The hypothetical bias can be described as the event when a respondent is unable to accurately define their WTP. This may happen if the respondent was not exposed or was not informed about GM food (or in this case GM vs. non-GM). The nonexistence of real actual purchasing choices reinforces the aforementioned weakness of the WTP model approach. Finally, some studies have shown that even the order in which questions are asked can affect WTP measures by a significant magnitude.

Factors Affecting GMF Attitudes

When it comes to food, attitudes present a unique pattern. Consumers' views on what they consume appear to be sensitive, and sensitivity toward GM food has been reported to vary greatly from country to country. Different markets present different views and information needs. It has been shown that Canadian consumers responded similarly to US consumers, in a forwarded survey. Japanese and Chinese consumers' attitudes differed more from each other than those between Japanese and Norwegian consumers. The Chinese consumers were the most favorable toward GM foods. It has been argued that cultural attitudes including valuing tradition and skepticism of science are the prevailing factors when marketing GM products. It has been attempted in a study to analyze how public attitudes had accustomed the acceptance of GM food in the European Union in general and specifically in Spain and the United Kingdom. The authors found important information reliance and wide-ranging diversity in attitudes toward the uses of biotechnology.

The authors also highlighted the importance of information gateways in showing that consumer participation should precede the adoption of communication policies, as there is a need to align to the local cultural constructs and characteristics of each country. Thus, culture is central to adoption, acceptance, and shaping in general of consumer attitudes toward GM food. In the case of United Kingdom, which is well known for its opposition in introducing GMO cultivation and GMF in their markets, there is a historical trend in sensitivity when it comes to food products.

With a rich history of food scares, the United Kingdom presents a good example on how certain cultural sensitivities on food can affect consumer preferences and, in many cases, create a feeling of fear toward food. Good examples of UK food scares are those of Bovine spongiform encephalopathy or mad cow disease as formed in cattle and Creutzfeldt–Jacob Disease, the foot and mouth disease outbreak, the avian flu, swine flu, and more recently the horse meat scandal. GM food was brought to the spotlights creating, in a similar way, a controversy that resulted in the removal of GM ingredients and products from supermarkets in the United Kingdom or the strict labeling reformed laws that were applied by the EU, which was driven by consumer concern and media coverage. Clearly, there is a well-recorded spillover effect of such issues toward GM food debate; hence, the opposition to this important biotechnology development can be characterized as persistent. More recently (June 2013), the British Government has started a campaign for GM food. According to BBC (2013), Owen William Paterson, the Secretary of State for Environment, Food and Rural Affairs, said

> The EU chief scientist Anne Glover has said it pretty bluntly – there is no substantiated case of any adverse impact on human health on animal health or on environmental health.

This change of UK government policy toward GM food could find its roots on the current food crisis and the search for cost-effective agricultural developments, but considering the long period of resistance to GMO and GM food technologies would present a greater challenge to shift public opinion, attitudes, and perceptions toward GM food.

Perceptual Issues with GM Food: Risks and Benefits

It is essential for consumers to decide on whether they will consume or not GM food, and for this decision to be made accurately, as previously discussed, it is important for the consumers to have access to up-to-date information on GMF and GMO technologies. The term information currently refers to all the external and internal stimuli that a person receives from his or her environment enabling the person to form an

experience. Perception is defined as the organization, identification, and interpretation of sensory information in order to represent and understand the environment. Perception is not the passive receipt of these signals, but can be shaped by learning, memory, and expectation. Perception involves these 'top-down' effects and the 'bottom-up' process of processing sensory input. 'Bottom-up' information refers to low-level neural information (sensory stimuli), and 'top-down' information refers to more complex constructs such as memory, knowledge, and experience.

One factor that directly affects perceptions or attitudes is fear. Fear is an emotion that is often expressed in food-related issues. As discussed previously, in the case of the United Kingdom, several food scares have dominated the market for many years, and research shows that these food scares have a direct impact on consumer behavior. In the case of GMOs, food-related fears affect the behavior of the consumer.

The frequent appearance of fear messages in the media plays a significant role in promoting widespread fear of GMF ('Frankenfood') in the global market for food. Some authors have validated a scale to measure consumers' fear of GMF and found that Dutch consumers feel significantly more fearful of GMF than of other new food types. The results of the Dutch study did not find a relationship between demographics and fear toward GMF, assuming that GMF fear is consistent across the society.

A niche category among the different types of fear related to GMF is that of neophobia. Humans naturally display some degree of aversion to new foods, a trait that has been termed food neophobia. It is reported that food neophobia is widespread in omnivores and has been detected in warblers, rats, and chimpanzees, among other species. It is argued that beliefs about risks and benefits of the production and introduction of GMF in the food market are key in defining consumer acceptance. Moreover, the associated fears along with the current price sensitivity due to the squeezed consumer income are all considered to affect attitudes toward technology. This is proof that nonirrational factors could be influencing the outcome, and this is a trend supported by many studies that refer to 'superstition,' 'religious fears,' and 'magical beliefs,' factors that have been linked with negative attitudes toward GM foods.

Consumers are reluctant in seeing the benefits in European countries and the United Kingdom, for example, as they have accumulated experience of years of food scares as discussed previously or because they simply do not trust the corporations to 'manage' their food resources. It has been reported that plant-related or 'universal' uses were more acceptable than animal-related applications. Moreover, risk perceptions were greater in Europe than North America and Asia and the opposite was evident for benefit perceptions. Moral fears are higher in North America and Asia and both benefit and risk perceptions were found to change over time. On the other hand, in India, perceptions about the consumption of GM food are often distorted. Moreover, communication of information in India regarding GM food was leaning toward the benefits misrepresenting the risks, in order to promote to both farmers and consumers and accelerate the adoption of the GM food products. Four main factors of concerns on GM food products have been identified in India:

- Attitudes toward GM food
- Concern for health
- Knowledge for food
- Information about GM food

One of the major concerns of the general public about transgenic crops relates to the mixing of genetic materials between species that cannot hybridize by natural means. Two new concepts have been recently developed – cisgenesis and intragenesis – which imply that plants must be transformed with genetic material derived from the species itself or from closely related species. Several surveys in the United States and Europe clearly show that both intragenic and cisgenic crops are acceptable to a greater number of people than transgenic crops. At present, in most countries, the release of cisgenic or intragenic crops currently falls under the same regulatory guidelines as transgenic crops. However, the regulation of intragenic/cisgenic crops is presently under evaluation in the EU, and in the United States, regulators are considering if a subgroup of these crops should be exempted from regulation.

Different scientific committees concluded that cisgenic crops are as safe as traditionally bred varieties. So, cisgenesis is a powerful new tool for plant breeding with traditional traits.

Intragenesis in particular permits the introduction of new gene mixtures through *in vitro* rearrangements of functional genetic elements. Recent studies conducted surveys to investigate public perception of this more 'natural' approach to genetic modification and found higher public acceptance of intragenic/cisgenic when contrasted with persistent public negative views of transgenic-based techniques. In Denmark, a study that surveyed a random sample of 2000 Danish consumers investigated the impact of knowledge in the probability that a person would differentiate his or her views on medical and agricultural applications, and they found that this was true, with an exception on consumer opinion differentiation over the cisgenic and transgenic cereals. Presently, intragenic/cisgenic plants are labeled as transgenic plants worldwide despite their difference in production techniques. However, the aforementioned techniques are closer to traditional breeding techniques; thus, in the future, less strict regulatory measures can be anticipated. 'Cisgenic and intragenic' techniques are new and have been introduced only 9 and 7 years ago; thus, it is too early to judge consumer acceptance and more research has to be conducted to study more comprehensively any arising consumer attitudes toward intragenic/cisgenic crops against their more 'hated' transgenic cousins. Moreover, this is a proof of the importance of the two of the four concern factors (knowledge of the issue and quality and clarity of information), which ultimately enables the consumer to have a clear position on important issues in the area of food technology.

The Role of Ethics

Ethics is a field widely published with regard to GM food products and GMOs. It is undoubtedly the most debated field and one of the inconclusive chapters of the GM food issue. The ethics or moral dimensions of the GM issue usually are presented in recent literature as a medley of religious constructs

('playing god'), or moral dilemmas, sometimes mixed with ecological concerns. The field is equally skewed between those authors that are pro-GM and those that are against, leaving the subject without a constructive agreement but with many unresolved arguments. Popular themes involve the domination of multinational corporations, environmental risks, the fear of playing god, and the unfairness on offering GM food as a food resource solution to poorer regions of the globe.

The pluralism of arguments and rifts within this field as said before renders many times the arguments as inconclusive as subjects such as morals and ethics usually include personal bias. Often, scientists, those behind the engineering process and in the core of GM developments, are those found unable to communicate effectively to the public a conclusive answer to the consumer questions on the issue. There are a number of studies that attempt to summarize and conceptualize the field in order to disseminate information in a simpler way and enable the academic debate to move further faster. GM food ethical considerations have been summarized in three main propositions used to yield a positive response to GM crops:

- The rights of people in various countries to choose to adopt GM technology
- The balance of likely benefits over harms to consumers and the environment from GM technology
- The wisdom of encouraging discovery, innovation, and careful regulation

Key findings have summarized moral concerns in three main types:

1. The consequences of GM food–ecological/risk concerns (84% of the studies)
2. The value of naturalness, the value of biotic entities, and conceptual reductionism (57% of the studies)
3. Handling of risks and application of GM crops (43% of the studies)

Five main ethical concerns against GM crops have been raised: the prospective damage to human health, the prospective harm done to the environment, the harmful influence on traditional farming practice, the unwarranted corporate domination, and the 'unnaturalness' of the technology.

Taking under consideration the findings of the studies discussed, it is essential to note that the core concerns are those that link in with the perceived risks and benefits. When these concerns will be answered with unbiased information dissemination, then the consumer will be in a better position to decide, whether they wish to adopt/buy the technology or not buy and reject GM food products altogether.

Genetically Modified Microorganisms

Introduction

Microorganisms have a long history of use in food applications. Various types of fermented foods such as wine, beer, fermented milks, cereals, vegetables, meat and fish products, and cheeses have been manufactured for millennia using bacteria, yeasts, and filamentous fungi. While traditional processes, still used in many parts of the world, rely on spontaneous fermentations controlled mainly by external factors like water activity, temperature, and pH, defined starter cultures are nowadays commonly used in industrial-scale production. A more recent application is functional foods, in which health-promoting viable bacteria or yeasts are introduced into the food. In addition to their direct use in food, microorganisms are harnessed in the mass production of enzymes, pigments, sweeteners, antioxidants, vitamins, acidity regulators, flavor enhancers, thickeners, and preservatives for use as food additives or processing aids to make bread, sausages, dairy products, juices, ice cream, and other goods.

Industrial microorganisms have been gradually improved for a long time, often without detailed knowledge about the changes that have occurred in their genetic makeup. Genetic alterations can emerge spontaneously or can be induced in the laboratory by mutagenic chemicals, the cells with desired characteristics being then selected from the pool of genetic variants. 'Genetically modified microorganism' (GMM) has, however, a special meaning in the EU legislation (Directive 2009/41/EC). It is defined as "micro-organism in which the genetic material has been altered in a way that does not occur naturally by mating and/or natural recombination." Usually, it means the construction of new DNA sequence combinations in vector systems, followed by incorporation into host organisms. Mutagenesis and natural processes such as conjugation, transduction, and transformation are not considered as genetic modification.

The optimization of GMMs includes factors like host selection, central metabolism of the cell and its relationship with product biosynthesis, degradation, and by-product formation. The benefits that optimized GMMs can provide compared to other production systems are that they are efficient and robust, are easy and rapid to cultivate using safe raw materials, and do not produce toxic or otherwise undesirable compounds. With these properties, GMMs compete with solvent extraction from natural sources, or with chemical synthesis, which sometimes requires high temperatures and pressures and strong chemicals. Many of the produced compounds can thus originate from different sources, and the GMM-derived products are often indistinguishable from those produced by other means. In the absence of positive lists and labeling of the GMM-derived products, no exact figures can be given about their usage.

In this article, we review the development of GMMs for their possible use as live microorganisms in food and as production platforms for compounds utilized by the food processing industry. Health and safety aspects are discussed briefly.

Food Microorganisms and Their Genetic Modification

Although hundreds of bacterial species and thousands of bacterial strains are used in food production as either starters, probiotics, protective cultures, or production platforms, the vast majority are lactic acid bacteria (LAB), propionic acid bacteria, brevibacteria, staphylococci, micrococci, and bacilli. In the production of amino acids, *Escherichia coli* (mainly derivatives of *E. coli* K-12) and *Corynebacterium glutamicum* (also known as *Brevibacterium lactofermentum*) are important species. The eukaryotic microorganisms used in food processes include some yeasts such as *Saccharomyces cerevisiae*, *Komagataella* (previously *Pichia*) *pastoris*, and *Kluyveromyces lactis* and the filamentous fungi *Aspergillus niger*, *A. oryzae*, and *Trichoderma reesei/longibrachiatum*. It is possible that in the future, photosynthetic microorganisms (cyanobacteria, purple photosynthetic bacteria, and microalgae) are used increasingly, as they have the specific advantage of using economic resources (light, water, and carbon dioxide) for growth.

One of the main reasons for the use of limited selection of microbial species in food applications is that they have a long history of use in large-scale industrial processes. The strains have been optimized for growth on inexpensive nutrient sources and at high density and are easy to handle. Often, these microorganisms are also generally recognized as safe (GRAS) or qualified presumption of safety, which is similar to GRAS in concept and purpose but is modified by the European Food Safety Authority to take account of the different regulatory practices in Europe compared to the United States. One microorganism is not optimal in all cases and the choice of host organism is an important step in the strain development process.

The genes used for engineering can originate from diverse sources but can also be (semi)synthetic or tailored for the specific purpose. The genes can be expressed from plasmids or native or artificial chromosomes. The host genome can be edited in a site-specific manner by taking advantage of its natural mechanism, which repairs nuclease-mediated double-strand breaks in the DNA. Such nucleases used in editing are, for example, zinc finger nucleases, TALE nucleases, and RNA-linked CRISPR–Cas9 nuclease system. Gene expression levels can be optimized with promoters of suitable strength. For fine-tuning the expression, predicting and modeling tools are available for promoters and their regulatory elements.

In any case, in order to introduce, integrate, and express (foreign) genes in the host organism as a result of genetic modification, or to carry out gene editing, suitable DNA constructs and efficient transformation systems are needed. In the

following, specific features of common vector and transformation systems in different types of microorganisms are briefly discussed.

Genetic Modification of Bacteria

A majority of food fermentations around the world are based on LAB, either spontaneously grown or intentionally added in food matrices. The LAB, natural inhabitants of gastrointestinal tract, have been a focus of intensive genetic research since late 1970s, and currently, approximately 40 complete genomic sequences of LAB belonging to the main genera are in the public domain. Many important LAB species were originally rather recalcitrant to genetic modification, which was based on transformation of protoplast ('naked' cells). Electroporation or permeabilization of the cell walls by a short electric shock has subsequently made most of the species transformable. Many LAB contain natural plasmids, which can be used for the construction of transformation vectors. Based on these plasmids, a wide range of expression and integration vectors, the latter ones often utilizing phage attachment sites, have been developed. Various systems to control the expression of cloned genes have been introduced, such as NICE (based on autoregulation of the biosynthesis of the bacteriocin nisin) and SICE (based on stress-specific promoters). Because of the potential use of genetically modified LAB either in food or for therapeutic purposes, special attention has been paid to the selectable markers, as antibiotic resistance genes are not considered appropriate. Typical food-grade selectable markers include bacteriocin or heavy metal resistance or systems based on metabolic complementation.

Compared to LAB, no systematic genetic research has been carried out on other food bacteria such as *Propionibacteria*, *Brevibacteria*, and *Kocuria*. A notable exception is the bifidobacteria because of their potential uses as probiotics. Several bifidobacterial genomes are already in public domain, and the genetic modification systems are under development.

Metabolic engineering efforts for the production of various compounds have focussed for some time in *E. coli*, which can be modified using standard vectors and DNA transfer techniques. Genetic modification of the amino acid-producing species *C. glutamicum* has been more challenging. As its name implies, it was originally isolated and utilized as an efficient producer of L-glutamic acid. *C. glutamicum* is not naturally transformable, and protoplast transformation has not been very effective. Furthermore, it has restriction systems that impede the introduction of foreign DNA. However, electroporation combined with various cell wall-weakening treatments has enabled the genetic modification. Endogenous plasmids have provided a basis for vector construction, and the fact that *E. coli* promoters are functional in *C. glutamicum* has further enhanced the genetic modification possibilities.

Bacillus species are important producers of industrial enzymes. Bacilli, especially *B. subtilis*, are common experimental organisms in molecular biology, their genomes are well characterized, and genetic modification techniques are established. Bacilli are naturally transformable, both protoplast and electroporation systems being used in transformation. Small endogenous plasmids have provided the basis for vector construction. Accordingly, both integration and expression vectors, including efficient secretion systems to allow the harvesting of expressed proteins from the growth medium, have been developed.

Genetic Modification of Yeasts and Fungi

In contrast to the prokaryotic bacteria, yeasts and filamentous fungi are eukaryotic organisms. Their genomic organization, gene regulation systems, and secretion machineries are more related to those in animal and plant cells. On the other hand, they share with bacteria the ability to grow fast on relatively simple substrates and media, making them attractive for biotechnological purposes.

The yeasts are fungi characterized by nonfilamentous growth. Baker's yeast, *S. cerevisiae*, is the best-known species due to its many traditional uses in baking, brewing, and winemaking and to its extensive use in molecular biological research. It was the first eukaryotic organism that was successfully transformed by foreign DNA and was the first eukaryote to have its total genome fully sequenced in 1996. It is one of the few fungi that contain natural plasmids, the 2 μm circular plasmids that were used in the early vector constructs, and the yeast episomal plasmids.

Transformation methods applied in *S. cerevisiae* include protoplast (spheroplast) techniques, divalent cation-mediated transformation, and electroporation. Standard cloning vectors currently in use are shuttle vectors between *E. coli* and *S. cerevisiae*. Typical vectors consist of a bacterial replication region and a selectable marker (antibiotic resistance gene) combined with a yeast selectable marker (usually a gene that complements a defect in host amino acid biosynthesis, such as *LEU2*), yeast origin of replication (*ARS*), yeast centromere, and yeast telomeres. These vectors enable the cloning of large DNA fragments, which, when linearized, function as artificial chromosomes and are stably maintained in the GM yeast. Yeast integrative plasmids are shuttle vectors without the yeast origin of replication. After transformation, homologous recombination occurs between the selectable marker in the plasmid and the corresponding mutated host gene, integrating the plasmid into the chromosome and restoring the defective function.

Besides *S. cerevisiae*, a methanol-utilizing yeast *K. pastoris* has gained popularity as an alternative eukaryotic host in the production of recombinant proteins. Integration vectors utilizing the strong inducible *K. pastoris* alcohol oxygenase promoter *AOX1* have been designed to allow for optimized and easily controlled expression of the inserted genes.

Compared to yeasts, genetic modification of filamentous fungi represents a much greater technical challenge. Filamentous fungi apparently lack natural plasmids, and their chitinous cell walls resist transformation. The genomes are much larger, and the regulatory systems more complex. However, filamentous fungi, particularly *Aspergillus* and *Trichoderma*, are traditional producers of enzymes and organic acids like citrate, isocitrate, succinate, and fumarate, and there has been a strong incentive to apply genetic techniques also to these organisms.

Techniques applicable to filamentous fungi include protoplast transformation, electroporation, biolistics (bombardment of cells with DNA-coated particles), and *Agrobacterium tumefaciens*-mediated transformation normally used for plants. Approaches using protoplasts are technically challenging and

tend to yield multiple DNA insertions in the recipient genome. In contrast, *A. tumefaciens*-mediated transformation typically results in fewer and more targeted insertions. Thus, the selection of transformation techniques may depend case by case on the desired outcome.

The lack of natural plasmids from filamentous fungi led to the experiments with artificial plasmid constructs. These proved to be unstable, leaving chromosomal integration as the only reasonable alternative. However, in contrast to yeasts in which homologous recombination can be routinely achieved, the integration of transformed DNA in filamentous fungi occurs often in nonhomologous sites. In the selection of promoters, one also has to take into account the rather complicated induction/repression patterns typical to these organisms. Despite these difficulties, GM fungi are successfully used in industrial scale as enzyme producers.

Strain Improvement by Genetic Engineering

Microorganisms used as food cultures can be modified for fermentation profiles or enzymatic activities to improve the flavor, texture, keeping properties, and nutritional value of fermented foodstuffs. Although numerous GMM starter strains have been developed, including phage-resistant and bacteriocin-producing LAB, they have not been introduced into the market, mainly due to uncertainties related to consumer reactions. Recently, two GM wine yeasts have been approved for commercial use in the United States and Canada. One of the GM yeasts (ML01) has enhanced malolactic fermentation properties as a result of the introduction of a malolactic enzyme-encoding gene from LAB and a malate transporter-encoding gene from another yeast species, *Schizosaccharomyces pombe*. The other GM yeast (522^{ec-}) has been modified to improve the degradation of urea by placing the responsible gene under a constitutive promoter, thus preventing the formation of carcinogenic ethyl carbamate during wine fermentation. These two cases might represent the first signs of the introduction of viable GMMs into the food chain.

Much less controversial are GMMs used for the production of valuable compounds such as enzymes, amino acids, organic acids, and flavorings for food use. These microbial strains are under continuous optimization to make the processes economically more viable by increasing the yield or by improving other cellular functions or product quality or safety.

There are a number of ways to improve the production microorganism. Considering general performance, the GMM can be made capable of utilizing a mixture of different types of sugars, like galactose, xylose, and mannose in the presence of glucose, which in *E. coli* and in *S. cerevisiae* inhibits the use of other sugars. On the other hand, *E. coli* has been modified to enhance tolerance to high concentrations of glucose and sucrose. Robustness, that is, stability and resistance of enzymes to fluctuations in fermentation process conditions like medium composition and oxygen concentration, can be increased by introducing genetic switches that control cellular metabolism. Resource efficiency can be improved by using energetically preferable alternative reactions. As cofactors are important in transferring energy to the cell, one target is to increase the availability of redox carriers (NADH and NADPH) and energy metabolites (ATP). Increases in lysine production were achieved in *C. glutamicum* by overexpressing NAD kinase or replacing an NAD-dependent enzyme by NADP-dependent enzyme from *Streptococcus mutans*. To increase consumer safety, pathways that generate toxic or other harmful compounds can be deleted or interrupted, thus minimizing their accumulation in the production organism or culture medium.

The goals are increasingly achieved by the application and integration of the latest tools and strategies in systems biology, protein engineering, process engineering, high-throughput technologies for cultivation, screening, and analytics. Integrating comprehensive omics (fluxomics, metabolomics, proteomics, transcriptomics, and genomics) data with computational prediction algorithms can lead to the optimization of GMMs and to new designs with increasing speed and success. To replace traditional recombinant DNA methods, rapid pathway engineering has been developed, which combines enzymatic *in vitro* assembly and *in vivo* homologous recombination. However, strain design is still a major undertaking. The future scenario is to create highly efficient synthetic microbial minifactories, but this requires a full understanding of the minimal genome requirements of a microbe.

Many examples of how all of these approaches have been successfully employed exist, but it is unclear how extensively they have been used in the GMMs currently employed for the industrial production of compounds for food use.

Production of Industrial Enzymes

Enzymes isolated from GMMs are widely used today (Table 1). In the simplest case, a desired gene is introduced in the host to express the enzyme. Yield can be improved by increasing gene copy number in the plasmid or chromosome. Performance of the enzyme in food matrix can be improved by taking into account the conditions, in which the catalysis is expected to take place, for example, pH optimum, temperature or salt concentration, and also cofactor requirement. Selectivity of the enzyme can be improved by optimizing natural enzymes for novel substrates or for entirely new catalytic activities. In some cases, this can also decrease unwanted side reactions and products.

Major improvements in catalytic efficiency and substrate specificity have been achieved by enzyme engineering. The method combines different experimental and analytic tools (random mutations, error-prone PCR, DNA shuffling, saturation mutagenesis, and site-directed mutagenesis) with computational design tools (structural analysis, phylogenetic analysis, and *de novo* engineering). For example, to obtain cellulase with greatly enhanced thermostability, a computational structure-guided recombination method was used to inform the design of libraries of synthetic variants, which were then screened for the desired trait.

Production of Small Compounds

Only a few compounds such as amino acids, organic acids, and vitamins are produced on a large scale using industrial microorganisms. One reason is that engineering microorganisms to produce small compounds is highly complex. To achieve high production rates, high yields, and purer products, enzymes in metabolic pathways usually have to be improved for catalytic

Table 1 GMMs as platforms for food enzyme production

Enzyme	*Function in food; examples of possible applications*	*Production organism*
Acetolactate decarboxylase	Conversion of acetolactate to acetoin; reduction of butter aroma in beer	Ba, Bsu, Ss
α-Amylase family: α-amylase, branching glycosyltransferase, cyclodextrin glucanotransferase, glucanotransferase, glucoamylase, α-glucosidase, maltodextrin α-D-glucosyltransferase, maltogenic amylase, maltotetraohydrolase, pullulanase	Starch degradation and modification; baking, cereals, sweeteners, beverages	An, Ba, Bl, Bst, Bsu, Sv, Tr or Tl
Asparaginase	Asparagine (precursor of acrylamide) breakdown; bakery	An, Ao
Cellulose-degrading enzymes: cellobiose dehydrogenase, cellulase, endo-1,3(4)-beta-glucanase	Cellulose degradation; beverages, baking, diet products	Ao, Ba, Bsu, Fv, Tr or Tl
Chitinolytic enzymes: acetylhexosaminidase, chitinase	Chitin degradation; preservation (bakery)	Sv
Cross-linking enzymes: laccase, peroxidase, sulfhydryl oxidase	Produce covalent bonds between food polymers; cereal, dairy, meat, fish	An, Ao, Bsu
α-Galactosidase	Liberates terminal α-galactosyl groups, for example, from glyco-oligosaccharides; legumes (flatulence), sugar beet	Sc
Endo-1,3-β-glucanase	Breakdown of certain carbohydrate polymers; brewing	Sv
Glucose isomerase	Conversion of glucose to fructose; fructose syrup, low-calorie products	Sr
Hemicellulases: endo-1,3(4)-β-glucanase, hemicellulase, pentosanase, xylanase	Breakdown of plant cell walls; baking, beverages	An, Ao, Ba, Bsu, Sv, Tr or Tl
Hydrogen peroxide producing and decomposing enzymes: catalase (CAT), glucose oxidase (GOx), hexose oxidase (HOx)	CAT: hydrogen peroxide breakdown; GOx, HOx: hydrogen peroxide production; used alone or in combination: egg processing, baking	CAT: An; GOx: An, Ao; HOx: Pa or Hp
Lactase (beta-galactosidase)	Lactose hydrolysis; dairy products, ice cream, chocolates	Ao, Kl
Lipases: acyltransferase, monoacylglycerol lipase, triacylglycerol lipase, phospholipases A2, B, C, and D	Fat splitting and modification; cheese, spices, aromas, baking, noodles	An, Ao, Bl, Pc, Pa or Hp, Pf, Pp, Sv, Tr or Tl
Lysozyme	Bacterial cell wall rupture; antibacterial, cheese	Sv
Pectinases: pectin lyase, pectin methylesterase, polygalacturonase, and pectinase	Pectin degradation; beverages, fruits, vegetables	An, Ao, Tr or Tl
Phytase	Phosphate release from phytic acid; cereals, legumes	An, Ao, Tr or Tl
Proteases: aminopeptidase, serine carboxypeptidase, chymosin, other proteinases	Protein degradation and modification; dairy (milk-clotting), cheese, meat, baking, fish, beverages, baby food	An, Ao, Ba, Bl, Bsu, Cp or Ep, Fv, Kl, Sv, Tr or Tl

An, *Aspergillus niger*; Ao, *Aspergillus oryzae*; Ba, *Bacillus amyloliquefaciens*; Bl, *Bacillus licheniformis*; Bst, *Bacillus stearothermophilus*; Bsu, *Bacillus subtilis*; Cp, *Cryphonectria parasitica*; Ep, *Endothia parasitica*; Fv, *Fusarium venenatum*; Hp, *Hansenula polymorpha*; Kl, *Kluyveromyces lactis*; Pa, *Pichia angusta*; Pc, *Penicillium camemberti*; Pf, *Pseudomonas fluorescens*; Pp, *Pichia pastoris*; Sc, *Saccharomyces cerevisiae*; Sr, *Streptomyces rubiginosus*; Sv, *Streptomyces violaceoruber*; Tr, *Trichoderma reesei*; Tl, *Trichoderma longibrachiatum*.

Source: amfep

efficiency and perhaps also for selectivity. Optimal process should include robust microbial strain that provides high titer ($g\,l^{-1}$ product), yield (g product g substrate^{-1}), and productivity ($g\,l^{-1}\,h^{-1}$) and has acceptable by-product profile. A complicated factor is that while high titer facilitates product purification, the levels can be inhibitory to enzymes or toxic to the organism. The yield can be limited by low or inefficiently directed pathway flux, as well as nonoptimal energetics and NAD(P)H balance. Bottleneck enzymes can limit the productivity.

To improve the production organisms, several approaches can be taken, usually in combination. For optimal pathway flux (production rate or yield), carbon end energy resources can be redirected from central metabolism (biomass production) to the pathway leading to the desired product. Competing pathways from relevant endogenous intermediates can be deleted. Pathway bottlenecks caused by, for example, poor precursor (substrate or cofactor) availability or inefficient enzyme can be identified using metabolic flux analysis and protein design.

Fine-tuning of gene expression is important to attain proper (usually not maximal) level of each enzyme and thus to achieve optimal flow of metabolites through the pathway. Natural promoter can be tuned by mutagenesis, or a synthetic promoter can be created through shuffling of multiple promoters. Native regulation (regulatory genes, promoters, or small RNAs) can be replaced by a new, perhaps inducible system. RNA-based synthetic control modules can be used to obtain predictable fine-tuning of expression levels. Several genes that function in a common process can be introduced into a single bacterial operon. Rate of protein synthesis can be controlled using designer ribosomal binding sites. The optimization of codon usage can facilitate effective expression (translation) in a different host and to remove cryptic regulatory elements.

The titer is primarily dictated by the inhibition of some enzymes in the pathway or by end product toxicity to the production organism. An example is the amino acid L-valine, which at high concentrations is toxic to *E. coli*. Structure of

bottleneck enzymes can be improved to eliminate unwanted allosteric regulation in case the natural enzyme suffers from inhibition by the end product or a key metabolite. Toxic end products can be moved in safe storage compartments or exported out of the cell by introducing specific pumps. Spatial targeting of enzymes may increase yield by reducing the loss of intermediates via side reactions but can also decrease effects of possibly toxic intermediates. For example, in yeast, the subcellular compartmentalization allows for pathway isolation and increased fluxes.

Examples of amino acids are L-lysine, L-valine, and L-threonine in *C. glutamicum*. The production strains have been developed through classical mutagenesis, genetic modification, and metabolic engineering. All this would not have been possible without detailed knowledge of the interconnections between the glycolytic and biosynthetic pathways.

In the production of organic acids such as citric acid, lactic acid, malic acid, and succinic acid, yeasts have been attractive hosts because of their good tolerance to low pH. In glucose-grown batch cultures, an engineered *S. cerevisiae* strain produced malic acid at high concentrations. Yeast and *E. coli* have been successfully engineered to achieve near-theoretical yield of succinic acid.

Riboflavin (vitamin B2) can be derived from the pentose phosphate pathway intermediate ribulose 5-phosphate. Unconventional yeasts *Ashbya gossypii* and *Candida famata* have been used as hosts for riboflavin production. Coenzyme Q10 is a well-known vitamin-like ubiquinone involved in cellular electron transport. For instance, expression of genes from other bacteria enabled the production of coenzyme Q10 in *E. coli*. Total biosynthesis of vitamin C (ascorbate) from glucose has been reported in metabolically engineered yeast.

Potential to produce entirely new products in microorganisms is huge, as a whole biosynthetic gene cluster can be introduced into the new host by metabolic engineering. By mixing enzymes or their domains from different donors and pathways and altering enzyme specificities, even further diversity can be achieved. With the advent of metabolic engineering tools, the successful reconstitution of heterologous pathways in *E. coli* and other microorganisms provides an alternative to meet the increasing demand of, for example, natural antioxidants.

Sugar alcohols are calorie-free versions of sugars that can be used as sweeteners or flavoring agents. In *S. cerevisiae* strain, engineering has improved xylitol and ribitol titers. In *E. coli*, xylitol production increased by engineering an enzyme that converts NADH into NADPH. In the yeast *Yarrowia lipolytica*, high production of erythritol and mannitol was achieved from glycerol.

Plant secondary metabolites such as flavonoids and isoprenoids (β-carotene and lycopene) are used as food colorants and flavors. Extraction of pure compounds from plants is often problematic because of their low quantity and a multitude of structurally very similar compounds. Due to these reasons, synthetic compounds have gained increasing importance in the food industry. Metabolic engineering of microorganisms is a powerful approach to gain access to the bioactive compounds. Advances in the knowledge of the biosynthetic pathways in plants have driven the rational development of high-producing microbial strains.

Carotenoids have been subject to extensive metabolic engineering efforts for production in *S. cerevisiae*, *K. pastoris*, and, in particular, *E. coli*. One success story is the development of lycopene production in *E. coli* through knockout and overexpression of multiple gene targets. The approach was to divert carbon flux with an artificial regulatory circuit to lycopene pathway, inactivate competing pathways, and balance the supply of central metabolism. The tools used included systematic model-based search combined with random transposon mutagenesis, screening of shotgun library, and use of high-throughput method for automated genome engineering to create targeted genomic diversity and to program and expedite evolution of lycopene-producing cells. Heterologous production of other carotenoids (e.g., zeaxanthin, astaxanthin, and lutein) was achieved by extending the established lycopene and β-carotene production platforms.

Antioxidant activity of many phenolic compounds, such as flavonoids, has raised significant interest in the health-protecting effects of these compounds. Polyphenols have been produced in *E. coli* and *S. cerevisiae* by pathway reconstruction and optimization via metabolic engineering approaches. Phenolic acids represent simple polyphenols that include the hydroxybenzoic (e.g., gallic and vanillic acid) and hydroxycinnamic acids (e.g., *p*-coumaric, caffeic, ferulic, and chlorogenic acid). Biosynthesis of vanillin has been established in *S. pombe* and *S. cerevisiae* through metabolic engineering. Microbial platform for caffeic acid production has been developed in *E. coli*. Flavonoids and anthocyanins have been synthesized in *E. coli* after extensive pathway engineering. An economic process for the production of flavonoid naringenin from glucose has been developed in *E. coli* through the expression of four plant enzymes in the pathway and other modifications to metabolic fluxes.

Safety and Legislation

Depending on the type of GMM or product in question, that is, whether it is crystallized amino acid, food enzyme preparation, or live starter culture, the safety issues vary. Such issues include toxicity or pathogenicity of the organism, fermentation by-products and impurities, allergenicity, and effects on gut microbiota. International standards for the safety assessment of GMOs, including GMMs, have been developed under Codex Alimentarius Commission and OECD. Many countries have also developed specific GMO legislations. European Union has one of the most comprehensive systems for GMO safety evaluation, which follows the main internationally agreed principles. The EU is in a process of preparing a list of food enzymes based on their established safety and technological need.

Health Aspects

While the focus of the legislation on GMMs and their use is on the prevention of their potential harmful effects on the health and environment, GMMs can actually contribute positively to human health and well-being. By providing cheap, highly purified food ingredients without the need to use potentially hazardous traditional techniques, such as organic extractions

or poorly characterized raw materials, GMMs can improve the safety, nutritional quality, and sensory properties of food.

GMMs could, in the future, also be directly used to improve both intestinal health and general health. Already documented positive health effects of probiotics could be further enhanced through engineering metabolic pathways involved in the positive interactions with the host. An example of this approach is the elimination in *Lactobacillus acidophilus* of a gene involved in the synthesis of lipoteichoic acids (apparently inflammatory components of the cell wall of Gram-positive bacteria). In animal experiments, this GMM strain downregulated the synthesis of proinflammatory cytokines and markedly alleviated the symptoms of induced colitis.

Delivery of therapeutic molecules, such as vaccines, by genetically modified probiotics, which involves cloning and expression of antigens or in the probiotic hosts, has been a much-studied area during the past 20 years. In animal experiments, the results have been promising, but their eventual application to humans would require both an absolute certainty of safety and general consumer acceptance. This type of products would fall into a gray area between food and medicine legislations.

Future Prospects

Advances in understanding metabolic pathways and their regulation make the microorganisms increasingly attractive for metabolic engineering. While there is much research on the potential of LAB and Bacilli, the great metabolic diversity of yeasts and especially of filamentous fungi makes them particularly promising candidates for future metabolic engineering and even for generating entirely novel applications and products. Engineering microorganisms for plant natural product synthesis is expected to be an increasing focus as the beneficial compounds can be present in plants in very low amounts as mixtures with potentially harmful compounds.

The construction of genome-minimized hosts seems to be a feasible approach. The efforts thus far have resulted in *E. coli* strains with a genome size reduced by up to 15%. Together with the advances in synthetic biology, future metabolic engineering efforts of microorganisms will greatly expand the number of economically viable products.

Ghee

SS Deosarkar and CD Khedkar, College of Dairy Technology, Pusad, India

Introduction

Ghee (synonyms: ghritam, ghrit, havi, maslea, samna, samn, and rognezard), also known as clarified butter or anhydrous milk fat, is a fat-rich dairy product originally produced in India. It can be prepared from cow milk (CM), buffalo milk (BM), or mixed milk. Milk is separated into cream that may be directly converted into ghee or that can be first converted into butter and then into ghee. Ghee is prepared by heating butter or cream to evaporate nearly all the moisture content and to produce the characteristic flavor and then filtering out the precipitated milk solids. Heating destroys most of the microorganisms and enzymes. Low water activity hampers the growth of organisms that survive heat treatment or those contaminating the product. The origin of technology for ghee making is recorded in Indian epics and Vedas, which relate it to the third century BC. Ghee is the most widely used milk product in the Indian subcontinent. It is considered as the supreme cooking or frying medium.

Milk is utilized for ghee production due to the concentration of milkshed areas in rural localities, which are far away from the nearest urban-consuming centers. It is also used for shallow frying and deep-frying of traditional Indian foods. BM is preferred over CM to prepare ghee due to its higher fat content. Milk fat has commercial significance as payment to milk producers is based on the level of fat percentage. Ghee production is an important activity of the organized sector of the dairy industry, which employs mechanized systems for this purpose. Ghee is incidental to the product mix in the dairy plants, which manufacture dairy products.

In the Indian context, ghee is a product of the sacred cow and hence pure and confers purity to other foods when used in making them. Almost the entire range of Indian sweets, prepared with admixtures of milk, cereals, fruits, vegetables, and nuts, are preferably cooked using ghee as the medium. It is one of the basic elements in the Indian cooking. Sweets and meals cooked in ghee are recognized for their distinguished flavor attributes. Meals for special occasions are cooked in ghee. Ghee is also marketed in many African and Asian countries, the United Kingdom, Australia, Armenia, Belgium, the Netherlands, New Zealand, and the United States.

Technology of Ghee Manufacture

The method of ghee manufacture varies according to the base material used (milk, cream, or butter), intermediate treatment of raw materials, and handling of the semifinished or fully formed ghee. Because of its commercial importance, considerable refinement and mechanization have taken place in the manufacturing processes of ghee. In India, a considerable amount of ghee production is manufactured according to traditional methods used for cottage-level production. Some processes, developed for ghee production, are described later in the text.

Indigenous Milk–Butter Process

The indigenous methods of ghee making usually involve direct churning of raw milk or lactic acid fermentation of heat-treated milk followed by churning. Hand-driven wooden beaters are usually employed for separating the butter. The butter is melted in a metal pan or ceramic vessel on an open fire until almost all moisture is removed. The extent of frothing may be used as an index to judge when to terminate heating. After heating, the contents are left undisturbed. When the curd particles have settled, the clear fat is carefully decanted off into ghee storage vessels. The traditional ghee-making practice contributes about 90% of the total ghee production in India. This method leaves behind a large quantity of buttermilk of varying quality and also leads to low fat recoveries (75–80%).

Direct Cream Method

The small dairies use a technologically improved method for ghee making, which involves the separation of cream from milk by centrifugation. This process omits the need of production of butter because cream is directly converted into ghee. The fresh cream, cultured cream, or washed cream is heated to 115 °C in a stainless steel, jacketed ghee kettle fitted with an agitator, steam control valve, and pressure and temperature gauges. Heating is discontinued as soon as the color of the ghee residue turns to golden yellow or light brown. One of the limitations of this method is that it requires a long heating time to remove the moisture. A high content of serum solids in the cream may also produce a highly caramelized flavor in the ghee and lead to about 4–6% loss of butterfat in the ghee residue or during handling operations, depending upon the fat percentage in the cream. Economically, this method is less labor-intensive as compared to the creamery butter method. Lower recovery of fat and slightly greasy texture in the ghee obtained by this method are the demerits.

Creamery Butter Method

Most dairies use unsalted creamery butter or white butter as a raw material for ghee making. A typical plant assembly for this method comprises a cream separator; a butter churn; butter-melting outfits; steam-jacketed ghee kettle with agitator and process controls; ghee filtration devices; storage tanks for cream, butter, and ghee; pumps and pipelines interconnecting these facilities; crystallization tanks; and product filling and packaging lines.

In brief, the process involves melting of butter mass at 60 °C, which is pumped into the ghee boiler set at 90 °C. This temperature remains constant as long as the moisture is being driven off. The scum that collects on the top surface of the product is removed from time to time with the help of a perforated ladle. The temperature gradually rises and the heating at the last stage is carefully controlled. The end point shows the disappearance of effervescence, appearance of finer air bubbles on the surface of fat, and browning of the curd particles. At this stage, the typical ghee aroma is also produced. The final temperature of clarification is adjusted to 110 °C. The ghee is then pumped through an oil filter/clarifier into settling tanks, which are cooled by circulating water at 60 °C. After cooling and sedimentation, the ghee is filtered through a muslin cloth so as to separate it from the sediment – known as ghee – residue (consisting mostly of burned casein). It then goes on for granulation and packaging. The merit of this method is saving in labor costs, physical exertion, and exposure to uncomfortably high temperatures and humidity during actual ghee making compared to the direct-cream heating method.

Prestratification Method

This method takes advantage of gravity settling for removing most of the moisture from butter and saves the large thermal energy required for removing moisture from butter. In this method, cream is first churned into butter, and it is melted in the butter-melting vat. It is then pumped into a vertical storage tank and left undisturbed for 30 min. When butter is left undisturbed at a temperature of 80–85 °C, it stratifies, that is, separates into distinct layers, viz., a top layer of floating denatured particles of curd, a middle layer of fat, and a bottom layer of buttermilk. This separation into layers has been called prestratification. The bottom layer of buttermilk contains 60–70% of solids-not-fat (SNF) and also over 80% of the moisture originally present in the butter. The buttermilk is mechanically removed without disturbing the top and middle layers. The temperature of the remaining two upper layers is raised to the usual clarifying temperature of 110–120 °C. This process is essential to promote the development of a more characteristic aroma. This method offers the advantages of economy in fuel consumption up to 35–50%, saving in time and labor up to 45%, and production of ghee with lower free fatty acid (FFA) levels. The provisions of pressure gauge, safety valves, temperature regulators, and condensate outlet pipe make ghee of better quality and amenable to process controls. Economy in fuel consumption as compared to direct clarification, production of ghee with a lower acidity, and longer shelf life are the advantages of this method.

Continuous Ghee Making

To overcome the problems of batch methods of ghee making like limitations of scale of operation and excessive exposure of the plant operators to the stress of heat and humidity, the dairy plants have evolved continuous ghee-making system to suit their requirements. The process uses three successive stages of scraped surface heat exchangers, followed by flashing into vertical vapor separators. Molten butter is pumped through the successive stages. Ghee leaving the final stage is passed through a centrifugal clarifier to remove residue and clarified ghee is stored in a tank for final packing. A continuous ghee plant has been developed, the details of which are shown in Figure 1. In this method, the concentration of fat and breaking of fat-in-water emulsion are done mechanically with the help of centrifugal force in the clarifixator and concentrator, and the use of heat is limited to development of flavor and removal of traces of moisture. The plant requires low energy input and can be adapted for much larger volumes. The process also results in lower SNF losses and better fat recovery. The product compares well in flavor and other chemical characteristics with ghee prepared by the batch process. To produce 100 kg of ghee, the plant utilizes 32 kg of steam and 0.45 KWh of electrical energy.

Chemical Composition of Ghee

Ghee is largely made up of triglycerides (98%) and other minor constituents, such as diglycerides (1–2%), monoglycerides (0.1–0.2%), FFAs (1–10 mg/l00 g), phospholipids (0–80 mg/l00 g), cholesterol (0.25–0.4%), fat-soluble vitamins,

carbonyls (traces), glyceryl ethers (0.8 μmol g^{-1}), and alcohol (1.8–2.3 μmol g^{-1}). The chemical composition of ghee is shown in Table 1.

The majority of fatty acids in milk possess even-numbered carbon chains $C_{4-18.}$ The total proportion of polyunsaturated fatty acids is only 3–4% in ghee. Ghee prepared from BM is richer in butyric, palmitic, stearic, tetraenoic, and pentanoic acids than that of CM. The levels of other short-chain fatty acids (caproic to myristic) are higher in CM ghee than those in BM ghee.

At the temperature employed for clarification of ghee during its manufacture, the phospholipid content of ghee also increases progressively due to enzymatic actions.

Derived lipids are the fatty acids originated as a result of fat decomposition by enzymes or other fat splitting conditions, alcohols such as glycerol, and cholesterol and organic bases such as choline (associated with lecithin).

Dehydrocholesterol occurs in close association with fat as far as the physical properties are concerned. When its compound is irradiated with UV light, it is converted to vitamin D. It is insoluble in water but soluble in fat. Its content in milk is around 12 mg/100 g or 0.3–0.4% of fat, equivalent to ~400 mg in 100 g of fat.

Other compounds of significance from nutritive and health point of view present in milk fat are cephalin, sphingomyelin, and glycolipids. Associated flavor compounds of lipid nature are diacetyl and acetyl methyl carbinol. These compounds play an important part in the flavor development of butter. Diacetyl in low concentration has a butter-like aroma. Diacetyl ranges from 0.0002% to 0.004% in butter and its increasing amounts are said to increase flavor. This compound is frequently added to oils and fats to give a butter aroma. Considerable amounts of diacetyl have been found in starter culture and ways have been studied to increase its concentration. Starter distillates are concentrated sources of diacetyl. Accordingly, butter and ghee made from cultured milk/dahi have more pronounced aroma and flavor.

Carotene is the chief coloring material in milk fat, although other related carotenoids (xanthophylls) are present in small amounts. Carotene is derived from green plant sources in the feed of the lactating cow, which is the only mammal to transfer such a color to milk fat. The BM fat has no color because carotene in it has already been converted to colorless vitamin A. It is normally stable to oxidative agents, but in fat, it may be oxidized and bleached under unfavorable storage conditions. Carotene can be converted into two molecules of vitamin A by reacting with two molecules of water. The type of feed and breed of the cow affect the amount of carotene in milk fat. Winter stall-feeding results in 0.2–0.3 mg of carotene/100 g of fat, whereas summer pasture feeding increases it to 0.7–0.9 mg/100 g of fat.

The fatty acid composition greatly influences the fat constants and rheological properties, such as melting and crystallization behavior, solubility, surface activity, and ability to form emulsions. As per the Indian legislation, following are some of the important analytic constants or standards of mixed ghee produced under standard conditions:

- Melting and solidifying points: The melting point varies from 28 to 44 °C, while the solidifying point varies from 28 to 15 °C. (Being a mixture of glycerides, ghee does not have sharp melting or solidifying points.)
- Specific gravity: This varies from 0.93 to 0.94.
- Refractive index: The butyro refractometer reading (at 40 °C) varies from 40 to 45.
- Reichert–Meissl value: This should normally be not <28 (except for ghee from cottonseed feeding areas, where the limit is 20).
- Polenske value: This should normally be not more than 2 (except for cottonseed feeding areas, where the limit is 1.5).
- Saponification value: This should normally be not <220.
- Iodine value: This should normally vary from 26 to 38.

Comparative Appraisal of CM and BM Ghee

The ghee obtained from CM and BM has different physicochemical characteristics due to significant difference in their fatty acid composition. Fresh BM fat is white, unlike the light yellow color of CM fat due to carotene. Table 2 depicts the fatty acid composition of BM and CM fats. Preponderance of long-chain, saturated fatty acids, like palmitic and stearic acid, and substantially high amounts of high-melting triglycerides make BM fat harder than CM fat. This property contributes to the development of granular texture in ghee. Carbonyl compounds, besides FFAs and other fractions, are known to be important contributors to flavor. The BM ghee contains higher amounts of total carbonyls (saturated and unsaturated) and free monocarbonyls (saturated, alk-2-enals, and alk-2, 4-dienals) than CM ghee. Milk fat hydrolyzes faster in liquid state than in solid state. Because of the more solid fat in BM, its rate

Table 2 Fatty acid composition of buffalo and cow milk fat[a]

Fatty acids	*Buffalo milk fat%*	*Cow milk fat%*
Butyric	4.2–4.6	3.1–3.3
Caproic	1.4–1.6	2.0–2.2
Caprylic	0.7–0.9	1.1–1.3
Capric	1.2–1.4	2.5–2.7
Lauric	1.7–1.9	2.7–2.9
Myristic	10.4–10.12	11.8–12.0
Palmitic	33.0–33.2	30.5–30.7
Stearic	11.9–12.1	10.0–10.2
Oleic	27.1–27.3	27.3–27.5
Linoleic	1.49–1.51	1.48–1.52
Linolenic	0.49–0.51	0.59–0.61

[a]Values are ranges.
Source: Compiled from various sources.

of fat hydrolysis is slower than CM. This is why the CM ghee is more prone to developing rancid flavor during storage. The constituents of ghee tend to vary with the method of its manufacture. The cholesterol content of CM ghee made by the traditional method from dahi, cream, and butter displays average values of 292, 306, and 324 mg/100 g, respectively. The corresponding values for BM ghee have been observed to be 263, 275, and 294 mg/100 g, respectively. Generally, the composition of various constituents in ghee does vary.

Ghee Flavor

Aroma and taste constitute the flavor of ghee. A perfect ghee flavor is characterized by a multitude of sensory perceptions, which are pleasant, enjoyable, and lingering in the mouth. This is the most important characteristic looked for in ghee by the trade. The flavor is ascertained by rubbing a small quantity of the sample briskly on the back of the palm and inhaling it. Normally, a well-prepared sample of ghee has a pleasant, cooked, and rich flavor. The taste is usually sweet and characteristic of the milk fat, although a slight acidic flavor is preferred. Consumers always resist any change in the flavor of ghee, as this is one characteristic that predominantly determines acceptability. There are regional preferences for flavor in ghee. The preferred ghee flavors range from 'slightly curdy' to 'pronounced curdy,' cooked to caramelized and, at times, slightly oxidized in some quarters of the population. Technologies have been developed to produce ghee with desired flavors of both 'curdy' and 'cooked' types.

The flavor of ghee is mainly contributed by the heat interaction products formed between the unfermented serum portion, comprising the native carbohydrate and protein system, and by metabolic products of the starter culture when ripened cream is used for ghee making. The most important flavor components of ghee are FFAs (6–12 mg g^{-1}), methyl ketones (6–12 ppm), and a complex mixture of 44 lactones, both 5-lactones and y-lactones (29–43 ppm), aldehydes, ketones, and alcohols. About 34 monocarbonyls were found in the flavor volatiles of ghee.

Ghee Texture

Granulation of ghee is an important criterion for its selection. Consumers appreciate a good grainy texture. Milk fat has the unique property of forming grain/crystals because of a wide variety of complex triglyceride mixtures with varying melting points. The texture of ghee depends on source of the fat (animal species), method of preparation, temperature of clarification, rate of cooling, amount of FFAs, rate of seeding, and storage temperature. Seeding with grains of ghee at the rate of 2% by weight of ghee improves grain/crystal formation. The grain shape becomes needle-like in contrast to the spherical shapes obtained without seeding. The large number of fatty acid residues present in ghee results in a wide variety of crystallization patterns. The maximum amount of solid fraction (about 74%) is obtained at 28 °C in 20–24 h from BM ghee closely followed by CM ghee (39.5%) and a distinct low in goat milk ghee (30%). There can be significant differences in the melting curves of fat from the milk of buffalo, cows, and goat. The changes in the conditions of cooling have a pronounced effect on ghee texture. If ghee is cooled rapidly, a larger number of very fine crystals will be formed, all consisting of a mixture of high- and low-melting fats, leading to smooth, grease-like character. Slow cooling of ghee from a temperature higher than the melting point will lead to the formation of few crystals with a high melting point. As cooling proceeds, more and more fat solidifies, forming a mass of large crystals suspended in liquid fat.

Ghee Color

BM ghee appears whitish in color owing to the absence of carotene, which imparts a yellow color to CM ghee. In the village method of ghee making, the development of a greenish-yellow tinge in BM ghee is caused by the action of lactic acid bacteria. Ghee produced by the direct-cream method has a brownish color compared to that prepared by the creamery butter process. Stratification results in a lighter color. A more intense heating in the presence of a high SNF content will result in a darker color, especially if the raw material has been fermented.

Ghee Residue

This refers to the charred (burned) light to dark brown residue, which is obtained on the strainer after the ghee is filtered. It is a useful by-product of the ghee industry. It is largely made up of the SNF present in butter, cream, or butter appearing in the form of small particles during the manufacture of ghee. It contains considerable amounts of milk fat, protein, and minerals. Taking an average yield of ghee residue as one-tenth the quantity of ghee produced, at present level of about 3 383 000 metric tons, the bulk of ghee residue produced per annum works out to about 338 300 metric tons. Its composition is influenced by the composition of the nonfatty constituents butter or cream, the technique adopted for the production of ghee. Essentially, it contains heat-denatured milk proteins, caramelized lactose, and varying amounts of entrapped fat, besides some mineral and water. Chemical composition of ghee residue is depicted in Table 3.

Packaging of Ghee

Ghee is susceptible to deterioration from exposure to light, air, and metals. Therefore, it is packed in tin-coated (nontoxic and nontainting) containers. Food-grade plastic containers and polyethylene pouches are also used. Ideally, ghee should be stored in a cool and dry place for long shelf life. Ghee packaged in plastic film laminates should not be exposed to light to minimize the development of oxidative rancidity. Due to large institutional (military/temples) consumption of ghee, about 60% of the country's production is packed in 15 kg tin containers. The remainder is packed in consumer size tin containers (100 ml, 200 ml, 500 ml, and 1, 2, and 5 l packs), paper/plastic stand-up packs (100 ml, 200 ml, 500 ml, and 1 l), and pillow pouches of metalized polyester and plastic polylaminated film (500 ml and 1 l size).

Table 3 Chemical composition of ghee residue[a]

Source of ghee residue	Average % fat of source	Chemical composition (%)				
		Moisture	Fat	Protein	Lactose	Ash
Desi butter (from buffalo milk)	77.0	13.4	33.4	32.8	15.4	5.2
Creamery butter (unsalted)	85.0	5.7	65.0	25.5	Trace	3.8
Sweet cream	67.0	4.1	63.2	18.0	12.3	2.4
Sour cream	67.0	8.0	38.8	41.6	7.3	4.3
Washed sweet cream	71.0	1.7	80.8	16.2	Trace	1.3

[a]Values are the means.

Adulteration of Ghee

Ghee has an important place in Indian diet because of its good flavor, pleasant aroma, high calorific value, fat-soluble vitamins, and essential fatty acids. However, its supply falls short of demand in the lean season. Therefore, to extend the available supplies and to earn extra profits, ghee is adulterated by unscrupulous traders with cheaper oils/fats which leads to health hazards. The problem of adulteration is further complicated by the fact that the composition of ghee varies with the species, season, and the diet given to the animals.

Gin

M Riu-Aumatell, Universitat de Barcelona, Santa Coloma de Gramenet, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Spirit-based beverages account for a total of 39 million hectoliters in the European Union (EU), of which 8% are jenever (genièvre) and gin. The economic importance of gin and related beverages is evidenced in the extensive exportation from certain member states (notably the United Kingdom, France, and Germany) to the rest of the world. The United States is by far the most important import market.

Gin is an alcohol-based flavored beverage in which the predominant flavor is derived from juniper. It began its evolution in Holland around 1550 when Franciscus de la Boe, a professor of medicine, tried to create a cure for stomach complaints, based on the diuretic properties of juniper berries. Today, it is a colorless beverage containing at least 37.5% alcohol. It is consumed usually mixed with tonic water, ice, and lemon, or with other beverages, such as vermouth in preparing cocktails, notably dry martinis.

According to EU legislation, flavored spirit-based beverages are divided into four categories: juniper-flavored spirit drinks, gin, distilled gin, and London dry gin. In all types, juniper must be the predominant flavor. The following article focuses on the production, raw materials, and consumption of gin worldwide.

Gin: Legislation and Definitions

Flavored spirits are usually sold between 35% and 40% alcoholic and are colorless beverages with a wide range of formulations. According to European legislation, only juniper-flavored beverages may have a lower percentage of alcohol (30%). The latter is ethyl alcohol (of agricultural origin) flavored with juniper, whereas distilled and London gins are derived from distilling ethanol (96% vol.), in the presence of juniper berries (*Juniperus communis* L.) and other botanicals, such as coriander seed, angelica root, sweet and bitter orange peel, aniseed, and licorice root to add complexity. It is necessary that these botanical materials be of high quality, despite the predominant flavor being donated by juniper. The specific mixture involved in each brand is a proprietary secret.

According to European regulations, a geographical indication is a designation that identifies a spirit-based beverage originating in a territory or country, or a region or locality within a specific country, where the given quality, reputation, or other characteristics of that beverage is essentially attributable to its geographical origin. Table 1 notes the geographical indications registered by juniper-flavored beverages. Apart from the requirements specified in European legislation, only organoleptically neutral alcohol can be used in gin production.

To date, the scientific literature on gin has focused on identifying its key aroma constituents, its sensory profile, and investigation of newer distillation technologies.

Gin Production

There are two principal gin production methodologies: those with or without distillation. Distilled gins are considered of higher quality, particularly London dry gin. The latter is considered a separate category by the EU, to assist in maintaining its high standards and protect it from counterfeit versions. Gin distillation uses a batch process involving traditional copper stills employed uniquely for each brand. In addition, the mixture of botanicals and their quantities are specific to each brand. Usually, London dry gins, produced in the UK, are exported in stainless steel tanks and bottled locally to reduce cost.

At the onset of production, water, alcohol, and botanicals are added to traditional stills (usually of 20 000 l) before heating. Botanicals could be added either loose, or in a clean cotton bag, suspended in the headspace above the liquid. Usually these are added as whole ingredients, but may also be added as a powder, or prior maceration for 24 h in alcohol. The botanicals, the quantities used, and the method of distillation are specific to each brand of gin. The rate of heating is carefully controlled (up to 70–80 °C) and the alcoholic strength closely monitored. The first and the last fractions of the distillate (head and tail, respectively) have poor quality and are combined and redistilled to recover neutral-flavored alcohol. The head may contain impurities, such as other more volatile alcohols (notably methanol) as well as small amounts of flavorants because the degree of extraction is low. On the other hand, at the end of the distillation, the alcoholic strength of the distillate tail drops, and the character changes because less volatile botanical congenerers start to dominate the sensory characteristics of this fraction. The main fraction of the distillate is appropriate for use in the generation of high-quality gin. Recent investigation has studied the value of using vacuum distillation instead of traditional heat-based distillation. The benefits of vacuum distillation include higher yields, with more monoterpene oxides possessing greater stability than other related hydrocarbons. In addition, studies on lower distillation temperature suggest improved recovery rates, and thereby economic savings.

To ensure an appropriate quality in the distillate, both chemical and sensory aspects are investigated. Because the distillate is of high alcoholic strength, it must be reduced to the required strength by dilution with water. In the United States, the final alcohol strength can be as high as 40%, whereas within the EU 37.5% is legislated.

Alternatively, and simpler, is the maceration of botanicals in flavorless alcohol for a period, followed by separation of the botanical and reduction of alcohol strength to the desired value.

Ingredients

As noted, the principal ingredients of gin are water, neutral-flavored alcohol, and botanicals. All must be of appropriate quality to produce a commercial beverage.

Table 2 Characteristics of neutral ethyl alcohol (of agricultural origin) as designated by European legislation

Minimum alcoholic strength	96%
Acidity (maxim)	1.5 g acetic acid/HL of 100% alcohol
Esters	1.3 g ethyl acetate/HL of 100% alcohol
Aldehydes	0.5 g acetaldehyde/HL of 100% alcohol
Higher alcohols	0.5 g methyl-2-propanol/HL of 100% alcohol
Methanol	30 g/HL of 100% alcohol
Dry extract	1.5 g/HL of 100% alcohol
Volatile bases containing nitrogen	0.1 g nitrogen/HL of 100% alcohol
Furfural	Not detectable

Neutral alcohol is the main essential ingredient in any spirit-based beverage. It must be of agriculture origin. It is usually produced by a company unconnected with beverage production. Depending on the carbohydrate source, production may involve various stages, such as cooking and mashing, as well as the obligate fermentation and distillation. The characteristics of a neutral alcohol, as defined by European legislation, are listed in Table 2.

The second, and principal, ingredient is water. It may be distilled, demineralized, softened, or permuted and must comply with all directives related to water intended for human consumption. Water is added to reduce the alcoholic strength to the legislated value. Historically, distilleries were located near a good source of quality water. With modern means of purifying water this is no longer essential.

The third essential ingredient in the gin production is natural botanicals. Of these, *Juniperus communis* is the most important. *J. communis* is a member of Cupressaceae and a native evergreen shrub found in the Northern Hemisphere, notably in Europe and North America. Juniper 'berries' are the female seed cones produced by the various juniper species. They are not true berries, but the cone of a conifer with unusually fleshy and merged scales. This property gives them a berry-like appearance. The plant grows from western Alaska, throughout Canada and the northern United States, throughout Europe, and into northern Asia and Japan, normally between 500 and 1600 m. Although it can develop into a small tree of up to 7 m, it is usually found in bush form of less than 2 m in height. The plant's more characteristic features are its needle-like leaves, with a white band on the upper face, encircling the stem in groups of three. The fruit matures in the autumn after a 2-year development period on the plant. They are a low maintenance plant to grow, and although they prefer an acidic pH soil, they can grow on nonacidic soils. Shaped like irregularly sided spheres, the berries are green at first, but ripen after 18 months to a dark, blue-purple color – ready for harvesting and use in gin production. Juniper berries are primarily used dried, as opposed to fresh, but their flavor and odor are at their strongest immediately after harvest and declines during the drying process and subsequent storage.

Juniperus berries have been associated with medicinal properties, including diuretic, hypoglycemic, anti-inflammatory, antibacterial, and antifungal attributes. Recently, it has also been shown to prevent cell division in one type of cloned human cancer lines. The fragrant and spicy aroma of juniper oil has also been used as an ingredient in perfumes and to flavor meat and other alcohol-based beverages, for example, grappa. The essential oil content of juniper berries, varying between 0.2 and 3.5%, is comprised mostly of monoterpenes (58–85%), sesquiterpenes (2–10%), and their oxidized terpenes. Of some 74 terpenes, sesquiterpenes, and oxides isolated and quantified in the headspace of juniper berries, more than 80% have been detected in brands of London dry gin. The compounds found in the highest concentrations in juniper berries are terpinen-4-ol, *p*-cymene, β-myrcene, γ- and δ-cadinene, and α- and γ-muurolene. Despite this, the aromatic profiles of separate brands differ significantly.

Coriander seed is the second most commonly used plant material in gin production. It is a member of the Umbelliferae family and is typical grown in Mediterranean countries. *Coriander sativum* L. has been used since ancient Greek times as a medicine for digestive problems and diarrhea, as well as an aphrodisiac. It also possesses antioxidant, diuretic, antidiabetic, sedative, antimicrobial, anticonvulsant, hypnotic, anthelmintic, and antimutagenic properties. Coriander seed oil is one of the major essential oils found in consumer markets because of its stability and agreeable odor. Coriander seed contains less than 1% essential oil. Its main constituent is linalool (between 50% and 80%). Its concentration is highly dependent on the growth temperature, degree of sun exposure during fruit development, and the water supply. Other constituents in coriander seed oil are geraniol, terpinen-4-ol, α-terpineol, and hydrocarbons. The presence of linalool as the main monoterpenol in some gin brands has been interpreted as suggesting the use of coriander seed in their production.

Other ingredients potentially added as supplemental sources of flavor include cardamom, angelica root, and/or

citrus peel. Cardamom (*Elettaria cardamomum*) is usually obtained from India or Central America, where it grown as a major spice crop. Its fruit and seeds are commonly used in the food and cosmetic industry as a flavoring agent. Its essential oil has also been used as a hepatoprotective and anti-inflammatory, among other medicinal uses. Another essential oil often used in flavoring gin is angelica root (*Archangelica officinalis*). The essential oil was often used for its antispasmodic, carminative, depurative, diaphoretic, digestive, diuretic, expectorant, febrifuge, nervine, stimulant, stomachic, and tonic actions. In addition its pharmaceutical uses, the essential oil has been used due to its green-spicy 'top-note' and a pleasant musky 'dry-out.' The spicy notes are attributable to its terpene hydrocarbons (notably α-pinene, β- and α-phellandrene, limonene, p-cymene, and δ-3-carene). The musty odor is attributed to the macrolides, 13-tridecanolide, 15-pentadecanolide, 16-hexadecanolide, and 17-heptadecanolide. Finally, among other possible botanicals used, citrus peel is often used to flavor gin. Terpenes are the main compounds detected in citrus oil, with limonene being the principal component.

Analytic Methods Used in Quality Control

The principal objectives of gin analysis are quality control, brand authentication, and the nature of its raw materials. The analytic methods used in distilleries are highly diverse. The sensory and chemical analyses involve primarily its three principal ingredients (alcohol, water, and botanicals). European regulation recommends specific methods for analyzing spirit-based beverages. Alcohol strength is usually determined by pycnometry, refractometry, electronic densimetry, or densimetry using a hydrostatic balance. Total dry extract is determined by gravimetry, whereas more specific analyses usually involve chromatography. The ethanol used must comply with certain requirements relative to total acidity and congeners, such as aldehyde, higher alcohol, and ethyl acetate content. The method of choice is gas chromatography (GC), coupled with detectors such as flame ionization (FID) or mass spectrometry (MSD). To measure the presence of higher alcohols, methanol, ethyl acetate, and other congeners, direct injection is used. Before chromatographic analysis was developed, extraction was needed for minor constituents, based on their volatility (headspace techniques), solubility (solvent extraction), or both.

In the other hand, analysis of the dilutent water used in gin production involves conductivity measurements and sensory analysis to ensure the absence of any odors. The presence of trace minerals, such as sodium, potassium, calcium, and magnesium, is assessed by absorption spectrophotometry.

Because traditional methods are time consuming and expensive, alternative techniques that are both faster and more economical are under investigation. These include near-infrared spectroscopy (NIR), nuclear magnetic resonance (NMR), and Fourier transform infrared spectroscopy (FTIR).

Precise characterization of gin's aromatic constituents is complicated due to their multiple and diverse chemical nature. Minor volatile compounds are usually assessed using gas chromatography. Although it may be coupled with various detectors, the most common is a mass spectrometer. They have been frequently used to identify the key aroma compounds that characterize gin. The older literature, based on liquid–liquid extraction, identified the main six terpenes and sesquiterpenes found in gin aroma. Subsequently, different terpenic markers for different brands of gin have been identified, based on α-pinene, sabinene, myrcene, limonene, and linalool contents. Recently, headspace solid-phase microextraction has been used to compare the volatile composition of several London dry gins (Figure 1). Such studies have also been used, in combination with sensory profiles, to establish their chemical origins and to suggest the types of botanicals used in gin flavoring. For example the citric attribute has been associated with gins rich in linalool and γ-terpinene. Equally, a spicy note was correlated with a model gin containing sabinene, δ-3-carene, and p-cymene.

Sensory Profile and Gas Chromatography-Olfactometry

Despite advances in instrumental and analytic procedures, the flavor sensations perceived by the consumer can be assessed only by sensory analysis. Thus, sensory analysis remains an essential tool for assessing the properties of gin. In addition to gin's predominant alcohol and juniper attributes, the botanicals used in production donate much of each brand's distinctiveness. The individual contribution of each botanical depends of its source, concentration, and interaction with other ingredients. For sensory analysis to be used effectively as a quality control tool, a clear definition of gin's quality specifications must be established and adequate methods developed to adequately evaluate these specifications.

Spirit profile is usually assessed using a small number of attributes determined by a panel of tasters. Depending on the purpose of the analysis, a wide variety of sensory test methods may be employed: discrimination tests, descriptive methods, time-intensity scaling, and consumer tests. Discrimination tests often involve the triangle test, where two products are assessed on whether they are significantly different from a third. In contrast, consumer tests are often used in early stage product development to estimate whether it is likely to be commercially successful. Nevertheless, descriptive analysis is usually the sensory method preferred in quality control assessments and used with a specifically trained panel. Descriptive analysis has the potential to provide intensity rating for a variety of attributes considered to characterize a product.

In previous studies, the number of descriptors considered adequate to characterize gin have varied from 2 to 21. Nonetheless, most researchers have confirmed the need for a more refined vocabulary and the development of reference standards for each term. In addition, the techniques used in panel training have often been inconsistent. More recently, panel members have been trained specifically for intensity ranking, using hydro-alcohol extracts of botanicals and in their precise description and recognition. Vocabulary generation sessions have been performed. Statistical methods, such as principal components analysis (PCA) and one-way ANOVA, have been used to reduce the number of terms to those that are the most discriminatory. These include juniper, citrus, aniseed, licorice, and spice. Subsequent correlation of sensory analysis with

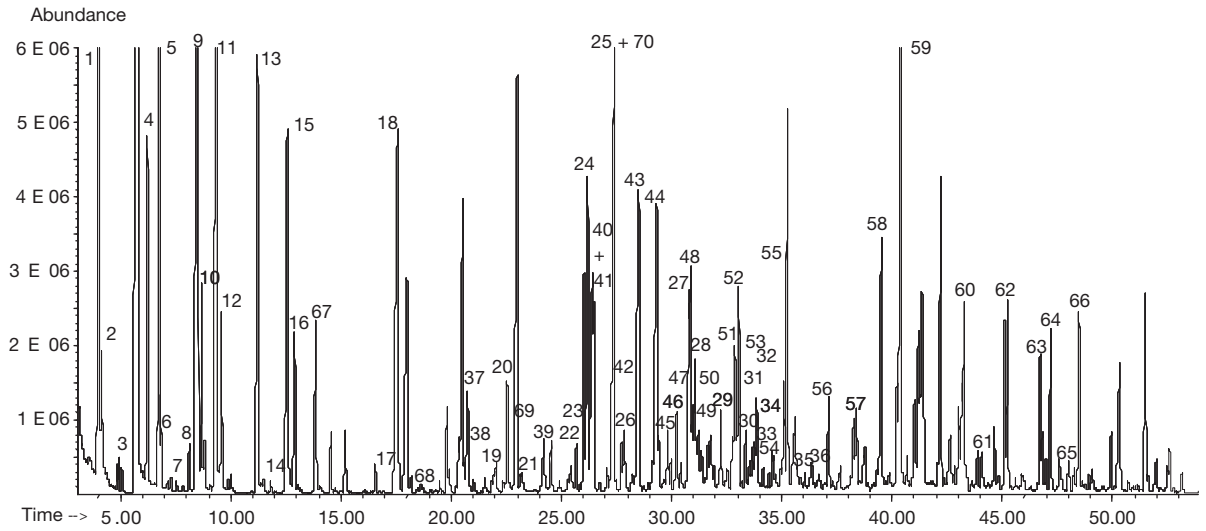

Figure 1 Volatile profile of London dry gin. 1, α-pinene; 2, α-thujene; 3, camphene; 4, β-pinene; 5, sabinene; 6, verbenene; 7, δ-3-carene; 8, l-phellandrene; 9, β-myrcene; 10, α-terpinene; 11, DL-limonene; 12, β-phellandrene; 13, γ-terpinene; 14, *t*-ocimene; 15, *p*-cymene; 16, α-terpinolene; 17, *c*-rose oxide; 18, verbenyl ethyl ether; 19, citronellal; 20, campholenal; 21, camphor; 22, linalool; 23, *c*-sabinene hydrate; 24, bornyl acetate; 25, l-4-terpineol; 26, myrtenal; 27, α-terpineol; 28, terpenyl acetate; 29, neryl acetate; 30, geranyl acetate; 31, cuminal; 32, β-citronellol; 33, myrtenol; 34, nerol; 35, *t*-carveol; 36, *t*-geraniol; 37, α-cubebene; 38, α-copaene; 39, β-cubebene; 40, *t*-β-caryophyllene; 41, β-elemene; 42, sesquiterpene; 43, γ-elemene; 44, α-humulene; 45, *t*-β-farnesene; 46, γ-muurolene; 47, sesquiterpene; 48, germacrene D; 49, α-selinene; 50, α-muurolene; 51, δ-cadinene; 52, γ-cadinene; 53, cadina-1,4-diene; 54, sesquiterpene; 55, germacrene B; 56, sesquiterpene; 57, α-calacorene; 58, sesquiterpene; 59, caryophyllene oxide; 60, torreyol; 61, elemol; 62, spathulenol; 63, *t*-cadinol; 64, *t*-muurolol; 65, eudesmol; 66, α-cadinol; 67, non identified; 68, nonanal; 69, benzaldehyde; 70, 2-undecanone.

volatile composition has shown the citrus note to be associated with γ-terpinene, linalool, and limonene, whereas α-pinene seems to be important to a juniper note.

The correlation between chemical constituents and sensory perception has to be facilitated by gas chromatography-olfactometry. Volatile compounds are separated by conventional gas chromatography with a human detecting the sensory attributes as individual compounds are released. The technique has also been used to develop a new odor classification wheel. One such wheel contains 12 super-categories: vegetable, unpleasant, spice, pungent, nut, microbiological, fruity, floral, earthy, chemical, caramelized, and woody, whereas another uses terms such as juniper, floral, fruity, spicy, licorice, vegetable, woody, and chemical.

Patterns of Consumption

The European Union is the area in the world where alcohol consumption is the highest. This may be associated with its extensive recreational use for at least 7000 years. Nonetheless, alcohol consumption and cultural preferences differ widely among individual states. Additional sources of variation include regional factors, age, gender, socioeconomic status, religion, and occupation. Average consumption is 11 l per year (based on alcohol equivalency of the various beverages). Of this, 44% is beer, 34% wine, and 23% spirits. Concern has recently been focused on the increased consumption by underage youth. Promotional campaigns to increase awareness of responsible consumption, accentuating sensory quality, and judicious social relationships are attempting to reverse inappropriate consumption of alcohol-based beverages.

The main spirits consumed in the EU and exported, amounts to about 4.6 million hectoliters (assessed by pure alcohol equivalency). Of exports, whiskey constitutes about 45%, vodka and brandy about 21% and 13%, respectively, whereas gin and jenever amount to about 8%. An indicator of the economic importance of gin is noted in the annual use of more than 79 000 t of cereal grains in gin production, being the equivalent of more than 10 million euros. The principal markets for gin consumption in the EU are the United Kingdom, Spain, the Netherlands, the Czech Republic, and Latvia, with considerable growth in Greece. Emerging markets in terms of spirit consumption include China, India, Turkey, Vietnam, Brazil, the Philippines, and Korea.

Availability, Absorption, and Metabolism – Health Effects and Clinical Studies

The main ingredient in all alcoholic beverages, including gin, after water, is ethanol. According to the scientific community 'moderate drinking' is defined as no more than 3–4 standard drinks per drinking episode, and no more than nine drinks per week for women and 12–14 for men. Epidemiological data suggest that moderate alcohol consumption is associated with reduced risk of fatal and nonfatal coronary heart disease as well as other cardiovascular disease, independent of the type of alcoholic beverage consumed. Moderate alcohol consumption is also related to a decreased risk of developing type-2 diabetes and may also reduce the likelihood of developing Alzheimer dementia. However, other researchers attribute most of the health benefits of alcohol-based beverages to their phenolic content, or their joint influences. Few studies have specifically

looked at gin in relation to health issues. Furthermore, limitations in clinical studies make it difficult to reach definitive conclusions relative to any specific beneficial effects related to gin consumption.

In contrast to the health benefits in moderate alcohol-based beverage consumption, some European countries have a serious alcohol problem. This situation is linked with enhanced morbidity and premature mortality. Excess alcohol intake is a contributing factor in about 60 diseases and conditions, including several cancers, liver disease, cardiovascular ailments, gastrointestinal problems, immunological disorders, lung disease, skeletal and muscular issues, reproductive disorders, and prenatal harm, including increased risk of prematurity and low birth weight.

Introduction

Diabetes mellitus and obesity have reached epidemic proportions globally with the adoption of a Westernized lifestyle characterized by excess energy intake and inadequate physical activity. In the United States, 21.1 million people have diabetes, an increase of about 3 million over the last 2 years. Moreover, at least a quarter of people with diabetes are thought to be undiagnosed. As the prevalence of diabetes has increased, diabetes-related morbidity and mortality have become major public health issues. The 2025 worldwide projection for people with impaired glucose tolerance (IGT) is 418 million (8.1% of the adult population). Apart from the social aspects of the disease, the economic aspects are also significant: Annual diabetes-related costs in the United States are $174 billion (about 15% of national health costs), and costs related directly complications and medical care are $116 billion, while indirect costs (e.g., disability and premature mortality) amount to $58 billion.

Patients with diabetes are prone to multiple and complex complications. These complications include both macrovascular diseases (e.g., heart disease, stroke, and peripheral vascular disease) and microvascular diseases (e.g., retinopathy, neuropathy, and microalbuminuria). Epidemiological data from the last 5 years have shown complications begin early in the path from normal glucose tolerance (NGT) to diabetes. There is a time in glycemic control, between NGT and diabetes, when blood glucose levels are the harbinger of future diabetes and its complications. Thus, early detection and therapeutic intervention are crucial in reducing or delaying progression to diabetes and limiting the occurrence of related macro- and microvascular complications.

Prediabetes and Preventing Type 2 Diabetes Mellitus (T2DM)

Prediabetes is characterized by either impaired fasting glucose (IFG) with fasting blood glucose between 100 and 125 mg dl^{-1} (5.6–7 mmol l^{-1}) or IGT with fasting blood glucose within normal limits but between 140 and 199 mg dl^{-1} (~7–11 mmol l^{-1}) 2 h after an oral glucose tolerance test. These conditions may occur separately or coexist. According to a recent consensus statement of the American Diabetes Association (ADA), diagnosis of diabetes is appropriate when

- fasting blood glucose average of two measurements is >126 mg dl^{-1} (7 mmol l^{-1}),
- fasting blood glucose is >200 mg dl^{-1} (11 mmol l^{-1}) two hours after glucose load,
- blood glucose is >200 mg dl^{-1} (11 mmol l^{-1}) in random measurement, or
- HbA1c (glycated hemoglobin) is greater or equal to 6.5%.

Prediabetes constitutes an earlier stage in the evolution of type 2 diabetes, but this metabolic disorder, even in the absence of clinical symptoms, needs to be detected and treated early.

Prediabetes Check

The issue of prediabetes is of major importance, and based on diabetic standards, it is set to assume global epidemic dimensions. Worldwide, the number of people with prediabetes is about 314 million, but it is predicted that in 2025, numbers will reach 418 million. It is known that prediabetes increases short-term risk of type 2 diabetes mellitus (T2DM) from three to 10 times and some populations are at higher risk. Screening for prediabetes should be performed in populations with increased risk of diabetes such as those

- with a family history of DM,
- with cardiovascular disease,
- who are obese or have a sedentary lifestyle,
- who are hypertensive or hyperlipidemic,
- who take antipsychotic medicines,
- women with a history of gestational diabetes or polycystic ovary syndrome.

Pathophysiology of Prediabetes

Significant epidemiological differences between IFG and IGT indicate that different pathophysiological mechanisms contribute to the development of disorders in glucose homeostasis. While both conditions are associated with insulin resistance, they differ in the manifestation of insulin resistance at the tissue level. Those who have only IFG demonstrate hepatic insulin resistance and normal muscle insulin sensitivity, while those with IGT demonstrate normal or slightly reduced hepatic insulin sensitivity and moderate or severe muscle insulin resistance.

Therapeutic Intervention

Promotion of a healthy lifestyle is the option of choice for reducing incidences of pre- and type 2 diabetes, but it is challenging. Any dietary intervention must address both the quality and quantities of food consumed in all age groups and include personalized adjustments. However, recent studies have shown that meaningful intervention should also include exercise and weight loss since the benefits, especially in glucose tolerance, are limited if only one aspect is addressed. Apart from any debate about the treatment of prediabetes, according to the ADA recommendation, metformin (biguanide class antihyperglycemic drug) is recommended only when prediabetes

(IFG and IGT) coexists with an additional risk factor, such as age <60 years, BMI >30 kg m^{-2}, family history of diabetes in first-degree relatives, elevated triglycerides, reduced HDL, hypertension, or HbA1c $>6\%$.

Monitoring and Evaluating the Development of Prediabetes

The need for monitoring depends on overall risk but should include annual fasting glucose and HbA1c and oral glucose tolerance tests in those who have deteriorated. Microalbuminuria, fasting lipid concentration, and blood pressure should also be measured at least once every 12 months. In the future, biomarkers, genetic factors, and tools to measure risk of diabetes might be used to assess relative probabilities and allow more targeted monitoring and management of those with prediabetes.

In individuals with IGT, the main site of insulin resistance is muscle with only minor changes to insulin sensitivity in the liver and impaired early and late (60–120 min) insulin response during the course of the oral glucose tolerance test. Although the fasting blood glucose is not increased, there is a progressive prolonged increase in glucose during the oral glucose tolerance test, and the glucose values are higher than fasting levels after 2 h. This is supported by the finding that total glucose disposal may deteriorate gradually from NGT to IFG, IGT, and, finally, T2DM. Despite this, the clinical significance of these pathophysiological differences has not yet been established. Dysfunction of pancreatic β-cells is observed in subjects with IFG and IGT. Those who have only IFG exhibit a severely impaired early insulin response during oral glucose tolerance test, but insulin levels improve during the second phase of the test. Conversely, people who have only IGT exhibit reduced insulin secretion throughout the test.

Epidemiology

People with elevated blood glucose concentrations can be observed in both developed and developing countries. Aggregated data from 2.7 million adults, who participated in surveys for health and epidemiological investigations, suggest that mean fasting blood glucose corrected for age in 2008 was 99 mg dl^{-1} (5.5 mmol l^{-1}) for men and 97 mg dl^{-1} (5.3 mmol l^{-1}) for women. Compared with those in 1980, these values have increased by 1.8 mg dl^{-1} (0.1 mmol l^{-1}). People living in Oceania have the highest mean fasting blood glucose (110 mg dl^{-1} or 6.1 mmol for men and women). Elevated fasting blood glucose increases the prevalence of prediabetes although, in some populations, numbers with IGT have not increased despite the increase in T2DM. This might be because rates of obesity have increased, affecting fasting blood glucose (IFG) rather than values 2 h after glucose administration (IGT). The NHANES (National Health and Nutrition Examination Survey), during the period 2005–2008, assessed fasting blood glucose and HbA1c and showed that 35% of US adults older than 20 years and half of those older than 65 years were prediabetic. Extrapolating these results to the entire US population in 2010 led to the estimation that 79 million US adults are prediabetic.

The prevalence of IFG and IGT varies between different ethnic groups. Both are more prevalent in people over 40 years of age. Moreover, IFG is more common in men than in women, although the reasons behind this are not fully understood. The number of prediabetic adults (IGT) is expected to grow worldwide reaching 472 million people by 2030. Areas where the largest increases are expected are Southeast Asia and the western region of the Pacific Ocean.

It has been estimated prediabetes occurs in about 5–10% of people annually, but the incidence varies depending on the population and the diagnostic criteria. According to the ADA, up to 70% of people who are prediabetic may eventually develop diabetes. A meta-analysis of prospective studies published between 1997 and 2004 showed that the annual incidence of diabetes for those with IGT (4–6%) or IFG (6–9%) was lower than in individuals where IFG and IGT (15–19%) coexisted.

Healthy Lifestyle

Change in lifestyles, especially diet and exercise, has been shown to prevent or delay the onset of T2DM and its complications. However, proposed change in lifestyle should be personalized to strengthen implementation and compliance in the long term. Dietary management during the prediabetic stage involves significant changes in planning meals, selection and preparation of food, portion control, and eating away from home, which means most people struggle to comply. Common modifications suggested by health professionals relate to glycemic control including frequency of meals (small frequent meals), time of consumption (fixed hours), and the allocation of carbohydrates. The idea behind the smaller-sized, frequent meals at fixed hours is to help appetite control, possibly by reducing overconsumption of food during the main meal. However, the few studies investigating prediabetics, which have been published, present conflicting results.

Overall Metabolic Health

Recommended treatments to improve metabolic health include changes in diet and physical activity, which promote adipose tissue loss, enhance metabolically active skeletal muscle mass, and hence improve metabolic control. Energy-restricted diets are widely recommended for weight loss in overweight or obese individuals with poor metabolic health. However, about quarter of weight loss can be attributed to decreased skeletal muscle mass, which is undesirable because muscle is essential for mobility, maintaining and changing posture, activities of daily living, glycogen storage, etc. In addition, skeletal muscle has a major role in glycemic control accounting for up to 75% of tissue glucose uptake. Mitochondrial oxidative capacity is decreased in obese skeletal muscle as well as T2DM, possibly due to underlying physical inactivity.

Advancing age and a sedentary lifestyle are also risk factors for gradual loss of skeletal muscle mass, function, and, in turn,

muscle strength. The problem is further compounded by increased adipose tissue accumulation and myocellular lipid infiltration, which provide the basis of sarcopenic (accelerated muscle loss) obesity, and may lead to insulin resistance and increase metabolic risk. Intramyocellular lipid accumulation in obese individuals is difficult to reverse through weight loss. Activation of skeletal muscle protein anabolism is blunted in both obese and elderly people, although this may be associated with common underlying physical inactivity and insulin resistance.

Meal Frequency

There are several claims in the literature that support a correlation between eating frequency and glucose/insulin blood levels. Several mechanisms have been proposed to support an inverse relationship between frequency of meals and risk of diabetes. These are

a. reduced glycemic load resulting from the allocation of nutrients during the day;
b. suppression of free fatty acid secretion from adipose tissue, which promotes glucose disposal;
c. possible inverse correlation of insulinotropic polypeptide, which is glucose-dependent, with higher frequency of meals, whereby high meal frequency leads to less insulin secretion; and
d. potentially slower stomach emptying, fewer meals, and reduced distension of the stomach, which result in delayed movement of nutrients in the gut, so less insulin is needed to regulate blood glucose levels.

It is unclear whether long-term adherence to dietary pattern, namely, prandial high frequency, ultimately will improve glucose tolerance. Some correlation can be explained in terms of the frequency of meals and risk of diabetes. It is likely a longer period than most studies allow is needed for participants to adapt to a higher meal frequency compared with the time needed to observe changes in glucose and insulin. Moreover, the metabolic benefits of higher prandial frequency can be mitigated during weight loss, which also reduces glycemic load. More frequent meals may be beneficial to people with NGT at the start of the intervention, especially in comparison with T2DM. Furthermore, a greater number of meals (up to 16 per day) may be needed to achieve a metabolic advantage, while a lack of conformity in prandial frequency may explain in part the lack of benefits observed in epidemiological studies.

Insulin resistance was not examined in any of these studies. The effects of eating frequency on insulin resistance in T2DM or prediabetics, either in the retention phase or during weight loss, are largely unknown. There may be no effect since there are very few data suggesting a relationship between the frequency of meals and concentrations of glucose/insulin.

In two studies performed in healthy populations, observed glucose and insulin levels were flatter in the group consuming nine meals per day than those consuming three meals. However, the area under the curve (AUC) did not differ significantly between the two interventions (2 weeks apart). Moreover, a study with healthy individuals showed no significant effect of meal frequency (three meals per day against one meal per day) on glucose concentration or insulin indicators for T2DM risk. On the other hand, studies with prediabetic and diabetic individuals are largely inconclusive. Prediabetic (IGT) and type 2 diabetics consumed isocaloric diets with three and nine meals per day, respectively, for 4 weeks each. The results of this study could not confirm potential benefits of increased meal frequency in either group. Other studies that included only type 2 diabetics showed more frequent meals (between 3 and 17 meals per day) could reduce pronounced changes of glucose and insulin and improve glycemic control.

Lifestyle modification, including nutrition, is vital to manage the prediabetic state. Macro- and micronutrients, fiber, and other components of the diet modulate meal-induced insulin secretion through changes in gastrointestinal transit time and nutrient absorption rates.

Evidence to date suggests the frequency of meals has limited use as a strategy for weight management and physical health. Results from long-term randomized clinical trials are required to determine whether meal frequency should be integrated into recommendations for health promotion and disease management. Until then, it is necessary to estimate dietary habits and provide personalized diet programs. However, it is also important to note that no adverse effects have been observed from eating six meals per day. Thus, meal frequency for prediabetics could be left to personal choice provided energy balance is maintained.

High and Low Glycemic Index Diets

Glycemic index (GI) quantifies the response stimulated by carbohydrates in different foods and glycemic load (GL) is the mathematical product of the GI and carbohydrate content. GL was proposed as an indicator that reflects the response of glucose and insulin initiated by a portion of food.

Carbohydrates, as the primary component of food affecting blood glucose, by both volume and type, have a direct effect on postprandial blood glucose and insulin concentrations. There have been several studies examining difference between high GI (HGI) and low GI (LGI) diets in terms of insulin response, postprandial hyperglycemia, time challenge saturation, etc. Data obtained from short-term interventions in humans indicate that LGI meals have no significant positive effect on satiety compared with HGI meals. Generally, however, there are limited data in humans showing slow digestion of starch (i.e., LGI diet) may mitigate the postprandial blood glucose and insulin response leading to prolonged saturation compared with rapid digestion of starch from a HGI diet. However, LGI diets rich in dietary fiber (LGI-HF) are advantageous compared with HGI counterparts. The primary benefits are related to glucose metabolism after a meal and the corresponding postprandial hyperglycemia and hyperinsulinemia, especially in diabetics, compared with HGI diets. This is due to reduced regulation of glucose metabolism, particularly at the postprandial period.

HGL diets require increased insulin secretion for blood glucose to be regulated. However, there is a time point beyond which pancreatic β-cells are unable to complete this operation because of increasing insulin resistance, which can result in increased postprandial glucose and postprandial

hyperglycemia. Thus, LGI diets rich in fiber can help prevent diabetes and reduce insulin resistance, which predisposes a large group of people to diabetes.

Almonds

Frequent consumption of nuts is in alignment with the concept of an LGI diet. In addition, the content of one meal has the potential to affect insulin sensitivity at a second by altering circulating nonesterified free fatty acid concentrations and daylong insulin demands. Including almonds at breakfast decreased blood glucose concentrations and increased satiety acutely in IGT adults even after a second meal. Almonds are high in fiber and unsaturated fat and low in carbohydrate content. There is an inverse relationship between nut consumption and risk of T2DM. In addition, almond consumption increases satiety, reduces cardiovascular disease risk, and decreases postprandial glycemia and reduces oxidative damage. The lipid component of almonds appears to be responsible for the immediate postconsumption response, although it cannot account for the second-meal response. Daylong glucose, insulin, and nonesterified free fatty acid concentrations were attenuated with consumption of whole almond and almond oil, eliciting an improved hormonal profile. Importantly, the absolute magnitude of the blood glucose-lowering response equaled that achieved with acute administration of acarbose (a starch blocker used to treat T2DM and prediabetes) in IGT individuals, suggesting the findings are physiologically relevant.

Vitamin D

Over the last decades, there has been considerable scientific interest in the role of vitamin D in glucose homeostasis. Emerging evidence suggests that vitamin D (25-hydroxyvitamin D_3; calcidiol) has a role in the etiology of T2DM. Vitamin D levels are lower in people with T2DM and IGT compared with NGT. The bioavailability of cholecalciferol (unhydroxylated form of vitamin D) decreases with increasing proportion of body fat, due to preferential accumulation in the adipose tissue. In turn, imbalanced vitamin D status may reflect an increased risk of T2DM in the general population. The mechanism through which vitamin D acts on glucose metabolism is not clear, but possible mechanisms include direct effects on insulin synthesis and release or increased insulin sensitivity. A possible link between vitamin D and glucose metabolism could be the lipoprotein lipase, which is upregulated by vitamin D. Nevertheless, there is a great debate on the potential effects of vitamin D status on insulin sensitivity, as studies have variously found the correlation between vitamin D and insulin to be only modest to highly significant.

Obese patients with IGT tend to cluster more frequently with altered vitamin D status, after controlling for potential confounding factors. Data from adults showed vitamin D insufficiency is correlated with the development of IGT and an inverse correlation has been described between vitamin D concentrations and the risk of developing T2DM in a 22-year Finnish cohort study. Prospective studies revealed an inverse association between $25(OH)D_3$ levels and future glycemia and insulin resistance. Vitamin D supplementation in prediabetic obese patients has been shown to increase in $25(OH)D_3$ concentrations in association with increased insulin secretion and C-peptide concentration (C-peptide assesses insulin secretion even if insulin is injected).

Further studies are required to better define the impact of vitamin D status on changes in glucose metabolism. Furthermore, there are no data on the effect of vitamin D supplementation on glycated hemoglobin. Recently, however, poor vitamin D status has been inversely associated with fasting insulin and HOMA-IR (a method used to quantify insulin resistance and β-cell function) in obese adolescents, but the effect on HbA1c levels was not investigated.

Herbal Treatments

Recently published data suggest that some herbal medicines alone or in conjunction with current therapies may offer alternatives for preventing diabetes. In particular, a combination of ten Chinese medicinal herbs in a capsule reduced progression to T2DM in people with IGT in a randomized placebo-controlled trial in China. The key herb in the combination was Huang Lian (Coptidis Rhizoma). The critical component in this herb is berberine, which has been reported to exert potent antidiabetic effects. Huang Lian has been used traditionally for treating diabetic symptoms. Although no direct comparisons were made, the results were comparable with those of antidiabetic prescription drugs. The data also showed that, after a termination of the herbal treatment, the preventive effects on T2DM development remained significant. Given that the safety profile of this herbal medicine is satisfactory, without obvious adverse effects, this option seems promising if additional future data from large clinical trials verify these findings. However, an issue with herbal supplements remains their variation in potency. Herbal preparations are highly variable because amounts and potency of the active ingredient differ from plant to plant or even in different parts of the same plant. Thus, one capsule may not be equivalent to another, and there are currently no regulatory bodies supervising quality or distribution.

Intermittent Fasting

Several large studies have investigated lifestyle changes in prediabetics with a view to slowing or preventing progression to T2DM. However, there is considerable debate regarding the most effective manner lifestyle changes, such as whether diet and/or exercise should be implemented. Currently, intermittent fasting is generating particular interest.

Intermittent fasting can be undertaken in several ways, but the basic format alternates periods of normal caloric intake with days when caloric consumption is severely restricted. This can be done on an alternating daily basis or, more recently, on a 5:2 strategy where 2 days each week are assigned as fasting days (<600 cal for men, <500 cal for women). Importantly, this type of intermittent fasting has been shown to be as effective as or more effective than continuous modest

caloric restriction for weight loss, improved insulin sensitivity, and other biomarkers of health.

Those who undertake this form of diet are required to limit their calorie intake for 2 days each week. The calorie limit is approximately 25% of total daily energy expenditure (600 cal for men and 500 for women). On nonfasting days, individuals can eat normally up to approximately 2500 for men and 2000 for women. The majority of studies show positive effects on markers of metabolic health and body composition, in part due to the impact on metabolic tissues. In addition, caloric restriction studies undertaken in animals and humans have suggested fuel selection is altered and metabolic efficiency improved, while oxidative stress is reduced.

Research has identified several biological effects of intermittent fasting and/or caloric restriction on tissues that are central to metabolic and cardiovascular health. It is possible that short periods of fasting mobilize ectopic triacylglycerides (TAG) in nonadipose depots, reducing the detrimental effects of intramyocellular and intrahepatic TAG deposition and redistributing TAG into adipose tissue.

Original treatment regimens were based on intermittent fasting as opposed to restricted intake, a harsh regimen that challenges adherence. Despite the seemingly strict nature of fasting, intermittent fasting has, generally, a good adherence record and can cause significant reductions in body weight especially in obese individuals, suggesting this is a clinically relevant therapeutic approach. Intermittent fasting can reduce the incidence of diabetes among experimental animals, and there is evidence that fasting may also slow the progression of T2DM in obese individuals.

Early data reported a reversal of T2DM with daily caloric restriction, improved pancreatic function, and reduced occult TGA deposition. The diet limited intake to 600 cal daily, which may be too severe for many T2DM patients. Intermittent fasting may be more acceptable and still improve metabolic parameters, glucose levels, and insulin sensitivity. Indeed, intermittent fasting has been shown to achieve much of benefits seen with bariatric (weight loss) surgery, without the costs, restriction on numbers, and risks associated with surgical intervention. Whether intermittent fasting can be used as a tool to prevent diabetes, in those with IGT or IFG, or limit progression in those recently diagnosed with T2DM remains to be verified.

Fructose Intake

Chronic administration of fructose or sucrose to animals not only causes insulin resistance but also may result in T2DM. The major sources of fructose in the Western diet are soft and fruit drinks, which account for approximately 7% of caloric intake in adults and upward of 15% in adolescents. Intakes of sugar and soft drinks are higher in populations at increased risk for insulin resistance and T2DM, including African Americans, Hispanics, Native Americans, and individuals with lower incomes. A meta-analysis in 2010 concluded the intake of soft drinks is an independent predictor for the development of metabolic syndrome and/or T2DM.

Fructose increases intracellular and circulating uric acid levels due to increased nucleotide turnover and nucleotide synthesis. Elevated serum uric acid is one of the best independent predictors of T2DM and commonly precedes the development of both insulin resistance and T2DM. Furthermore, fructose increases body weight, and the mechanism of action is likely to be stimulation of hunger and blocking satiety responses.

The ability of fructose (and sucrose, which contains fructose) to stimulate food intake and reduce metabolic activity provides a mechanism for how high fructose intake may enhance weight gain and visceral fat accumulation. However, fructose and sucrose also alter fat stores and metabolism independent of excess energy intake. Although weight gain is largely controlled by overall energy intake, other aspects of metabolic syndrome can occur independent of weight gain. For example, rats fed with fructose develop fatty liver, hypertriglyceridemia, and insulin resistance when compared with rats fed with isocaloric glucose or starch-enriched diets. Indeed, hypertriglyceridemia, fatty liver, and T2DM can be induced in metabolic syndrome-prone rats with caloric restriction, provided the diet is high (40%) in sucrose. Epidemiological analysis in humans also found an association between prevalence of T2DM and sugar availability that was independent of total energy intake. The observation that uric acid can induce mitochondrial oxidative stress and fatty liver may explain how fructose induces insulin resistance.

Uric Acid

Uric acid may contribute to insulin resistance in the liver by inducing mitochondrial oxidative stress and steatosis (adipose degeneration). Uric acid also blocks the ability of insulin to stimulate vasodilatation, which is important for the delivery of glucose to the skeletal muscle. Uric acid also induces inflammation in the adipose tissue with a reduction in the production of adiponectin (hormone that modulates a number of metabolic processes, including glucose regulation and fatty acid oxidation). Finally, uric acid may also have direct effects on the pancreatic islet cells leading to local oxidative stress and islet dysfunction.

Physical Activity

Regular physical activity and adoption of a healthy lifestyle may prevent or delay the onset of T2DM. The prediabetic state is characterized by IFG and/or IGT and is associated with a substantially elevated risk of T2DM. Thus, prevention efforts through lifestyle modification are particularly important for those exhibiting prediabetic indicators. Several large-scale prospective trials have examined the role of physical activity as part of more comprehensive lifestyle interventions in prediabetic individuals to delay or prevent transition to T2DM. The Da Qing Diabetes Prevention trial found exercise with or without dietary intervention was more effective than dietary changes alone in preventing T2DM. Other trials using multifactorial lifestyle interventions, with exercise combined with diet and/or weight loss programs, found that T2DM can be delayed or prevented effectively in the majority of prediabetic individuals. Data from several trials indicated that

lifestyle interventions are at least as effective as pharmaceuticals for most prediabetic individuals for prevention of T2DM.

In one study, a favorable effect of moderate-intensity aerobic training in older individuals was observed, driven by a subset of IGT individuals at baseline.

In a 2011 study, it was shown that metabolic adaptations to endurance exercise training were greater in magnitude among prediabetics than in normoglycemic individuals. However, traditional endurance exercise training without weight loss did not reverse completely IGT and insulin resistance in all prediabetic individuals.

The literature is mixed regarding possible relationships between changes in dietary habits and/or body composition and glucose metabolism in prediabetic individuals. Several large-scale trials have targeted IGT patients with the objective of reducing progression to T2DM. Generally, these trials have concluded the degree of weight loss with lifestyle intervention – a mixed intervention aiming to increasing energy expenditure through physical activity while reducing caloric intake – is associated with progression to T2DM. However, one of these large-scale trials (Da Qing study) compared the effects of exercise or diet alone and exercise with diet on the risk of developing T2DM and found exercise, with or without changes in dietary habits, was more effective than diet alone in preventing T2DM. Thus, the relative contributions of diet and exercise in the prevention of T2DM are not yet clear.

Recent data proposed that high-intensity interval training programs would have greater insulin-sensitizing magnitude for prediabetic individuals compared with traditional moderate-intensity programs. Whether high-intensity interval training is practical for widespread use in this population is, however, debatable.

Undoubtedly, the increasing prevalence of T2DM and obesity in recent decades is associated with increased comorbidities, including atherosclerotic macrovascular disease and premature mortality. Individuals with prediabetic hyperglycemia, such as IGT and IFG, are also at increased risk of premature cardiovascular disease, emphasizing the importance of interventions to improve glucose homeostasis in prediabetic and diabetic individuals.

Introduction

Glucose is the main product of carbon fixation by the photosynthetic organisms. It can be found as a monomer or polymer, including glycogen, cellulose, starch, and other complex molecules. Glucose is a vital metabolic substrate since it is an intermediate in the synthesis of many other molecules. Of pivotal significance, glucose is the first fuel used by most organisms, serving as substrate for ATP production (also under anaerobic conditions) through glycolysis and subsequent metabolic pathways (e.g., tricarboxylic acid (TCA) cycle and oxidative phosphorylation).

Breakdown of endogenous liver glycogen stores (glycogenolysis) delivers glucose to the muscles and whole-body energy stores are replenished from dietary glucose. In higher organisms, glucose comes directly from the diet or indirectly when disaccharides and polysaccharides are hydrolyzed. Glucose is taken up when it reaches target cells, stored, or further metabolized. The first step is transferred from the lumen of the small intestine to gut epithelium cells followed by transport to each organ, tissue, and cell via the circulation. These processes require that glucose cross the phospholipid bilayer cell membranes, which is mediated by specialized integral transporter proteins classified – based on functional and phylogenetic data – as sodium–glucose linked transporters (SGLTs) or facilitative glucose transporters (GLUTs).

Homeostasis aims to keep blood glucose concentrations constant within a narrow range. This is maintained by a dynamic equilibrium between glucose utilization and endogenous glucose production, which are controlled by the coordinated regulation of three processes:

1. Glucose absorption via the small intestine
2. Glucose production in the liver
3. Consumption of glucose by nearly all tissues

Hormones, metabolites including glucose, free fatty acids (FFAs), and carbon-3 compounds, such as lactate, alanine, and glycerol, regulate these processes. Insulin and glucagon are the most important hormones involved in the regulation of glucose. Most notably, insulin reduces blood glucose by increasing transport into insulin-sensitive cells (e.g., the muscles) and facilitating conversion to storage compounds, via glycogenesis and lipogenesis. Glucagon is produced in response to low glucose levels or hypoglycemia and aims to increase blood glucose by promoting glycogenolysis and gluconeogenesis. However, following a glucose-rich meal, glucagon is inhibited by hyperinsulinemia, which suppresses hepatic glucose production and helps maintain normal postprandial glucose tolerance. The bulk of glucose uptake in peripheral tissues occurs in skeletal muscles, where glucose can be used directly for energy production or stored as glycogen.

Muscles are insulin-dependent and, therefore, require insulin to activate glycogen synthase (GS), which is crucial in regulating glycogen formation. While the adipose tissue is responsible for a limited amount of peripheral glucose uptake, it has a significant contribution in total glucose homeostasis through the regulation of FFA release (which increases gluconeogenesis) from stored triglycerides, influencing insulin sensitivity in the liver and muscles. The kidneys also have an important role in glucose homeostasis, via the release of glucose into the circulation (gluconeogenesis), uptake of glucose from the circulation to cover renal energy demands, and reabsorption of glucose at the proximal tubule. The kidneys also contribute in the elimination of excess glucose through excretion in urine. While the liver does not require insulin to facilitate glucose uptake, it does need insulin to regulate glucose output. Consequently, hepatic glucose output increases when insulin levels are low. Furthermore, insulin aids storage of the majority of glucose absorbed from the diet in the form of glycogen in the liver.

In a well-fed individual, glucose is largely the only fuel for the brain. During starvation, ketone bodies (acetone, acetoacetic acid, and β-hydroxybutyric acid) are the predominant fuel. Insulin signals the fed state, stimulating the formation of glycogen, triglycerides, and proteins. Conversely, glucagon signals low blood glucose and induces degradation of glycogen and gluconeogenesis in the liver and hydrolysis of triglycerides in the adipose tissue. After a meal, the rise in blood glucose leads to increased insulin and reduced glucagon, resulting in glycogen synthesis in the muscles and liver. These phenomena are reversed when the levels of blood glucose fall, and glucose is produced by degradation of glycogen and the gluconeogenetic pathway, while fatty acids are released by hydrolysis of triglycerides. The liver and muscles use fatty acids instead of glucose to meet their energy needs, ensuring sufficient glucose is available for the brain. Metabolic changes during starvation are designed to reduce degradation of proteins. Large amounts of ketone bodies are produced in the liver from fatty acids and released into the bloodstream within a few days. After several weeks of starvation, ketone bodies are the main fuel for the brain. The reduced need for glucose decreases the degradation of muscle proteins, and thus, the probability of survival is increased.

Glycolysis and Glycogenesis

Glycolysis is a conserved metabolic pathway that converts glucose to pyruvate with a net gain of two ATP and two NADH molecules per glucose molecule. It takes place in the cytoplasm of cells in virtually all tissues. This pathway is unique in the sense that it can take place under aerobic and anaerobic conditions. Glycolysis is regulated by three enzymes:

(i) glucokinase (GCK), which provides glucose-6-phosphate (G6P); (ii) phosphofructokinase, which is inhibited by fructose-1,6-bisphosphate; and (iii) pyruvate kinase (PK), the final enzyme in this ten-step metabolic pathway.

PK is activated by its substrate and inhibited by ATP. Insulin, epinephrine/adrenaline, and glucagon also regulate PK via the phosphatidylinositol 3-kinase (PI3K) pathway, and carbohydrate-responsive element-binding protein (ChREBP) induces PK transcription in the presence of glucose. Pyruvate is further decarboxylized to acetyl-CoA and processed through the TCA cycle or utilized for *de novo* lipogenesis (DNL). The pentose phosphate pathway is an alternative for the degradation of G6P in hepatocytes, which provides cells with reducing equivalents, in the form of NADPH, an important antioxidant and cosubstrate for DNL, cholesterol, nucleotide, and aromatic amino acid syntheses. GS catalyzes the synthesis of glycogen after conversion of G6P to UDP-glucose; GS is regulated by the allosteric effector G6P and inactivated by phosphorylation. Glycogen synthase kinase 3 (GSK3) phosphorylates GS and is a downstream target for protein kinase Akt/PI3K and, thus, insulin signaling. GSK3 is a multifunctional kinase involved in cell senescence, apoptosis, and lipid metabolism via the phosphorylation of sterol regulatory element-binding protein-1c. Other protein kinases, which phosphorylate GS, are AMP-activated protein kinase (AMPK) and protein kinase A (PKA). Insulin activates glycogenesis via repression of PKA. The growing glycogen polymer is further branched by a specific glycosyltransferase (branching enzyme).

Glycogenolysis (Degradation of Glycogen to Glucose) and Gluconeogenesis (Glucose Formation)

In the fasting state, the liver supplies the body with glucose by glycogenolysis and, following prolonged fasting, gluconeogenesis. Glycogenolysis is catalyzed by glycogen phosphorylase, which cleaves glucose from the glycogen polymer to produce glucose-1-phosphate, which is converted to G6P by phosphoglucomutase. A debranching enzyme with glycosyltransferase and glucosidase activity cleaves the last four glucose monomers. Allosteric activation by AMP and phosphorylation by PKA, which is inhibited by insulin, regulate glycogen phosphorylase. Hepatic gluconeogenesis occurs during prolonged fasting episodes and begins in the mitochondria with the induction of pyruvate carboxylase in response to an abundance of acetyl-CoA. Gluconeogenesis is further regulated by allosteric and transcriptional activation of phosphoenolpyruvate carboxykinase (PEPCK), fructose-1,6-bisphosphatase, and glucose-6-phosphatase (G6Pase). Overexpression of PEPCK promotes insulin resistance in mice. Insulin inhibits PEPCK expression via Akt-mediated FoxO1 (Forkhead box protein O1) phosphorylation. This pathway is suppressed by the activation of peroxisome proliferator-activated receptor-α (PPAR-α) signaling-mediated induction of the pseudokinase tribbles homologue 3 (TRB3); TRB3 expression is associated with human insulin resistance. Other nuclear receptors (PPAR-γ coactivator-1α (PGC-1α) and farnesoid X receptor), glucagon, and glucocorticoids also affect the expression of PEPCK and G6Pase. PGC1a, HNF4a, CREBP, and PPAR-α directly and indirectly activate FoxO1, a transcriptional activator of G6Pase and PEPCK. Accordingly, PEPCK-knockout mice exhibit not only reduced gluconeogenesis but also more significantly decreased removal of TCA anions, which causes the accumulation of hepatic triglycerides and steatosis (fatty degeneration).

Role of Key Organs in Glucose Metabolism and Regulation

Brain

The brain is the largest consumer of glucose in the fasting or 'postabsorptive' state. In fact, glucose is the only fuel for the human brain, excluding periods of prolonged starvation. The brain does not store fuels and, thus, needs a continuous supply of glucose. The brain receives a constant amount of glucose, and glucose metabolism in the brain is not altered by mental activity, although local increases occur with specific activities. Glucose transport to the brain cells is mediated mainly through the glucose transporter GLUT3.

When blood glucose falls below approximately 40 mg dl^{-1} (2.2 mmol l^{-1}), glycolysis is reduced to ensure sufficient glucose for the brain. Fatty acids cannot be used by the brain for fuel: FFAs are bound to plasma albumin and, therefore, unable to cross the blood–brain barrier. During starvation, ketone bodies, produced in the liver, partially substitute glucose as fuel for the brain.

Muscle

The main fuels for muscles are glucose, fatty acids, and ketone bodies. The skeletal muscle is the major store and consumer of fatty acids as well as glucose. Glucose enters muscle cells via the GLUT4 transporter. During reduced oxygen availability or energy compromise, aerobic metabolism of glucose and fatty acids cannot proceed, and muscles rely on anaerobic metabolism of glucose to restore cellular energy status. Increased glucose uptake by the muscle is a key response to stimuli requiring rapid energy supply. Approximately three-quarters of the total glycogen in the body is stored in the muscles. Glycogen is rapidly converted to G6P for the muscle to use. Muscles, like the brain, lack G6P phosphatase and, thus, are unable to extract glucose. Instead, muscles retain glucose for use during periods of intense activity.

In an active contracting muscle, the rate of glycolysis greatly exceeds that of the TCA cycle. Pyruvate, produced under these conditions, is reduced to lactate, some of which goes to the liver where it is converted into glucose. These interconversions (known as Cori cycle) shift part of the metabolic load of the muscle to the liver. Furthermore, active muscles produce large amounts of alanine via transamination of pyruvate. Alanine, like lactate, can be converted to glucose in the liver. Muscles can absorb and transaminate branched-chain amino acids, but cannot form urea. Thus, nitrogen is released into the blood as alanine. The liver absorbs alanine, removes nitrogen, which is excreted as urea, and converts the resulting pyruvate into glucose or fatty acids. Resting muscle metabolism is quite different: the main fuel is fatty acids, which cover most energy demands.

Unlike the skeletal muscle, the cardiac muscle works almost exclusively under aerobic metabolism, as evidenced by its high number of mitochondria. Fatty acids are the main fuel for the

heart, although ketone bodies and lactate may also provide energy for the heart. The cardiac muscle has almost no glycogen reserves and will consume acetoacetate in preference to glucose.

Adipose Tissue

Triglycerides stored in the adipose tissue form a huge reservoir of metabolic fuels. The adipose tissue specializes in the esterification of fatty acids and their release from triglycerides. Adipose cells need glucose for triglyceride synthesis. Triglycerides in the liver are not employed directly by fat cells, but first hydrolyzed by an extracellular lipoprotein lipase. Processes triggered by insulin stimulate this lipase. Triglycerides are hydrolyzed to fatty acids and glycerol by intracellular lipases. Triglycerides in adipose cells are hydrolyzed and resynthesized constantly. The liver extracts glycerol, produced by hydrolysis, from the circulation. Most fatty acids produced by hydrolysis of triglycerides are reesterified in the presence of abundant glycerol-3-phosphate. Conversely, fatty acids are released into the blood if glycerol-3-phosphate is scarce, due to the lack of glucose. Thus, levels of glucose in lipocytes are a major factor in determining when fatty acids are released into the bloodstream.

Kidneys

The main function of the kidney is urine production, which acts as a vehicle for excretion of metabolic waste while maintaining the osmolality of body fluids. Daily, approximately 1–2 l of urine is produced. Water-soluble plasma components (e.g., glucose) and water are reabsorbed to prevent unnecessary and (metabolically) costly loss. The maximum capacity for glucose reabsorption (tubular maximum for glucose) corresponds to a blood glucose concentration of approximately 200 mg dl^{-1} (11 mmol l^{-1}). Glycosuria occurs once this threshold is reached and transporters are unable to reabsorb all the glucose (as in type 2 diabetes mellitus (T2DM)). Much of the reabsorbed glucose is transferred to kidney cells by the SGLT. Of the various GLUT proteins expressed in the kidneys, GLUT2 is the major transporter, releasing glucose into the circulation from that reabsorbed by SGLT proteins in the proximal tubular cells. In the case of T2DM, abnormal glucose metabolism in the liver and kidneys is observed; up to a threefold increase in renal glucose release has been measured in diabetics. Over time, the glomeruli are damaged and unable to filter blood efficiently. Thus, glomerular membranes leak protein (more than half of which is albumin) into the urine. In diabetics, the kidneys may be particularly susceptible to hyperglycemia, as these cells are unable to decrease glucose transport rates to prevent intracellular hyperglycemia in the presence of increased glucose concentrations. Importantly, during starvation and acidosis, the kidneys are an important site of gluconeogenesis and can generate up to half-blood-glucose concentrations.

Liver

Metabolic activities of the liver are necessary to supply fuel for the brain, muscles, and other peripheral organs. Most of the compounds absorbed by the intestine pass first through the liver. This enables it to regulate the levels of several metabolites in the bloodstream (e.g., glucose and folate). The liver metabolizes carbohydrates in a complex manner; it absorbs two-thirds of blood glucose and all the other monosaccharides. Other tissues use the small portion of remaining glucose. In the liver, glucose is converted to G6P by hexokinase and hepatic glucokinase. G6P has many metabolic possibilities, although the liver uses a small amount to meet its needs. Most of G6P is converted to glycogen. Excess G6P is metabolized to acetyl-CoA, which is used for fatty acids, cholesterol, and bile salts. The liver can release glucose into blood circulation by the degradation of glycogen and gluconeogenesis. The main precursors for gluconeogenesis are lactate and alanine from muscles, glycerol from adipose tissue, and glycogenic amino acids from foods.

The Three States of Glucose Homeostasis

The night starvation-feeding cycle has three phases:

1. Postabsorptive state after a meal
2. Initial period of overnight fasting
3. Refeeding state after breakfast

A major objective of the many biochemical changes during these phases is to maintain glucose homeostasis (i.e., constant appropriate level of glucose in the bloodstream).

Postabsorptive State (Well-Fed or Postabsorptive State)

After consuming and digesting the final meal of the day, glucose and amino acids are transported from the intestine into the bloodstream. Lipids are packed into chylomicrons (lipoprotein particles that consist of triglycerides, phospholipids, cholesterol, and proteins) and transported into the bloodstream by the lymph system. This results in postprandial insulin secretion from β-cells in the pancreatic islets stimulated by glucose and the parasympathetic nervous system. Essentially, insulin signals 'adequacy' and stimulates storage of fuel and synthesis of proteins. Thus, insulin stimulates glycogen synthesis in the liver and muscles and suppresses gluconeogenesis in the liver. Insulin also accelerates glycolysis in the liver, which increases the synthesis of fatty acids.

The liver also helps to limit the amount of glucose in the blood during periods of abundance, by saving it as glycogen, to be released during periods of starvation. Excess glucose is removed by the action of insulin, which accelerates uptake by the liver via GLUT2. Consequently, the liver produces G6P faster when blood glucose is increasing. The combination of increased G6P and insulin leads to increased storage of glycogen. High levels of insulin after a meal also promote uptake of glucose by the muscle and adipose tissue. Insulin stimulates glycogen synthesis in both the muscle and the liver and glucose provides glycerol 3-phosphate for triglyceride synthesis in the adipose tissue.

The Initial Period of Fasting (Early Fasting State)

The levels of glucose in the blood decrease after several hours, leading to a reduction in insulin secretion and increased

glucagon secretion. Glucagon is secreted from the alpha cells of pancreatic islets in response to low levels of blood glucose. Just as insulin signals the fed state, glucagon signals 'starvation.' It serves to mobilize glycogen reserves when there is no glucose uptake from food. The main target organ of glucagon is the liver. Glucagon induces glycogen degradation and inhibits glycogen synthesis. Glucagon also inhibits synthesis of fatty acids. Moreover, glucagon stimulates gluconeogenesis in the liver and inhibits glycolysis. The mobilization of glycogen stores, for glucose production by glucagon, is very rapid. The liver releases large amounts of glucose, formed by the G6P hydrolysis of glycogen, into the circulation. Glucose uptake by the muscle and adipose tissue is reduced in response to decreased blood insulin levels. Reduced utilization of glucose by the muscle and adipose tissue also helps maintain blood glucose levels. The net result of these actions is significantly increased glucose release into the blood from the liver.

Both the muscle and liver use fatty acids as fuel when blood glucose decreases. Thus, blood glucose remains at or above 80 mg dl^{-1} (4.4 mmol l^{-1}), due to

1. mobilization of glycogen to glucose production and release of the latter by the liver,
2. release of fatty acids from the adipose tissue,
3. switching from glucose into fatty acids for fuel by the muscle and the liver.

Depletion of glycogen stores in the liver results in gluconeogenesis using lactate and alanine sourced from peripheral tissues. Furthermore, the brain oxidizes glucose completely to CO_2 and H_2O. Thus, in order to have net glucose synthesis, another carbon source is required. Glycerol released from adipose tissue lipolysis provides a small number of carbon atoms, but the rest of the carbon required is provided via muscle proteolysis.

Refeeding State

When a hearty breakfast is consumed, fat metabolism continues as normal. However, this is not true for glucose metabolism: the liver does not initially absorb glucose from the blood, but leaves it for uptake by peripheral tissues. Furthermore, the liver continues with gluconeogenesis, but newly synthesized glucose is used to replenish glycogen reserves. While levels of blood glucose continue to increase, the liver continues to replenish diminished glycogen reserves and starts synthesizing fatty acids (lipogenesis) from excess glucose.

Prolonged Starvation

In case of prolonged starvation, fuel stores are sufficient to meet caloric needs for 1–3 months. However, carbohydrate reserves can be depleted in one day. Even under conditions of starvation, blood glucose is maintained above 40 mg dl^{-1} (2.2 mmol l^{-1}). The first priority for the metabolism during starvation is to provide sufficient glucose for the brain and other tissues (e.g., erythrocytes) that depend entirely on it for fuel. However, precursor molecules for glucose are not abundant. Most energy is stored in the triglycerides of fatty acid. The second priority for the metabolism during starvation is preservation of proteins, which is achieved by changing the predominant fuel from glucose to fatty acids and ketone bodies.

Metabolic changes on the first day of starvation are similar to those after an overnight fast. Low blood sugar leads to diminished insulin and increased glucagon secretion. The dominant metabolic processes are mobilization of triglycerides from adipose tissue and gluconeogenesis in the liver. The liver acquires energy for its needs by the oxidation of fatty acids released from adipose tissue. Glycolysis is suppressed while glucose uptake by the muscle is drastically reduced, because insulin is low, while fatty acids enter the muscle freely. Accordingly, the muscle changes almost completely from glucose for fuel to fatty acids. Pyruvate, lactate, and alanine are exported to the liver for glucose conversion. Glycerol, derived from the cleavage of triglycerides, is another resource for glucose synthesis in the liver. During starvation, degraded proteins are not replenished but serve as a carbon source for the synthesis of glucose. Primary protein sources are those recycled quickly, such as those of the intestinal epithelium and pancreatic secretions. Proteolysis of muscle proteins provides part of three carbon chains needed for synthesis of glucose.

After approximately three days of starvation, the liver synthesizes large amounts of ketone bodies and the brain begins to consume significant quantities of acetoacetate instead of glucose. About one-third of the energy needs of the brain are covered by ketone bodies. The heart also uses ketone bodies as an energy source. After several weeks of starvation, ketone bodies become the main source of fuel for the brain. Essentially, ketone bodies are the equivalent of the fatty acids, which can pass the blood–brain barrier. Efficient conversion of fatty acids to ketone bodies, by the liver, and their use by the brain reduce substantially the need for glucose. Survival time of an individual in a state of starvation is determined by the size of triglyceride reserves. Once triglyceride stocks have been exhausted, the only remaining fuel is protein. Protein degradation is accelerated and death, inevitably, occurs because of malfunction of the heart, liver, or kidney.

Regulation

Insulin is released by pancreatic β-cells prior to an increase in blood glucose concentrations. This so-called cephalic phase reflex is induced upon activation of taste receptors (and subsequently afferent projections) in the oral cavity. In addition, macronutrients in the intestine trigger duodenal K-cells and ileal L-cells to secrete incretins glucose-induced insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GUM), respectively. Both hormones stimulate insulin secretion. Besides its direct effects on glucose metabolism, insulin suppresses the secretion of glucagon by the pancreatic α-cells, thereby affecting hepatic glucose production indirectly.

Glucose thresholds for counterregulatory responses in humans are approximately 80 mg dl^{-1} (4.4 mmol l^{-1}) for glucagon, less than 68 mg dl^{-1} (3.8 mmol l^{-1}) for adrenaline and noradrenaline, and less than 66 mg dl^{-1} (3.7 mmol l^{-1}) for corticosterone and growth hormone. Glucagon secretion is stimulated during hypoglycemia and stimulates glucose production by the liver. Noradrenaline, released from

sympathetic nerve endings, and adrenaline, released from the adrenal glands, stimulate lipolysis. Glycogenolysis decreases insulin secretion and reduces insulin sensitivity.

The liver is the exclusive site of glucose production in humans during the postabsorptive state. Although animal and studies *in vitro* have documented that the kidney is capable of gluconeogenesis, glucose production by the human kidney has been regarded as negligible. This is based on net balance measurements across the kidney. However, recent studies combining isotopic and balance techniques have demonstrated that the human kidney is involved in the regulation of glucose homeostasis, making glucose via gluconeogenesis, taking up glucose from the circulation, and reabsorbing glucose from the glomerular filtrate. The human liver and kidneys release approximately equal amounts of glucose, via gluconeogenesis, in the postabsorptive state. In the postprandial state, although overall endogenous glucose release decreases substantially, renal gluconeogenesis increases by approximately twofold. Following ingestion of a meal, kidney glucose utilization increases.

Increased glucose uptake by the kidney may be implicated in diabetic nephropathy. Normally each day, the kidneys filter approximately 180 g of glucose, almost all of which is reabsorbed by means of sodium–glucose linked transporter 2 (SGLT2) expressed in the proximal tubules. However, the capacity of SGLT2 to reabsorb glucose from the renal tubules is limited and, when blood glucose exceeds the threshold, glucose appears in the urine. Renal glucose release is stimulated by adrenaline and is inhibited by insulin. Glucose handling in the kidney is altered in T2DM. Renal gluconeogenesis and glucose uptake are increased in both the postabsorptive and postprandial states, and glucose reabsorption is increased. Since renal glucose release is almost exclusively due to gluconeogenesis, it seems likely that the kidney is as important a gluconeogenic organ as the liver.

Although all cells require glucose, the brain consumes most in the fasting or 'postabsorptive' phase, accounting for approximately half the glucose uptake. A quarter of glucose consumption occurs in the splanchnic area (the liver and gastrointestinal tissue), and the remainder (25%) takes place in insulin-dependent tissues, including the muscle and adipose tissue. Approximately 85% of endogenous glucose production is derived from the liver, with glycogenolysis and gluconeogenesis contributing equally to the basal rate of hepatic glucose production. The remaining approximately 15% of glucose is produced by the kidneys.

In healthy adults, blood glucose is tightly regulated within a range of 70–99 mg dl^{-1} (3.9–5.5 mmol l^{-1}) and maintained by specific hormones (e.g., insulin, glucagon, and incretins), as well as the central and peripheral nervous system, to meet metabolic requirements. Various cells and tissues (in the brain, muscle, gastrointestinal tract, liver, kidney, and adipose tissue) are also involved in blood glucose regulation by means of uptake, metabolism, storage, and excretion.

This highly controlled process is particularly evident during the postprandial period, during which, under normal physiological circumstances, glucose levels rarely rise above 140 mg dl^{-1} (7.8 mmol l^{-1}), even after consumption of a meal rich in carbohydrates.

Amylin (islet amyloid polypeptide (IAPP)) is a 37-amino-acid peptide hormone that is cosecreted with insulin from the pancreatic β-cells in a ratio of approximately 100:1. It acts synergistically with insulin in glycemic regulation by slowing down gastric emptying and inhibiting digestive secretion (gastric acid, pancreatic enzymes, and bile ejection) and, as a result of reduced food intake, prevents postprandial spikes in blood glucose. Amylin is regulated by factors similar to insulin since they share a common regulatory promoter motif. The amylin promoter is also activated by stimuli that do not affect insulin, such as tumor necrosis factor alpha and fatty acids.

Incretins, GIP and GLP-1 (both glucose-dependent hormones secreted only when blood glucose rises above normal fasting blood glucose), are also involved in the regulation of blood glucose, in part by their affects on insulin and glucagon. Normally, these hormones are released in response to meals and stimulate insulin secretion by activating certain receptors on pancreatic β-cells. When glucose levels are low, however, GLP-1 and GIP (and their affects on insulin secretion) are diminished.

The human GLUT protein family consists of at least 14 members, indicating glucose delivery to cells is highly complex. GLUT4 is the major transporter for muscle, adipose, and cardiac tissues, whereas GLUTs 1, 2, 3, and 8 facilitate glucose entry into other organs (e.g., the brain and liver). Activation of GLUT4, and, in turn, facilitated glucose diffusion into muscle and adipose tissue, is dependent on the presence of insulin, whereas the function of other GLUTs is more independent of insulin.

While adipose tissue is responsible for much smaller amounts of peripheral glucose uptake (2–5%), it has an important role in maintaining total body glucose homeostasis by regulating release of FFA (which increase gluconeogenesis) from stored triglycerides and influencing insulin sensitivity in the muscle and liver. While the liver does not require insulin to facilitate glucose uptake, it does need insulin to regulate glucose output.

The pancreas has a remarkable capacity to adapt to conditions of increased insulin demand (e.g., in obesity, pregnancy, and cortisol excess) to maintain normoglycemia. Compensatory hyperinsulinemia also maintains glucose homeostasis. However, hyperglycemia occurs when β-cell secretion of insulin becomes inadequate for the glucose load. Progressive deterioration in β-cell function and mass over times is well known in T2DM, and the resultant state of impaired insulin secretion is found uniformly in T2DM of all ethnic backgrounds. Based on analyses from the UK Prospective Diabetes Study, a direct correlation exists between progressive loss in β-cell function and poor glycemic control (as measured by glycated hemoglobin (HbA1c)).

The exact cause of insulin resistance in any given individual is complex but may include defects in insulin-mediated cell signaling pathways, reduced insulin-stimulated muscle glycogen synthesis, or perhaps potentially fewer insulin receptors (IRs) (particularly in the muscle, liver, and adipose tissue in obese subjects).

The relative contributions of insulin secretion and insulin resistance to the development of hyperglycemia may differ. Under most circumstances, insulin resistance is the earliest detectable defect in prediabetes. Initially, enhanced insulin secretion may compensate for the insulin resistance, but early-phase insulin secretion is impaired. In the transition

from normal glucose tolerance to impaired glucose tolerance and diabetes, insulin sensitivity deteriorates by about 40%, whereas insulin secretion deteriorates three- to fivefold. In T2DM, chronic hyperglycemia may result in further deterioration of insulin sensitivity and secretion (glucotoxicity), which is worsened by elevated FFAs (lipotoxicity).

Considerable evidence implicates deranged metabolism and altered disposition of fat in the pathogenesis of glucose intolerance in T2DM. Because fat cells are resistant to the antilipolytic effect of insulin, the resulting chronic elevated plasma FFA levels stimulate gluconeogenesis, induce hepatic/muscle insulin resistance, and impair insulin secretion. These FFA-induced disturbances are referred to as lipotoxicity. Beyond this phenomenon, dysfunctional fat cells also develop insulin resistance, inducing inflammatory and atherosclerotic-provoking cytokines, and fail to secrete normal amounts of insulin-sensitizing adipocytokines (adiponectin).

The development of glucose intolerance involves multiple organs including the muscle, liver, pancreas (β-cells, insulin production, and α-cell, hyperglucagonemia), adipose tissue (accelerated lipolysis), gastrointestinal tract (incretin deficiency/resistance), kidney (increased glucose reabsorption), and brain (insulin resistance).

CNS and Glucose Regulation

The arcuate nucleus (ARC) of the hypothalamus contains two sets of neurons that express either the neuropeptide pro-opiomelanocortin (POMC) or coexpress agouti-related protein (AGRP) and neuropeptide Y (NPY). Both sets of neurons express leptin receptors (OBRs) and IRs. The actions of leptin and insulin on POMC neurons have an additive effect on the regulation of hepatic glucose production, possibly because they act on different POMC populations within the ARC. In addition, the action of insulin on neuronal populations of unknown phenotype results in the activation of ATP-sensitive potassium (KATP) channels, mammalian target of rapamycin (mTOR), and peroxisome proliferator-activated receptor-γ (PPAR-γ) to regulate hepatic glucose production. Leptin acts on PPAR-γ to regulate food intake, but it is not known whether this pathway also regulates glucose homeostasis. Thus, leptin and insulin signaling in the ARC use divergent and overlapping circuits and mechanisms. The hypothalamic ARC melanocortin system, consisting of POMC and NPY-AGRP neurons, has a key role in regulating both energy and glucose homeostases. There are also neurons within the paraventricular nucleus that are important for both energy and glucose homeostases. Within the ARC fuel-sensing systems, both mTOR and AMPK are also important for regulating energy and glucose homeostasis, whereas KATP channel activation is only important in regulating glucose homeostasis. Various molecular machineries sense the bioavailability of glucose, amino acids, and lipids as well as ATP stores. Metabolism of glucose and amino acids (leucine) via glycolytic and TCA cycle pathways results in events associated with the regulation of hepatic glucose production. In general, as nutrients become bioavailable, overall hepatic glucose production decreases.

Essentially, multiple mechanisms and hormones in many tissues interact to mediate glucose metabolism and homeostasis under different conditions. Knowledge of the fundamentals of normal glucose homeostasis is vital to understanding pathophysiological derangements that result from glucose imbalance disorders. Conditions such as insulin resistance, type 2 diabetes, and metabolic syndrome are characterized by an imbalance in glucose handling. A better comprehension of these processes should help researchers and clinicians to better manage these disorders and ameliorate clinical outcomes.

Introduction

D-Glucose, the most abundant carbohydrate and the most abundant organic compound (if all its combined forms are considered), belongs to the class of carbohydrates called monosaccharides. Monosaccharides are carbohydrate molecules that cannot be broken down to simpler carbohydrate molecules by hydrolysis, so they are sometimes referred to as simple sugars. They can be joined together to form larger structures, namely, oligosaccharides and polysaccharides, that can be converted into monosaccharides by hydrolysis.

Glucose, also called dextrose, belongs to a group of carbohydrates known as simple sugars (monosaccharides). Glucose has the molecular formula $C_6H_{12}O_6$. It is found in fruits and honey and is the major free sugar circulating in the blood of higher animals. It is the source of energy in cell function, and the regulation of its metabolism is of great importance (gluconeogenesis). Molecules of starch, the major energy-reserve carbohydrate of plants, consist of thousands of glucose units, as do those of cellulose. Also composed of glucose is glycogen, the reserve carbohydrate in most vertebrate and invertebrate animal cells, as well as those of numerous fungi and protozoans.

Nomenclature of Glucose and Related Polymers

Glucose

Glucose was first isolated in 1747 from raisins by Andreas Marggraf. The name glucose was coined in 1838 by Jean Dumas, from the Greek word *gleucos*, which means 'sweet' or 'sugar,' and the structure was discovered by Emil Fischer around the turn of the century. The compound D-(+)-glucose or dextrose is 2,3,4,5,6-pentahydroxyhexaldehyde, more conventionally expressed as $C_6H_{12}O_6$, with a molecular weight of 180.16 kDa. Glucose is readily soluble in water in a powder form. Below 50 °C, α-D-glucose hydrate is the stable form; at 50 °C, the anhydrous form is obtained; and at higher temperatures, α-D-glucose is obtained. Glucose is also present in the diet as part of the disaccharides sucrose (glucose and fructose), lactose (glucose and galactose), and maltose (glucose).

D-Glucose is both a polyalcohol and an aldehyde. It is classified as an aldose, a designation for sugars containing an aldehyde group. The ending *-ose* signifies a sugar and- *ald* signifies an aldehyde group. Glucose has four chiral carbon atoms: C-2, C-3, C-4, and C-5. Naturally occurring glucose is designated as the D form, specifically D-glucose. It has a molecular mirror image, termed the L form, specifically L-glucose. Since each chiral carbon atom has a mirror image, there are 2^n arrangements for these atoms. Therefore, in a six-carbon aldose, there are 2^4 or 16 different arrangements of the carbon atoms containing secondary hydroxyl groups, allowing formation of 16 different six-carbon sugars with an aldehyde end. Eight of these belong to the D-series; eight are their mirror images and belong to the L-series.

All sugars that have the hydroxyl group on the highest numbered chiral carbon atom (C-5 in case of glucose) positioned on the right-hand side are arbitrarily called D-sugars, and all with a left-hand-positioned hydroxyl group on the highest numbered chiral carbon atom are designated as L-sugars. Two structures of D-glucose in its open-chain, acyclic form (called the Fischer projection) with the carbon atoms numbered in the conventional manner are given in Figure 1. In this convention, each horizontal bond projects outward from the plane of the page and each vertical bond projects into or below the plane of the page. It is customary to omit the horizontal lines for covalent chemical bonds to the hydrogen atoms and hydroxyl groups as in the structure on the right. Because the lowermost carbon atom is nonchiral, it is meaningless to designate the relative positions of the atoms and groups attached to it. Thus, it is usually written as $-CH_2OH$. D-Glucose and all other sugars containing six carbon atoms are called hexoses, the most common group of aldoses. The categorical names are often combined, with a six-carbon atom aldehyde sugar being termed an aldohexose.

L-Sugars are less numerous and less abundant in nature than are the D forms but nevertheless have important biochemical roles. Two L-sugars found in foods are L-arabinose and L-galactose, both of which occur as units in carbohydrate polymers (polysaccharides).

Glucose Oligosaccharides

Oligosaccharides (Greek *oligo*, 'few') are sugar polymers; the term usually refers to compounds containing 2–9 units but may include polymers containing up to 19 units. The dimer, trimer, and tetramer forms in which glucose molecules are joined by (1–4) linkages are referred to as maltose, maltotriose, and maltotetraose, respectively, since these substances are the products of starch digestion in the malting process. Sucrose, maltose, and lactose are common dietary disaccharides.

Starches

Starches are large-molecular-weight, α-linked polymers of glucose $(C_6H_{10}O_5)_n$. Most starches show a mixture of α(1–4) and α(1–6) linkages. The α(1–4)-linked polymer forms a linear structure that allows for hydrogen bonding between polymer chains and a more compact starch structure. Introduction of (1–6) linkages results in branch points and a more open structure that allows the (1–4)-linked backbone with the hemiacetal bond in the alpha configuration to coil like a spring into a helical form. Branched starches with the (1–6) linkage are more readily hydrated and digested compared to the (1–4)-linked linear starch. The (1–4)-linked starches are referred to as

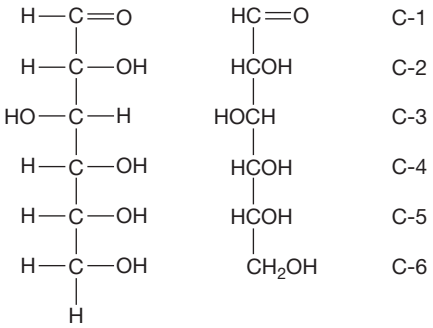

Figure 1 Structure of D-glucose (open-chain structure).

amylose starch, and (1–6)-linked starches are amylopectin starches.

Resistant Starch

Resistant starches are defined by their resistance to digestion in the human upper gastrointestinal tract. As with the term 'dietary fiber,' the definition is largely physiological. One proposed classification divides resistant starches into three classes: RS_1, RS_2, and RS_3. The first class, RS_1, is starch that escapes small intestinal digestion owing to the food form and incomplete enzymatic attack (e.g., large particle size or compact nature of food or starch entrapment by dietary fiber). The second, RS_2, includes the more crystalline starches that resist digestion (e.g., high-amylose starches that resist gelatinization). The RS_3 starches are retrograded starches (e.g., high-amylose starches that upon cooling after cooking form a compact, hydrogen-bonded crystalline structure that excludes water).

Cellulose

Like starch, cellulose is a (1–4)-linked glucose polymer $(C_6H_{10}O_5)_n$, but in this instance, the glucose molecules are β-linked, allowing the development of a linear polymer with strong intrachain hydrogen bonding. Cellulose polymers may consist of as many as 10 000 glucose monomer units. Cellulose is both resistant to small intestinal digestion and insoluble in cold or hot water and most dilute acids and alkali. It is partially degraded by colonic bacteria; the proportion degraded is dependent on the source, with cellulose from vegetables broken down to a greater extent than cellulose from cereals such as wheat.

β-Glucans

In many ways, these predominantly (1–4)-linked glucose polymers are the cellulose equivalent of the starch amylopectin. Here, it is the (1–3) linkages interspersed throughout the polymer that prevent the compact structure achieved with the cellulose polymer where only the (1–4) linkages exist. As a result of the more open molecular structure of the β-glucan, unlike cellulose, it is readily hydrated and soluble in water, forming a solution of high viscosity. The viscosity, in turn, is dependent on the molecular weight and the presence of the (1–3) linkages. The greater the molecular weight, the greater the viscosity. Thus, reduction of molecular weight by acid or enzymatic hydrolysis, which may also occur during food processing, may greatly reduce viscosity. The common feature shared by cellulose and the β-glucans is that both are resistant to digestion by small intestinal enzymes. However, whereas cellulose is only partially fermented by the colonic bacteria, β-glucans are completely fermented.

Hemicellulose

The term 'hemicellulose' should not be taken to imply a class of (1–4)-linked glucose polymers. The similarity with cellulose lies not in the chemical structure but in the fact that hemicellulose is also insoluble in hot or cold water or hot dilute acid. It is, however, soluble in dilute alkali. The polymeric structure is heterosaccharitic with two or more sugars (e.g., arabinoxylans found in cereals), with a relatively small molecular size (50–200 saccharide units).

Occurrence

Glucose is the primary carbohydrate energy source of vertebrates. In healthy humans, fasting blood glucose levels are approximately 3.5–5.5 mmol l^{-1} (depending on the laboratory) and increase postprandially to values considerably < 10 mmol l^{-1} (the renal threshold for complete reabsorption, above which glucose 'spills' over into the urine). Blood levels higher than 7.8 mmol l^{-1} 2 h after a 75 g glucose load are one of the diagnostic criteria for diabetes. Glucose is stored as glycogen, an α-linked polymer, predominantly in the liver and muscles ('animal starch'). On average, a 70 kg man may store 500 g of glycogen. Glucose can also be synthesized *de novo* by gluconeogenesis from the gluconeogenic amino acids lactate, glycerol, and pyruvate. Breakdown of glycogen into glucose is known as glycogenolysis.

Erythrocytes, renal tissue, and nervous tissue require glucose as an energy source. In erythrocytes and renal tissue, the glucose is not oxidized but is returned to the liver as part of the Cori cycle for glucose synthesis. The brain oxidizes glucose and requires 140 g day^{-1}. Despite this requirement, carbohydrate is still recommended to comprise between 45% and 65% of dietary calories. Glucose is present in fruit and vegetables, and although less sweet on a per gram basis than fructose or sucrose, it is responsible together with fructose and sucrose for the sweet taste of vegetables and fruit. With the exception of fruit such as green banana, seeds (grain and dried legumes), and tubers, in which starch is the major carbohydrate form, foods containing glucose, fructose, and sucrose in various ratios comprise the major available (i.e., absorbable in the small intestine) carbohydrate sources.

Physical Properties of Glucose

Glucose contains alcohol, ester (in the ring form), and aldehyde (in the linear form) as the functional groups, which are responsible for the majority of the chemistry that glucose undergoes. Some of the physical characteristics of glucose, such as melting point, solubility, and density, are listed in Table 1.

Structure

Glucose ($C_6H_{12}O_6$) contains six carbon atoms and an aldehyde group and is therefore referred to as an aldohexose. The glucose molecule can exist in an open-chain (acyclic) and ring (cyclic) form (in equilibrium), the latter being the result of an intramolecular reaction between the aldehyde C atom and the C-5 hydroxyl group to form an intramolecular hemiacetal. As the ring contains five carbon atoms and one oxygen atom, which resembles the structure of pyran, the cyclic form of glucose is also referred to as glucopyranose. In this ring, each carbon is linked to a hydroxyl side group with the exception of the fifth atom, which links to a sixth carbon atom outside the ring, forming a CH_2OH group. The formation of pyranose and furanose rings (cyclic hemiacetals) of glucose has been presented in Figure 2.

Table 1 Physical properties of glucose

Physical properties	*Characteristics*
Appearance	White, crystalline
Molecular weight	180.16 g mol^{-1}
Melting point	150 °C
Density	1.5620 g cm^{-3} (at 18 °C)
Solubility in:	
Water	Very soluble
Ethanol	Slightly soluble
Ethyl ether	Insoluble
Pyrimidine	Soluble

Solubility

One of the important physical properties of glucose is its ability to dissolve in aqueous, that is, water-based, solution. Since the blood, the extracellular fluid, and the fluid inside cells are all water-based, for glucose to dissolve in the bloodstream and be able to pass into cells, it must also dissolve well in water. Compounds consisting of only carbon and hydrogen show very poor water solubility. Elements such as oxygen and nitrogen, which are common in organic and bioorganic molecules, help increase water solubility. Glucose's six oxygen atoms increase its ability to dissolve in water, In particular, since five of those oxygen atoms are found in the form of alcohol groups, which allows it to readily form hydrogen bonds with water molecules and makes it very water-soluble, glucose dissolves quite readily in water.

All forms of glucose are colorless and easily soluble in water, acetic acid, and several other solvents. They are only sparingly soluble in methanol and ethanol. Table 2 shows the change in solubility with changing temperature for glucose in water.

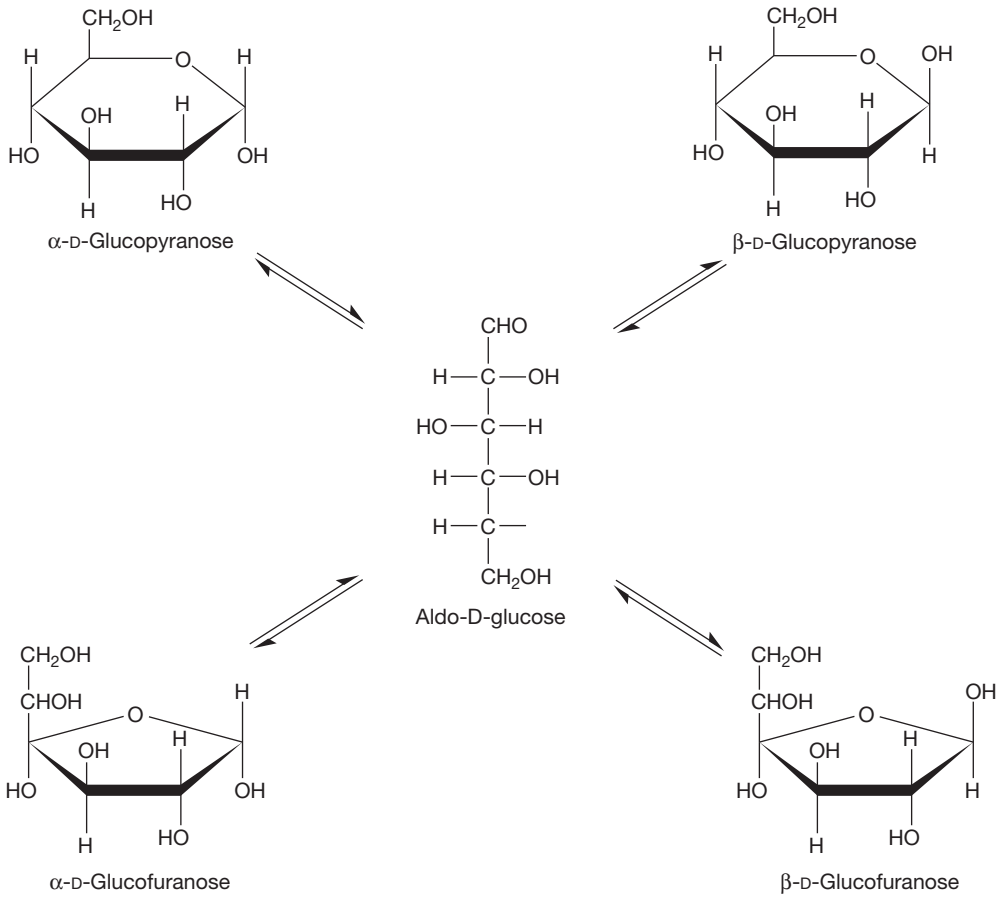

Figure 2 Pyranose and furanose rings (cyclic hemiacetals) of glucose.

Solid State

Depending on conditions, three major solid forms of glucose can be crystallized from water solutions: α-glucopyranose, β-glucopyranose, and β-glucopyranose hydrate.

Mutarotation

The open-chain form is thermodynamically unstable, and it spontaneously isomerizes to the cyclic forms. When sugar molecules are dissolved in aqueous solutions, a series of reactions, involving molecular rearrangements around the C-1, take place. These rearrangements are associated with the change in optical rotation and lead to the formation of a mixture of products that are in equilibrium. This process, first observed for D-glucose, is called mutarotation.

If one dissolves α-D-glucopyranose ($[\alpha]_D$ +112°) or β-D-glucopyranose ($[\alpha]_D$ +19°) in water, an equilibrium is formed with the $[\alpha]_D$ of the resultant solution being +52.7°. Theoretically, the mixture contains five different structural forms of glucose: α-D-glucopyranose, β-D-glucopyranose, α-D-glucofuranose, β-D-glucofuranose, and open-chain free aldehyde (Figure 2). The four-ring structures are transformed into each other via the open-chain form. The process will take place if the starting material represents any of the five forms. The mutarotation process is slow (it may take several hours to reach equilibrium) if conducted in water at 20 °C. The rate of mutarotation increases, however, 1.5–3 times with each 10 °C increase in the temperature. Both acids and bases increase the rate of mutarotation. Certain enzymes, such as mutarotase, will also catalyze the mutarotation reactions. The rate and the relative amount of products are also affected by the polarity of the solvent, with less polar solvents decreasing the rate of mutarotation. The reaction begins upon dissolution of sugar molecule and an attack, by either acid or base, on the cyclic sugar. It involves the transfer of a proton from an acid catalyst to the sugar or the transfer of proton from the sugar to a base catalyst as shown in Figure 3.

Table 2 Solubility of glucose

Temperature (°C)	*Solubility in grams of glucose per 100 ml of water*
25	91
30	125
50	244
70	357
90	556

Enolization and Isomerization

In the presence of alkali, sugars are relatively easily interconverted. The transformation involves epimerization of both aldoses and ketoses as well as aldose–ketose isomerization. The mechanism of the reaction is shown in Figure 4. The enolization reaction is a general reaction of a carbonyl compound having an α-hydrogen atom. Starting with *aldehydo*-D-glucose, the 1,2 enediol is first formed, which can be converted into another aldose (with opposite configuration at C-2) and the corresponding ketose. Therefore, by enolization and isomerization, D-glucose, D-mannose, and D-fructose can be easily interconverted. Either a base or an enzyme catalyzes isomerization, and it will also occur under acid or neutral conditions, although at a much slower rate.

Optical Activity

Whether in solution or in the solid form, D-glucose is dextrorotatory, meaning it will rotate the direction of polarized light clockwise. The effect is due to the chirality of the molecules, and indeed, the mirror-image isomer, L-glucose, is levorotatory (rotates polarized light counterclockwise) by the same amount.

The D- prefix does not refer directly to the optical properties of the compound. It indicates that the C-2 chiral center has the same handedness as that of D-glyceraldehyde (which was so labeled because it is dextrorotatory). The fact that D-glucose is dextrorotatory is a combined effect of its four chiral centers,

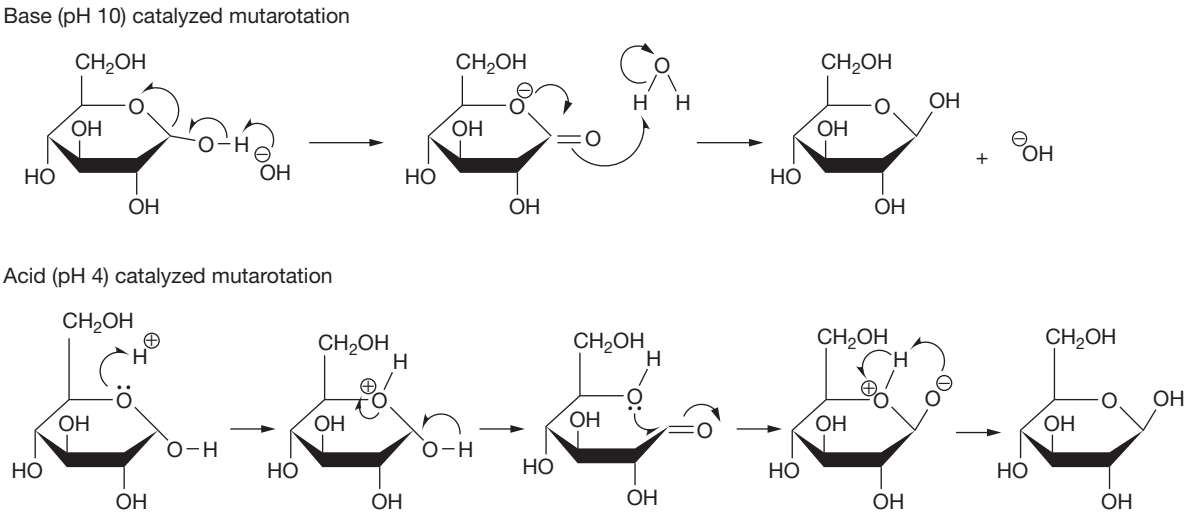

Figure 3 Mechanisms of base- and acid-catalyzed mutarotation reactions.

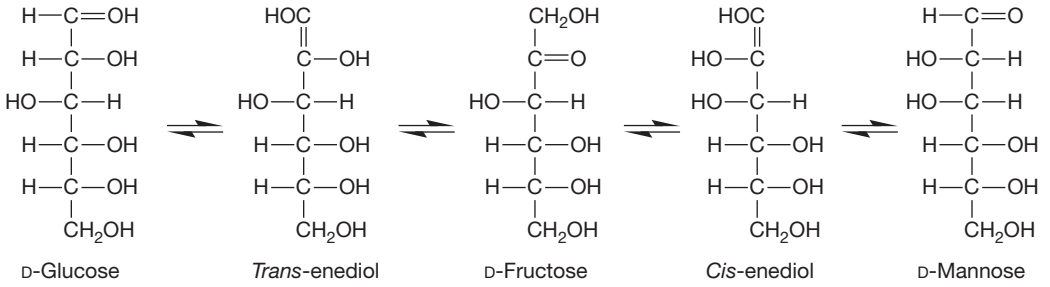

Figure 4 Enolization and isomerization reactions.

not just of C-2; and indeed, some of the other D-aldohexoses are levorotatory.

Chemical Properties of Glucose

All carbohydrate molecules have hydroxyl groups available for reaction. Glucose and most other low-molecular-weight carbohydrate molecules also have carbonyl groups available for reaction.

Oxidation of Glucose to Produce Sugar Acids

One of the earliest methods for quantitative measurement of glucose employed Fehling solution. Fehling solution is an alkaline solution of copper(II) that oxidizes an aldose to an aldonate and in the process is reduced to copper(I), which precipitates as brick-red Cu_2O. Variations, the Nelson–Somogyi and Benedict reagents, are still used for determining amounts of reducing sugars in foods and other biological materials.

Glucose is known as a reducing sugar, because in the process of oxidizing the aldehyde group of glucose to the salt of a carboxylic acid group, the oxidizing agent is reduced.

Ketoses are also termed as reducing sugars because, under the alkaline conditions of the Fehling test, ketoses are isomerized to aldoses. Benedict reagent, which is not alkaline, will react with aldoses but not with ketoses.

Glucose, when oxidized under different conditions, forms (i) gluconic acid, (ii) glucaric acid, and (iii) glucuronic acid as indicated in Figure 5.

Gluconic acid

Glucose is readily oxidized to gluconic acid. The reaction is commonly used for quantitative determination of glucose. Oxidation of glucose with Br_2–water converts the aldehyde (–CHO) group to a -COOH group. Br_2 reacts with water to form hypobromous acid, which acts as an oxidizing agent:

$$\text{D-Glucose} \xrightarrow[H_2O]{Br_2} \text{D-gluconic acid}$$

Another simple and specific method for quantitative oxidation of D-glucose to D-gluconic acid uses the enzyme glucose oxidase, with the initial product being the 1,5-lactone (an intramolecular ester) of the acid (Figure 6). The reaction is commonly employed to measure the amount of D-glucose in foods and other biological materials, including the D-glucose level of blood. D-Gluconic acid is a natural constituent of fruit juices and honey. The reaction given in Figure 3 is also used for the manufacture of commercial D-gluconic acid and its lactone. D-Glucono-delta-lactone (GDL), D-glucono-1,5-lactone according to systematic nomenclature, hydrolyzes to completion in water in about 3 h at room temperature, effecting a decrease in pH. Its slow hydrolysis, slow acidification, and mild taste set GDL apart from other food acidulants. It is used in meats and dairy products but particularly in baked goods as a component of chemical leavening agents for preleavened products.

Glucaric acid

Oxidation of glucose with conc. HNO_3 under proper conditions converts both aldehyde and primary alcohol groups to –COOH groups, forming a dibasic sugar acid, saccharic or glucaric acid:

$$\text{D-Glucose} \xrightarrow{\text{conc. } HNO_3} \text{D-Glucaric acid}$$

D-Glucaric acid is a naturally occurring aldaric acid, typically found in small amounts in a variety of fruits and vegetables. Potential commercial applications for D-glucaric acid include use as a metal sequestering agent, retarding agent for metallic mordants in the dyeing of textiles, and corrosion inhibitor for metals. A current commercial use of a salt form of D-glucaric acid as a dietary supplement claimed to help maintain healthy cholesterol levels and prevent cancer. As a dietary supplement, D-glucaric acid functions as a precursor to the β-glucuronidase inhibitor and D-glucaro-1,4-lactone. In addition to these end uses, D-glucaric acid is the starting material for the synthesis of other chemicals, particularly as a diacid monomer used to make a number of polyhydroxypolyamides.

Glucuronic acid

The terminal carbon atom (at the other end of the carbon chain from the aldehyde group) of a monosaccharide unit of an oligo- or polysaccharide may occur in an oxidized (carboxylic acid) form. Such an aldohexose with C-6 in the form of a carboxylic acid group is called as uronic acid.

When glucose is oxidized in such a way that the primary alcohol group is converted to –COOH group, without oxidation of aldehyde group, a glucuronic acid is formed:

$$\text{D-Glucose} \rightarrow \text{D-Glucuronic acid}$$

In the body, D-glucuronic acid is formed from glucose in the liver by uronic acid pathway, an alternative pathway for glucose oxidation. It occurs as a constituent of certain mucopolysaccharides. In addition, it conjugates toxic substances,

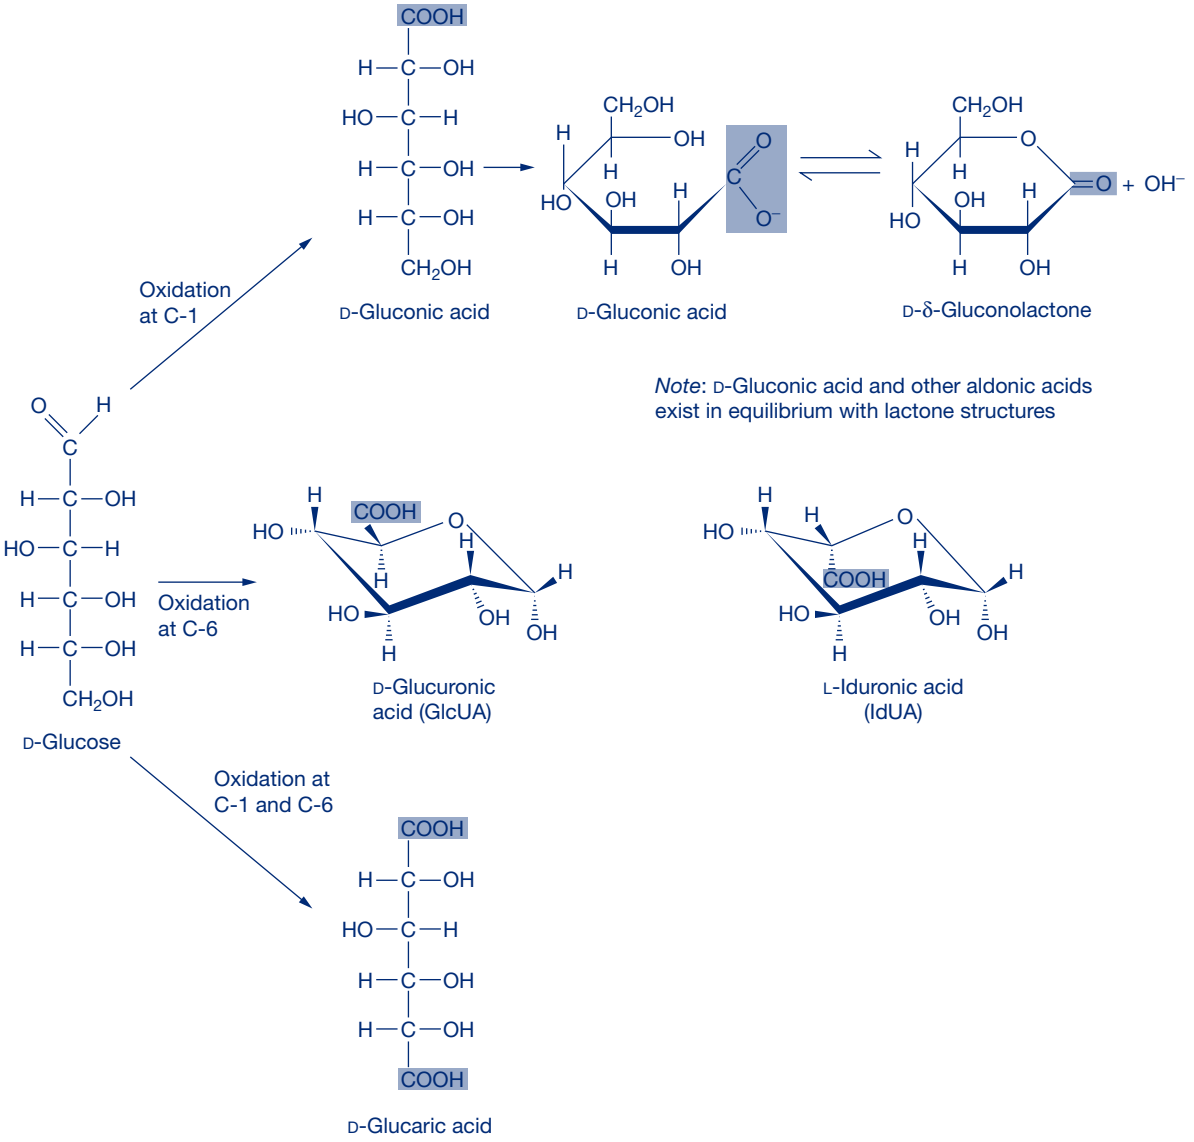

Figure 5 Oxidation of D-glucose to produce sugar acids.

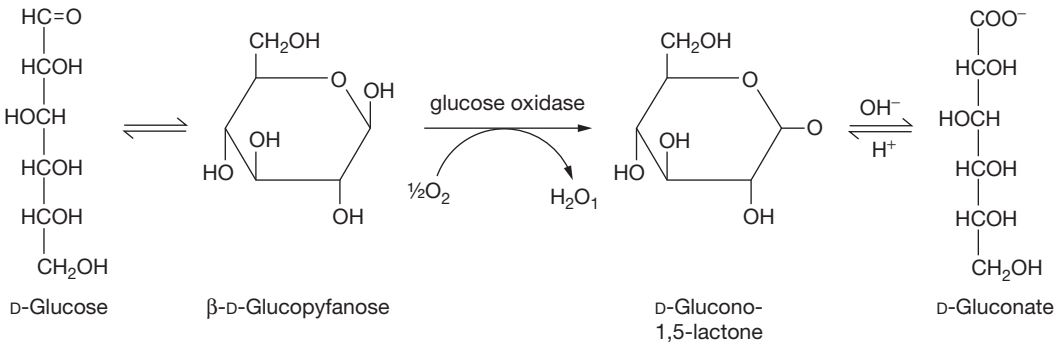

Figure 6 Oxidation of D-glucose catalyzed by glucose oxidase.

drugs, hormones, and even bilirubin (a breakdown product of Hb) and converts them to a nontoxic substance, glucuronide, which is excreted in urine.

Reduction of Glucose to Produce Sugar Alcohols

Hydrogenation is the addition of hydrogen to a double bond. When applied to carbohydrates, it most often entails addition of hydrogen to the double bond between the oxygen atom and the carbon atom of the carbonyl group of an aldose or ketose. Hydrogenation of D-glucose is easily accomplished with hydrogen gas under pressure in the presence of Raney nickel. The product is D-glucitol, commonly known as sorbitol, where the -itol suffix denotes a sugar alcohol (an alditol) (Figure 7). Alditols are also known as polyhydroxy alcohols and as polyols. Because it is derived from a hexose, D-glucitol (sorbitol) is specifically a hexitol. It is found widely distributed throughout the plant world, ranging from algae to higher orders where it is found in fruits and berries, but the amounts present are generally small. It is 50% as sweet as sucrose, is sold both as syrup and as crystals, and is used as a general humectant.

Formation of Hydroxyl Group Esters

The hydroxyl groups of carbohydrates, like the hydroxyl groups of simple alcohols, form esters with organic and some inorganic acids. Reaction of hydroxyl groups with a carboxylic acid anhydride or chloride (an acyl chloride) in the presence of a suitable base produces an ester.

Acetates, succinate half-esters, and other carboxylic acid esters of carbohydrates occur in nature. They are found especially as components of polysaccharides. Sugar phosphates are common metabolic intermediates (Figure 8). Monoesters of phosphoric acid are also found as constituents of polysaccharides. For example, potato starch contains a small percentage of phosphate ester groups. Cornstarch contains even less. In producing modified food starch, cornstarch is often derivatized with one or the other or both mono- and distarch ester groups. Other esters of starch, most notably the acetate, succinate, and substituted succinate half-esters, and distarch adipates are in the class of modified food starches. Sucrose fatty acid esters are produced commercially as emulsifiers. Members of the family of red seaweed polysaccharides, which includes the carrageenans, contain sulfate groups (half-esters of sulfuric acid, R-OSO_3^-).

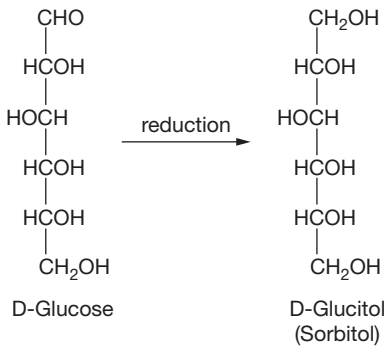

Figure 7 Reduction of D-glucose.

Formation of Hydroxyl Group Ethers

The hydroxyl groups of carbohydrates, like the hydroxyl groups of simple alcohols, can from ethers as well as esters. Ethers of carbohydrates are not as common in nature as are esters. However, polysaccharides are etherified commercially to modify their properties and make them more useful. Examples are the production of methyl (–O–CH_3), sodium carboxymethyl (–O–CH_2–$CO_2^-Na^+$), and hydroxypropyl (–O–CH_2–CHOH–CH_3) ethers of cellulose and hydroxypropyl ethers of starch, all of which are approved for food use. A special type of ether, an internal ether formed between carbon atoms 3 and 6 of a D-galactosyl unit, is found in the red seaweed polysaccharides, specifically agar, furcellaran, kappa-carrageenan, and iota-carrageenan. Such an internal ether is known as a 3,6-anhydro ring, whose name derives from the fact that the elements of water (HOH) are removed during its formation.

A series of nonionic surfactants based on sorbitol (D-glucitol) are used in foods as water-in-oil emulsifiers and as defoamers. They are produced by esterification of sorbitol with fatty acids. Cyclic dehydration accompanies esterification (primarily at a primary hydroxyl group, i.e., C-1 or C-6) so that the carbohydrate (hydrophilic) portion is not only sorbitol but also its mono- and dianhydrides (cyclic ethers). The products are known as sorbitan esters (Figure 9). The product called sorbitan monostearate is actually a mixture of partial stearic ($C_{18:0}$) and palmitic ($C_{16:0}$) acid esters of sorbitol (D-glucitol), 1,5-anydro-D-glucitol (1,5-sorbitan), 1,4-anhydro-D-glucitol (1,4-sorbitan), both internal (cyclic) ethers, and 1,4:3,6-dianhydro-D-glucitol (isosorbide), an internal dicyclic ether. Sorbitan fatty acid esters, such as sorbitan monostearate, sorbitan monolaurate, and sorbitan monooleate, are sometimes modified by reaction with ethylene oxide to produce so-called ethoxylated sorbitan esters, nonionic detergents for food use.

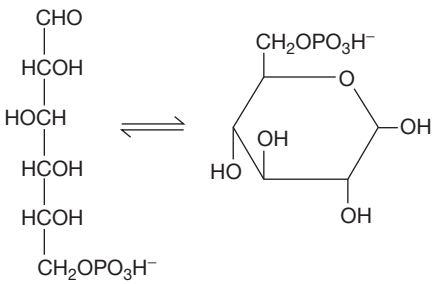

Figure 8 Example of sugar phosphate metabolic intermediate (D-glucose 6-phosphate).

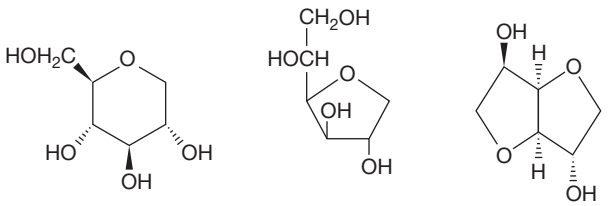

Figure 9 Anhydro-D-glucitols (sorbitans).

Nonenzymatic Browning

Under some conditions, reducing sugars produce brown colors that are desirable and important in some foods. Other brown colors obtained upon heating or during long-term storage of foods containing reducing sugars are undesirable. Common browning of foods on heating or on storage is usually due to a chemical reaction between reducing sugars, mainly D-glucose, and a free amino acid or a free amino group of an amino acid that is part of a protein chain. This reaction is called the Maillard reaction. It is also called nonenzymatic browning to differentiate it from the often rapid, enzyme-catalyzed browning commonly observed in freshly cut fruits and vegetables, such as apples and potatoes.

When aldoses or ketoses are heated in solution with amines, a variety of reactions ensue, producing numerous compounds, some of which are flavors, aromas, and dark-colored polymeric materials, but both reactants disappear only slowly. The flavors, aromas, and colors may be either desirable or undesirable. They may be produced by frying, roasting, baking, or storage.

The reducing sugar, D-glucose, reacts reversibly with the amine to produce a glycosylamine, as illustrated in Figure 10. This undergoes a reaction called the Amadori rearrangement to give a derivative of 1-amino-1-deoxy-D-fructose. Reaction continues especially at pH 5.0 or lower, to give an intermediate that dehydrates. Eventually, a furan derivative is formed, which is 5-hydroxymethyl-2-furaldehyde (HMF) (Figure 11). Under less acidic conditions (higher than pH 5.0), the reactive cyclic compounds (HMF and others) polymerize quickly to a dark-colored, insoluble material containing nitrogen.

Maillard browning products, including soluble and insoluble polymers, are found where reducing sugars and amino acids, proteins, and/or other nitrogen-containing compounds are heated together, such as in soy sauce and bread crusts. Maillard reaction products are important contributors to the flavor of milk chocolate. The Maillard reaction is also important in the production of caramels, toffees, and fudges, during which reducing sugars also react with milk proteins. D-Glucose undergoes the browning reaction faster than does D-fructose. Application of heat is generally required for nonenzymatic browning.

While Maillard reactions are useful, they also have a negative side. The reaction of reducing sugars with amino acids destroys the amino acid. This is of particular importance with L-lysine, an essential amino acid whose ε-amino group can react when the amino acid is part of a protein molecule. Also, a relationship has been found between the formation of mutagenic compounds and cooking of protein-rich foods. Mutagenic heterocyclic amines have been isolated from broiled and fried meat and fish and from beef extracts.

Analysis of Glucose

The analysis of glucose may involve chemical, enzymatic, electrochemical, and high-performance liquid chromatography (HPLC) systems. Prior to the introduction of enzyme-based analyses, chemical techniques were based on the reducing ability of glucose, and techniques employing copper sulfate were popular. Such techniques were influenced by other reducing sugars and reducing substances, including uric acid and vitamin C. With the introduction of the more specific glucose oxidase-based tests, the chemical tests were abandoned, although there was debate over the potential carcinogenicity of the early chromogens, *O*-dianisidine and *O*-toluidine. Later, more specific, hexokinase-based enzyme assays were introduced. Current methods for rapid determination of blood

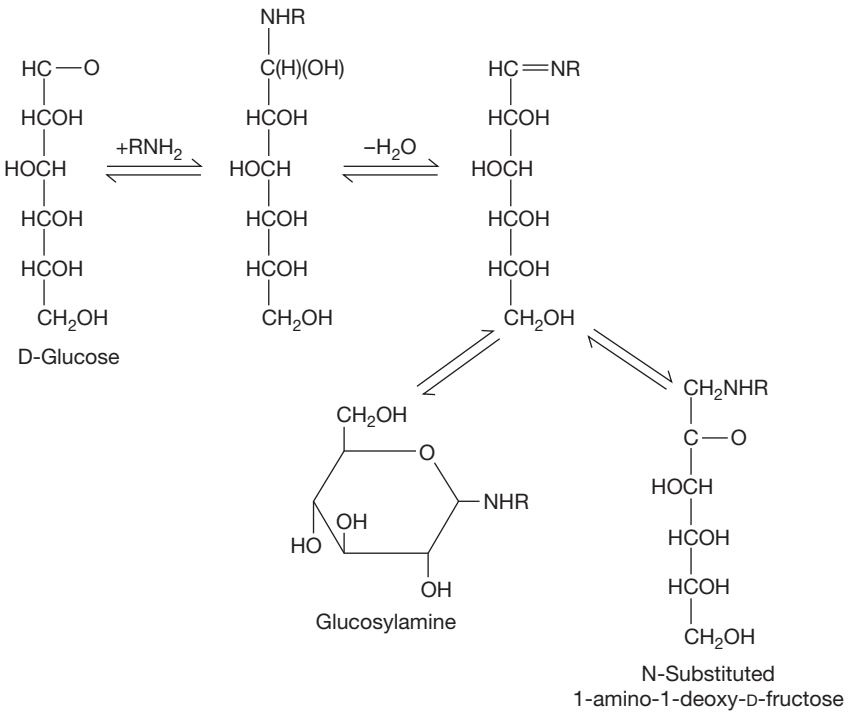

Figure 10 Products of reaction of D-glucose with an amine (RNH_2).

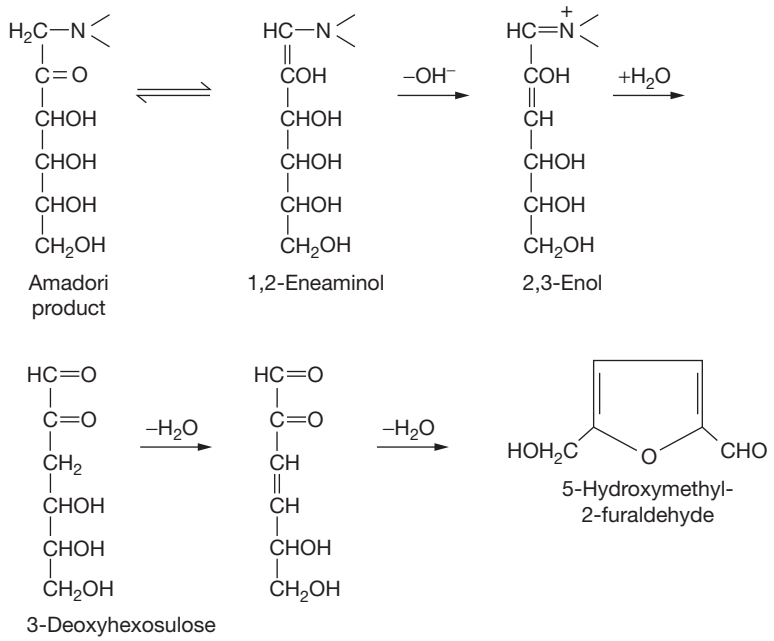

Figure 11 Conversion of the Amadori product into HMF.

glucose, which no longer require prior precipitation of plasma proteins, involve electrochemical detection. These methods rely on silver electrodes to detect electrons generated by the oxidation of glucose by glucose oxidase contained in membranes on the surface of the electrodes. For determination of glucose and α-limit dextrins resulting from starch digestion, HPLC techniques have proved useful.

Much attention has been given to the analysis of the glucose polymers – starches, resistant starches, cellulose, and β-glucans – in the context of dietary fiber. The ultimate assessment depends on the use of specific enzymes or enzyme systems to break the macromolecules down to their component glucose and other sugars when mixtures containing other polymers (dietary fibers) are being analyzed. These are then assessed by gas chromatography or HPLC and the ratios of the sugars determined. More routine assessment may involve a variety of chemical techniques combined with enzymatic digestion and, in the case of a popular Association of Official Analytical Chemists (AOAC)-approved technique for dietary fiber analysis, with a gravimetric determination. However, there is debate as to whether the resistant starch, which in the gravimetric AOAC technique is analyzed as dietary fiber, should be included as fiber or whether it is physiologically distinct. It is also debated whether a determination of β-glucan is sufficient without knowledge of its viscosity and molecular weight – factors that determine its physiological effect.

Background

Glucosinolates impart a sharp, somewhat fiery character to many edible plants. Efforts to understand the chemical origin of these pungent flavors led to the first observations on the unique properties of glucosinolates when, in 1831, French chemists Pierre-Jean Robiquet and Antoine François Boutron-Charlard isolated the glucosinolate sinalbin from white mustard (*Sinapis alba*). Formerly referred to as mustard oil glycosides, the glucosinolates comprise a relatively small but chemically diverse group of defensive plant secondary metabolites. Plants employ intact glucosinolates as host recognition cues (as both deterrents and attractants) for specialist insect and generalist insect oviposition. Glucosinolates further serve as potent biopesticides, participating in a binary chemical defense system that protects plants from environmental stressors such as insect herbivory and microbial pathogen attacks. Glucosinolate-producing plants are of major economic and nutritional importance, demonstrating versatility in a wide range of applications that encompass industrial, agricultural, and phytopharmacological usages. In particular, glucosinolate degradation products have been identified as potent chemoprotective agents in humans against the pathogenesis of many chronic diseases such as cancer, cardiovascular disease, and neurodegenerative disease, among others. The diminutive, glucosinolate-rich thale cress (or, mouse-ear cress, *Arabidopsis thaliana*), a member of the Brassicaceae family, is highly valued as a model organism for plant biology and genetics research.

Sources and Production

The majority of glucosinolate-producing plants are members of the Brassicales order (formerly Capparales), which includes the cruciferous families Brassicaceae, Capparaceae, and Caricaceae. The Brassicales alone comprise more than 350 genera and 3000 species. Of the many hundreds of cruciferous species investigated, all are able to synthesize glucosinolates. Glucosinolates have also been identified in more than 500 species of diverse noncruciferous dicotyledonous angiosperms; of note are the singular glucosinolate-producing genus *Drypetes* (syn. *Putranjiva*) of the Euphorbiaceae family (no other members of this vast plant family have been shown to contain them) and the monogeneric family Moringaceae, which contains 13 species that all produce chemically unique glucosinolates.

Glucosinolates are decidedly stable compounds with little biological activity. Conversely, some glucosinolate degradation products, such as the isothiocyanates, are unstable electrophilic compounds that react spontaneously with biological nucleophiles. Glucosinolates and their degradation products lend a pungent aroma and sharp flavor (sometimes described as bitter) to edible plants and are responsible for the 'heat' most notably associated with wasabi and horseradish.

Glucosinolate distribution in plant structures varies widely between roots, leaves, stems, and seeds and is strongly influenced by plant age. As such, the highest concentrations of glucosinolates are usually found in the reproductive organs of plants, with substantially higher concentrations present in young plants versus mature plants. Following *de novo* synthesis in siliques, glucosinolates are transported from mature to developing plant structures where they are stored as inert, hydrophilic precursors to toxic isothiocyanates and other biologically active compounds. Glucosinolates coexist with but are compartmentally segregated from plant myrosinases, an endogenous family of β-thioglucosidase enzymes (EC 3.2.1.147), whose sole known substrates are glucosinolates. These enzymes are strategically sequestered throughout plants in specialized idioblast, or myrosin, cells of plant leaves, stems, and flower clusters in a species-specific manner; multiple forms of myrosinase can exist within the same plant.

Upon plant injury and subsequent loss of cellular integrity due to insect herbivory, human mastication, or food processing techniques, myrosinase hydrolyzes the neighboring glucosinolates to yield glucose, hydrogen sulfate, and unstable aglycones that spontaneously rearrange to form a diverse group of bioactive compounds that vary depending on chemical structure, environmental conditions (such as pH and presence of ferrous ions), and the coexistence of other factors present in the plant, such as epithiospecifier proteins (ESP) or epithiospecifier modifier proteins (ESM). Whereas the presence of ESP favors epithionitrile formation (primarily from aliphatic glucosinolates), ESM promotes isothiocyanate formation. Myrosinases have also been identified, but little characterized, in fungi and bacteria including many bacteria commonly associated with human and animal gut microflora. Myrosinases are activated to various degrees by ascorbic acid, and in some instances, the enzyme is almost inactive in its absence. Activation is not dependent on the redox reactivity of ascorbate, rather, it has been suggested that ascorbate provides a nucleophilic catalytic group to the reaction.

In humans, myrosinase-producing intestinal microflora convert unhydrolyzed glucosinolates to their cognate isothiocyanates. Microbial-induced conversion is highly variable and subject to interindividual differences in commensal microbiota population. As such, conversion is distinguished by high converters (individuals with high elimination profiles) and low converters (individuals with low elimination profiles). Antimicrobial agents or mechanical bowel cleansing abrogates microbial conversion (see **Figure 1**).

Chemical Structure

The defining characteristic of glucosinolate structure is a β-D-glucopyranose moiety, sulfur-linked to a β-thioglucoside-*N*-hydroxysulfate and an amino acid-derived side chain (R).

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00354-8

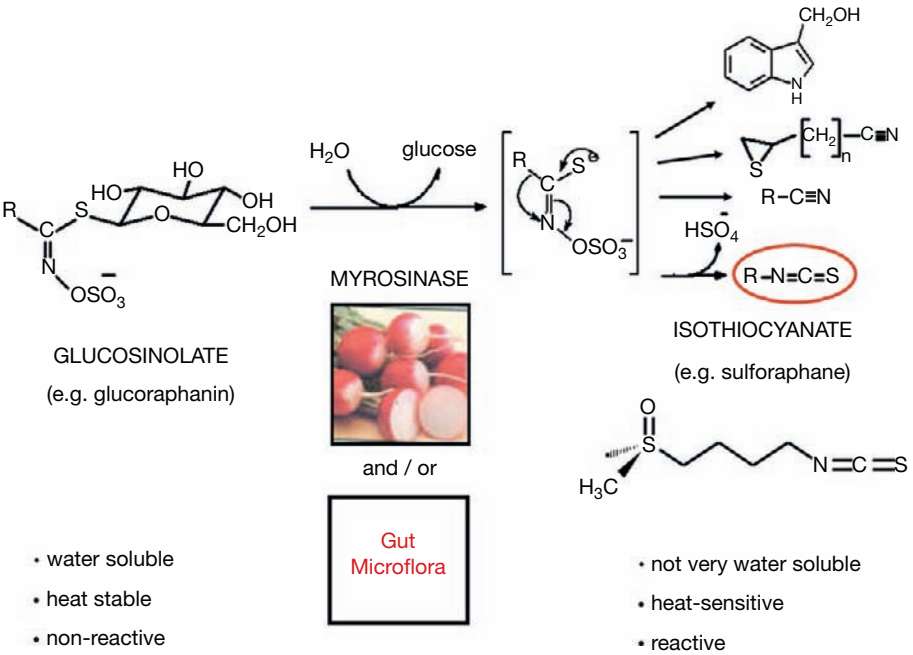

Figure 1 Glucosinolates are hydrolyzed to isothiocyanates by the enzyme myrosinase, which is physically segregated within the plant from its substrate. Myrosinase-like activity is also present in the gut microflora but is highly variable between persons.

During glucosinolate biosynthesis, the precursor side chains undergo extensive modification and may contain straight or branched carbon chains and aromatic or indole moieties. Further side-chain modifications include glycosylation, desaturation, or functionalization with hydroxyl groups, carbonyl groups, or sulfur linkages in various oxidation states, the latter occurring in more than one-third of all nonsynthetic glucosinolates. About 120 distinct glucosinolate structures have been identified and are broadly classified as aliphatic, aromatic, or heterocyclic (or indole), based upon structural similarities of their amino acid precursor and the extent to which their side chain is modified. Aliphatic glucosinolates are derived from alanine, isoleucine, leucine, methionine, or valine; aromatic glucosinolates are derived from phenylalanine or tyrosine; indole glucosinolates are derived from tryptophan. Methionine, in particular, undergoes the most extensive transformation and gives rise to the large family of methylthioalkyl-, methylsulfinyl-, and methylsulfonyl-glucosinolates. Some aromatic benzyl glucosinolates have an additional sugar moiety (rhamnose or arabinose) in glycosidic linkage to the aromatic ring. The implication of these sugars' presence has only been speculated upon to date, but their occurrence in two families of plants (Moringaceae and Resedaceae) whose genera are widely exploited for their pharmacological properties is significant.

Biosynthesis

The biosynthetic pathway of glucosinolates shares homology with that of the cyanogenic glycosides and likely occurs sequentially in the cytoplasm, endoplasmic reticulum, and chloroplast. The universally accepted model of this pathway transpires in a stepwise fashion involving side-chain elongation, core (glycone) biosynthesis, and side-chain modification. Side-chain elongation proceeds by *N*-hydroxylation of select precursor amino acids followed by decarboxylation. Multifunctional cytochrome P450 enzymes (CYP79s and CYP83s), glucosyltransferases, and sulfotransferases mediate biosynthesis of the core glycone structure, with aldoximes, aci-nitro or nitrile oxides, S-alkyl -thiohydroximates, thiohydroximic acids, and desulfoglucosinolates serving as transitory intermediates. The precise mechanism of side-chain modification, the terminal step of glucosinolate biosynthesis, has been the source of much speculation and little experimental work; however, during side-chain modification, oxidations, hydroxylations, and desaturations give rise to the wide range of structural diversity present in glucosinolates. This diversity further influences reactivity, solubility, and human biological activity of not only the glucosinolates but also the resultant products (isothiocyanates). For example, whereas initial oxidation of the side chain sulfur of methionine and its chain-elongated homologues likely gives rise to the large family of methylsulfinyl- and methylsulfonyl-glucosinolates, conjugation of a hydroxyalkyl glucosinolate with benzoic acid is expected to give rise to the benzoyloxyalkyl glucosinolates. Furthermore, oxidation of glucoerucin, the major glucosinolate present in arugula, gives rise to glucoraphanin, the precursor to the potent anticarcinogenic isothiocyanate sulforaphane. However, other metabolic modifications of glucoerucin may give rise to the goitrogenic glucosinolate progoitrin, with no demonstrated anticarcinogenic activity, but with the potential to cause dietary goiter (hence its name) if consumed at high levels. It is noteworthy that at least ten of the aromatic and indole glucosinolates, which exhibit high bioactivity, are singly or multiply methoxylated.

Hydrolysis of aliphatic and aromatic glucosinolates generally yields isothiocyanates while indole hydrolysis yields nitriles and unstable isothiocyanates that rapidly form indole-3-carbinol (I3C), indoleacetonitrile, thiocyanate ions, and 3,3′-diindolylmethane (DIM). I3C may then spontaneously condense under

the acid conditions of the stomach to form compounds that closely resemble 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) in structure, toxicity, and carcinogenicity. Despite this toxicity, indole glucosinolate metabolites, in particular, I3C and DIM, have been investigated for their potential as cancer chemoprotective agents.

Glucosinolate biosynthesis within individual cruciferous vegetables is both constitutive and inducible and varies considerably in response to genetic factors and environmental influences, such as jasmonate and salicylic acid signaling, pathogenic attack, insect herbivory, and soil nitrogen or sulfur content. As many as 25 glucosinolates may be present in a single plant (*Arabidopsis* spp.), although a census in the range of five to ten is far more typical; total content in plants can range from 1% of dry weight in vegetative tissues of many *Brassica* vegetables to as much as 10% in the seeds of some plants.

Patterns of Consumption

Cruciferous vegetables from the *Brassica* genus are the primary dietary source of glucosinolates in humans and include broccoli, bok choy, Brussels sprouts, cabbage, cauliflower, collard, kale, kohlrabi, mustard, rutabaga, and turnips. In addition, edible plants from other genera including arugula, capers, cress, moringa, papaya, radish, wasabi, and watercress contribute substantially to glucosinolate intake. (See Figure 2 and Table 1.)

Regional and cultural dietary patterns strongly influence glucosinolate consumption. Food disappearance data indicate Asian populations consume markedly higher quantities of cruciferous vegetables, many of which are consumed rarely in Western cultures. For example, whereas daikon, or Japanese white radish, is the most commonly consumed cruciferous vegetable in Japan (20 kg year^{-1}), broccoli ranks the highest in the United States (2.5 kg year^{-1}). Total crucifer intake varies considerably by country but average intake is estimated at 7.6 kg year^{-1}; the highest total intake is observed in China (37 kg year^{-1}) and the lowest in Greece (2.1 kg year^{-1}). Although selective breeding to increase glucosinolate content is advocated for health reasons, efforts to decrease glucosinolate content have been promoted as means to reduce bitterness, a quality perceived (by some) as an obstacle to palatability. (See Box 1.)

Accurate assessment of dietary glucosinolate intake has proved problematic. Traditional dietary assessment methods such as food frequency questionnaires and dietary recalls may be susceptible to reporting bias and fail to consider differences in glucosinolate content in plants, which demonstrates remarkable variability across species and cultivars. Environmental factors such as soil and growing conditions, cultivar, harvest time, and postharvest storage further modulate glucosinolate levels in foods. In addition, food processing and preparation methods may reduce exposure of humans to glucosinolate degradation products by 60–90%. For example, glucosinolates are water-soluble and may leach into cooking water; alternatively, heat-labile myrosinases are readily inactivated at most cooking temperatures. Furthermore, in light of the complex interactions between gut microbiota and host metabolism, circadian rhythms may influence exposure as well: Recent work suggests that whereas conversion of intact glucosinolates to bioactive metabolites predominates during the day, metabolism of isothiocyanates is more efficient during the night.

Cruciferous vegetable intake can serve as a proxy for glucosinolate intake but biomarkers such as urinary isothiocyanate metabolites may provide more definitive, complementary measures of habitual intake as well as metabolite-specific

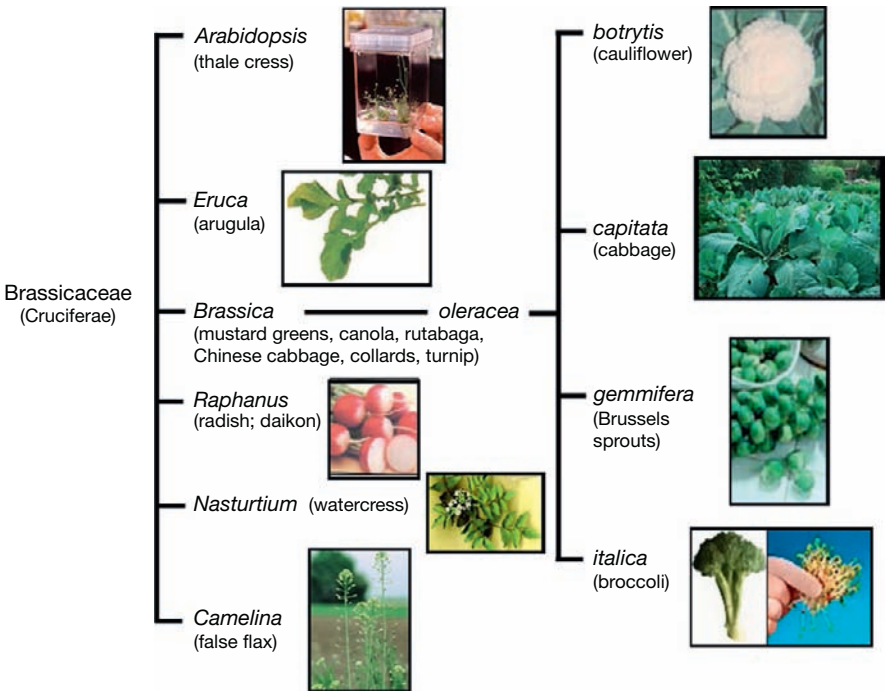

Figure 2 Commonly consumed vegetables in the family Brassicaceae (Cruciferae).

exposure levels. However, human exposure to nondietary sources of synthetic analogs of isothiocyanate metabolites such as those used extensively in agricultural and industrial applications can further distort quantification of exposure. Examples include the dithiocarbamates, which are used as pesticides against insects, fungi, and bacteria; accelerators in the vulcanization of natural rubber and synthetic rubber; precursors in the synthesis of sulfide materials and nanoparticles; and flocculants for the remediation of heavy metal-contaminated wastewater.

Availability, Absorption, and Metabolism

The chemical structure and properties of intact glucosinolates preclude absorption, and little, if any, of the parent

Box 1 Glucosinolates as Modulators of Bitter Taste Receptors

Glucosinolates have been described alternately as sharp, pungent, acrid, astringent, or lacrimatory, but they are most widely regarded – in some cases inaccurately – as bitter. Whereas the glucosinolates sinigrin and gluconapin (prominent in Brussels sprouts, cabbage, cauliflower, turnip, rutabaga, and kale) are associated with strong bitterness, glucobrassicin and neoglucobrassicin (prominent in mature broccoli) confer moderate bitterness. The glucosinolates glucoerucin, glucoiberverin, and glucoraphanin do not contribute appreciably to bitterness.

Isothiocyanates typically are not associated with bitterness but they do contribute to overall flavor. One notable exception is goitrin, the hydrolytic degradation product of the nonbitter glucosinolate progoitrin. Goitrin contributes to the bitterness of rutabaga, Brussels sprouts, cabbage, turnip, and cauliflower and presents a significant barrier to consumer acceptance.

Humans' innate aversive reaction to bitterness is a highly conserved protective measure against ingestion of toxic substances. Oral perception of bitterness entails the binding of hydrophilic molecules to G protein-coupled receptors encoded by the TAS2R family of taste receptor genes and ensues via subsequent initiation of attendant downstream signaling pathways. This activation of oral chemosensors elicits a cascade of events that induces local epithelial changes or alterations in autonomic responses, such as excessive salivation or increased gut motility, respectively. TAS2R receptors are expressed in humans in oral taste receptor cells and extraoral sites including tissues of the gut, airways, and testes, where they exhibit variable ligand specificity. Although their functions in these tissues have not been clearly identified, TAS2Rs have been implicated in a diverse portfolio of activities that mediate reflexive actions to protect humans (or their reproductive capacity), including neuroendocrine signaling, airway patency, and spermatogenesis. Whether bitter-tasting compounds such as some glucosinolates modulate cell signaling pathways regulated by TAS2Rs to elicit beneficial (or deleterious) health effects remains to be seen.

glucosinolates is recovered in urine or feces. As such, nearly all glucosinolate bioactivity in humans is attributable to their respective hydrolytic degradation products, of which the isothiocyanates are prominent examples. Only a small fraction of the 120 or so known glucosinolates, and even fewer isothiocyanates, occur frequently in the diet, however.

Isothiocyanates, as lipophilic nonnutrients, encounter the same biotransformative events as other xenobiotic compounds and are subject to a vigorous metabolic response in the small intestine and liver. Nevertheless, isothiocyanates exhibit variable absorption kinetics, high levels of metabolic disposition, strong modulatory effects on ATP-binding cassette (ABC) transporters, and an expansive range of bioavailability. The liver is the predominant site of isothiocyanate metabolism due to high hepatocellular expression of glutathione S-transferases (GST), phase 2 cytoprotective enzymes central to isothiocyanate biotransformation; however, the rapid rate of isothiocyanate clearance – within hours of ingestion – implicates other tissues in metabolism, including the oral, gastric, and intestinal epithelia. The small intestine, in particular, demonstrates uniform and abundant expression of GST and actively participates in isothiocyanate metabolism. Although traditional models of xenobiotic metabolism rarely consider extraintestinal uptake, sublingual and buccal tissues in the oral cavity demonstrate moderate permeability and absorption of other lipophilic compounds. Furthermore, they express the requisite enzymes and efflux transporters involved in isothiocyanate metabolism, raising the question regarding the location of these activities.

Although the sites wherein isothiocyanate biotransformation occurs have not been fully characterized, the processes that mediate the compounds' metabolic disposition likely transpire in this fashion: Following passive diffusion into cells, CYP450 enzymes may oxidize isothiocyanates to their cognate isocyanates, unstable intermediates of amines, carbamates, or benzene derivatives. More frequently, however, isothiocyanates undergo spontaneous or enzyme-enhanced conjugation to glutathione and subsequent cellular efflux via ABC transporters. The isothiocyanates are exceptionally avid substrates of multidrug resistance proteins (MRP2); as such, isothiocyanate conjugates are readily deconjugated and may be shuttled in and out of cells multiple times via MRP2, providing repeated exposures to cells. Intact glucosinolates, isothiocyanates, and their glutathione conjugates may enter the enterohepatic circulation, the bidirectional cycling of xenobiotic compounds and their metabolites between the intestine and liver via bile transporters. Enterohepatic circulation subjects these compounds to repeated bouts of recycling and may prolong the compounds' half-life; alternatively, they may be transported to the distal gut where they are subject to microbial hydrolysis and subsequent absorption or elimination in feces.

Absorbed isothiocyanate species are metabolized primarily by the mercapturic acid pathway, during which nonenzymatic and enzymatic conversions yield the dithiocarbamates cysteinylglycine, cysteine, and N-acetylcysteine conjugates. These metabolites are preferentially eliminated in urine, likely due to their low molecular weight, which is generally less than 500–600 Da. Generally speaking, glucosinolates, isothiocyanates, and their metabolites are cleared from urine within 72 h of ingestion. Over half of ingested glucosinolates, which require initial degradation to isothiocyanates by myrosinase, are cleared in the urine within 24 h, and they are fully cleared within 72 h. Over half of ingested isothiocyanates are cleared in the urine within 8 h, and they are fully cleared within 24–48 h. As such, N-acetylcysteine conjugates in urine serve as a biomarker of isothiocyanate (and glucosinolate) uptake and metabolism. However, interindividual differences in cellular metabolic competence, gut microbiota population, bowel transit time, and the presence of other dietary components may influence elimination rates.

The collective processes of MRP2 transport, enterohepatic circulation, and mercapturic metabolism likely play a key role in isothiocyanate bioavailability. Indeed, isothiocyanates demonstrate biphasic serum concentrations and urinary output rates, which may have implications for health effects as well as extrapolation of data across individuals. These redundant, iterative processes speak to the toxicity of isothiocyanates yet ultimately they may be responsible for the protective cellular responses induced by exposure to these compounds.

Health Effects

The health effects associated with the consumption of glucosinolates are incumbent upon conversion to their bioactive form, the isothiocyanates. Postabsorptive metabolism of isothiocyanates may be responsible for producing therapeutic moieties that mediate these beneficial effects; however, toxicities have been reported from consumption of some

non-isothiocyanate metabolites of certain glucosinolates not commonly consumed. Nevertheless, compelling evidence links increased consumption of fruits and vegetables, especially cruciferous vegetables, to reduced incidence of many chronic diseases, including cancer, cardiovascular disease, neurodegenerative disease, metabolic dysregulation and its pathological sequelae, and autoimmune dysfunction. A variety of clinical trials addressing the role of isothiocyanates in the prevention and management of these and other chronic diseases are under way as this article goes to press, with new data promising further insight into the mechanistic actions of this unique class of bioactive plant compounds.

Anti-Inflammatory and Immunomodulatory Agents

Inflammation and altered immune function are prominent features in the pathogenesis of many chronic diseases. The anti-inflammatory and immunomodulatory activities of isothiocyanates likely contribute to the putative protective effects associated with these compounds. For example, in rodents, sulforaphane, one of the most extensively studied isothiocyanates, has been shown to inhibit endothelial cell response to the vascular endothelial growth factor and downregulate the expression of cyclooxygenase-2 and proinflammatory cytokines such as interleukin (IL)-1β, IL-6, granulocyte macrophage colony-stimulating factor, and tumor necrosis factor-α (TNF-α). Sulforaphane also inhibits activation of the transcription factor NFκB, thus suppressing gene expression of proinflammatory mediators and reducing the number of activated macrophages in rodent models. Recent evidence suggests that through direct covalent binding to the N-terminal proline, isothiocyanates potently inhibit the tautomerase activity of the macrophage migration inhibitory factor, a proinflammatory cytokine implicated in the pathogenesis of inflammatory and autoimmune diseases.

Cancer

Isothiocyanates have been studied extensively for their role in preventing carcinogenesis. Ingestion of approximately two servings per day of cruciferous vegetables may reduce the relative risk for cancer by as much as 50% at certain sites. At least some, and perhaps most, of the cancer chemoprotective activity of these vegetables is believed to be due to their content of minor dietary components such as glucosinolates, a role supported by *in vitro* animal and human data. In particular, epidemiological data indicate that aliphatic and indolyl glucosinolate intakes are inversely associated with risk of some types of cancer; however, genetic polymorphisms in isothiocyanate metabolism and elimination may mitigate the protective effects. In rodent models of both spontaneous and chemically induced cancers, isothiocyanates confer protection at multiple sites including the lungs, esophagus, stomach, colon, mammary glands, bladder, pancreas, and skin. In addition, the isothiocyanates inhibit growth of human tumor cells in xenograft models of prostate, colorectal, esophageal, and breast cancer. Multiple mechanisms are likely at play including altered carcinogen metabolism due to modifications in the activities of drug-metabolizing enzymes, induction of cell cycle arrest and apoptosis, inhibition of angiogenesis and metastasis, altered histone acetylation status, and antioxidant, anti-inflammatory, and immunomodulatory activities. Critically, it is this ability of a single agent to exert such diverse effects on events that are intimately involved in the pathogenesis of cancer that makes the isothiocyanates such efficient protective agents. Early discoveries that isothiocyanates were capable of reducing the activation of procarcinogens by inhibiting phase 1 drug-metabolizing enzymes and inducing the transcription of cytoprotective phase 2 enzymes, ultimately decreasing the levels of the carcinogens available to mutate DNA, provided the impetus for the development of a quantitative bioassay for screening induction capabilities based on increased transcription of NAD(P)H: quinone oxidoreductase 1 (NQO1). Induction of this widely distributed NAD(P)H-dependent flavoprotein, which promotes obligatory 2-electron reductions of quinones to hydroquinones, is a salient feature of the phase 2 response and is of central importance in protecting cells against oxidative stress.

Broccoli extracts demonstrate the greatest capacity for NQO1 induction of any glucosinolate-producing plants evaluated thus far, and sulforaphane has been isolated as the principal active compound. In fact, no other phytochemicals in broccoli extracts have been shown to contribute to this activity. In addition, induction of other cytoprotective proteins, including both subunits of glutamate–cysteine ligase, the rate-limiting enzyme of glutathione biosynthesis, heme oxygenase-1, and GSTs, has been observed. Importantly, induction has long-lasting protective effects because the cytoprotective proteins typically have long half-lives of several days. Global gene expression profiling has confirmed that isothiocyanates serve as broad-spectrum chemopreventive agents and modulate extensive networks of cytoprotective genes and signaling pathways.

Many of the genes encoding cytoprotective proteins share a common transcriptional regulation through the Keap1–Nrf2–ARE pathway, a key mediator of cytoprotective responses to oxidative stress and electrophilic stress. Kelch-like ECH-associated protein 1 (Keap1) serves as the ubiquitin ligase substrate adaptor that presents the nuclear factor-erythroid 2 p45-related factor-2 (Nrf2) for ubiquitination and subsequent proteasomal degradation. Isothiocyanates react with specific cysteine residues of Keap1, eliminating Keap1's ability to target the Nrf2 for degradation. Consequently, the Nrf2 accumulates and translocates to the nucleus where it binds to antioxidant response elements (AREs), specific DNA sequences in the upstream regulatory regions of cytoprotective genes, and activates transcription. Nrf2 activation induces the coordinate transcription of a diverse group of cytoprotective enzymes, altering the metabolism and elimination of environmental procarcinogens in humans and affording protection against the damaging effects of environmental toxins by enhancing their detoxification. Sulforaphane is the most potent naturally occurring small-molecule inducer of cytoprotective proteins. In effect, isothiocyanates such as sulforaphane expedite their own metabolism and elimination through upregulation of phase 2 enzymes and subsequent formation of readily excretable metabolites. Isothiocyanates further reduce cancer risk through modulation of epigenetic marks via inhibition of histone deacetylase,

promotion of global histone acetylation, and the induction of cell cycle arrest and apoptosis of cancer cells, thus reducing tumor growth. Further, sulforaphane induces perturbations in several signaling pathways, such as transforming growth factor-β receptor, endothelial growth factor receptor, and insulin signaling. Because these pathways are associated with carcinogenesis and inflammation, it is reasonable to assume that the net effect of their modulation will be reduction in cell proliferation and maintenance of tissue homeostasis.

Cardiovascular Disease

Similarly, isothiocyanates' ability to induce cytoprotective proteins and prevent chronic inflammation reduces oxidative stress in cardiovascular tissues, as evidenced by increased glutathione, glutathione reductase, and glutathione peroxidase levels and decreased protein nitrosation. In rodent models of hypertension and stroke, endothelial-dependent relaxation of the aorta is improved, the number of infiltrating activated macrophages is reduced, and blood pressure is decreased. Similarly, in rodent models of cardiovascular ischemia and reperfusion, oral delivery of isothiocyanate-containing extracts improves postischemic ventricular function, reduces myocardial infarct size, and decreases cardiomyocyte apoptosis.

Nervous Tissue Injury and Neurodegenerative Disease

Oxidative stress and chronic inflammation are also central to the pathogenesis of diseases of the central nervous system, and the protective effects of isothiocyanates are evident in models of nervous tissue injury and neurodegeneration. In models of spinal cord injury, sulforaphane administration decreases infarct size, brain (or spinal cord) edema, and cortical apoptosis, reduces inflammatory markers and tissue damage, attenuates loss of endothelial cell markers and tight junction proteins, preserves blood–brain barrier function, and decreases the presence of neurological deficits. In addition, sulforaphane decreases both microglial activation and the upregulation of inflammatory markers following endotoxin injection. Sulforaphane also demonstrates a protective effect in rodent models of brain ischemia and reperfusion, traumatic brain and spinal cord injury, intracerebral hemorrhage, and contusion.

In the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine mouse model of Parkinson's disease, sulforaphane protects nigral dopaminergic neurons against cell death and reduces astrogliosis, microgliosis, and the release of proinflammatory mediators in the basal ganglia. Intrathecal administration of sulforaphane reduces oxidative stress and proinflammatory cytokine expression caused by spinal nerve transection and inhibits the development of neuropathic pain. Following exposure to methylmercury, decreased mercury accumulation was observed in the brain of sulforaphane-treated mice, suggesting the potential of isothiocyanates to accelerate the metabolism and elimination of neurotoxins. In most cases, the neuroprotective effects of sulforaphane are accompanied by activation of the transcription factor Nrf2 and upregulation of its target genes. Furthermore, mice that are deficient in Nrf2 (knockout mutants) are more sensitive to damage and cannot be protected by sulforaphane, strongly suggesting that the transcriptional program orchestrated by Nrf2, and not the isothiocyanate itself, is largely responsible for the protective effects of sulforaphane.

Metabolic Dysregulation and Pathological Sequelae

Diabetes is a metabolic disorder characterized by a chronic, subacute state of inflammation. As such, anti-inflammatory therapeutic approaches are critical in the prevention and management of its pathological sequelae. Sulforaphane has been shown to reduce the serum C-reactive protein, IL-6, and TNF-α, common biomarkers of inflammation observed in individuals with type 2 diabetes. In addition, sulforaphane improves renal performance and minimizes pathological changes in the glomerulus while improving motor nerve conduction velocity and blood flow and reducing pain. These very recent findings encourage the potential development of dietary isothiocyanates as therapeutic agents to alleviate metabolic disorders and protect against renal damage and pain associated with diabetes. Interestingly, intervention in humans with diets rich in glucosinolates causes a decrease in the acylcarnitine levels in plasma and urine, indicating enhanced integration of fatty acid oxidation with the activity of the tricarboxylic acid cycle, which may have implications for metabolic derangements, as well as cancer and neurodegeneration.

Antimicrobial Activity

The antimicrobial activities of isothiocyanates against human pathogens such as *Escherichia coli*, *Salmonella typhimurium*, and *Candida* spp. are well documented. For example, the long history of use of cruciferous vegetables such as cabbage and mustard as wound poultices and antitumor agents likely is attributable to isothiocyanates. Sulforaphane, in particular, is bactericidal and bacteriostatic to *Helicobacter pylori*, and it decreases markers of colonization and inflammation associated with *H. pylori* infection in humans and rodents, which is strongly associated with the development of gastric cancer. In addition, isothiocyanate activity against a range of soil-borne fungal, bacterial, and nematode plant pathogens is profound and has been extensively characterized. It underpins the burgeoning use of cruciferous plants as green manure and soil biofumigation to exploit the fungicidal and nematicidal activities of isothiocyanates.

Antinutritional Characteristics

Some antinutritional effects of isothiocyanates have been reported. In particular, hydrolysis of ß-hydroxyalkenyl glucosinolates (e.g., progoitrin and epi-progoitrin) gives rise to ß-hydroxyalkenyl isothiocyanates, which further cyclize to oxazolidine-2-thiones. These compounds may elicit goitrogenic effects in mammals, a phenomenon first observed in rabbits and described as 'cabbage' goiter. Efforts to suppress the goitrogenicity of rapeseed (*Brassica napus*), an oilseed crop of significant economic and agricultural importance, have led to the highly successful development of the oilseed crop canola in Canada and the 00-rapeseed in northern Europe. The

goitrogenicity of dietary glucosinolates and isothiocyanates in humans is much less clear in the context of normal dietary intake or even enthusiastic consumption.

Conclusion

Glucosinolates are amino acid-derived plant secondary metabolites whose role in plant defense has been well characterized. A wealth of evidence supports the assertion that glucosinolates and their isothiocyanate metabolites provide myriad beneficial health effects in humans as well. In the human dietary context, it is not abundantly clear whether delivery of the glucosinolate (which might be viewed as a prodrug in pharmaceutical terminology) leads to a very different outcome, but clearly, tissue exposure is different with ingestion of isothiocyanate versus glucosinolate. The induction of cytoprotective enzymes, inhibition of inflammatory processes, and modulation of signaling pathways are among the many diverse pharmacological outcomes ascribed to isothiocyanate exposure. Unlike most small-molecule pharmacological agents that affect single targets, the intracellular targets of isothiocyanates are multiple. The activation of transcription factor Nrf2 alone, a major outcome of isothiocyanate exposure, leads to an orchestrated regulation of a vast network of genes comprising approximately 2% of the human genome, with cytoprotective, antioxidant, and anti-inflammatory functions. It is this ability to induce versatile and long-lasting responses, which ultimately protect against oxidative stress, electrophilic stress, and chronic inflammation (the fundamental underlying causes of most chronic diseases), that makes these unique phytochemicals exceedingly efficient protective agents. Although cell culture and animal studies strongly support the beneficial health effects of glucosinolates and isothiocyanates, it is challenging yet critical to translate the findings to human populations.

It is noteworthy that many glucosinolate-containing genera comprise plants that have been used for food or medicinal purposes by various cultures for many centuries. In addition, many tropical and subtropical species have such a compelling ethnopharmacology and such manifold food and medicinal uses that future, more rigorous investigations of their glucosinolates' properties seem promising. Undoubtedly, research in the area of functional genomics will serve to enhance our knowledge and understanding of the diverse biological roles of these unique compounds.

Introduction

Milk has been part of our staple diet since the agricultural revolution, so eliminating its consumption has nutritional consequences. Milk supplies an economical source of nutrients and confers numerous health benefits: it plays a critical role in nutrition and health. In recent years, cow milk (CM) and its derived products have suffered poor public perception. People believe it to be high in fat and energy, with consequent negative health effects. In addition, heightened awareness of intolerant and allergic symptoms arising from CM consumption has led those affected to look for alternatives. The goat milk (GM) with its unique composition could be a valuable alternative.

A number of recent scientific studies have examined differences between CM and GM. Disparities in their fat, protein, and sugar composition may explain why an increasing number of GM consumers report significant health benefits including improved digestion and asthma and reduced catarrh and eczema. GM production ranks third after bovine and buffalo milk but it is the milk of choice in most of the world. Nutritionally, it is comparable to CM as it contains similar levels of calcium, potassium, phosphorus, and many other nutrients that confer health benefits.

Dairy goat farming plays an important role in the diet and economy of many developing countries. It serves as one of the principal sources of animal protein, calcium, and phosphorus in many regions, such as the Middle East, southern Asia, and some tropical countries. It is often recommended by medical professionals in situations where bovine milk may cause allergic responses in consumers. Although GM, like CM and human milk, contains lactose, many people with lactose intolerance can drink GM because of its lower amount of αs1-casein. It is a nutritious dairy option for many patients of different age groups and lifestyle needs. Young children and seniors can be especially sensitive to CM and so can certain ethnic groups, including Asians, Hispanics, African-Americans, and Native Americans.

GM is an excellent option for any patient who is CM- or soy milk-sensitive and is necessarily concerned with obtaining adequate calcium from a natural dietary source. It is also an excellent source of dietary calcium important in the prevention of high blood pressure, osteoporosis, and other bone-related problems. For menopausal women, GM provides 13% more calcium than CM and can be consumed comfortably even by those women with milk sensitivity. While it is often recommended that children who have problems digesting CM change to vegetable protein soy-based milk, that is not always the answer. An estimated 20–50% of children with CM protein intolerance will react adversely to soy proteins. GM is a natural milk that children like and can consume comfortably, even if they are sensitive to CM and/or soy milk. The nutrient composition of GM is very different from that of CM containing 13% more calcium, 25% more vitamin B_6, 47% more vitamin A, 134% more potassium, and 350% more niacin. GM is also higher in chloride, copper, and manganese and contains 27% more of the essential nutrient selenium.

GM contains none of the controversial bovine growth hormones. It is available nationwide in evaporated and powdered forms and in fresh one-quart, refrigerated cartons (whole and 1% low fat), as well as aseptic quarts with an unopened 8-month shelf life. Nevertheless, GM products are considered speciality foods and nowadays becoming more popular in developed countries. The GM industry will continue to grow in the near future for the well-being of hundreds of millions of people worldwide and may become an important part of the economy in many countries.

Composition

Research in the past decades has extended knowledge on the basic and unique features of the composition and properties of GM. Composition varies according to several factors, such as animal, breed, feed, age of lactation, stage of lactation, and environment.

Lipid Content of GM

Fat is present in milk as droplets of triglycerides surrounded by a complex membrane derived from the mammary epithelial cell called milk fat globule membrane. The percentage of total fat in goat and CM is quite similar, and the fatty acid composition depends to a large extent on the diet composition in both species. Fat globules of GM resemble those of CM in lipid composition and properties of the globule membrane, but GM lacks 'agglutinin' that causes fat globules of CM to cluster when cooled. The GM fat is composed of several hundred fatty acids, the share of which in the total FA pool is considerably differentiated. The share of five of those acids (C10:0, C14:0, C16:0, C18:0, and C:18-1 cis) comprises over 75% of total FA in milk. Five principal proteins of GM, α-lactalbumin, β-lactoglobulin, κ-casein, β-casein, and αs2-casein, closely resemble their homologue in CM. GM lacks a homologue of bovine βs1-casein, the most abundant protein in CM.

Casein micelles of GM contain more calcium and inorganic phosphorus, are less solvated and less heat-stable, and lose β-casein more readily than bovine micelles. Average GM fat differs in the contents of its fatty acids significantly from average CM fat, being much higher in butyric (C4:0), caproic (C6:0), caprylic (C8:0), capric (C10:0), lauric (C12:0), myristic (C14:0), palmitic (C16:0), and linoleic (C18:2) acids, but

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00358-5

lower in stearic (C18:0) and oleic (C18:1) acids. A characteristic trait distinguishing GM from CM is the relation between the lauric acid (C12:0) and capric acid (C10:0) (0.46% vs. 1.16% of sum of acids). This is an important indicator, as it may be used to detect falsifications of GM with CM.

In the fat of GM, saturated fatty acids are the dominating group and their share in the milk fat ranges from about 67% to about 75%. The high concentration of the acid in the GM fat is not a characteristic of this animal species, but of a majority of mammals. In turn, the share of monounsaturated fatty acids (MUFAs) in the total FA pool of the GM fat may range from about 20% to about 32%. Among the MUFAs, oleic acid (C18:1) is characterized by the highest content, which is typical for a majority of mammals. Three of the medium-chain triglycerides (MCTs) (C6–C14) have actually been named after goats, because of their predominance in GM. Capric acid, caprylic acid, and MCT have become established medical treatments for an array of clinical disorders, including malabsorption syndromes, chyluria, steatorrhea, hyperlipoproteinemia, premature infant feeding, children with failure to thrive, infant malnutrition, epilepsy, cystic fibrosis, and gallstones. They are recommended after intestinal resection and coronary bypass because of (a) their unique metabolic ability to provide direct energy instead of being deposited in adipose tissues, (b) their actions of lowering serum cholesterol, and (c) inhibiting and limiting cholesterol deposition.

GM exceeds CM in MUFAs, PUFAs, and MCTs, which all are known to be beneficial for human health, especially for cardiovascular conditions. This biomedical superiority has not been promoted much in marketing GM, goat yogurt, and goat cheeses, but has great potential in justifying the uniqueness of GM in human nutrition and medicine for treating the various gastrointestinal disorders and diseases, besides its value in alleviating CM allergies. Fatty acid composition of GM fat can also be changed toward even more of the beneficial fatty acids by different regimes of feed supplementation to goats including changes of forage-to-concentrate ratios.

Protein Content of GM

Dairy products are a reliable source of high-quality proteins, which are well balanced in amino acids. The variation of total protein content is now well known. For GM, it depends on genetic polymorphism of αs1-casein. CM and GM do not differ significantly as far as the protein percentage is concerned, and, in contrast to milk fat, the protein content in both species is less amenable to dietary manipulation. GM proteins differ in genetic polymorphisms and their frequencies in goat populations. The presence of the αs1-casein trait has been studied much in recent years, when it was discovered that it has six different types, A, B, C, E, F, and 'null' in GM. In CM, αs1-casein is the major αs-casein. The 'null' type or absence in some GM means that in different goats, the major αs-casein is the αs2-casein variant, which has different digestibility and cheese-making properties.

The differences in genetic types are due to amino acid substitutions in the protein chains, which in turn are responsible for the differences in digestibility, cheese-making properties, and flavors of GM products, but the amino acid substitutions also enable the detection of even small amounts of adulteration with CM. Peptides formed from GM casein by proteases tasted much less bitter than those from CM casein. Casein micelles, the form of casein molecule suspended in GM, also differ markedly from those of CM: they have less complete sedimentation rate, greater β-casein solubilization, smaller size of micelle, more calcium and phosphorus, less salvation, and low heat stability.

Carbohydrate Content of GM

Lactose is the main carbohydrate in GM comprising about 4.4%. Its concentration does not vary excessively. However, GM lactose content is often largely increased by dietary plant oil supplementation in contrast to CM. Lactose is a valuable nutrient, because it favors intestinal absorption of calcium, magnesium, and phosphorus and the utilization of vitamin D. Lactose is a disaccharide made up of a glucose and a galactose molecule, which may also be present in small free amounts. Lactose is of major importance for maintaining osmotic equilibrium between the blood stream and the alveolar cells of the mammary gland during milk synthesis. Lactose content of GM is about 0.2–0.5% less than that of CM. Carbohydrates other than lactose found in GM are oligosaccharides, glycopeptides, glycol–proteins, and nucleotide sugars in small amounts. Milk oligosaccharides have considerable antigenic properties and are valuable in the growth promotion of the intestinal flora of the newborn. Nucleotide sugars in milk are of particular interest, since they are the glycosyl donors for glycosyltransferase in milk and the mammary gland and are the precursors of glycoproteins, glycolipids, and oligosaccharides in the biosynthesis of milk.

Mineral Content of GM

Mineral content in GM is much higher than cow and human milk. It varies from 0.70% to 0.85%. GM is distinguished by its high chloride and potassium content. Partition of calcium, phosphorus, and magnesium between the soluble and colloidal phases of milk is similar for CM and GM. Iron bioavailability is higher in GM than in CM due to higher nucleotide content contributing to better absorption in the gut. Bioavailability for zinc was found higher in the case of human milk, lower values for sheep milk, and average values for GM and CM.

Vitamin Content of GM

As goats convert all β-carotene into vitamin A in the milk, GM has higher amounts of vitamin A than CM. Caprine milk is whiter than bovine milk. GM supplies adequate amounts of vitamin A and niacin and excesses of thiamin, riboflavin, and pantothenate for a human infant. The vitamin content of GM is similar to that of cow and human milk. Nevertheless, GM is poor in folic acid and vitamin E. GM lacks β-carotene, which is entirely converted into retinol.

Nutritional Properties of GM

Milk is a complex biological fluid produced by the mammary gland that has three main functions: (i) nutritional, (ii)

immunologic, and (iii) physiological. Traditionally, GM and CM have been considered a fundamental food in the diets of many cultures. Milk provides an easily accessible matrix, rich in a large variety of essential nutrients like minerals, vitamins, and easily digestible proteins with balanced amino acid profiles, important in supporting most body functions. Both human and animal studies indicate that GM fat is utilized more efficiently than CM fat. This feature of GM most likely relates to its unique enrichment in medium-chain fatty acids.

It has been demonstrated that the GM powder prevented the loss of the intestinal barrier function that follows heat stress in a rat model, which may relate to the peculiar lipid profile and the relatively higher content of oligosaccharides. Feeding GM also increased the biliary secretion of cholesterol and decreased plasma cholesterol levels in rats. Growing piglets fed with GM generally had higher bone mineral density, less body fat, and less fat mass than those fed with bovine milk. The greater bone density in the GM-fed piglets may have been due to the greater concentrations of plasma minerals, reflecting a better uptake of minerals. Taurine in goat and sheep milk derived from sulfur-containing amino acids has important metabolic functions as does carnitine, which is a valuable nutrient for the human neonate. Mineral and vitamin contents of goat and sheep milk are mostly higher than those of CM.

Growth Factors in GM

GM is an excellent source of physiologically active compounds known as growth factors. Human milk contains physiological levels of growth factors, while bovine milk has much lower growth factor activity (GFA). Colostrum of most mammals usually contains rich levels of growth factors and other bioactive compounds, whereas the levels of these molecules decrease rapidly during the first 3 days of lactation. Epidermal growth factor (EGF) was identified using antibody neutralization assays along with several other growth factors in human milk, including hepatocyte growth factor and vascular endothelial growth factor.

Growth factors in milk have been shown to be involved in the development of the neonatal gastrointestinal tract. The EGF enhances the establishment of the epithelial barrier in the gastrointestinal tract and protects the gastroduodenal mucosa by activating ornithine decarboxylase in polyamine synthesis. Growth factors can withstand the harsh conditions of gastric acid exposure and can be absorbed through the GI tract to act on other tissues. It was suggested that milk-derived growth factors may be useful as an orally administered treatment for a wide variety of gastrointestinal disorders. GM has a much higher level of GFA than that of CM, whereby GM may be a feasible nutraceutical for gastrointestinal disorders.

The presence of EGF in caprine milk was observed using a human EGF (hEGF) polyclonal antibody. Caprine milk also has been shown to possess the ability to reduce heat-induced gastrointestinal hyperpermeability. It was found that Nubian GM contained the highest GFA among the five breeds of dairy goats tested. It was showed that Nubian milk contained higher total protein and nonprotein nitrogen contents than the Alpine breed, which might be associated with the highest growth factor activity. It was also found that the milk of pregnant goats does have a significantly higher GFA than those of postpartum goats. The GFA decreased during the first 8 weeks of lactation, fluctuated thereafter, and then increased dramatically after natural mating. The GFA during weeks 1 to 8 was inversely correlated with milk yield and week of lactation, while no correlation was found during weeks 9 to 29. The GFA in the milk after natural mating of goats correlated significantly with somatic cell count and conductivity, but was inversely correlated with milk yield. By using dialysis and ultrafiltration with 50, 30, and 3 kDa cutoff membranes, it was reported that more than 90% GFA was present in the 50 kDa fraction, in contrast to the 6 kDa molecular weight of EGF (hEGF). The GFA of GM was around pH 6.3 fraction, which differed from the pH 4.6 of EGF. It proves that the major growth factor of the molecular fraction of GM was different from that of human milk.

GM Products

GM and its processed products are greatly useful as functional foods, maintaining nourishment and health for the young and elderly, especially those who have CM allergy. GM has also been known for its beneficial and therapeutic effects on the people who have CM allergy. These nutritional, health, and therapeutic benefits enlighten the potentials and values of GM and its specialty products. The chemical characteristics of GM can be used to manufacture a wide variety of products, including beverages (low fat, fortified, or flavored) and ultrahigh-temperature milk, fermented products (such as cheese, buttermilk, and yogurt), frozen products (such as ice cream or frozen yogurt), butter, condensed/dried products, sweets, and candies.

Nevertheless, high-quality products can only be produced from good quality GM. The quality milk should have the potential to tolerate technological treatments and be transformed into a product that satisfies the expectations of consumers, in terms of nutritional, hygienic, and sensory attributes. Taste is the main criteria used by consumers to make decisions to purchase and consume GM and its products. Typical goat taste is considered as a quality component in certain goat cheese products.

Cheeses from GM

Cheese may have been one of the first manufactured foods consumed by humans. History records its usage more than 4000 years ago, but no one really knows when the first GM was made into cheese. Goat cheese originated in Mesopotamia. The milk was probably made into soft cheese, and then hard, ripened goat cheeses were later developed in the Mediterranean Basin countries. There are goat cheeses made from raw and pasteurized milk. In many countries, the manufacture of goat cheese from raw milk is prohibited due to food safety issues (e.g., brucellosis). Numerous varieties of goat cheeses are produced worldwide. Maturation or ripening of cheeses from GM and milk from other species is governed by many different factors. Besides, manufacturing techniques include wide variations in amount and species of organism used in culturing, incubation procedures, and forming or pressing techniques. Variations in aging time and conditions play the most

important part in determining the flavor, body, and texture of cheese. The type of milk used significantly influences the finished cheese. Southern European countries are known for the production of most caprine and ovine milks worldwide. Almost all such raw milk is converted into cheeses. The cheesemaker often relies on adventitious lactic acid bacteria and nonstarter microflora to lower pH and bring about ripening. Artisanal production of regional cheeses is a part of the cultural heritage of many countries in Europe (e.g., Portugal and Spain).

Most artisanal cheeses obtained from ovine and caprine milks are seasonal, and peak production is in spring and lowest production is in fall. Increased logistic difficulties associated with artisanal production (e.g., exodus of farmers toward urban areas and suboptimal exploitation of complementary agriculture activities) have led to a drastic reduction in the numbers of persons associated with some artisanal cheese varieties. It is reported that the production of artisanal cheeses in the European Union countries has increased to 65% (on average) from 1984 to 1996, with an extremely high increase (223%) in Spain and a moderate increase (19%) in Portugal. The large number of varieties of cheese made from GM has resulted in a great diversity in the nature of the products.

GM whey cheese is especially popular in Norway, the process where caramelized lactose in concentrated whey is combined with fat and whey proteins to make Gjetost cheese. Ricotta is a kind of cheese that may be made from goat cheese whey; cheeses of a similar nature have other names when made in other countries. Brocciu is a whey cheese made by combining GM with the whey from goat cheese. Many traditional goat cheeses are made in developing countries.

Fermented Milks from GM

The proportion of GM processed into cheeses and yogurts is higher in comparison to CM. Since 5000 BC, the nutritional and health values of fermented milk and beverages were described. As a process, fermentation consists of the transformation of simple raw materials into a range of value-added products by utilizing the phenomenon of growth of microorganisms and/or their activities on milk. Kefir is a viscous, refreshing drink, with high acidity and varying amounts of alcohol and carbon dioxide.

Commercial production of kefir occurs in many countries, particularly in eastern Europe. It is also manufactured under a variety of names including kephir, kiaphur, kefer, knapon, kepi, and kippi, with homemade production occurring in countries as widespread as Argentina, Taiwan, Portugal, Turkey, and France. Kefir is still most familiar to consumers in eastern Europe. Kefir has had a long history of health benefits in eastern European countries, where it is associated with general well-being and often the first weaning food received by babies. Stimulation of the immune system, inhibition of tumor growth, antimicrobial properties, gastrointestinal tract benefits, and positive effects on cholesterol metabolism are among the health benefits of kefir. Dahi, an Indian fermented milk product, is also popular because of its nutritional and therapeutic value. Many traditional fermented GMs are made in developing countries.

Ice Cream and Desserts

Ice cream made from GM is an attractive alternative for children and other consumers due to its nutritional and antiallergenic properties and creamy organoleptic properties. Ice cream and frozen yogurt manufactured from GM are usually flavored. Vanilla, chocolate, and premium white chocolate mix are the most commonly used flavors. GM produces the most acceptable ice cream followed by CM with a softer texture and specific melting characteristics.

Chakka is a concentrated product obtained after draining the whey from Dahi (fermented milk product). Mixing of chakka with sugar and other condiments results in shrikhand, a very popular and traditional dessert in India.

Fat-Rich Dairy Products from GM

Cream is produced by mechanical agitation of the whole milk to separate the fat globules. The fat globules are aggregated to form a semisolid mass with 80–85% fat, transforming into butter. Cream and butter are manufactured from GM, but are almost entirely consumed by those seeking to avoid cow dairy products for health reasons. Butter milk is usually made from skim GM ($<0.5\%$ fat) using a by-product from butter processing. Traditional Turkish 'yayik' butter made from GM had the most acceptable organoleptic characteristics. Ghee or heat clarified butter fat or butter oil is a fat-rich product, mostly used as a cooking medium in India and other tropical countries. It is manufactured by fermenting whole milk into curd and churning out butter, followed by heat clarification at 105–145 °C. GM is not suitable for the manufacture of ghee because of the relatively small fat globules, which may present problems during cream separation.

Whey Products from GM

GM whey has higher levels of α-lactalbumin, but is often discarded or given to animals as nutritional supplement, and little information on it is available. However, presently, there are many products made from GM whey; among them are GM whey-flavored beverage, tablets (chewable), whey protein concentrate, and athletic supplements.

Other Food Usages of GM

In some countries, customers can find breakfast cereals with GM and baby food and sweet and salty pies made from GM and cheese. These products are increasing in variety and quantity. Industrialized whole GM is also used for pet consumption.

Conclusion

GM has a high nutritional content. It is a rich source of calcium, phosphorous, chlorine, and vitamins. It is highly digestible and has a mild laxative effect. It is a good source of vitamin B1, which is useful in relieving symptoms of stress (neurotic indigestion, constipation, and insomnia). It may be used to replace CM for those suffering from allergy. It has a higher fat content than CM and low cholesterol levels than CM, hence suitable for people with high blood pressure. It is low in sugar than CM, hence good

for those suffering from diabetes. GM is closer to human milk and is therefore easily accepted especially by those young or frail. It has an alkaline reaction like mother's milk. It does not form mucous (phlegm) and is therefore better tolerated by asthmatics and those with allergies.

Grapes

SA Dhekney, University of Wyoming, Sheridan, WY, USA

© 2016 Elsevier Ltd. All rights reserved.

Sources and Production

The grapevine is the most valuable fruit crop in the world and is grown widely for consumption as fresh fruit and processed products. A majority of the grapes produced worldwide are used for wine production followed by fresh consumption and other processed products such as jams, jelly, and juice.

The grapevine is believed to have originated and domesticated in areas of the Middle East and the Caucasus Mountains from where it spread to other regions of the world. The earliest chemical evidence of wine was obtained in the form of tartaric acid, an important component of wine, in jars believed to have been produced in 5400–5000 BC. Paintings in Egyptian civilizations depict grapevine cultivation and production of wine, which point to evidence of viticulture and wine production during this period. The grapevine was spread throughout Europe by the Romans and Greeks and introduced to the Americas in the sixteenth century. Grape is currently grown in subtropical and temperate regions of several countries with China, the United States, Italy, France, and Spain being the top five producers. Worldwide acreage under grapevine is currently estimated at 6.7 million ha with an annual production of 67 million tons.

Grape belongs to the *Vitaceae* family comprising 17 genera and more than 1000 species. The genus *Vitis* is of economic importance comprising approximately 60 species that are native to North America, Asia, and Europe. Although more than 3000 varieties, predominantly belonging to the *Vitis vinifera* group, are grown worldwide, approximately 35 elite varieties constitute more than 50% of the total acreage. 'Thompson Seedless' is the most popular grapevine cultivar worldwide for fresh consumption, while 'Chardonnay,' 'Cabernet Sauvignon,' 'Merlot,' and 'Shiraz' are popular wine cultivars.

A number of North American *Vitis* species have been used as parents in hybridization programs with *V. vinifera* to develop cultivars (commonly known as bunch grapes) with specific characteristics. For instance, *V. aestivalis* has been used as a source to develop grape cultivars with Pierce's disease resistance, a bacterial disease that limits the cultivation of pure *V. vinifera* cultivars in the southern United States. Popular grape cultivars developed from interspecific hybridization of *V. vinifera* and *V. labrusca* are used exclusively for the production of juice, jam, and jelly. A number of cold-hardy grapevine cultivars suitable for production in colder regions have been developed through breeding programs involving *V. riparia*. Several desirable traits such as drought, salt, and nematode tolerance have been exploited from North American species including *V. berlandieri*, *V. rupestris*, and *V. champinii* to develop rootstocks, which are extensively used to impart specific advantages under less than optimum growing conditions. *V. rotundifolia*, commonly known as the muscadine grape, is native to the Southeastern United States where it is commercially grown on more than 5000 acres for juice, jelly, and wine production. The muscadine grape exhibits greater tolerance to insects and diseases and performs better under hot and humid conditions where *V. vinifera* cannot be grown. A number of improved muscadine grape cultivars have been developed through conventional breeding; however, traits such as seedlessness and thin skin present in *V. vinifera* cultivars cannot be transferred to muscadine grape germplasm due to marginal sexual compatibility between the two species.

Vitis species are creeping vines that are supported by trellis systems in commercial production. Elite grapevine cultivars have an ancient pedigree and are exclusively propagated by clonal means. Hardwood cuttings obtained from 1-year-old growth are used for establishment of new vineyards. Vines established from hardwood cuttings can flower and bear fruit in the first year of planting itself, but commercial production can only be realized after 2–3 years. Flowering occurs from compound buds that develop in the current season to produce a crop for the subsequent season. Most commercial cultivars have perfect flowers; however, native species can be dioecious with male and female flowers borne on separate plants. Some muscadine grape cultivars have female flowers, which necessitates the planting of cultivars with perfect flowers to facilitate pollination and ensure sustainable yields. Bunch grape cultivars have fruit clusters comprising of 40–200 berries with varying size and color. Berries of muscadine grape are borne in small clusters of 3–10 berries with individual berries being much larger compared with those of bunch grapes. Berry development in grapevine can be separated into two phases. The first phase occurs from bloom to 60 days during which the berry is formed and increases in volume. Berry growth during this period coincides with the accumulation of acids (tartaric, malic, and hydroxycinnamic acids) and tannins in addition to other compounds, which contribute to the final wine quality. During the second developmental phase, the berry doubles in size leading to a decline in organic acids produced during the first phase. Color development in berries (veraison) is accompanied by accumulation of sugars and flavor and aroma compounds. Grape is classified as a nonclimacteric fruit, and harvesting occurs following completion of ripening. Grapes grown for wine or juice production are harvested mechanically, while table grapes destined for fresh consumption are harvested manually, graded, and then packed for ensuring high quality.

Patterns of Grape Consumption

Grape is either consumed fresh; processed into beverages, jam, and jelly; or dried to produce raisins. Grapes used for fresh consumption mainly include *V. vinifera* seedless grape cultivars, which are characterized by large-sized berries, high sugar content, mild flavor, and thin skin. A number of green and colored table grape cultivars developed from public and private

breeding programs are currently grown for fresh consumption. The muscadine grape is also used for fresh consumption in the Southeastern United States. Muscadine grape cultivars are characterized by a typical flavor and aroma, thick skin, and the presence of seeds. They differ significantly in nutritional composition compared with seedless table grapes and are considered to have higher levels of health beneficial compounds.

A majority of the grapes produced worldwide are crushed for wine production. Red wine is consumed in larger quantities than white wine. The United States is the largest wine consumer in the world followed by France and other European countries. While a majority of the wine produced and consumed contains alcohol, nonalcoholic wine is being increasingly consumed as the health benefits of various compounds present in wine are being identified. Grapes are also used for the production of other alcoholic beverages following distillation of fermented juice. Wine is extensively used for cooking purposes in addition to being consumed as a beverage.

A number of seeded and seedless grape cultivars are grown worldwide for the production of raisins. Raisin production consists of drying ripened grapes under natural conditions for 2–4 weeks until a change in color and significant decrease in moisture content occur. Drying emulsions are used in some cases to accelerate the drying process. Sulfur dioxide is also used during raisin production to prevent browning and preserve natural flavor and health beneficial compounds. 'Thompson Seedless' is most widely used for raisin production followed by other cultivars including 'Fiesta,' 'Zante currant,' 'DOVine,' and 'Muscat of Alexandria.'

Grape juice is largely produced from *V. labrusca*-based interspecific hybrid cultivars such as 'Concord,' 'Niagara,' and 'Delaware' with smaller quantities made from the muscadine grapes. Grape juice quality is governed by several factors including cultivar, management and harvesting procedures, and postharvest handling and processing. Processing of grapes to produce juice involves a hot-press or cold-press method where the crushed grapes are heated to 60–63 °C or used at room temperature for treating with pectinolytic enzymes to break down the pectins. Crushed and treated juice, and pulp, undergo further processing for obtaining the final product. Differences in yield and quality are observed between the two processing techniques. Grape juice concentrate is made by evaporating and concentrating grape juice to achieve 55–68% total soluble solids (TSS). Grape juice concentrate is used in fruit cocktails and as a sweetener in other food products. A substantial amount of juice concentrate is made from 'Thompson Seedless' in addition to the aforementioned cultivars. Other processed products include jam, jelly, and fruit spreads. Grape pomace left over following crushing and fermentation of berries accounts for 20–25% of the grape crushed for wine production. Grape pomace mainly consists of the skin, seed, and stems and has potential applications in the food industry. Grape pomace powder/flour is an optimum source of antioxidant dietary fiber when added to yogurt, salad dressings, and baked goods such as bread, muffins, and cookies. Components such as pectin, celluloses, and sugars are present in wine grape pomace and make it an ideal material for formation of edible films and coating to store fruits, vegetables, and food products. Additionally, the pomace can be ground into flour and used as a health supplement in the form of capsules. Grape pomace also has suitable applications as animal feed for ruminants and nonruminants. Grape seed extract and oil are increasingly being used as a health supplement and in the cosmetic industry. Grape seed extract is rich in a number of phenolic antioxidants and available as a dietary supplement in the form of capsules and liquid extract. Grape seed contains 13–19% oil that is rich in linoleic acid and vitamin E content and low in cholesterol, and its consumption may be beneficial in alleviating cardiovascular and circulatory disorders. Phenolic compounds, which are rich in grape seed, are found in low quantities in the oil; such compounds are lost during the extraction process. Grape leaves are widely used for cooking in Middle Eastern and Mediterranean cuisines. Tender leaves can be used fresh or canned in brine and used for cooking.

Availability, Absorption, and Metabolism

Grape and its processed products are a rich source of health beneficial compounds (Table 1). A number of phytochemicals are present in addition to water, sugars, acids, amino acids, and mineral elements. Glucose and fructose are the predominant sugars that contribute to its sweetness and converted to alcohol during the fermentation process. Thus, the amount of alcohol occurring in wine can be correlated to the amount of sugar initially present in the juice. Sugars predominantly accumulate during the later stages of fruit ripening. The final sugar content in berries varies widely with grape species and cultivars. Grape berries accumulate a significant amount of organic acids that include tartaric acid and those such as malic acid produced during respiratory catabolism of sugars during the early stages of berry development. The acid components are responsible for imparting the fresh and crisp taste of juice and wine. Grapes are also an important source of mineral elements and vitamins while having no sodium and cholesterol. Raisins produced by drying grapes are a rich source of energy, minerals, and vitamins. Grape and its products contain a number of phenolic compounds that mainly occur in the skin and seed of berries. Such compounds can be classified into simple phenolics, flavonoids, and stilbenoids. Simple phenolics are products of hydroxycinnamic and hydroxybenzoic acids that accumulate in berries during the early stages of development. A number of health beneficial flavonoids including flavones, flavonols, and anthocyanidins are found at varying levels in red and white grape cultivars. Stilbenoids are essentially located in the skin of grape berries and are predominantly found in red wine where the skin is retained during the fermentation process. Resveratrol is an important stilbenoid found in red wine. Wide variations are observed in the concentrations of phytochemicals among different *Vitis* species and cultivars. Total phenolic levels in muscadine grape are up to five times higher than those observed in bunch grapes, with greater levels found in the seed and skin compared to the pulp. Muscadine grape leaves exhibit up to 15 times greater antioxidant capacity compared to the skin, seed, and pulp of berries and have great potential for use in nutraceutical products. Another potential source of dietary supplements is the muscadine pomace that is discarded during the production of juice, jelly, and wine.

Wine is widely known for its health benefits and ranks among the top five beverages consumed worldwide. A number

Source: USDA national nutrient database, http://ndb.nal.usda.gov/ndb/.

of chemical constituents produced in berries accumulate in their concentrated forms during the production of wine. The chemical composition of wine has thus far revealed the presence of more than 500 compounds. Ethanol is the most prevalent alcohol in wine and ranges from 10 to 13% depending on the cultivar, the growing conditions, and the vinification process. Fortified wines may contain higher levels of alcohol. Anthocyanins are pigments responsible for wine color. Anthocyanins combine with other phenolic compounds to impart color stability to wine during the aging process. Tannins in wine are responsible for the astringency and bitterness occurring in wine. Levels of phytochemical compounds in wine vary widely with cultivar, soil, climate in which grapes are grown, and cultural operations adopted for grapevine production.

The beneficial effects of grape consumption depend on the availability of polyphenols present. A number of polyphenols present in red and white wines including anthocyanins and stilbenes are reported to be absorbed and metabolized. Absorption rates are influenced by chemical structure of such compounds, the amount ingested, and dietary sources. A few studies indicate that beneficial effects of wine are enhanced due to the presence of the alcohol component and an increase bioavailability can result from the fermentation process that occurs during the production of wine.

Health Effects

Grape and its products including juice, wine, and grape-derived dietary supplements are known to possess an array of health beneficial compounds. Wine is one of the oldest medicines in the history of mankind with potential applications for a number of aliments and disorders. Beneficial properties of grape products have been a subject of intense study for the past three decades since the formulation of the 'French paradox' concept in the 1980s by French epidemiologists. Studies indicated that the French had significantly lower levels of coronary

heart disease despite the consumption of food rich in fats and a poor lifestyle, which was attributed to the regular consumption of red wine. Studies also estimated that individuals who consumed no wine had a three to five times risk of mortality from heart disease compared with those who occasionally consumed wine. Critics of the 'French paradox' have put forth numerous aspects to contradict the findings including better socioeconomic class of wine consumers leading to a better lifestyle, inaccurate reporting of cardiovascular health disease by the French physicians, and an inability to separate the effects of alcohol and phytochemicals on improved health. A majority of the health benefits have been attributed to phytochemicals present in wine, which act in a variety of mechanisms to prevent or minimize inflammatory responses, thereby providing cardio-, neuro-, and chemoprotective properties. In general, greater health benefits are observed with red wine compared with white wine, and general recommendation for wine consumption includes a daily intake of 150 ml (one drink) for women and 300 ml (two drinks) for men. Such recommendations may however vary with age, genetics, body type, and daily medication/supplement use.

Benefits of cardiovascular health have been most widely reported in studies involving wine consumption. The cardioprotective properties of wine have been attributed to the alcoholic and nonalcoholic portions that contain antioxidants. Wine, rich in flavonoids and nonflavonoid polyphenols with potent antioxidant properties, may contribute to preventing atherosclerosis by inhibiting the oxidation of low-density lipoprotein and its subsequent buildup as plaques in arteries, which leads to clogging of arteries. Various phenolic compounds exhibit differential antioxidant capacities; thus, the antioxidant activity of wine is directly correlated with the content and level of polyphenols present. Such antioxidants may act early by preventing lipid oxidation of foods in the digestive system, suggesting that the best protection may be offered when wine is consumed along with a meal. Regular moderate consumption of wine has been associated with an increase in beneficial lipids, which impart cardioprotective properties. Wine consumption has also been correlated with decreased platelet activity and clumping, a reduction in blood pressure levels in case of hypertension, and decreased reactive oxygen molecules in the blood.

A number of phytochemicals present in wine and grape juice exhibit anticancer properties. Resveratrol is an important anti-inflammatory stilbenoid that has been intensively studied for its health beneficial properties in grape products. Resveratrol is the final product of the stilbene synthase pathway in grapevines and occurs at varying levels depending on the cultivar and vineyard management practices. Resveratrol has been shown to increase in concentration in response to pathogen infection and UV radiation of grapevines. Resveratrol exhibits antimutagenic and antiproliferative properties that contribute to prevention of tumor formation in a number of tissues. It also disrupts a number of inflammation-related pathways, thereby reducing overall inflammation and associated disorders including the development of cancer. The anticancer properties of resveratrol and other polyphenols are attributed to their ability to initiate changes in gene expression resulting in apoptosis or necrosis of cancer cells that ultimately decrease tumor initiation, promotion, and progression. Resveratrol has also been demonstrated to enhance the chemosensitivity of several types of cancers to chemotherapy due to its involvement in a number of stress signaling molecules. There are contradicting reports on the effect of resveratrol on breast cancer. Resveratrol has been suggested to exhibit either estrogenic or antiestrogenic properties in a dose-dependent manner; however, the affinity of these components towards estrogen receptor is extremely low, and their ability to compete with estrogen will be minimal. While higher concentrations can inhibit breast cancer, lower levels have shown to exhibit mammary tumor growth and metastasis in some animal models. Polyphenols from wine, and specifically merlot grape juice, were able to inhibit growth and tumor development of estrogen receptor-negative MDA-MB-231 cells in athymic nude mice. In other studies, muscadine grape skin extract was shown to inhibit prostate cancer cell growth and induce apoptosis without affecting growth of normal cells. Grape phytochemicals are known to exhibit antiproliferative properties with higher effects seen in colored berried cultivars containing greater polyphenols than white cultivars. Other chemicals including ellagic acid that occurs in muscadine grape, but not in wine grapes, are also known to exhibit anticancer properties. Antioxidants and fiber present in grape-derived dietary supplements may contribute towards a reduction in the prevalence of colon cancer.

Phytochemicals present in wine and other grape products have been linked to improved cognition and decreased risk of cognitive decline. Moderate wine consumption can impart protection against neurodegenerative diseases. Resveratrol may act as an antioxidant in neuronal cells, reduce oxidative stress, and prevent neural cell dysfunction and death, ultimately providing neuroprotection. It has also been shown to increase expression of genes associated with longevity. Other phytochemicals such as catechin and epicatechin gallate may suppress neuroinflammation and provide protection against Parkinson's disease, which occurs from brain injuries due to the production of endogenous neurotoxins. Anthocyanins may also improve cognitive brain function and provide neuroprotective abilities by reducing age-associated oxidative stress. Daily consumption of 'Concord' grape juice has been shown to provide cognitive and learning benefits probably from anti-inflammatory compounds present in the juice.

Other health benefits obtained from consuming grape products include a better control in blood sugar balance, insulin regulation, and increased insulin sensitivity; all leading to better management of diabetes. Grapes are classified as a low-glycemic index food and can be consumed by people who have difficulties in maintaining blood sugar balance. Regular consumption of dark-colored grape juice can improve immunity by significantly improving circulation of immune surveillance cells that are responsible for pathogen detection and serve as the immediate line of defense in pathogen attack. Grape seed extract that is used in a number of dietary supplements is known to exhibit antibacterial properties. Growth of several Gram-positive and Gram-negative bacteria was inhibited at varying concentrations of seed extracts, which was attributed to the presence of gallic acid in the extracts.

Growth Promoters: Characteristics and Determination

F Toldrá, Instituto de Agroquímica y Tecnología de Alimentos (CSIC), Valencia, Spain
M Reig, Universitat Politècnica de Valencia, Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Growth promoters are mainly used in farm animals with the purpose to promote growth, to improve the distribution of fat and protein, and to increase the feed-to-muscle conversion rate. However, some residues may remain in the tissues of the treated animals several days after its administration at toxicologically unacceptable concentrations. Other promoters like β-agonists affect consumers with certain phenomena like gross tremors of the extremities, tachycardia, nausea, headaches, and dizziness. This makes it necessary to provide accurate control rules and inspection services and analytic methodologies for safety assurance purposes.

Most growth promoters are orally active and can be administered either in the feed or in the drinking water, while other active hormones can be administered in the form of small implants into the subcutaneous tissue of the ears. This allows for slow release that may last for several weeks or even months and the ears are discarded at the slaughter. Growth promoters contribute to a better efficiency in the feed conversion rate. They allow for an increased protein deposition, partly due to muscle protease inhibition. The resulting meat is leaner and tougher due to the production of connective tissue and collagen cross-linking. Some fraudulent practices consist of the use of mixtures of several substances like β-agonists and corticosteroids at very low amounts in order to obtain a synergistic effect for a similar growth promotion but reducing the probability of detection by official control laboratories. This type of practice makes its detection rather difficult and justifies the need for advance analytic instrumentation.

Control

International and national legal bodies have established what is defined as maximum residue limits (MRLs) for substances allowed for veterinary use. These MRLs are derived from their respective acceptable daily intakes (ADIs) from foods of animal origin. In this way, the MRLs ensure that even at very high consumption patterns, there is no risk for consumers toward the intake of residues from such growth promoter. An MRL is set for each relevant food, like meat or liver, and for each relevant species. The reason is that the MRL is linked not only to the amount of the active substance remaining in the animal tissue at the end of the medical treatment but also to the amount of the daily consumption of the food. The MRLs may vary from country to country depending on the consumption patterns, the control services, and analytic methodology available. The withdrawal period or time period required for the active substance to decrease below the MRL is determined through depletion studies. Such withdrawal period guarantees that the foodstuff does not contain the given residues in quantities over its MRL. However, no MRLs are established for banned drugs, including carcinogenic substances, because there is no ADI.

Some outbreaks of residue-contaminated foods of animal origin have scared the consumers and increased the public's awareness of the use of growth promoters in farm animals. The possibility that some of such substances might exert carcinogenic, genotoxic, or other undesirable effects on health prompted the health authorities to establish accurate measures in order to ensure consumers' safety. Some growth promoters like estradiol, progesterone, and testosterone are allowed in the United States, but they are applied under strict measures, considering acceptable withdrawal periods. The use of certain growth promoters is also allowed in other countries like Canada, Mexico, Australia, and New Zealand. However, the use of growth promoters is officially banned since 1988 in the European Union where the monitoring of residues of substances having hormonal or thyreostatic action and β-agonists is regulated through the Council Directive 96/23/EC. **Table 1** lists the main veterinary drugs and substances with anabolic effect as defined in such directive. Group A includes unauthorized substances with anabolic effect, while group B includes veterinary drugs, some of them also exerting some growth-promoting effect and having established MRLs.

Commission Decision 2002/657/EC (EC, 2002) implemented the Council Directive 96/23/EC (EC, 1996) and is in force since 1 September 2004. This decision provides rules for the analytic methods to be used in the testing of official samples and specific common criteria for the interpretation of the analytic results of official control laboratories for such samples.

Characteristics

Growth-promoting agents are mainly based on anabolic agents added to improve feed conversion efficiency by increasing the lean-to-fat ratio. The main groups of substances are steroid hormones (androgens, gestagens, and estrogens) and other substances having hormonal action (testosterone, progesterone, trenbolone acetate, zeranol, and melengestrol acetate), resorcylic acid lactones, stilbenes (diethylstilbestrol), antithyroid agents, β-agonists (clenbuterol, mabuterol, cimaterol, salbutamol, etc.), and glucocorticoids (dexamethasone and corticosterone).

Other substances that exert a growth-promoting effect through an indirect action are antimicrobial agents. These substances might exert its growth promotion by making more nutrients available to the animal and not to the gut bacteria. However, this practice increases the abuse of antibiotics that has raised the concern of health authorities due to its contribution to the development of bacteria resistance to antibiotics. Some of these substances are β-lactams (penicillins,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00362-7

Table 1 List of substances having anabolic effect (group A) and veterinary drugs (group B) in accordance with the Council Directive 96/23/EC (EC, 1996)

Group A: Substances having anabolic effect	*Group B: Veterinary drugs and contaminants*
1. Stilbenes	1. Antibacterial substances
2. Antithyroid agents	Sulfonamides and quinolones
3. Steroids	2. Other veterinary drugs
Androgens	(a) Anthelmintics
Gestagens	(b) Anticoccidials, including nitroimidazoles
Estrogens	(c) Carbamates and pyrethroids
4. Resorcylic acid lactones	(d) Sedatives
5. β-Agonists	(e) Nonsteroidal anti-inflammatory drugs
6. Other compounds	(f) Other pharmacologically active substances

β-lactamase inhibitors, and cephalosporins), tetracyclines (tetracycline, oxytetracycline, and chlortetracycline), carbadox, and olaquindox, among others.

Sampling for Determination

Sampling

The choice of the target tissue or matrix is very important. It is advisable to choose the sample where the analyte is expected to accumulate (e.g., in the liver, kidney, and urine) because the concentrations are low and need very sensitive techniques for their detection. Of course, larger concentrations may be detected near the injection site. The sample must be chosen in a way that the result reflects the residue status of the laboratory sample and thus that of the sampled tissue or body fluid. A recommended practice is to portion the laboratory sample, either at the sample collection site or in the laboratory, for further analysis in case of doubtful results or any other analytic problem. This is usually done for legal inspection purposes where part of the sample is under custody for future contradictory analysis in case of need.

Sample Storage

The storage of samples is also very important because some time may elapse between the sample collection and analysis. The storage must be under correct freezing conditions ($-20\,^{\circ}C$) because not only some physicochemical reactions (like oxidation, proteolysis, and precipitation, even being covalently linked to proteins) but also microbiological or enzymatic reactions may occur.

Sample Extraction

The extraction must be focussed on the target analyte, considering not only the parent molecule but also its metabolites. The analyte may be extracted with aqueous buffers or organic solvents. However, some caution must be taken because most growth promoters may be conjugated as a way of detoxification, usually excreted through the urine and thus be present in the sample as conjugate forms (glucuronide or sulfate). It is necessary to hydrolyze the sample under mild conditions, typically achieved by incubating with *Helix pomatia* juice, which is a mixture of arylsulfatases and β-glucuronidases or any other hydrolysis procedure.

Solid matrices, including fat, kidney, liver, retina, and skin, are usually extracted by homogenization of the sample in the presence of solvents. Waring blenders, ULTRA-TURRAX, glass grinders, and stomachers can be used for homogenization; of course, heating of the sample must be avoided in order to preserve the integrity of the analyte. Sometimes, the sample can be ground in liquid nitrogen. Extraction is followed by cleanup in order to remove any matrix components that might be coextracted. The solid-phase extraction (SPE) is extensively used because the analyte can be isolated and concentrated in a single step with minimal sample and solvent consumption compared with the classic liquid–liquid extraction. SPE cartridges have evolved into miniaturized columns integrated in microwell assay plates and into disks consisting of membranes with high reversed-phase and ion exchange phase capacity. Immunoaffinity cartridges contain a support with linked antibodies for the specific target analyte that facilitates the affinity extraction with a high degree of specificity. An enormous concentration can be reached in a single step. Molecularly imprinted polymers (MIPs) are another alternative. MIPs can be synthesized from highly cross-linked polymers in the presence of the print molecule (a variant of the analyte). Removal of the print molecule leaves an imprinted sorbent for highly selective extraction of the analyte.

Other advanced extraction procedures are matrix solid-phase dispersion (simultaneous homogenization and extraction), microwave-assisted extraction (rapid heating of the solvent and accelerated extraction by reducing the needed time and consuming less solvent), supercritical fluid extraction (solvent extraction for lipophilic substances with carbon dioxide), and pressurized liquid extraction (fast and efficient extraction of the analyte). Once the analyte is extracted, the solution is concentrated by removing the excess of solvent by either evaporation or sublimation.

Analytical Determination

Analytic strategies are very important considering the wide variety of residues to be analyzed and the large number of samples to be analyzed in a short time. The initial phase usually consists of using low-cost screening methods having a high throughput and an acceptable false-positive incidence rate and a very low false-negative rate. Those noncompliant samples are then subject to further confirmatory methods that require expensive instrumental techniques, almost exclusively based on mass spectrometry (MS) detection, and highly skilled operators.

Those samples containing a residue at a concentration above the detection limit, or the CCα within the EU, are considered as noncompliant (positive). A sample containing a substance, which is above its MRL, will be also considered as noncompliant.

Screening Methods

Different types of screening methods are available and can be selected depending on the type of residues. The main types of screening techniques are listed in Table 2. So, residues of antimicrobial drugs can be screened with microbiological growth-inhibition assays like the EU Four-Plate Test, the New Dutch Kidney Test, and the Delvotest SP. The availability of relatively large amounts of immunoglobulins has also contributed to the development of a range of immunoassays (IAs) for many types of growth promoters and antimicrobials, including radioimmunoassays, enzyme IAs, enzyme-linked immunosorbent assays (ELISAs), and strip-based and dipstick-based IAs. Some of these assays are coupled to commercial instrumentation to facilitate its use and rapid obtention of the result. Other screening methods are based on the detection of an interaction between the biomolecule and analyte, like the surface plasmon resonance biosensors. Finally, high-performance liquid chromatography and more recently ultrahigh-pressure liquid chromatography (UHPLC) are also used for the screening of multiple residues in a sample in a relatively short time.

Confirmatory Methods

These methods are used as a next step for noncompliant samples. An internal standard is used to allow continuous assessment of the performance of the designed assay and to facilitate calibration in quantitative determinations. MS is the most reliable detection system. Hyphenated techniques, such as gas chromatography–MS (GC–MS), liquid chromatography (LC)–MS, LC–nuclear magnetic resonance (NMR), and GC–Fourier transfrom-infrared (FTIR), have been introduced as very powerful tools for the separation and molecular identification of residues. The main techniques are listed in Table 2, and the major advantages and disadvantages of confirmatory methods are summarized in Table 3.

In GC analysis, the universality and discriminative power of the MS using electron ionization as a universal source have led to this being the method of choice for some residues like steroids. In LC analysis, the atmospheric pressure ionization techniques (atmospheric pressure chemical ionization and electrospray ionization) coupled to triple quadrupole or linear ion traps have made MS the standard equipment in a residue analysis laboratory. Furthermore, the evolution of high-resolution MS (Fourier transform ion cyclotron resonance, magnetic sectors, orbitrap, and time of flight) is opening new prospects within the identification even though this does not always reach the required sensitivity.

Table 2 List of the main analytic techniques available for screening and confirmatory purposes

Screening methods	*Confirmatory methods*
Microbiological plate bioassays	Gas chromatography coupled to MS, MS–MS, or MS^n
Dipsticks or ELISA test kits	Liquid chromatography coupled to MS, MS–MS, or MS^n
Radioimmunoassay	UPLC coupled to MS, MS–MS, or MS^n
Multiarray biosensors	Liquid chromatography or UHPLC coupled to time of flight
High-performance thin-layer chromatography with full-scan UV/vis	Liquid chromatography or gas chromatography coupled to infrared spectrometry detection
Gas chromatography coupled to electron capture detector	
High-performance liquid chromatography (HPLC) coupled to UV/vis, DAD, or fluorescence detector	
Ultrahigh-performance liquid chromatography (UPLC) coupled to UV/vis, DAD, or fluorescence detector

Validation

Regulatory action can be taken only after unequivocal identification of the residue or its metabolite. When testing for the presence of a given prohibited substance or its metabolite(s), the control laboratories must comply with the minimum required performance level, which is an analytic parameter of technical performance based on the metabolism, stability, pharmacokinetics, and pharmacodynamics of the substance. The European Commission released the Commission Decision 2002/657/EC that describes the required quality performance criteria and guidelines for the interpretation of analytic results and validation of the methods. The Commission Decision 2002/657/EC also includes the decision limit (CCα), which is defined as the limit at and above that can be concluded with an error probability of α that a sample is noncompliant and the detection capability (CCβ) that is defined as the smallest content of the substance that may be detected, identified, and/or quantified in a sample with an error probability of β.

Topics that have to be assessed are trueness and precision of the result and specificity and selectivity of the method and its ruggedness. The validation of analytic methods is largely based on the fortification of control samples with a known quantity of the analyte. Finally, the Commission Decision 2002/657/EC also establishes the need to accomplish a number of the so-called identification points (IPs) for the correct identification

Table 3 Major advantages and disadvantages of current confirmatory methods

Advantages	*Disadvantages*
High sensitivity	Need of sample preparation (analyte extraction and purification)
High specificity	High initial investment (equipment)
Lots of information about the analyte	High maintenance costs
Short time (few minutes/sample) to obtain the results	Expertise required
Screening and confirmation in one injection	

Source: Toldrá, F. and Reig, M. (2014). Residue analysis. In: Devine, C. and Dikemann, M. (eds.) *Encyclopedia of meat sciences* (2nd ed.), vol. 1, pp. 217–221. London: Elsevier Science.

Table 4 Some examples of the number of identification points earned for different analytic techniques

Technique	*Number of ions*	*Identification points*
GC–MS electron ionization (EI) and chemical ionization (CI)	Two (EI) and two (CI)	4
GC–MS EI or CI	N	N
LC–MS	N	N
GC–MS–MS	One precursor and two daughters	4
LC–MS–MS	One precursor and two daughters	4
GC–MS–MS	Two precursor ions each with one daughter	5
LC–MS–MS–MS	One precursor, one daughter and two granddaughters	5.5

Source: EC (2002) Commission Decision 2002/657/EC of 17 August 2002 implementing Council Directive 96/23/EC concerning the performance of the analytical methods and the interpretation of results. *Official Journal of the European Community*, L 221, 8.

of the residue substance. Examples of the number of IPs earned when using different techniques are shown in **Table 4**. At least three IPs should be obtained for a satisfactory detection of a substance with MRL, whereas four IPs are needed for the positive identification of banned substances.

In summary, sensitivity and selectivity of the analytic methods will continue to improve in the next years thanks to the rapid developments in analytic instrumentation, especially in computerization and miniaturization so that the levels of detection will drop to very low ultratrace levels. The trends toward high-throughput techniques will continue so that more multiresidue methods will be developed with more analytes per sample to be analyzed per unit of time. New advanced biosensor systems, with microchips containing antibodies against many different analytes in one single chip, are also expected.

Guavas

KS Gill, Punjab Agricultural University, Ludhiana, India

© 2016 Elsevier Ltd. All rights reserved.

Scientific Classification

Kingdom: Plantae	Division: Magnoliophyta	Class: Magnoliopsida
Subclass: Rosidae	Order: Myrtales	Family: Myrtaceae
Subfamily: Myrtoideae	Genus: *Psidium* L.	

Introduction

Guava (*Psidium guajava* L.), the '*apple of the tropics*,' is considered to be one of the most exquisite, nutritionally valuable, and remunerative fruit crops of tropical and subtropical regions of the world. Guava fruits are relished world over for fresh consumption and processed into other delicacies. It outshines other tropical fruits in productivity, hardiness, adaptability, and nutritional value and ensures higher economic returns to the grower with minimal inputs. Guava cultivation is not seriously hampered by unfavorable weather patterns, namely, high temperature, low rainfall, marginal soils, waterlogging, and lack of quality inputs such as irrigation water and fertilizers. However, precise management is required to produce a profitable crop of good quality.

Guava originated in tropical America stretching from Mexico to Peru, but due to its wide adaptability, it is now grown throughout tropical and subtropical areas of the world. The English name 'guava' probably came from the Haitian name 'guajaba.' The Spaniards brought the crop across the Pacific to the Philippines and the Portuguese disseminated it to India. It spread rapidly and easily throughout the tropics by virtue of its abundant and highly viable seeds. Guava became naturalized to the extent that people in different regions consider that it is native to their own land. Today, the fruit can been found growing in more than 60 countries including some of the Mediterranean regions.

Guava cultivation became a commercial preposition in recent years, due to increasing international demand, for fresh and processed products with well-established market in more than 60 countries. India is the world's largest producer of guava followed by China, Kenya, Thailand, Indonesia, Pakistan, Mexico, Brazil, Bangladesh, Nigeria, the Philippines, Vietnam, and Egypt.

Botany

Guava is an important member of the family Myrtaceae. Some commercially important plants like cloves, eucalyptus, nutmeg, cinnamon, and java plum also belong to it. The genus *Psidium* consists of 150 species, but a few of them are of commercial importance and outgrow the others. The commercially cultivated guavas mostly belong to the *P. guajava* species. The characteristics of other important species of *Psidium* are as follows:

- *P. cattleianum* Sabine: It is a bushy ornamental shrub that may grow up to 7 m high. The bark is smooth and gray-brown in color and the young branchlets are cylindrical. The leaves are elliptic to obovate in outline, 5–7 cm in length, thick and leathery in texture, and deep green in color. The flowers are white, solitarily produced on axillary peduncles, and nearly about 2.5 cm in width. The calyx is lobed; the corolla is composed of four orbicular petals. The fruit is small, obovate to round in form, 2–3 cm in diameter, and purplish red in color, with a thin skin; the soft flesh is white toward the center and contains numerous hard seeds. The seeds are small and white in color and can be roasted as a substitute for coffee. The flavor is sweet and aromatic, suggesting that of strawberry. This species is more tolerant to low temperature than *P. guajava* L.
- *P. cattleianum* f. *lucidum*: This species is found in Hawaii. The tree height (up to 12 m) of this species is comparatively higher than that of Cattley or strawberry guava. Generally, it is propagated through seeds. The fruit is yellow in color and suitable for jelly making.
- *P. guineense* Swartz: It is a small tree or shrub of slender habit. The young branchlets are compressed, cylindrical, and finely hairy. The leaves are long-oval, acute or obtuse, and 8–12 cm long, with the lower surface pubescent. Red hairs are found on the midveins. Generally, 8–10 pairs of primary veins are found in one leaf. The flowers are borne upon a single peduncle, resembling that of *P. guajava*. The corolla is of creamy color with 5–7 petals and 150–185 stamens, and stigma is medium in size with 3–8 chambers in the ovary. Flowering occurs throughout the year. The fruit is round or nearly so, 2–3 cm in diameter, greenish-yellow in color, and rather hard when ripe, with whitish flesh containing numerous small seeds. The flavor is subacid and not as musky as that of *P. guajava*.
- *P. friedrichsthalianum* Berg: It is a shrub or small tree with square branchlets. Branches are thin and slender, with smooth brown to dark brown bark. Leaves are smooth, deep green, and oval or oblong–oval, with a prominent midrib below, pointed apex, and narrow base. Flowers appear axillary on young branchlets and solitary, with five petals and five locules in the ovary. It bears sulfur yellow, small-sized fruits. The fruits are globose in shape with high acid content. It can be used for jam and jelly making. Plants are tolerant to guava wilt.
- *P. montanum* Swartz: It is also called mountain guava found in the mountains of Jamaica. Its plants are similar to that of a shrub and attain a height of about 1.5 m, with flat-spreading branches; the branchlets of this species are square-angled; the leaves are oblong to oval and glabrous; apex is acuminate and spiny; and peduncles are with many flowers. The fruits are round in shape. The flesh is white with numerous seeds. Fruits are also poor in quality.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00363-9

- *P. molle* Bertd: The tree is small, similar to the size of a shrub. The leaves are green and obviate; the apex of the leaf is pointed. The lower surface of leaves is reddish and velvety. Red hairs are found on the central veins. Flowers occur in clusters of threes in leaf axils, with 5–11 petals and 196–239 stamens; stigma is long with a big ovary of 3–5 chambers. Its fruits are pale yellow in color and with an acidic white flesh. The seeds are numerous. Its fruits are small in size with an average weight of 13 g. It contains vitamin C at about 70 mg/100 g pulp.
- *P. pumilum*: The tree is pyramidal in shape. The leaves are small in size, light in color, and nonpubescent having 13–17 pairs of primary veins. There are seven petals, smooth and creamy color that drop immediately after anthesis. There are 252–327 stamens and small stigma with a medium-sized ovary having 4–5 chambers. It flowers twice in a year. It takes about 130 days before attaining the maturity of fruits. The average fruit weight is about 19 g and average vitamin C content is 171 mg/100 g of pulp.
- *P. cujavilis*: The growth characters and flowering habit of the plant are just like those of *P. guineense*. The fruit is small to medium, with an average weight of 30–50 g, and is sour in taste.
- *P. policarpum*: The growth characters are similar to those of *P. guajava* except the shape of the fruits is pyriform. The average fruit weight is about 200–250 g. The flavonoid pattern shows the close affinity between *P. guajava* and *P. molle*. However, in spite of the morphological similarities with *P. molle and P. guineense*, they show minute differences in flavonoid pattern.
- *P. araca* Raddi: It is found plenty in the uplands of Brazil. It is usually a large shrub, with young growth highly marked with hairs; its leaves are large oblong–oval with soft velvety pubescence above and dense pubescence below. The veins are conspicuous and reticulate. The flowers are axillary and formed in clusters of 1–3. The fruit is ovoid or oblong, is yellow in color, and is sweet when ripe.

Guava (*P. guajava* L.)

The Plant

The guava is a small tree or big shrub, which may grow up to 10 m. The plant grows into a symmetrical dome shape, with spreading and low branching canopy (Figure 1). It is a shallow-rooted small tree, branching close to the ground, and often heavily suckering from the base of the trunk. The trunk is slender with greenish brown scaly bark, which peels off in thin flakes from older branches and trunk. Its young twigs are quadrangular in shape. Its leaves are simple, opposite, 7–15 cm long, and 3–5 cm wide. They are oval to oblong–elliptic in shape, with short petioles, smooth, and light green in color. The leaves are finely pubescent below, with the venation conspicuously impressed on the upper surface. Depending on the climatic conditions, the flowering period can differ from one location to another. However, in the mild tropical climate region, the guava trees can bloom and bear fruit throughout the whole year, as long as the humidity and temperature do not become limiting factors. The flowers are perfect, epigynous, 25–30 mm in diameter with four incurved white petals, and a large tuft of white stamens with yellowish anthers borne solitary or in clusters of 2–3 in leaf axils on new growth from mature wood (Figure 2). Self-pollination is conspicuous (60–75%) since even isolated trees produce good crop; however, the distribution of cross-pollination by insects is about 35%.

Figure 1 A guava plant in bearing.

Figure 2 A flower of guava.

The Fruit

Botanically, the fruit of guava is a berry; its shape may vary from round to oblong, ovate, or pear. It may have rough to smooth skin and with small, hard or semihard seeds embedded in the center of the pulp. The skin color of ripe fruits ranges from pale green to bright yellow skin with or without a red blush. The flesh color varies from white, deep pink, to salmon red depending on the cultivar (Figure 3). The fruits of guava possess a strong, unique, and alluring flavor and aroma due to esters and terpenes. The predominant aroma volatile compounds in mature fruit consists of the esters (*Z*-3-hexenyl acetate, *E*-3-hexenyl acetate, ethyl hexanoate, and ethyl butanoate), 1,8-cineole, monoterpenes (myrcene and limonene), and sesquiterpenes (caryophyllene, α-humulene, and

Figure 3 Diversity in shapes and color among guava cultivars.

Figure 4 Fruits of guava 'Allahabad Safeda'.

β-bisabolene). However, the aroma compound profiles may vary with the stage of maturity and cultivar.

Cultivars

The cultivars of guava are classified into two broad categories, based on the fruit shape, namely, the pyriferum (the pear-shaped guava) and the pomiferum (the round-shaped guava), often called as pear guava and apple guava, respectively. They may be further grouped into red-fleshed or white-fleshed based on the flesh color of the ripe fruit. However, both types of cultivars are being grown commercially for fresh fruit and for processing purposes. There are about 400 cultivars of guava, but only a few of them under are commercial cultivation worldwide. 'Allahabad Safeda' (Figure 4) seems to be the world's most cultivated cultivar and is highly popular in India. It has a medium- to large-sized fruit, characterized by its thin, smooth skin; dense, white flesh; and only a few seeds, which makes it suitable for canning. The commercially important guava cultivars of different countries are listed in Table 1.

Table 1 Commercial cultivars of guava grown in various countries

Country	*Cultivars*
Australia	Indonesian Seedless, Allahabad Safeda, Lucknow-49, Beaumont, Ka Hua Kula, GA-11
Bangladesh	Swarupkathi, Mukundapuri, Kanchannagar, Kazi
Brazil	Paluma, Rica, Pedro Sato, Kumagai, Ogawa, Sassaoka, Yamamoto, Século XXI
Columbia	Puerto Rico, Rojo Africano, Extranjero, Trujillo Costa Rica, Tai-kuo-bar
Cuba	Enana Roja Cubana, EEA 1–23
Ecuador	Roja, Blanca, Crema
Egypt	Bassateen El Sabahia, Bassateen Edfina, Allahabad Safeda
India	Allahabad Safeda, Lucknow-49 (Sardar), Banarsi Surkha, Apple Color, Chittidar, Nasik, Dholka, Dharwar, Habshi, Seedless, Red-Fleshed, Behat Coconut
Indonesia	Indonesian Seedless, Indonesian White
Israel	Ben-Dov
Ivory Coast	Supreme, Elisabeth
Malaysia	Kampuchea, Jambu Kapri, Hong Kong Pink, Jambu biji, Putih; Maha 65, Bentong Seedless, Taiwan Pear
Mexico	Media China, Regional de Calvillo, China, la Labor, Acaponeta, Coyame, Kumagai, Paluma, Rica, White Ogawa, Red Ogawa
Pakistan	Safeda, Allahabad, Red-Fleshed, Seedless, Karela, Apple Color
Puerto Rico	Corozal Mixta, Corriente; Seedling 57-6-79 South Africa, Fan Retief, Frank Malherbe, TS-G2
Taiwan	Tai-kuo-bar, Chung-Shan, Shih-Chi, Li-Tzy, Red, Jen-Ju, Shuei-Jing
Thailand	Glom Sali, Glom Toon Klau, Khao Boon Soom
Trinidad	Centeno Prolific, Cayenne, Elisabeth
The United States (Hawaii)	Beaumont, Ka Hua Kula, Hong Kong Pink, Indonesian Seedless
The United States (Mainland)	Redland, Supreme, Red Indian, Ruby X, Miami Red, Miami White, Blitch, Patillo, Webber, Rolfs, Hart, Detwiler, Turnbull
Vietnam	Xa Ly Nghe, Ruot Hong Da Lang, Xa Ly Don

Source: Pommer, C. V., Murakami, K. R. N., and Watlington, F. (2006). A goiaba no mundo. *O Agronômico* **58**, 22–26; Singh, S. P. (2011). Guava (*Psidium guajava* L.). In: Yahia, E. M. (ed.) *Post-harvest biology and technology of tropical and subtropical fruits*. vol. 3. pp. 213–45. Cambridge, UK: Woodhead Publishing Limited

Climate and Soil Requirement

Guava can be successfully cultivated in tropical and subtropical climates. It can be grown in plains and submountainous regions provided with sufficient care and shelter against frost and cold winds during early stages of growth. The optimum temperature for guava production ranges between 23 °C and 28 °C. However, best quality guava fruit is obtained in the regions where low night temperature (10 °C) prevails in the winter months. Guava is fairly tolerant to high temperature and drought conditions but susceptible to severe frost as it may even kill the young plants. Annual rainfall ranging from 1000

to 2000 mm is ideal for guava cultivation, provided it should not coincide with the flowering and harvesting seasons.

Guava grows well in any type of soil ranging from alluvial to laterite, except severely waterlogged soils. However, for sustained commercial cultivation, it is better to grow these trees on fairly well-drained soils. It can tolerate pH ranging from 5.5 to 7.5. Shallow soils or those containing compacted layers may have adverse effect on growth and production. Ideally, guava prefers light sandy to clay loam soils; best quality guavas are produced in the river basins, which are known for their fertile top soil. Guava is one of the few tropical fruits that have some degree of tolerance to salinity.

Fruit Developmental Physiology

Guava is a climacteric fruit and exhibits a typical increase in respiration and ethylene production during the ripening period. Thus, it is a highly perishable fruit that completes its ripening process in just a few days after harvest at room temperature. Depending on the cultivar, guava fruits exhibit a change in skin color from green to yellow due to chlorophyll degradation during ripening. The flesh of the mature fruit changes color from white to creamy white, yellowish pink, deep pink, or salmon red depending on the presence of carotenoids, lycopene, and β-carotene. During different phases of guava maturation, ascorbic acid decreases while pectin methylesterase (PME)-specific activity increases with maturation.

A lot of physicochemical changes take place during the development of guava fruit. There is a gradual increase in fruit weight and volume up to the first 50 days after flowering, but the plant grows rapidly up to 100 days and then, the rate declines thereafter until maturity. Sugars build up in guava during ripening. Fructose content rises rapidly, but the glucose builds up slowly. The pectin content increases during fruit development but declines in overripe fruits mainly due to hydrolyzing action of pectin methylesterase. The extent of loss of total pectin content between cultivars correlates well with the differences in the rate of softening. The activities of the softening enzymes polygalacturonase (PG), PME, β-galactosidase, and cellulase increase with ripening.

Nutritional Value

Guava is highly nutritious, moderately good source of calcium and iron, and fairly rich in phosphorus. Its fruits contain high amounts of vitamins A, B_1 (thiamine), B_2 (riboflavin), and C (ascorbic acid). Vitamin C content of guava fruit is 2–5 times more than that of citrus. High concentration of pectin in guava fruit may play a significant role in the reduction of cholesterol and thereby decreases the risk of cardiovascular disease. Guava is an excellent source of dietary antioxidants; the skin is richer in ascorbic acid and phenols than the flesh. White-fleshed cultivars contain higher concentrations of ascorbic acid, phenols, and sugars compared with the red-fleshed cultivars. Red-fleshed guava is shown to be a richer source of lycopene, ascorbic acid, provitamin A, sulfur aroma compounds, and anthocyanins. Total phenol content is higher in seedless than seeded cultivars, while ascorbic acid was found higher in seeded cultivar.

Guava fruit is composed of 20% peel, 50% flesh, and 30% seed core. Guava fruit has a low caloric value (68 kcal/100 g) and protein (2.55 g) (Table 2). Mainly, the citric, malic, glycolic, tartaric, and lactic acids contribute toward the acidity of guava fruit. Guava cultivars differ in their sugar contents; fructose, glucose, and sucrose have been reported to be the predominant sugars in guava. Phenolic compounds decrease with firmness, more rapidly initially in white-fleshed than in pink-fleshed guava, but the content remains consistently higher than those of the latter. Guava fruit is one of the richest sources of pectin that is affected by variety, stage of maturity, and crop season. Upon hydrolysis, guava pectin dissociates into D-galacturonic acid (72%), D-galactose (12%), and L-arabinose (4%). Guava is a good source of antioxidant carotenoids (cryptoxanthin, lycopene, and β-carotene), and it contains about 140 μg retinol equivalents/100 g of provitamin A. Pulp and peel fractions are known to contain high contents of dietary fiber and extractable polyphenols. Frequent use of guava has been shown to have hypoglycemic effect. Therefore, guava can be ranked among the most nutritious and healthy fruits of the tropics and subtropics of the world.

Medicinal Uses of Guava

In addition to its use for fresh consumption, guava is also extensively used in folk and traditional medicine system

around the world. The plant is recognized for its antioxidant, hepatoprotective, antiallergic, antimicrobial, antigenotoxic, antiplasmodial, cytotoxic, antispasmodic, cardioactive, antispasmolytic, antidiabetic, anti-inflammatory, and antinociceptive activities, supporting its traditional uses worldwide. Different pharmacological experiments have identified many medicinally important phytoconstituents, with useful biological properties. These metabolites are mostly phenolic, flavonoid, carotenoid, terpenoid. and triterpenoid compounds. Extracts containing these metabolites, particularly those from leaves, bark, and fruits, possess useful medicinal properties (Table 3). The aqueous extracts of guava leaves are used in folk medicine for the treatment of various types of gastrointestinal disturbances such as vomiting, diarrhea, inhibition of the peristaltic reflex, gastroenteritis, spasmolytic activity, dysentery, abdominal distention, flatulence, and gastric pain. Guava plant finds its use in traditional medicine used as skin tonic and for the treatment of female reproductive problems like dysmenorrhea, miscarriages, uterine bleeding, and premature labor. The important active constituents are essential oils, flavonoids, carotenoids, polyphenolic compounds, pentacyclic triterpenoids, esters, and aldehydes. Leaf extract of guava possess strong antibacterial activity by virtue of its flavonoid glycosides, morin-3-*O*-α-L-lyxopyranoside, morin-3-*O*-α-L-arabinopyranoside, and quercetine-3-*O*-α-L-arabinopyranoside. Antidiarrhea effect is also contributed due to the content of quercetin. Among other major effects of the plant extract are antibacterial and trypanocidal activities, which may be attributed mainly to the broad antimicrobial property of the flavonoids and iron-chelating property of tannins. Traditionally, it is used to treat various conditions. Every part of the plant like leaves, roots, bark, and fruits is used for the medicinal use. The traditional uses are explained in the succeeding text according to the plant parts.

Root

In Fiji and Senegal, the roots of plant are used in the treatment of diarrhea, coughs, stomachache, dysentery, toothaches, indigestion, and constipation. The aqueous extract of root is used in the treatment of diarrhea and dysentery. The roots of the plant are used for their astringent property at a dose of 30–40 g for 1 l or 4–5 cups a day. In the Philippines, the

Table 3 The bioactive ingredient in different parts of guava plant and their medical uses

Part	*Bioactive constituents*	*Medical uses*
Fruit	Vitamin C; vitamin A; iron; calcium; manganese; phosphoric, oxalic, and malic acids; saponin combined with oleanolic acid Morin-3-*O*-α-L-lyxopyranoside and morin-3-*O*-α-L-arabinopyranoside, flavonoids, guaijavarin, quercetin Essential oil contains hexanal, 2,4-hexadienal, 3-hexenal, 2-hexenal, 3-hexenyl acetate, β-caryophyllene, nerolidol, 3-phenylpropyl acetate, caryophyllene oxide, pentane-2-thiol, 3-penten-2-ol, 2-butenyl acetate, 3-hydroxy-2-butanone, 3-methyl-1-butanol, 2,3-butanediol, 3-methylbutanoic acid, (*Z*)-3-hexen-1-ol, 6-methyl-5-hepten-2-one, limonene, octanol, ethyl octanoate (pink guava fruit)	Raw fruits: As astringent and treatment for diarrhea, ulcers, and wounds Ripe fruits: Treatment for anorexia, cholera, diarrhea, digestive problems, dysentery, gastric insufficiency, inflamed mucous membranes, laryngitis, swelling mouth, skin problems, sore throat, ulcers, vaginal discharge
Leaves	α-Pinene; β-pinene; limonene; menthol; terpinyl acetate; isopropyl alcohol; longicyclene; caryophyllene; β-bisabolene; caryophyllene oxide; β-copanene; farnesene; humulene; selinene; cardinene and curcumene; nerolidol; β-sitosterol; ursolic, crategolic, and guayavolic acids; cineol; quercetin; 3-L-4-4-arabinofuranoside (avicularin) and its 3-L-4-pyranoside; tannins; eugenol; caryophyllene; guajavolide and guavenoic acid (2 α-3 β-6 β-2,3-tetrahydroxy-12,20(30)-dien-28-oic acid); triterpenes such as oleanolic acid, triterpenoids; flavinone-2, 2′-ene; prenol; dihydrobenzophenanthridine; and cryptonine	Used as antiamoebic, anti-inflammatory, antispasmodic astringent, blood cleanser, febrifuge, gargle for sore throats and laryngitis, and treatment for bacterial infections, convulsions, cough, diabetes mellitus, diarrhea, dysentery, gastroenteritis, hypertension, itchy rashes caused by scabies, rheumatic pain, skin ulcers, vaginal irritation and discharge, sores, boils, sprains toothache, ulcers, and wounds
Bark	Polyphenols, resin, and crystals of calcium oxalate	Used as febrifuge, to expel the placenta after childbirth, as respiratory disturbance astringent, as a bath to treat skin ailments, and as treatment for colds, cough, hypoglycemia, affections of the skin, vaginal hemorrhage, wounds, dehydration
Root	Tannin, leucocyanidins, sterols, gallic acid, carbohydrates, salts, tannic acid	Used as skin tonic, treatment for painful menstruation, miscarriages, uterine bleeding, premature labor in women, wounds, diarrhea, coughs, stomachache, dysentery, toothaches, indigestion, constipation
Seed	Proteins, starch, oils, phenolics, flavonoid compounds, flavonol glycosides, quercetin-3-*O*-β-D-(2″-*O*-galloyglucoside)-4′-*O*-vinylpropionate	

Source: Joseph, B. and Mini, P. (2011). Review on nutritional, medicinal and pharmacological properties of guava (*Psidium guajava* Linn.). *International Journal of Pharmacy and Bioscience* **2**, 53–69; Gutiérrez, R. M. P., Mitchell, S. and Solis, R. V. (2008). *Psidium guajava*: a review of its traditional uses, phytochemistry and pharmacology. *Journal of Ethnopharmacology* **117**, 1–27

decoction and poultice of the root are used for the treatment of ulcers, wounds, and diarrhea.

Bark

The bark of the guava plant is extensively and anciently been used as astringent, febrifuge (antifever), and antiseptic properties. The decoction made from bark is used in the treatment of ulcers. The decoction and poultice form of the plant is used in Tahiti and Samoa to expel the placenta after childbirth and in the infection of the skin, caries, vaginal hemorrhage, wounds, and respiratory disturbances. In Kinshasa, the decoction form is also used to treat diarrhea and amoebic dysentery.

Leaf

The leaves of the plant have been known for the management of diarrhea, wounds, ulcer, toothache, stomachache, and diabetes. The infusion and decoction formulations of leaves are anciently used for the treatment of leucorrhea-like condition. Decoction of the leaves are used as gargles for sore throats, swelling of the mouth, laryngitis, external ulcer on the skin, and vaginal irritations in the Latin America, Central and West Africa, and Southeast Asia. Guava leaves possess anti-inflammatory properties and are also used in various lung problems. In addition to this, leaves are used in various bacterial infections, diarrhea, and blood cleansing. Leaf extract has also been reported to have the strong antimicrobial properties.

Fruit

Various evidences indicate that the ripe fruit of guava has laxative action, whereas the unripe fruit decoction is used as astringent and an antidiarrheic and has medicinal uses. It has been shown that fruit of *P. guajava* is used for the treatment of anorexia, cholera, diarrhea, digestive problems, dysentery, gastric insufficiency, inflamed mucous membranes, laryngitis, swelling of the mouth, skin problems, sore throat, ulcers, and vaginal discharge.

Harvesting and Postharvest Handling

Maturity of the fruits at the time of harvest determines its quality and storage life. The maturity of fruits is usually assessed on the basis of color, specific gravity, total soluble solids, acidity, etc. Fruits generally take 4–5 months after flowering to reach harvesting maturity, characterized by change in color from green to pale green. At the time of fruit harvest, the specific gravity of fruits becomes less than 1, that is, the mature fruits float in water. Various studies have reported that the fruits with specific gravity from 1.00 to 1.02 have better shelf life and tolerate long distance transport. Guava fruits are commonly picked by hand and carefully kept in containers under shade before transporting to grading and packing facility. Fruits stored in corrugated fiberboard boxes with ventilation and paper lining can be stored at 6–8 ° C with 85–90% relative humidity for 20 days.

Processing

Being a highly perishable fruit, guava is processed into a number of products to extend its availability throughout the year. Ascorbic acid content in these processed products is generally less than the fresh fruits as the losses during processing are inevitable. Ascorbic acid is highly heat-labile and the most critical factors in determining its stability in fruits are the storage temperature and duration. Guava can be either processed into juice, jam, jelly, squash, concentrate, toffee, etc., or preserved as pulp, canned as slices and dehydrated products, etc. The selection of guava cultivar for processing depends upon its quality characters like pulp, sugar/acid ratio, pectin, tannins, and vitamin C content. Some important processed products of guava are briefly discussed later in the text.

Puree

Guava puree is preferably made from slightly overripe guava fruits having yellow skin, soft flesh, and intense musky aroma. Both seriously spoiled and underripe fruits are sorted out from the lot meant for making puree. The underripened fruits are kept aside for further ripening. Fruits that meet the standards are washed and processed in a paddle pulper fitted with 0.008–0.11 cm screens. This pulp is then passed through a finisher fitted with 0.05 cm screens to remove stone cells. The fine puree thus obtained is deaerated and pasteurized for 60 s at 90 °C. This end product can be canned, preserved by freezing to −29 °C and storing at −18 °C, or aseptically packaged or dehydrated.

Juice

Guava juice is recognized for its refreshing taste and thirst-quenching and high nutritive value. Guava juice can be produced either from fresh fruits or from puree. Fully ripe fruits are cut into small pieces and supplemented with 0.2 g citric acid and 250 ml water/kg of fruit. The mix is cooked while stirring constantly and strained through a muslin cloth. The juice/extract thus obtained is collected and packed aseptically in bottles. Juice yield can be increased by using pectic enzymes. Similarly, juice can be prepared from the puree/pulp by diluting it with water followed by filtration. Guava juice is reported to have 11% TSS, 6.64% total sugars, 6.02% reducing sugars, 0.76% acidity, 3.85 pH, 243 mg/100 g ascorbic acid, and 1.02% pectin. Guava juice can be further processed and utilized for producing concentrates, beverages, jelly, powder, and other products.

Concentrate

It is convenient to make concentrate from guava puree or juice for facilitating overseas shipment and long-term storage. The equipments required for this purpose include a falling film evaporator, a rising film evaporator, and a centrifugal evaporator. Guava puree is treated with pectic enzymes before concentration to reduce its viscosity. This treated puree can then be easily concentrated to 34°Brix, whereas the clarified juice can be concentrated to 66°Brix as it remains flowable in an evaporator. The loss of flavor during evaporation is compensated by cutting back the product to a lower concentration or by diluting it with single-strength fresh-pasteurized puree or clarified juice.

Nectar

Guava nectar is a popular beverage that can be prepared from puree, clarified juice, or concentrate with sugar syrup, citric acid, and other flavoring additives. It is prepared using pulp, soluble solids, and acidity at a rate of 15%, 14%, and 0.25%, respectively. The nectar can be supplemented with vitamin C (100 mg/100 g). Guava nectar can also be diluted four times with water to prepare quality-bottled ready to serve (RTS) beverage. Guava nectar needs homogenization for maintaining consistency during storage. Then, it is either pasteurized or commercially sterilized for better shelf life. Under ambient storage conditions, canned guava nectar has a shelf life of 6 months.

Canned guava

It is another important product of guava that is quite popular in India, Pakistan, and Indonesia. The fruits are preserved by canning as halves or quarters. Fully ripe but firm guava fruits are either peeled with a knife or lye-peeled (by dipping for 15 s in boiling solution of 2.5% sodium hydroxide). After rinsing with water, it is dipped in 0.5% solution of citric acid to neutralize the remaining alkali. The fruit is cut into halves or quarters and the seed core is removed to obtain the shells. The cut pieces are dipped for 5 min in 2% brine solution and then canned in 40°Brix sugar syrup containing 0.25% citric acid. The cans are sealed, sterilized in boiling water for 20–25 min, and then cooled to room temperature.

Jelly

Guava jelly is a major product prepared from the guava fruits. Slightly underripe guava fruits are ideal for making jelly. The fruits are crushed and juice is extracted as explained earlier in the text. The juice is decanted and boiled with sugar for jelly making, whereas the pulp is used for the preparation of guava cheese. The quantity of sugar needed for making jelly depends on the pectin content of juice, which generally varies from 0.75 kg sugar/kg of pectin-rich juice to 0.5 kg sugar/kg of low-pectin juice. Boiling is continued until it forms a sheet when a small portion is cooled off in a spoon. This hot jelly is then filled into glass jars and sealed.

Guava fruit leather (or cheese)

Better quality cheese is prepared from fresh fruits rather than leftover pulp from jelly making. Firm ripe fruits are washed, sliced, and cooked in equal amounts of water for about 45 min. The pulp thus obtained is screened through a muslin cloth or filtered to remove the skins and the seeds. This pulp is supplemented with 1.25–1.50 kg sugar, 2.2–3.3 g citric acid, and 56 g butter per kilogram of fruit pulp. The mixture is cooked to a thick paste and small amounts of permitted color and common salt are added to improve the appearance of the final product. The hot cheese is spread on a greasy tray and is allowed to set. After cooling, it is cut into small pieces and wrapped in moisture-proof paper. This cheese can be stored at 4 °C for about 4 months without the loss of sensory quality.

Dehydrated guava products

Guava slices or chunks can be dehydrated by air-drying or osmotic dehydration. In air-drying technique, the guava slices are blanched in boiling water for 4 min, sulfured for 20 min, and then air-dried at 70 °C until final moisture level of 6–7% is achieved. Glazed guava slices are prepared by osmotic dehydration technique. Guava slices are heated in an equal amount of 70°Brix sugar syrup containing 0.1% KMS at 90 °C for 3 min. After cooling to room temperature, this mixture is allowed to stay overnight. Then, slices are drained and spread in glycerin-coated trays for drying at 80 °C for 1 h. The air temperature is then lowered to 65–70 °C for the next 7–8 h. The end product is packed in air-tight containers.

Future Development and Uses

Most of the nutritional and medicinal uses of guava are based on the traditional knowledge and very little is known about its bioactive ingredients. A detailed research is needed to identify and enhance these beneficial biomolecules so that it may be efficiently used to cure health problems. A few things that are needed for its further development and use are as follows:

- Dedicated breeding operations for developing the varieties for specific and dedicated use, namely, fresh consumption, processing, and medicinal uses.
- Colored varieties of guava are known to be more nutritionally rich, which calls for development of such cultivars packed with antioxidants.
- Identification, extraction, and isolation of the specific and medicinally important biomolecules need to be done from all parts of the plant.
- Biotechnological interventions are required to further enhance the content of medicinal and nutritional components in the plant.

Gums: Dietary Importance

CA Edwards, University of Glasgow, Glasgow, UK

© 2016 Elsevier Ltd. All rights reserved.

This article is reproduced from the *Encyclopedia of Food Sciences and Nutrition*, volume 5, pp. 3007–3011, © 2003, Elsevier Science Ltd., with an updated Bibliography section supplied by the Editor.

Background

The dietary importance of gums is related to their effects at various sites in the gastrointestinal tract from the stomach to the large intestine. Most of their actions in the upper gut have been related to the development of a high viscosity in the gut lumen. However, gums in natural foods may not be released in sufficient quantities to increase luminal viscosity. Isolated gums or foods fortified with gums, however, can have very significant effects on nutrient absorption and postprandial plasma nutrient levels. Other important effects relate to the fermentation of the gums by the microflora in the large intestine. A high intake of particular gums may help in the treatment of constipation and diabetes and in the prevention of colon cancer. However, only the benefits for treating constipation have been well established, and more research is needed in their use for other conditions.

Physiochemical Properties and Physiological Action

In this context, the term 'gum' covers a wide range of polysaccharide molecules that have varied structures, physical properties, and physiological actions. The term, for the most part, could be interchanged with 'soluble nonstarch polysaccharide' or soluble dietary fiber. There are many different dietary sources of gums. They are found naturally in plant cell walls (pectins and hemicelluloses) and as plant exudates (gum arabic) or mucilages (ispaghula[1]) and are produced by some bacteria (xylan) and algae (alginates). The effects of gums on human physiology will depend on whether the gum is ingested as part of a plant cell wall, as part of a food complex, or as an isolated polysaccharide.

Most, but not all, gums produce viscous solutions in their isolated form, and some (such as pectin) have cation-exchange properties. The extent of the viscosity or cation exchange depends on the length of the molecule and the constituent sugars. The physiological action of such gums in the diet can therefore vary enormously and may differ from one dietary source to another. If the gum is ingested within the framework of a plant cell wall, as with pectin in carrots, the pectin may not be released in sufficient amounts to have a significant action on small intestinal function but may still be available for fermentation in the large intestine. In addition, the cation-exchange properties of an isolated pectin may be greater than pectin contained in a food because the potential binding sites may already be taken up by minerals or other charged molecules found in the food matrix.

[1]The terms 'ispaghula' and 'psyllium' (used later) are interchangeable.

Another important consideration is the amount of gum ingested. The amount in foods, or added as stabilizers, emulsifiers, and fat substitutes, is small, and most of the effects described in the succeeding text require a substantial intake of isolated gum. For example, the standard dose of ispaghula for the treatment of constipation is 3–11 g per day. The dose recommended for the action of guar gum on small intestinal absorption is 15 g per day, whereas the amount of pectin in carrots is 1.5 g per 100 g, and there is only a trace of gums in ice cream.

The physical characteristics of each gum are determined by sugar composition as well as the order of sugars and degree of modification, e.g., the degree of methylation of pectin. Viscosity results from the entangling of free carbohydrate chains. This requires a disorganized network, and so the viscosity of gums is determined by their molecular weight and the degree of irregular versus regular sugar patterns, the latter allowing more ordered cross-linkage between chains.

The gums have a range of physiological and nutritional effects (Table 1) mediated mostly through effects on transit through the stomach, small intestine, and colon, by reducing mixing actions in the gut; by their actions on the interaction between nutrients, enzymes, and mucosal cells; and finally as a result of their fermentation by the colonic microflora.

Effects in the Stomach and Small Intestine

The effects of isolated gums on gastric emptying and digestion and absorption have been well studied. The effects of the same gums in foods are less well established. Viscous gums eaten as part of a mainly liquid meal can slow gastric emptying by

Table 1 Properties of gums that affect human physiology and health

Property	*Consequence*	*Main examples*
Viscosity	Slower absorption Lower blood glucose Reduced cholesterol Increased satiety	Guar gum, pectin, ispaghula (psyllium), oat gum
Cation exchange	Binding of minerals Binding bile acids Reduced cholesterol	Pectin
Fermentability	SCFA production Low colonic pH Altered microflora	Oat gum, pectin, guar gum
Butyrate production	Colonic fuel Colonic health Possibly anticancer	Oat gum
Stool bulking	Reduced constipation Dilution of carcinogens	Ispaghula (psyllium), gellan

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00365-2

making the liquid meal of a more solid consistency. Guar gum, which has one of the highest viscosities, can delay gastric emptying half time by 60%. However, it has also been shown that increased viscosity can facilitate the emptying of discrete solids. In this case, they may act as lubricants and ease passage through the small 2 mm opening of the pyloric sphincter.

In the small intestine, the main impact of increased viscosity is to resist the movement of the intestinal contractions, reducing the mixing of the digestive enzymes with their substrates and inhibiting the movement of the nutrients to the absorptive epithelium. This can give the impression of an increase in the thickness of the unstirred water layer adjacent to the intestinal mucosa, through which nutrients must pass by diffusion. These two effects, along with slowed gastric emptying, can delay the process of digestion and absorption, resulting in decreased postprandial glycemia and potentially reducing fat absorption.

In addition, the viscous matrix of a gum solution can trap endogenous molecules such as bile acids. Bile acids are essential for the emulsification of fats to allow digestion and for the formation of micelles to facilitate movement of the products of fat digestion to the mucosa for absorption. A decrease in bile acid concentration will therefore disrupt and delay fat digestion. If cation-exchange properties persist, then the bile acids may be bound to the charged gum, and this will have an additional impact in fat digestion. The trapped bile acids, if not released in the large intestine during fermentation, are excreted in feces, which will result in reduced plasma cholesterol as replacement bile acids are synthesized from this precursor.

There are, however, some problems with this simplistic explanation of the effects of viscous gums on postprandial glucose and fat absorption. The viscosity shown in *in vitro* models to delay digestion and reduce mobility of nutrients may not be achieved in the part of the small intestine where most digestion and absorption occur.

Most digestion occurs in the duodenum and jejunum. When foods enter the duodenum, pancreatic secretion of large amounts of bicarbonate- and enzyme-rich juice is stimulated. This relatively large volume of fluid will dilute the small intestinal contents and considerably reduce the concentration and therefore the viscosity of the food gum. The relationship between concentration and viscosity is not linear but exponential, and changes in concentration can have a major impact on the viscosity maintained. Experiments in rats have failed to find any large increases in upper small intestinal viscosity after ingestion of large amounts of guar gum. The gums are not digested, however, so the viscosity is regained as the nutrients and fluid are absorbed. Thus, the viscosity in the ileum where bile acids are reabsorbed, as part of the enterohepatic circulation, will be much higher. It is well established, however, that postprandial blood glucose is reduced considerably after ingestion of gums. Bread containing lower-molecular-weight guar still has the action of reducing postprandial glycemia, again suggesting that viscosity may not be the critical factor.

Blood Glucose and Diabetes Mellitus

In the past, the use of gums such as isolated solutions of guar gum to reduce the rise in postprandial blood glucose was thought to be of some therapeutic use in diabetes mellitus. Although the effects of guar gum reducing postprandial hyperglycemia and insulinemia are well established, this approach in treating diabetics was not very successful, as the gum solutions used had poor organoleptic properties with an undesirable mouthfeel and aftertaste. Since then, the incorporation of gums such as guar and oat gum in bread products has been explored. It has been found that very palatable breads with proved effects on intestinal absorption rate can be produced, but their use in the diabetic diet has still to be established. There has also been much recent interest in the production and action of cereal products containing oat β-glucans, ispaghula (psyllium), and konjac mannan.

Therapeutic Enteral Diets

Sometimes, patients, including children, have a problem in dealing with normal foods and are fed with a simplified synthetic fluid diet of easily assimilated nutrients. These diets often have to be liquid to allow administration through tubes directly into the gastrointestinal tract. Until recently, these elemental or polymeric diets have contained no source of dietary fiber. This can result in constipation and, after prolonged use, produce atrophy of the colonic mucosa. Some of these liquid diets have now been formulated with soluble gums as a source of dietary fiber to prevent these symptoms and to maintain a healthy microflora. The gums used include soy polysaccharide, pectin, and carboxymethylcellulose.

Effect of Gums on Plasma Cholesterol

Heart disease is one of the major killers of the developed world, and one of the main risk factors is high plasma low-density lipoprotein (LDL) cholesterol coupled with low high-density lipoprotein (HDL) cholesterol. HDL cholesterol is associated with clearance of sterol from the peripheral tissues to the liver. Many of the viscous food gums (oat, pectin, guar, psyllium, and others) have been shown to have a significant and long-term effect in reducing LDL cholesterol while having little effect on, or increasing, HDL cholesterol. The effect of the gums is modest but may be of significance in reducing the risk of heart disease.

It is not clear by which mechanisms the gums act (Table 2). They could reduce fat digestion either directly or by interfering

Table 2 Possible mechanisms for the effect of gums on serum cholesterol

Inhibition of fat digestion
Viscosity inhibits mixing of enzymes and lipids
Viscosity/cation exchange traps/binds bile acids
Viscosity inhibits the formation of micelles
Viscosity inhibits the movement of micelles
Increased bile acid synthesis from cholesterol
Binding of bile acids by cation exchange, viscosity
Increased fecal bile acid losses
Increased fecal cholesterol losses
Inhibited cholesterol absorption
Increased intestinal cell losses
Decreased cholesterol synthesis
Inhibition of hepatic cholesterol synthesis by propionic acid (probably only a pharmacological effect)

with micelle formation. Although there is likely to be only a small increase in total fat losses, the delaying of fat absorption can result in a change in the type of chylomicra or lipoproteins produced. For those gums like pectin with cation-exchange properties, the bile acids may be bound to the carbohydrate molecule, which are then excreted in the feces. Viscous fibers without cation exchange may also trap bile acids within their matrix. Several gums, including guar, pectin, and ispaghula (psyllium), have been shown to increase fecal bile acid losses, and this has been associated with reduced cholesterol. However, if the fiber is fermented, the bile acid would be released in the large intestine where they could be converted to secondary bile acids and returned to the bile acid pool. Moreover, low-molecular-weight (and therefore low-viscosity) guar gum in bread still reduced cholesterol, and not all studies demonstrating an effect on cholesterol show an increase in fecal bile acid. If fecal bile acid losses are increased, cholesterol in the liver is used to replace them, and hence, plasma cholesterol falls.

Cholesterol levels could also be decreased due to the higher fecal losses of cholesterol from increased intestinal cell loss seen with viscous fibers, and there has been much discussion about the potential actions of propionic acid produced from the fermentation of the gums. However, the inhibitory effects of propionic acid on hepatic cholesterol synthesis appear to require pharmacological levels of propionate rather than those that are produced from the fermentation of food gums under normal conditions. Acetate is a precursor of fat synthesis and lactulose, a highly fermentable saccharide, increased serum LDL cholesterol when fed to healthy volunteers. This was associated with higher levels of serum acetate in some subjects. It is evident that the actions of gums on serum cholesterol are mediated by different mechanisms for individual gums and for the same gums under different circumstances.

Satiety and Obesity

If gums had a major effect on satiety, they could be a useful adjunct to the prevention and treatment of the increasing public health problem of obesity. However, although highly viscous gums such as guar have been shown to increase satiety and even promote some weight loss in short-term studies, the unpalatability of such gums and the moderate effects they have on weight make them of unlikely benefit in weight-loss or weight-maintenance programs.

Gums and Mineral Bioavailability

Some food gums with cation-exchange properties have been shown *in vitro* to bind minerals such as calcium. Even those gums without direct binding sites may still entrap these minerals and delay or inhibit their absorption. *In vivo* human studies have shown an increase in fecal mineral output, but the overall mineral balance is not affected in adults. The effect in young children is unknown and is one of the reasons why a high dietary fiber intake has not been encouraged in the under-fives. However, there is no evidence of significant mineral imbalance in children on high-fiber diets, and the effects are unlikely to be great. Moreover, there are several studies now suggesting increased calcium absorption in the large intestine, perhaps encouraged by the reduced pH from the bacterial fermentation of soluble fiber.

Effects of Gums in the Large Intestine

Most food gums are readily fermented in the large intestine of man by the diverse and dense microflora. The products and consequences of this fermentation may have a major influence on human health, and these effects may outweigh the impact of the food gums in the small intestine.

Colonic Fermentation

The human colonic microflora is thought to contain over 400 different species (perhaps even more as new molecular techniques, which measure bacterial DNA and rRNA, are discovering that the majority of bacterial groups have never been cultured). The mainly anaerobic bacteria use the carbohydrates to produce short-chain fatty acids (SCFA), mostly acetic, propionic, and butyric acids, and the gases CO_2, H_2, CH_4, and H_2S. Colonic pH is also determined by the balance between the rate of fermentation and the buffering of the SCFA by bicarbonate exchanged when the SCFA are absorbed.

The fermentability of each gum depends on its structure and water solubility. The presence of bacteria with the required enzymes for each step of gum degradation is also essential. The degradation and fermentation of a complex carbohydrate structure may be the result of a synergy between several bacterial species, and some of the enzymes may take time to be expressed either by induction of enzymes, in originally predominant bacteria, or by an increase in dominance by new groups. It has been shown in rats that it can take many weeks before the colonic microflora is truly adapted to the introduction of a new gum into the diet.

The extent and rate of fermentation of food gums are important. The rate of fermentation may determine the site of SCFA production. Most colonic disease occurs in the distal colon, and yet, most fermentation occurs in the proximal colon. Therefore, food gums that are slowly fermented may encourage prolonged fermentation and SCFA at more distal sites.

The pattern of SCFA produced from each gum also differs. Pectin increases the proportion of acetic acid produced, guar gum and ispaghula tend to promote the production of propionic acid, and oat gum increases the production of butyric acid.

Health Impact of Increased Colonic Fermentation

The colonic fermentation of carbohydrates including food gums can result in a substantial fall in colonic luminal pH. There are several benefits of reduced colonic pH, which include the inhibition of undesirable bacterial activities such as 7α-dehydroxylase, which forms secondary bile acids that can help to promote cancer. Reduced colonic pH can also lead to precipitation of fatty acids, sterols, and other molecules, which have been implicated as procarcinogens. Low pH also reduces the rate of colonic cell proliferation, thought to be a risk factor for colon cancer. However, the SCFA produced during

fermentation can stimulate cell proliferation, and so under normal conditions, the effects of pH here may be canceled out. It has been noted, however, that populations in South Africa with a low risk of colonic cancer also have a lower colonic and fecal pH than those from high-risk populations.

The side effects of increased colonic fermentation and of ingestion of large amounts of food gums include flatulence and abdominal distention. These are usually associated with eating large amounts of fermentable material but may reduce over time as the colonic microflora adapts to the new carbohydrate substrate supply and adopts a more efficient fermentation process. This may take over a week.

The SCFA have many potential actions that are generally beneficial for health. They promote the absorption of water and electrolytes and inhibit the growth of pathogens, reducing the risk of diarrhea. They all stimulate cell proliferation throughout the gut, even though they are produced in the large intestine, and this may be important for wound healing after gut surgery or after gastrointestinal disease. In addition to these general effects, each fatty acid has its own idiosyncratic actions.

Actions of Individual SCFA

Acetic Acid

Acetic acid is always the main SCFA produced, usually making up 50–70% of the SCFA. Acetic acid is the only SCFA to reach the systemic circulation in significant amounts. It can provide energy for muscles and other tissues and is noninsulinogenic. Acetate has less effect on the colonic enterocytes in terms of proliferation and motility than the other SCFA. Pectin has been shown to increase the proportion of acetate when fermented by fecal bacteria *in vitro*. Acetate produced during pectin ingestion may also beneficially affect fibrin network architecture in patients with hypercholesterolemia, reducing the risk of heart disease.

Propionic Acid

Propionic acid is usually the second most abundant SCFA produced during fermentation. Propionic acid is absorbed into the portal vein but is mainly removed by the liver. It is gluconeogenic, unlike the other SCFA, and was previously thought to inhibit cholesterol synthesis by the liver. However, although this effect has been well demonstrated under experimental conditions, it is now thought that not enough propionic acid is formed in the colon and absorbed into the portal vain to have this effect. However, it is worth noting that those gums that are associated with cholesterol-lowering effects are often those that promote propionate production.

Butyrate

Butyric acid is the preferred fuel for the colonic enterocyte. It has also been associated with several potential anticancer properties. An increase in the rate of colonic cell proliferation is believed to be a risk factor for cancer. However, all cells in the colon are programmed with a time to die by a controlled process called apoptosis. It is probably the balance between the levels of proliferation and apoptosis that determine whether a cancer will or will not develop. Although butyrate has been shown to stimulate cell proliferation of normal colonic cells, it has been shown to stimulate apoptosis in cancer cells *in vitro*. It may also affect other important stages in carcinogenesis such as the promotion of cell differentiation and inhibition of histone deacetylase, which may promote DNA repair.

Gums as Prebiotics

There has been much recent interest in the beneficial health effects of certain strains of lactic acid bacteria or probiotics believed to have various health benefits. These include reducing the duration of rotavirus diarrhea, reducing eczema in atopic infants, and potentially having protective actions against intestinal diseases, including colitis and cancer. These probiotics are usually bifidobacteria, lactobacilli, or streptococci but may include certain strains of *E. coli*. The survival of these bacteria in the gut can be enhanced by the presence of certain fermentable carbohydrates. These are called 'prebiotics,' but to fulfill the definition, carbohydrates must selectively increase the populations of the probiotic organisms. The most accepted prebiotics are fructooligosaccharides and resistant starch, but some gums may also increase bacterial populations.

Calories from Fermentation of Gums

SCFA produced from fermentation can be used by the colonic cells and other body tissues for fuel. It is now recognized that dietary fibers, including gums, contribute energy, but the exact amount depends on the fermentability and any increased fecal nitrogen losses. After absorption, the SCFA have to be acylated before entering the major metabolic pathways, and this also has an energy cost. It is now estimated that, on average, fermentation provides 8.4 kJ (2 kcal) per gram of carbohydrate.

Constipation

If a dietary gum is poorly fermented, it may have sufficient residual water-holding capacity to increase stool output. Ispaghula (psyllium), which has a water-holding capacity of approximately $7\ g\ g^{-1}$, has been used successfully to treat mild to moderate constipation for many years. Gellan, a bacterially produced gum, has also been shown to be a potent stool bulker but is not used therapeutically. Other gums such as karaya and xanthan, which are slowly fermented, may increase stool wet weight and fecal SCFA without increasing stool solids.

Gums: Properties and Uses

PA Williams, Glyndwr University, Wrexham, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The term 'gums' refers to a range of natural polymers, mainly polysaccharides, that are widely used in the food industry to control the rheological and organoleptic properties of food products. They are employed to perform a number of functions including the thickening and gelling of products; the stabilization of foams, emulsions, and dispersions; the inhibition of ice and sugar crystal formation; and the controlled release of active compounds such as flavors and antioxidants. An area of considerable current interest is in the application of gums as edible films, which can be used to coat fruit and vegetables and hence increase their shelf life. Their film-forming properties are also facilitating their application in biodegradable packaging. The commercially important gums are listed in Table 1 together with their source, function, and market size. It is evident that the market is dominated by starch and gelatin.

The international numbering system (INS) for food additives has been developed so that additives approved for food use can be identified on food labels as an alternative to listing their names. In the European Union, they are referred to as E numbers, and where both INS and E numbers are available, they are interchangeable. The list of INS numbers are given in Tables 2 and 3.

Although gums have primarily been used in foods to control texture, organoleptic properties, and stability, consumers are now being made increasingly aware of their nutritional and health benefits. Many gums, including locust bean gum, guar gum, konjac mannan, gum arabic, xanthan gum, and pectin, have been shown to reduce blood cholesterol levels. In addition, the nonstarch polysaccharide gums are resistant to human digestive enzymes and pass through the stomach and small intestine without being metabolized. They are fermented in the large bowel to yield short-chain fatty acids, thus lowering the risk of colon cancer. Gums are nowadays widely used for fat replacement in a wide range of low-calorie products. They may be added in their natural form or as specifically fabricated microparticulates and serve to enhance the rheological properties of low-fat products.

Functional Characteristics

Gums will dissolve or swell in water, although in many cases, high temperature and vigorous agitation are required before complete dissolution is achieved. The solutions formed are usually thick and viscous even at very low concentrations (1%). There are, however, notable exceptions, for example, gum arabic solutions only become viscous at concentrations of ~50%. The viscosity of polymer solutions generally shows a marked increase at a critical polymer concentration, commonly referred to as C*, which corresponds to the concentration at which the polymer molecules start to touch and interpenetrate due to molecular crowding. C* decreases with increasing hydrodynamic volume of the gum molecules, which in turn is influenced by their molecular mass, shape, and charge density. Hence, high-molecular-mass, linear molecules possessing ionizable groups tend to be good thickeners.

Gum solutions normally exhibit Newtonian behavior at concentrations well below C*, that is, their viscosity is independent of the rate of shear. However, above C*, non-Newtonian behavior is usually observed, and the viscosity–shear rate profiles show three distinct regions, that is, a high-viscosity, low-shear Newtonian plateau (at shear rates typically $<1\ s^{-1}$), a shear-thinning region ($\sim 1–1000\ s^{-1}$), and a low-viscosity high-shear Newtonian plateau (typically $>1000\ s^{-1}$).

Some gums, notably xanthan gum, have a tendency to undergo weak intermolecular association in solution leading to the formation of a three-dimensional network structure, thus giving rise to a very high viscosity. The junction zones formed can be readily disrupted even at very low shear rates resulting in a dramatic drop in viscosity. Other polysaccharides self-associate and form stable junction zones, and as a consequence, strong gel structures are produced. The gels are referred to as 'physical gels' because the junction zones are formed through physical interaction, for example, by hydrogen bonding, hydrophobic association, and cation-mediated cross-linking, and differ from synthetic polymer gels, which normally consist of covalently cross-linked polymer chains.

Some gums form thermoreversible gels and examples exist where gelation occurs on cooling or heating. Some form non-thermoreversible gels. In such cases, gelation may be induced by cross-linking polymer chains with divalent cations. Gels may be optically clear or turbid and a range of textures can be obtained. Gel formation occurs above a critical minimum concentration, which is specific for each gum. Agarose, for example, will form gels at concentrations as low as 0.2%, while for acid-thinned starch, a concentration of ~15% is required. Typically, however, concentrations of less than 1% are required. Gel strength increases with increasing concentration.

Mixtures of gums are commonly used to impart novel textural characteristics to food products, and an added incentive is a reduction in costs. Classic examples include the addition of locust bean gum to kappa carrageenan to yield softer more transparent gels and also the addition of locust bean gum to xanthan gum to induce gel formation.

Gums are effective at either inducing or preventing flocculation in particulate dispersions. If insufficient gum is present to coat all the particles fully, aggregation occurs owing to polymer adsorbing onto two or more particles simultaneously, thus inducing bridging. If the particles are fully coated, particle aggregation is prevented by 'steric repulsion,' which arises as a result of interaction between the adsorbed polymer layers. Although nonadsorbed gum is generally considered to enhance the stability of dispersions (and emulsions) by increasing the viscosity of the aqueous phase, it can have the opposite effect and give rise to 'depletion flocculation.' This

Table 1 The main commercial gums

Gum	*Source*	*Principal function*	*Global market value $ million*[a]
Agar	Algae	Gelling agent	219
Alginate, (sodium)	Algae	Gelling agent	272
Propylene glycol alginate		Emulsifier and foam stabilizer	
Gum arabic	Tree gum exudate	Emulsifier	147
Carrageenan	Algae	Gelling agent	561
Processed *Eucheuma* seaweed		Gelling agent	
Carboxymethyl cellulose	Trees, cotton	Thickener	169
Hydroxypropyl cellulose		Thickener and emulsifier	80
Methyl cellulose		Thickener, emulsifier, and gelling agent	
Cellulose (microcrystalline)	Trees	Thickener and gelling agent	91
Gelatin	A protein obtained from the skins and bones of cattle and pigs and skins of fish	Gelling agent	1030
Gellan gum	Bacterial cell wall	Gelling agent	
Guar gum	Plant seeds	Thickener	94
Karaya	Tree gum exudate	Thickener	
Konjac mannan	Tuber	Thickener and gelling agent	
Locust bean gum	Plant seeds	Thickener	85
Pectin	Plant cell wall	Gelling agent	658
Amidated pectin		Gelling agent	
Starch (modified)	Plant seeds, roots, tubers, stem piths	Thickener and gelling agent	1275
Tragacanth	Tree gum exudate	Thickener	
Xanthan gum	Bacterial cell wall	Thickener	277

phenomenon occurs as a consequence of polymer molecules being excluded from the space between approaching particles. The difference in osmotic pressure between the depleted region and the bulk solution results in weak interparticle attractive forces, which induce aggregation.

Some gums, such as gum arabic, methylcellulose, and propylene glycol alginate, show amphiphilic character that has led to their use in the stabilization of emulsions and foams owing to their affinity to adsorb at the oil–water or air–water interface.

In systems containing sugar or ice crystals, gums can retard crystal growth either by adsorbing onto the crystals or by competing for available water molecules.

Properties and Uses of Individual Gums

Tree Gum Exudates

The four main tree gum exudates are gum arabic, gum karaya, gum tragacanth, and gum ghatti, with gum arabic being, by far, the most important commercially.

Gum arabic occurs as a sticky liquid that oozes from the stems and branches of acacia trees (*Acacia senegal* and *Acacia seyal*), which grow across the Sahelian belt of Africa, principally Sudan. The liquid dries in the sun to form glassy nodules, which are collected by hand. The gum from *Acacia senegal*, traditionally the main source of gum arabic, is a complex polysaccharide consisting of galactopyranose (~44%), arabinopyranose, arabinofuranose (~25%), rhamnopyranose (~14%), glucuropyranosyl uronic acid (~15.5%), and 4-O methyl glucuropyranosyl uronic acid (~1.5%). It also contains a small amount (~2%) of protein as an integral part of the structure. Analysis of the carbohydrate structure has shown that it consists of a core of (1,3)-β-D-galactose units with extensive branching at the C6 position. The branches consist of galactose and arabinose and terminate with rhamnose and glucuronic acid. As a consequence of the highly branched structure, viscous solutions are only formed at high gum concentrations (~50%w/w). The gum consists of three fractions that have been shown to differ principally in their molecular mass and protein contents. Most of the gum (~90%) contains very little protein and has a molecular mass of ~250 000 Da. A second fraction (~10% of the total) contains ~10% protein and has a molecular mass of ~1–2 MDa and has been shown to have a 'wattle blossom'-type structure where blocks of carbohydrates of molecular mass ~40 000 Da are connected to a common polypeptide chain. The third fraction (~1% of the total) contains up to 50% protein and has a molecular mass of ~250 000 Da. Fraction 2 has been shown to be responsible for the gum's excellent ability to stabilize oil-in-water emulsions. It has been proposed that the hydrophobic polypeptide chains adsorb onto the oil droplets and anchor the molecules to the surface, while the hydrophilic carbohydrate blocks protrude out into solution and prevent droplet aggregation and coalescence due to electrosteric repulsions. Its ability to act as an emulsifier has led to its use in stabilizing flavor oil emulsion concentrates for the soft drink

Table 2 INS numbers for polysaccharide gum additives

Polysaccharide	*INS number*
Alginic acid	400
Sodium alginate	401
Potassium alginate	402
Ammonium alginate	403
Calcium alginate	404
Propylene glycol alginate (propane-1,2-diol alginate)	405
Agar	406
Carrageenan (including furcellaran)	407
Processed *Eucheuma* seaweed	407a
Bakers yeast glycan	408
Arabinogalactan	409
Locust bean gum	410
Oat gum	411
Guar gum	412
Gum tragacanth	413
Gum arabic (acacia gum)	414
Xanthan gum	415
Gum karaya	416
Tara gum	417
Gellan gum	418
Gum ghatti	419
Curdlan gum	424
Konjac flour	425
Soybean hemicellulose	426
Pectins	440
Cellulose	460
Microcrystalline cellulose	460(i)
Powdered cellulose	460(ii)
Methyl cellulose	461
Ethyl cellulose	462
Hydroxypropyl cellulose	463
Hydroxypropyl methylcellulose	464
Methyl ethyl cellulose	465
Sodium carboxymethyl cellulose	466
Ethyl hydroxyethyl cellulose	467
Cross-linked sodium carboxymethyl cellulose	468
Sodium carboxymethyl cellulose, enzymatically hydrolyzed	469

Certain gums not included either are classed as food ingredients (e.g., gelatin) or have yet to complete the regulatory process.

Table 3 INS numbers for modified starches

*Modified starch**	*INS number*
Dextrin (roasted starch)	1400
Acid-treated starch	1401
Alkali-treated starch	1402
Bleached starch	1403
Oxidized starch	1404
Monostarch phosphate	1410
Distarch phosphate	1412
Phosphated distarch phosphate	1413
Acetylated starch	1414
Starch acetate	1420
Acetylated distarch adipate	1422
Hydroxypropyl starch	1440
Hydroxypropyl distarch phosphate	1442
Starch sodium octenyl succinate	1450
Starch, enzyme-treated	1405

*The Codex General Standard for the Labelling of Prepackaged Foods specifies that modified starches may be declared as such in a list of ingredients. However, certain countries require specific identification and use these numbers.

industry and also in the production of spray-dried encapsulated flavors for use in dry packaged products such as soup and cake mixes. In the latter case, the gum forms a film around the flavor particle, preventing oxidation and evaporation, and the gum's high solubility facilitates rapid flavor release. The ability of gum arabic to form concentrated solutions of low viscosity has led to its widespread use in confectionery products, particularly those with high sugar content such as pastilles where it functions by reducing sugar crystallization.

Gum tragacanth is obtained from shrubs of the *Astragalus* species notably *A. gummifer* and *A. microcephalus*, which are found in the dry mountainous areas in Iran and Turkey. It consists of a water-swellable fraction called tragacanthic acid (or bassorin) (60–70%) and a water-soluble fraction called tragacanthin. The former consists of a main chain of (1,4)-α-D-galactopyranosyl uronic acid residues with branches linked through (1,3)-β-D-xylose units terminating in L-fucopyranose. The latter is a highly branched arabinogalactan with a main chain of D-galactopyranosyl units either (1,6)- or (1,3)-linked with side chains consisting mainly of L-arabinofuranose but with a small proportion of D-galacturonic acid and L-rhamnose. Gum tragacanth gives rise to high-viscosity solutions even at 1% concentration. The viscosity decreases irreversibly on heating. The gum solution is stable under acid conditions and shows good emulsification characteristics, which has led to its use in salad dressings and sauces. Its cost and availability, however, have meant that it has been largely replaced in these products by other gums, notably xanthan gum. Gum tragacanth is still widely used in decorative icings for cakes.

Gum karaya is a gum obtained from *Sterculia urens* trees found in the highlands of central and northern India. It is a heavily acetylated polysaccharide composed of chains of α-D-galacturonic acid and α-L-rhamnose. The acid groups are glycosylated with β-D-galactose or β-D-glucuronic acid residues, whereas about half of the rhamnose groups carry β-D-galactose units as side chains. Gum karaya swells in water to yield highly viscous solutions; however, the solutions show a permanent loss in viscosity on heating. The gum finds some application in salad dressings.

Gum ghatti is obtained from *Anogeissus latifolia*, which is a large deciduous tree that grows in India. It has a main chain of alternating (1,4)-β-D-glucopyranosyl uronic acid and (1,2)-α-D-mannopyranose units and contains numerous side chains of L-arabinose, D-galactose, and D-glucuronic acid. It contains a water-soluble (>80%) and water-swellable fraction and was originally developed at the turn of the century as a replacement for gum arabic since it forms solutions of low viscosity at high concentrations and is also a good emulsifier.

Cellulosics

Cellulose is the most abundant of all the polysaccharides being the structural component of land plants. It is composed of linear chains of (1,4)-β-D-glucopyranose units that are

associated with hydrogen bonding giving rise to a number of crystalline forms. Although it is insoluble in water, it can be chemically modified to form a number of water-soluble derivatives with valuable functional properties. Derivatization usually involves etherification of the reactive hydroxyl groups on the glucose residues. The most common water-soluble cellulose derivatives used in food applications are carboxymethyl cellulose (CMC), methyl cellulose (MC), and hydroxypropyl methylcellulose (HPMC). Derivatization is carried out following the conversion of the cellulose to the sodium form by treatment with concentrated alkali. This process destroys the crystalline structure and yields alkali cellulose. The alkali cellulose is then reacted with the appropriate reagent, namely, sodium monochloroacetate for CMC, methyl chloride for MC, and methyl chloride/propylene oxide for HPMC. Since the reactions are heterogeneous, substitution can be very irregular.

CMC is the most widely used of the cellulose ethers and can be obtained in various grades, which vary in molecular mass and degree of substitution (DS). The minimum DS is ~0.4 (i.e., 4 hydroxyls substituted per 10 glucose residues) since below this, CMC is insoluble. Above this, CMC dissolves readily in water to form viscous solutions, but, since it is anionic, the viscosity is reduced upon the addition of electrolyte and at low pH due to compaction of the polymer chains. A synergistic increase in viscosity occurs in blends with guar gum and locust bean gum. CMC finds widespread use in ice cream and other frozen desserts and salad dressings, sauces, and gravies.

The nonionic cellulose ethers, MC and HPMC, are also supplied in a range of molecular sizes and DS. For HPMC, since the substituted moieties contain hydroxyl groups, they may also participate in the reaction. Hence, a molar substitution (MS) is also quoted to characterize the polymers. MC and HPMC dissolve readily in water to produce viscous solutions that on heating form thermoreversible gels. The gelation temperature is dependent on the degree of substitution. For MC containing 30% methoxyl groups, gelation occurs at ~50–55 °C, whereas for HPMC containing 20% methoxyl and 8% hydroxypropyl groups, gelation occurs at ~85 °C. Gelation is believed to be a consequence of molecular association through the hydrophobic methyl and hydroxypropylmethyl substituents. This functional characteristic has led to their use in combination with starch in soups and gravies to prevent undesirable loss of viscosity on heating. A further application is their use in fried foods, where gelation on heating helps retain the structural integrity of the product and additionally serves to prevent moisture loss and oil absorption. Since MC and HPMC are also surface-active, they are used in baked goods to aid uniform gas cell formation and in salad dressings to stabilize emulsion droplets.

Plant Extracts

Starch is obtained commercially principally from corn and potato and to a lesser extent from waxy corn, wheat, tapioca, rice, cassava, sorghum, pea, and sago. It is obtained in the form of granules that have varying degrees of structural order and consists of two polysaccharides, namely, amylose and amylopectin. The proportions of each depend on the source, for example, corn and potato starches contain ~27% and 21% amylose, respectively, while waxy corn contains <2% amylose.

Amylose consists of linear (1,4)-α-D-glucopyranose chains with very little branching (10 branch points per molecule) and has a molecular mass of typically 250 000–2 MDa. Amylopectin also contains sequences of (1,4)-α-glucopyranose units; however, it has extensive branching via (1,6) linkages and has a molecular mass of ~50 M–400 MDa. The starch granules are insoluble in water, but on heating, they swell and burst, releasing the polysaccharides and forming a viscous paste. The actual temperature at which the granules burst is very characteristic of the source of the starch and is (perhaps inappropriately) referred to as the gelatinization temperature. The typical values for corn and potato starches are 67 °C and 60 °C, respectively. On cooling, the amylose molecules readily self-associate, a process known as retrogradation, and it is then that a gel is formed. Natural starches form turbid gels that are prone to syneresis. Hence, most of the commercial starches used are derivatives that have a lesser tendency for retrogradation. Derivatives include hydroxypropyl starches, starch phosphates, oxidized starch, and acid- or enzyme-degraded starches. Starch derivatives are very widely used in food products including gravies, soups, sauces, fruit preparations, dairy products, baked goods, batters, and coatings.

Pectin is the general term for a group of polyuronans that occur as the structural components of plants. Commercial pectins are obtained from the pomace of apples or the peel of citrus fruits following hydrolysis, which renders the pectin water-soluble. Pectin molecules consist of linear chains of (1,4)-α-D-galacturonic acid residues, up to 80% of which occur as the methyl ester. The hydroxyls in the C2 and C3 positions may be acetylated. The chains also contain up to 4% (1,2)-α-rhamnopyranose units, which give rise to kinks. L-Arabinose, D-galactose, and D-xylose (10-15%) are linked to the rhamnose units forming ramified side chains, which are referred to as 'hairy regions' along the otherwise smooth galacturonan backbone. If the degree of esterification (DE) is >50%, it is referred to as high-methoxyl (HM) pectin. Deesterified pectin with DE < 50% is produced by mild acid or alkali treatment and is referred to as low-methoxyl (LM) pectin. If the alkali used is ammonia, amidated pectin is formed. Pectin is soluble in water and is most stable at pH 3–4. At lower pH, the glycosidic bonds are hydrolyzed. In alkaline conditions, the glycosidic and ester linkages are cleaved, yielding the free acid. Both HM and LM pectins form gels. For HM pectin (DE 60–75%), gelation occurs at high soluble solids content (typically 50–75% sugar) and at pH <3.5 over a period of time. The gels are not thermoreversible. Junction zone formation is believed to be a consequence of hydrophobic association between ester groups coupled with intermolecular hydrogen bonding between hydroxyl groups on the galacturonan backbone. For LM pectin (DE typically 20–40%), gelation is brought about by the addition of divalent cations that cross-link the galacturonic acid chains, and a high solids content and low pH are not a prerequisite. The gelation mechanism is referred to as the 'egg-box' model and is discussed further in the succeeding text.

Pectins are mainly used for the production of jams and jellies. High-ester pectins find widespread use in normal jams, whereas low-ester pectins are preferred for low-sugar jams. LM amidated pectin is used to stabilize fruit pulp, which is incorporated into products such as yogurt.

Konjac mannan is the soluble extract of konjac flour obtained by pulverizing the dried tuber of *Amorphophallus konjac*. It is a glucomannan and consists of a main chain of (1,4)-β-D-mannopyranosyl and D-glucopyranosyl units with (1,3)-linked branches approximately every 10 sugar residues. The ratio of mannose to glucose is 1.6:1. Approximately 1 in 19 sugar residues is acetylated. Konjac mannan forms highly viscous solutions on dissolution in water following heating. In the presence of alkali, thermally irreversible gels are formed as a consequence of deacetylation and aggregation of the glucomannan chains. In Japan, konjac mannan is made into noodles. The process involves pumping a solution of the gum through a spinnerette into a hot alkaline bath (e.g., calcium hydroxide solution), which results in the formation of long gel threads. The gum is also sold in blocks of gel, known as konnyaku, for use in traditional Japanese dishes and also as a dessert jelly. Konjac mannan is now finding application as a thickener and gelling agent. It forms thermoreversible gels with xanthan gum and also increases the gel strength, elasticity, and clarity of kappa carrageenan gels. For both mixtures, it has been argued that the synergistic behavior is due to the association of carrageenan and xanthan helices with the glucomannan chains.

Galactomannan Seed Gums

Locust bean (also known as carob), tara, and guar gums are storage polysaccharides obtained from the endosperms of leguminous seeds of *Ceratonia siliqua*, *Caesalpinia spinosa, and Cyamopsis tetragonoloba*, respectively. They have a molecular mass of the order of 1 MDa and consist of a linear main chain of β-(1,4)-linked D-mannopyranosyl units with galactopyranosyl units linked α-(1,6) to varying degrees. The mannose-to-galactose ratio, M/G, is approximately 4.5:1, 3:1, and 2:1 for locust bean, tara, and guar gums, respectively. The galactose residues are distributed nonuniformly along the mannan chain. The presence of galactose tends to inhibit intermolecular association between the galactomannan chains; hence, whereas guar gum is readily soluble in cold water, tara and locust bean gums have to be heated to high temperatures to disrupt the aggregation and achieve complete dissolution. Once dissolved, all three yield highly viscous solutions even at 1% concentration, and as a consequence, their main application is as thickeners.

Locust bean gum will self-associate in solution and will form thermally irreversible gels on freezing. It is commonly used in combination with other polysaccharides, particularly kappa carrageenan, since it leads to the formation of stronger, more elastic gels that have improved transparency and are less prone to undergo syneresis. Locust bean gum also forms strong thermoreversible gels with xanthan gum. It is believed that interaction occurs between the xanthan or carrageenan helices and mannose sequences along the locust bean gum backbone, which are devoid of galactose residues. This model also explains why guar gum is not as effective at forming gels.

Galactomannans are widely used as thickeners in a range of applications including convenience foods, dairy products, sauces, and bakery products.

Algal polysaccharides

The carrageenans are a family of sulfated galactans obtained from red seaweeds (*Rhodophyceae*) where they have a key structural function. The traditional method of extraction is by treatment of the seaweed with hot alkali for 10–30 h, followed by precipitation with alcohol and then drying. The three major types are kappa, iota, and lambda carrageenans. Kappa is obtained from a species of seaweed called *Eucheuma cottonii* and occurs together with lambda carrageenan in *Chondrus crispus*. Iota carrageenan is obtained from *Eucheuma spinosum*. They differ essentially in their degree of sulfation. The idealized structure for kappa carrageenan is a disaccharide repeat unit consisting of (1,3)-β-galactopyranose-4-sulfate and (1,4)-α-3,6-anhydrogalactopyranose residues. Iota carrageenan differs only in that the latter residue is sulfated at the C2 position. Lambda carrageenan is further sulfated and consists of (1,4)-α-galactopyranose 2,6 disulfate and (1,3)-β-linked galactopyranose, which is 70% substituted at the C2 position. The carrageenans are all soluble in water, but whereas lambda forms viscous solutions, kappa and iota form thermoreversible gels. In solution, the molecules undergo a thermoreversible coil-to-helix transition, and the helices self-associate giving rise to a three-dimensional gel structure (Figure 1). The temperature of gelation increases with increasing electrolyte concentration. It has been shown that potassium, rubidium, and cesium ions specifically bind to the helical structure of kappa carrageenan and hence promote helix formation and gelation at much lower concentrations than other electrolytes. As a consequence, kappa carrageenan gels are much stronger in the presence of potassium chloride compared with, say, sodium chloride. This ion specificity is not observed for iota carrageenan, which forms weaker more elastic gels compared with kappa. This is probably due to the fact that the increased charge on the iota carrageenan chains reduces the extent of helix self-association. Self-association results in the melting temperature being greater than the gelation temperature, and this hysteresis is more pronounced in kappa carrageenan.

Kappa carrageenan gels are more brittle and turbid than iota carrageenan gels and are more prone to syneresis. As discussed in the preceding text, the incorporation of locust bean gum or konjac mannan into kappa carrageenan gels

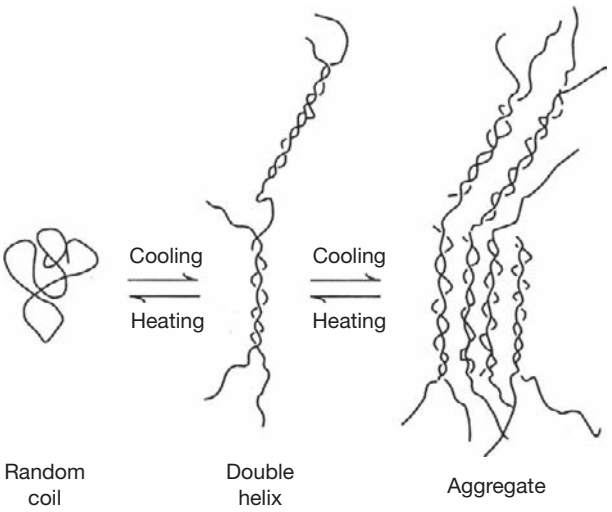

Figure 1 Schematic illustration of the coil–helix transition of carrageenan in solution.

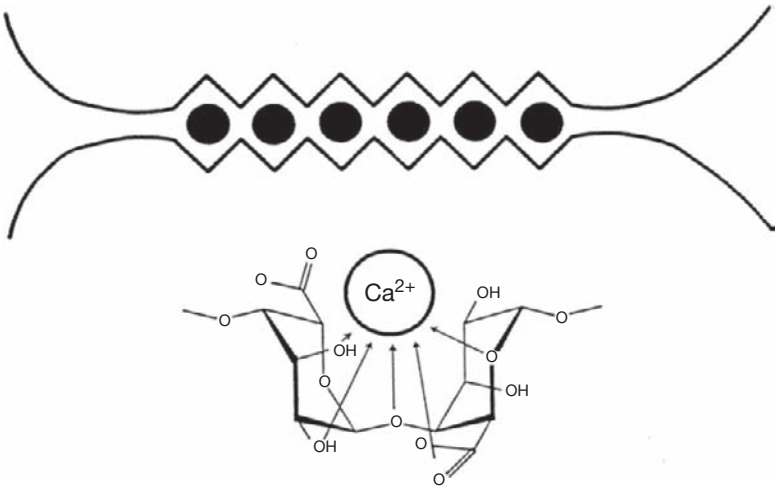

Figure 2 The egg-box model illustrating the cross-linking of alginate chains, which leads to gel formation.

reduces turbidity, brittleness, and syneresis and also increases gel strength.

Kappa carrageenan is widely used in dairy products because it interacts synergistically with kappa casein and prevents wheying off. Carrageenans are also used extensively in meat products such as cooked hams, poultry products, and sausages because of their ability to bind water and control the texture and structural integrity.

Agarose (the major component of agar) is also obtained from red seaweeds notably *Gelidium* and *Gracilaria* species. It is a linear neutral polysaccharide and has a similar structure to the carrageenans consisting of alternating (1,3)-β-D-galactopyranose and (1,4)-linked 3,6-anhydro-α-L-galactopyranose units. It dissolves in near-boiling water and gels on cooling to $\sim < 40^{\circ}$ C. The gelation mechanism is as described for the carrageenans, but, since the agarose chains are nonionic, extensive helix aggregation occurs resulting in the formation of very strong gels. The gels show pronounced hysteresis and melt only on heating to 80–90° C. Agar is used in the manufacture of a range of products including jams, jellies, pie fillings, icings, and gelled meats, but its use is far more restricted commercially than that of carrageenan owing to availability and cost considerations.

Alginate is obtained from brown seaweeds (*Phaeophyceae*) and is a linear (1,4)-linked polyuronan consisting of β-D-mannuronic and α-L-guluronic acids. The acids are present as blocks of separate or mixed sequences along the chain depending on the seaweed source. *Macrocystis pyrifera* and *Ascophyllum nodosum* have a high mannuronic acid content (61% and 65%, respectively), whereas *Laminaria hyperborea* has a high guluronic acid content (69%). Sodium alginate dissolves readily in water to form viscous solutions and forms thermally irreversible gels in the presence of divalent cations (notably calcium). It is the guluronic acid residues that are mainly responsible for gel formation, and their proportion and distribution along the polyuronan chain have a major influence on the properties of the gels produced. Adjacent diaxially linked guluronic acid residues form a cavity that acts as a binding site for cations, which interact with the carboxyl and hydroxyl groups. Intermolecular cross-linking of sequences results in the formation of junction zones and a three-dimensional gel network. This mechanism is often referred to as the 'egg-box model' and is illustrated in Figure 2.

Sodium alginate can be used to produce fruit analogs for pie fillings utilizing the so-called internal setting procedure. In this process, a sodium alginate solution containing a sparingly soluble calcium salt (e.g., calcium phosphate) is combined with a fruit puree, which contains a sequestrant (e.g., sodium citrate) and acid (citric acid). On mixing, the insoluble calcium salt begins to dissolve in the presence of the acid, releasing calcium ions that initially interact with the alginate, inducing gelation. The uniform gel formed is then cut, and a thickened fruit syrup is added to give the finished pie filling. Sodium alginate can also be used to prepare structured fruits using a coextrusion technique, and this is particularly appropriate for fruits such as black currants, which have an outer skin and liquid center. In the process, a sodium alginate solution and fruit puree mix are fed separately through nozzles consisting of coaxial tubes positioned above a bath containing a solution of calcium salt (e.g., calcium lactate). The flow of alginate solution is kept constant while that of the fruit puree is intermittent. As each drop of puree breaks away from the nozzle, it is coated with a film of the alginate solution, which gels instantly, forming a hardened skin upon hitting the calcium bath below. The fruit gels formed are then collected, and a thickened syrup is added to produce the pie filling.

Microbial Gums

Xanthan gum was first discovered in the 1950s and is now finding extensive application in the food industry since its introduction in the early 1970s. The gum is obtained from the genus *Xanthomonas*, notably *X. campestris*, by aerobic fermentation. The xanthan molecules have a (1,4)-β-D-glucopyranose backbone as in cellulose but in addition have a trisaccharide side chain on every other glucose residue linked through the C3 position. The side chain consists of two mannopyranosyl residues linked on either side to a glucuropyranosyl uronic acid group. The inner mannose residue connected to the backbone may be acetylated, while the terminal mannose residue may be pyruvated. The molecular mass of the xanthan molecules is very

high (>3 MDa), and the gum dissolves in water to yield highly viscous solutions. The xanthan molecules undergo a thermoreversible coil–helix transition in solution, which is shifted to higher temperatures by the addition of electrolyte. In the disordered coil form, the side chains are envisaged as protruding away from the backbone into solution, while in the ordered form, the molecules form a stiff fivefold helical structure with the side chains folded in and associated with the backbone. Most workers now believe that the helix is double-stranded. The stiff xanthan chains tend to associate in solution giving rise to a very high low-shear viscosity, which is sufficient to prevent particles from settling or oil drops from creaming. The associations are readily broken upon applying shear, giving rise to a dramatic drop in viscosity, and hence, the solutions readily flow. Unlike other polyelectrolytes, the viscosity of xanthan solutions is relatively insensitive to the addition of electrolyte since the electrolyte will promote helix formation. The helices are also stable over a broad range of pH. The high apparent yield stress and pronounced shear-thinning characteristics have led to a large increase in the use of this gum, which now finds application in a broad range of food products such as sauces, salad dressings and mayonnaises, and frozen and chilled dairy products.

Gellan gum is produced from *Pseudomonas elodea* by aerobic fermentation and consists of a linear tetrasaccharide repeat unit of (1,3)-β-D-glucopyranose, (1,4)-β-D-glucopyranose uronic acid, (1,4)-β-D-glucopyranose, and (1,4)-α-L-rhamnopyranose. In the native form, the (1,3)-linked glucose residues contain glycerate and acetate moieties. x-Ray fiber diffraction studies indicate that the gellan molecules form a 3-fold double helical structure and in solution undergo a thermoreversible coil–helix transition. The transition shifts to higher temperatures in the presence of electrolyte. Once formed, the helices tend to self-associate leading to the formation of a gel, as is the situation for agarose and carrageenan. Gels formed in the presence of monovalent ions are usually thermoreversible, although the melting temperature is normally much greater than the gelation temperature, a consequence of the extensive aggregation. If gels are formed by the addition of divalent ions, then they can be thermally irreversible. The native form produces soft elastic gels, whereas the deacetylated material, which is sold commercially, forms hard brittle gels. Gellan gum is used as a gelling agent for fruit fillings for pies and cakes, in dairy products such as milk beverages and yogurts, and in sugar confectionery.

Gut Hormones

REJ Clarke, SR Bloom, and T Tan, Imperial College London, London, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The gastrointestinal tract is the major endocrine organ in the body producing over 20 hormones from specialized enteroendocrine cells located throughout its epithelial lining. These hormones act both locally, for example, on the stomach and pancreas and distally, for example, on the hypothalamus and brain stem and are believed to play a part in mediating digestion, energy homeostasis, appetite, and satiety. They have an array of actions including smooth muscle contraction, further hormone release, and neuronal signaling, and many gut hormones act synergistically providing additional levels of control. Gut hormones are released in response to neural signals and/or receptors that sense nutrients including glucose, lipids, amino acids, bile salts, and short-chain fatty acids.

The role of gut hormones in patients with obesity, anorexia nervosa, and type 2 diabetes mellitus, among many other pathologies, is under investigation, as is the potential for gut hormones to be used therapeutically. Already, glucagon-like peptide-1 (GLP-1) agonists are used for the treatment of type 2 diabetes mellitus and obesity.

Ghrelin

Ghrelin was discovered as the endogenous ligand for the orphan growth hormone secretagogue receptor in 1999 by Kojima and colleagues. The human ghrelin gene is localized on the chromosome 3p25–26 and comprises five exons that are processed to give a 28-amino acid peptide. Ghrelin is the only circulating gut hormone known to have an orexigenic effect, that is, stimulating food intake and hunger. It is released from specific X/A-like enteroendocrine cells in the mucosal layer of the stomach in response to fasting, and secretion is suppressed by feeding. An octanoyl group on the serine residue in position 3, added by GOAT (ghrelin-*O*-acyltransferase), is required for binding to its receptor, the growth hormone secretagogue receptor.

Central or peripheral administration of ghrelin in rats increases food intake and stimulates growth hormone release, which chronically leads to weight gain. Human studies have also confirmed that the infusion of ghrelin causes increased food intake and feelings of hunger, and there is growth hormone release from the anterior pituitary, which increases adiposity and blood glucose. The plasma ghrelin concentration is particularly decreased by a high-fat meal. As well as controlling appetite, ghrelin also stimulates gastric acid secretion, gastric motility, and turnover of gastric and intestinal mucosae. Ghrelin concentrations are very high in anorexia nervosa and bulimia nervosa and are suppressed in obesity.

Gastrin

Gastrin's existence was first postulated in 1905 when British physiologist John Edkins noted in cats that the injection of a pyloric mucous membrane extract caused the release of gastric acid from the stomach. This was confirmed in 1938 and the structure elucidated in 1964. The human gastrin gene is localized on the chromosome 17q21 and consists of three exons of which two code for the precursor protein preprogastrin. Preprogastrin is cleaved to give progastrin, which is then further cleaved to give *C*-terminal glycine-extended gastrin-17gly and gastrin-34gly, which are then converted to *C*-terminal amidated gastrin-34 and gastrin-17. Gastrin acts on the cholecystokinin (CCK) 2 receptor, as it has an identical *C*-terminal pentapeptide sequence to CCK.

Gastrin is released from enteroendocrine G cells in the stomach in response to neuronal signaling, calcium, aromatic amino acids, and alcohol and is inhibited by somatostatin, whose release is controlled by intragastric pH. Gastrin stimulates acid secretion from the gastric parietal cell, as does histamine and neural stimulation. Gastrin also has a trophic effect causing gastric epithelial cell proliferation. Zollinger–Ellison syndrome is caused by gastrin-secreting tumors, and symptoms include multiple gastric and duodenal ulcers. Proton pump inhibitor therapy irreversibly blocks gastric acid secretion by the gastric parietal cell and hence causes increased gastrin release from G cells, due to the lack of negative feedback.

Cholecystokinin

CCK was previously called pancreozymin, as the stimulation of pancreatic exocrine secretion was the first of its functions to be discovered. The gene is located on chromosome 3, and CCK is really a family of peptides, of varying lengths, produced from the posttranslational modification of preprocholecystokinin. CCK usually has a sulfate group attached to tyrosine in position 7 in the *C*-terminus, which is essential for the activation of the CCK1 receptor.

CCK is released postprandially from enteroendocrine I cells in the small intestine and acts via CCK1 receptors on the vagal nerve to reduce food intake by inducing satiety. It is an acute signal; CCK has a half-life of 1–2 min, and secretion is activated by receptors on the I cells responding to aromatic amino acids and long-chain fatty acids in the gut lumen. It is particularly stimulated by fatty meals. CCK also acts in a paracrine way on the pancreas and gallbladder to stimulate pancreatic exocrine secretion and gallbladder contraction, allowing the digestion of the food intake. It also inhibits gastric emptying, which slows down transit and improves digestion and absorption, and stimulates feelings of satiety. The response to CCK is decreased in obese individuals. Experimentally, although CCK infusion reduces the amount of calories consumed at a meal, in the long term, subjects tend toward having more meals, and hence, there is no overall decrease in calories consumed. There is also a rapid development of tolerance and an increased risk of acute pancreatitis/pancreatic cancer.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00366-4

Secretin

Secretin was the first hormone ever discovered, by Bayliss and Starling in 1902. It is produced by enteroendocrine S cells, mainly in the duodenum, in response to the low pH of the gastric contents and the presence of products of protein digestion. It binds to the G protein-coupled secretin receptor. It is a 27-amino acid peptide. It inhibits gastric acid secretion and motility via the vagal nerve and stimulates pancreatic bicarbonate secretion, thus controlling the pH within the small duodenum.

Motilin

Motilin is a 22-amino acid peptide produced by enteroendocrine M cells in the duodenojejunum. During fasting, it has a cyclic release that helps to generate short bursts of peristalsis, which are thought to clear debris and bacteria from the stomach and small intestine. This stops after feeding. Motilin is similar in structure to ghrelin, and its receptor is part of the same family as the ghrelin receptor.

Glucose-Dependent Insulinotropic Polypeptide

Glucose-dependent insulinotropic polypeptide (GIP) is a 42-amino acid peptide hormone that is secreted from enteroendocrine K cells in response to nutrients especially glucose or fat. These cells are primarily located within the duodenum and proximal jejunum. It was initially known as gastric inhibitory peptide due to its ability to stop gastric acid secretion in dogs; however, this inhibitory effect only occurs at pharmacological doses. At physiological doses, it is an incretin, that is, it is secreted in response to enteral glucose to augment insulin secretion, more so than when the same amount of glucose is given intravenously. GIP also promotes pancreatic β cell growth and inhibits apoptosis. In adipose tissue, adipogenesis is stimulated. GIP is degraded by dipeptidyl peptidase-4 (DPP-4), which cleaves GIP(1–42) to form inactive GIP(3–42). GIP concentrations are normal to increased in type 2 diabetes mellitus, but the incretin activity of GIP is diminished.

Preproglucagon

The proglucagon gene is located on the long arm of chromosome 2. The precursor peptide is produced in the brain, gut, and pancreas. In the brain and gut, it is posttranslationally processed to give glicentin, GLP-1, and glucagon-like peptide-2 (GLP-2) by proprotein convertase subtilisin/kexin (PCSK) type 1. Glicentin is further processed to give oxyntomodulin and glicentin-related pancreatic polypeptide (PP). Preproglucagon is processed differently in the pancreas by PCSK type 2 to give glicentin-related PP, glucagon, and major proglucagon fragment (see Figure 1).

Glucagon-Like Peptide-1

The most common circulating active form of GLP-1 is the 7–36 amide, although 7–37 is also present and active. GLP-1 is degraded by DPP-4, which cleaves off two amino acids from the *N*-terminal forming inactive GLP-1 9–36 amide or GLP-1 9–37. GLP-1 exerts its actions through the GLP-1 receptor, which can also be activated by oxyntomodulin, although oxyntomodulin is a lower-affinity agonist by two orders of magnitude. GLP-1 is released 5–30 min after meals, from enteroendocrine L cells in the intestine, which are mainly distributed in the distal intestine, ileum, and colon. These L cells can also secrete oxyntomodulin and peptide YY (PYY), and there is sometimes cosecretion of GIP, which is more usually produced from K cells. The L cells sense nutrients both directly and indirectly, as GLP-1 levels rise before nutrients are present in the L cell-rich areas. Nutrients triggering GLP-1 release include sugars, free fatty acids, amino acids, bile acids, and short-chain fatty acids from bacterial fermentation of dietary fiber. There is also neural and hormonal regulation, with insulin, GIP, and leptin enhancing GLP-1 secretion and somatostatin inhibiting it. The amount of GLP-1 produced is in proportion to the calorie content of the meal. GLP-1 inhibits gastric acid secretion, gastric emptying, and intestinal motility to slow down digestion, improve absorption, and reduce food intake.

GLP-1 is a potent incretin like GIP. It also upregulates insulin gene expression, decreases pancreatic β cell apoptosis, and potentiates all steps of insulin biosynthesis. This is true even in patients with type 2 diabetes mellitus. GLP-1 also inhibits glucagon release from pancreatic α cells in a glucose-dependent manner that contributes to a lower plasma glucose concentration. It is important to note that because GLP-1 only augments the insulin response and inhibits the glucagon response, in the presence of an elevated glucose level, there is little risk of hypoglycemia developing. Human studies have

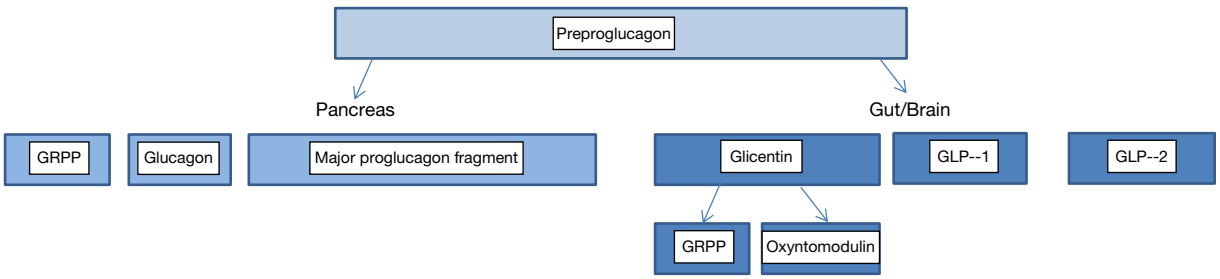

Figure 1 The posttranslational processing of preproglucagon in the pancreas and gut/brain. GRPP, glicentin-related peptide; GLP-1, glucagon-like peptide-1; GLP-2, glucagon-like peptide-2.

shown a reduction in gluconeogenesis upon infusion of GLP-1, consistent with its glucagon inhibitory effect.

GLP-1 also acts on the central nervous system to modulate feeding behavior. It is an anorexigenic hormone, that is, it reduces appetite and induces satiety. GLP-1 appears to modulate appetite through two different routes: directly via diffusion across the incomplete blood–brain barrier in the median eminence to activate GLP-1 receptors in the hypothalamus and indirectly via vagal afferents, which innervate the portal circulation and signal back to the dorsal vagal complex in the brain stem and further on to the hypothalamus. Energy expenditure is, controversially, increased, an observation that has been made in animal studies but has not been observed in studies in humans. There is reduced secretion of GLP-1 in obese individuals, although response is maintained, and infusion of GLP-1 reduces food intake in a dose-dependent way.

Glucagon-Like Peptide-2

GLP-2 is secreted from enteroendocrine L cells in the intestine in response to nutrient, neural, and hormonal signals as per GLP-1. There is also a strong GLP-2 response to intestinal injury. GLP-2(1–33) is degraded by DPP-4 to GLP-2(3–33) and then renally cleared.

The effects of GLP-2 are increased proliferation of the intestinal mucosa in both the small and large intestines, enhanced intestinal blood flow, decreased apoptosis of intestinal cells, and increased intestinal barrier function. This crypt cell proliferation and enhanced blood flow increase intestinal absorption, and GLP-2 analogs such as teduglutide have found a role in the treatment of short bowel syndrome by reducing intestinal losses and improving the absorption of nutrients.

Oxyntomodulin

Oxyntomodulin is secreted 5–30 min after food ingestion, especially if the food contains fatty acids, from the enteroendocrine L cells in the intestine. It has the same structure as glucagon with a short *C*-terminal extension (see Figure 1). The amount secreted is proportional to the calorie content of the meal. It inhibits gastric acid secretion and motility along with GLP-1 and seems to signal via the GLP-1 receptor. Its affinity for the GLP-1 receptor is approximately two orders of magnitude weaker than that of GLP-1, but despite this, it exerts a comparable effect on food intake, speculatively via an alternative oxyntomodulin receptor. Oxyntomodulin acts to reduce appetite both via a direct effect on the CNS (similar to GLP-1) and by inhibiting ghrelin release. Oxyntomodulin infusion reduces food intake and increases energy expenditure in lean and obese individuals.

Pancreatic Polypeptide

PP was first extracted from chicken pancreas in the early 1970s. It is mainly synthesized and released by the PP cells of the pancreatic islets. Its structure contains a PP-fold, a tertiary structure of an alpha helix and polyproline helix connected by a beta turn, resulting in a characteristic U-shaped peptide. Other hormones with a PP-fold structure include neuropeptide Y and PYY. The PP-fold family of peptides characteristically have 36 amino acids, require amidation at the COOH terminal for biological activity, and bind and activate neuropeptide Y receptors. In turn, the seven transmembrane domain Y receptors are coupled to G_i resulting in inhibition of adenylate cyclase and reductions in intracellular cAMP. PP's cognate Y receptor is the Y4 receptor.

PP release is controlled by feeding and an intrinsic circadian rhythm. In fasting individuals, the PP concentration is at its lowest at 0200 and highest at 2100. Postprandial release is vagally controlled. PP's main effects are to reduce appetite, delay gastric emptying, and increase energy expenditure. The quantity secreted is proportional to calorie load but is also increased by gastric distension. Secretion is biphasic, and the profile of release is dependent on the timing of the meal, with the first meal of the day having a reduced first-phase response.

Peptide YY

PYY was first isolated from porcine intestines in 1980 by Tatemoto. PYY is, like PP, a PP-fold peptide; it is produced by the enteroendocrine L cells in the gut, with higher concentrations found distally. The full-length PYY(1–36) binds to all Y receptor subtypes. The most common circulating form is the amino-terminally truncated form PYY(3–36), which preferentially binds to Y2 and Y5 receptors. DPP-4 is thought to mediate this conversion between 1–36 and 3–36. PYY(3–36) can freely cross the blood–brain barrier unlike PP, due to its different *N*-terminus.

The PYY concentration increases after a meal, but this increased secretion starts 15 min postfeeding, before the nutrients have time to reach L cells, and is therefore likely to be vagally controlled. Concentrations peak at 1–2 h postfeeding. Caloric content, macronutrient constituents, and consistency affect the profile and peak of PYY release, with a greater release seen for fat-rich meals.

CCK, gastric acid, and bile acids also cause PYY secretion, but unlike PP, it is not released by gastric distension. The principal effect of PYY is to suppress appetite. Obese people have lower fasting levels of PYY and attenuated postprandial PYY release associated with decreased satiety. However, they do not have resistance to the hormone as infusion does reduce food intake. Fasting PYY concentrations correlate negatively with the BMI, waist circumference, and 15 h resting metabolic rate. Postprandial PYY concentrations correlate negatively with changes in body weight over 6 months and 24 h respiratory quotient.

The Role of Gut Hormones in Metabolism

Digestion

There is a distal-to-proximal feedback mechanism, called the ileal brake, which slows digestion and causes feeling of satiety on food entering the ileum. The purpose of this is to control digestion, allowing adequate time and resources for

degradation and absorption of the nutrients and preventing hyperalimentation. The presence of not only fat but also protein and/or carbohydrate in the ileum leads to increased transit time in the duodenum and jejunum and delayed gastric emptying by decreasing the frequency of peristalsis and increasing the pyloric sphincter pressure. There is also a reduction in pancreatic exocrine secretion, gastric acid secretion, and gallbladder contraction. PYY, oxyntomodulin, and GLP-1 are postulated to be involved in this feedback, possibly acting via neural signaling of the vagal nerve.

Energy Homeostasis

Food intake is controlled by gut mechanoreceptors, plasma composition, gut hormones, pancreatic hormones, the central nervous system especially the hypothalamus, societal norms, and leptin signaling from adipose tissue. The role for gut hormones was suggested in 1937 when Maclagan showed that a crude preparation of ground-up intestines given to rabbits decreased food intake by almost 30%, suggesting a possible agent(s) present in the intestine modulated appetite.

Gut hormones act directly on the brain neurons and also indirectly via the vagal nerve. Central nervous system centers responsible for energy homeostasis are in the hypothalamus (especially arcuate and paraventricular nuclei) and brain stem. Removal of the lateral hypothalamus causes hypophagia, and removal of the ventromedial hypothalamus causes hyperphagia, again suggesting that the hypothalamus has a key role to play in controlling appetite. PYY(3–36), oxyntomodulin, and GLP-1 acting both directly and indirectly all cause anorectic effects. Ghrelin acting directly and indirectly stimulates food intake. The system is modulated by additive effects of multiple gut hormones and feedback loops involving the higher brain centers, sympathetic nervous system, and thyroid axis.

Bariatric Surgery

Obesity is a growing epidemic and is associated with increased morbidity and mortality. Affected individuals are at greater risk of type 2 diabetes mellitus, cardiovascular disease, and musculoskeletal pathologies.

The only current effective treatment for obesity is bariatric surgery. Initially designed to reduce food intake and gut surface area available for absorption, its effect on the gut hormones profile may be a better explanation for its success.

Post Roux-en-Y gastric bypass, there is higher meal-stimulated GLP-1 and PYY release. These higher concentrations of the satiety hormones GLP-1, PYY, and also oxyntomodulin cause not only decreased food intake but also change in types of food eaten with lower fat and sugar intake long term. Poor responders to Roux-en-Y bypass can be identified by suboptimal postprandial satiety gut hormone concentrations. Post gastric sleeve, as well as Roux-en-Y gastric bypass, there is reduced ghrelin, likely due to decreased ghrelin-producing cells, as it is also seen in short bowel syndrome. Sleeve gastrectomy also causes increased GLP-1 secretion but gastric banding does not.

Therapeutic Agents

The therapeutic use of gut hormones is limited by their short half-life and peptide structure, which requires injected routes for administration. Their development has been along the lines of making therapeutic agents resistant to DPP-4 cleavage, renal clearance, and investigating the possibility of oral administration.

Exendin-4 is a 39-amino acid peptide, which is a naturally occurring GLP-1 receptor agonist found in the venom of the *Heloderma suspectum* lizard and is resistant to DPP-4 degradation. A synthetic version, exenatide, has been marketed as a therapy for type 2 diabetes mellitus. Subsequently, GLP-1 analogs have been manipulated in other ways to prolong their half-life, and other analogs are now available as diabetes treatments. GLP-1 agonists reduce mealtime-related glycemic excursion and glucagon concentration and increase insulin concentration. This leads to a lower HbA1c, weight loss, and reduced free fatty acid levels, although there is inhibition of gastric emptying and nausea. Nevertheless, GLP-1 analogs are now successfully and routinely used for the treatment of diabetes. Even in nondiabetic patients, GLP-1 analogs appear to be a potential treatment for obesity and may be approved for this purpose in the near future.

DPP-4 inhibitors have also been investigated as therapies for type 2 diabetes mellitus given the role of DPP-4 in degrading GIP and GLP-1. Trials of the DPP-4 inhibitors vildagliptin and sitagliptin have shown increased levels of GLP-1 and GIP, associated with increased insulin release postprandially and improved glycemic control. They are weight neutral, unlike the GLP-1 analogs. This may be due to other hormones affected by the inhibition of DPP-4, for example, by inhibiting the conversion of PYY(1–36) to PYY(3–36) and therefore inhibiting the anorexigenic feedback effect of PYY(3–36) after eating.

Ghrelin antagonists would theoretically be a potential treatment for obesity, but this has yet to be shown in human studies. Studies in growth hormone secretagogue receptor knockout mice and ghrelin-deficient mice show resistance to diet-induced obesity and altered metabolic fuel preference with a tendency to a high-fat diet. Ghrelin agonists have been used in patients with anorexia secondary to cancer or renal dialysis and have been shown to increase appetite. There is also a therapeutic benefit in diabetic patients with gastroparesis from giving a ghrelin agonist.

However, postprandially, multiple anorexigenic gut hormones are secreted, leading to coordinated reductions in appetite and activation of metabolic pathways. It should also be noted that gastric bypass, one of the proved and effective treatments for obesity, also induces a rise in the secretion of multiple gut hormones as noted in the preceding text. Therefore, the effective treatment of obesity may require multiple gut hormones administered in combination, and this is being actively researched.

Conclusion

Gut hormones working independently and synergistically play an important role in preparing the digestive system for food,

matching digestion and absorption to the amount of food taken, causing feelings of satiety, and controlling energy homeostasis and hunger. Harnessing their potential could allow us to reduce the burden of obesity, stimulate hunger in malnourished patients, and improve glycemic control in type 2 diabetes mellitus patients.

HACCP and ISO22000: Risk Assessment in Conjunction with Other Food Safety Tools Such as FMEA, Ishikawa Diagrams and Pareto

T Varzakas, Technological Educational Institute of Peloponnese, Kalamata, Greece

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Food safety nowadays is an international challenge requiring close cooperation between countries in agreeing standards and systems. European consumers not only require much higher dietary quality and hygiene and health standards in the products they purchase but also look for certification and protected origin products (national or geographic) and processing methods.

The hazard analysis and critical control points (HACCP) system is a science-based system created to identify specific hazards and actions to control them in order to ensure food safety and quality. It can be considered as an efficient tool for both the food industry and health authorities in preventing food-borne diseases. 'Hazard' is "a biological, chemical or physical agent in, or condition of, food with the potential to cause an adverse health effect" according to Codex Alimentarius.

The HACCP system addresses and controls all significant hazards associated with a particular food.

Physical hazards include glass, metal, stones, wood, plastic, rubber, pests (typically larger pests), and sand. They commonly result from accidental contamination and poor food handling practices throughout the food chain from farm to fork.

Chemical hazards include cleaning chemicals, pesticides, fungicides, insecticides, fertilizers, allergens, toxic metals, nitrites and nitrates (when added to the product), plasticizers and packaging migration, veterinary residues, antibiotics, chemical additives, lubricants, paints, coatings, naturally occurring toxic substances and mycotoxins derived from fungi, drugs in water and milk, estrogens, phytoestrogens, and waterborne pesticides, for example, atrazine.

Biological hazards include food-poisoning bacteria such as *Salmonella*, *E. coli*, *Bacillus cereus*, *Campylobacter* spp., *Listeria* spp., and *Clostridium botulinum*, which are hazardous.

The adoption of a completely new system of managing food safety compared to HACCP led to the development of ISO 22000, which is the new international generic standard for food safety management systems (FSMS). It defines a set of general food safety requirements that apply to all organizations in the food chain. These requirements are listed in sections 4, 5, 6, 7, and 8 of ISO 22000. ISO 22000 controls food safety hazards through prerequisite programs (PRPs) and HACCP plans.

Risk Assessment

Risk assessment may be summarized as the evaluation of the likelihood of an adverse effect(s)/event(s) occurring under a defined set of conditions, together with a value judgment on the results.

Risk assessment is best addressed in four stages, namely, hazard identification, hazard characterization, exposure assessment, and risk characterization.

The term *hazard* is associated with the potential of an agent or situation to cause an adverse effect(s)/event(s).

Risk is widely recognized as a function of the probability and severity of an adverse effect/event occurring to man or the environment following exposure, under defined conditions, to a hazard.

Risk management is the process of weighing policy alternatives in the light of the result of a risk assessment(s) and of other relevant evaluations and, if required, of selecting and implementing appropriate control options (including, where appropriate, monitoring/surveillance activities).

Risk communication is the interactive exchange of information and opinions throughout the risk analysis process concerning risk. It should involve not only risk assessors and risk managers but also consumers and a wide range of other actual or potential stakeholders.

The elements of a structured approach to risk management are risk evaluation, risk management option assessment, implementation of management decision, and monitoring and review.

The microbiological safety of foods is principally assured by control at the source, product design, and process control and the application of good hygienic practices (GHPs) during production, processing (including labeling), handling, distribution, storage, sale, preparation, and use, preferably in conjunction with the application of the HACCP system. This 'preventive' system offers more control than end product testing, because the effectiveness of microbiological examination in assessing the safety of food is limited.

Control of *Listeria monocytogenes* in foods provides an example of the need to consider a structured risk management approach. Establishment of tolerable low levels of *Listeria* in specific foods may be one food safety objective established by risk managers after a rigorous and transparent risk analysis.

The Seven Principles of HACCP

The HACCP system consists of seven principles. These principles make up the Codex standard, which has become the reference for international food safety. They are as follows:

Principle 1: Conduct a hazard analysis.

Principle 2: Identify the critical control points (CCPs) in the process. CCPs are steps at which control can be applied and a food safety hazard can be prevented, eliminated, or reduced to acceptable levels.

Principle 3: Establish critical limits (CLs) for preventive measures associated with each identified CCP.

Principle 4: Establish CCP monitoring requirements and procedures for using monitoring results to adjust processes and maintain control.

Principle 5: Establish corrective actions to be taken when monitoring indicates that a particular CCP is not under control.

Principle 6: Establish procedures for verification to confirm that the HACCP system is working effectively.

Principle 7: Establish documentation concerning all procedures and records appropriate to these principles and their application.

HACCP Team Formation

A trained HACCP team is essential. The HACCP team has to provide the production-specific expertise and experience, which are necessary for the development of the HACCP plan. Responsibilities of the HACCP team include the organization and documentation of HACCP study, the review of deviations from CLs, the organization of internal audit of HACCP plans, and the communication, education, and training of employees in the operation of HACCP system.

Product Description

Information should be provided regarding ingredients, processing methods, retail, packaging and storage conditions, and their associated hazards. Moreover, information should be given on product shelf life, type of food packaging, intended use with preparation instructions focussing on specific population groups (infants, immunocompromised individuals, the elderly, etc.), labeling, storage, and distribution conditions.

Flow Diagram Construction

The flow diagram should be constructed by the HACCP team and should identify all processing steps including steps prior to and after processing in the plant.

On-Site Verification of Flow Diagram

The HACCP team should confirm the processing operation against the flow diagram during all stages and hours of operation and amend the flow diagram where appropriate. Modifications should be made to the flow diagram as necessary and documented. After these five preliminary tasks have been completed, the seven principles of HACCP are applied.

Prerequisite Programs

PrPs are normally in place before the HACCP plan is developed. They include personal hygiene, good manufacturing practices (GMPs), GHPs, supplier quality assurance, maintenance schedules, and training. These PrPs should be properly implemented before assessing HACCP implementation.

Good Manufacturing Practices

GMPs provide general rules for the manufacture, handling, and preparation of various kinds of food products. They aim at safeguarding good hygienic and sensory quality traits, which are essential for safe food production. In the United Kingdom, the Institute of Food Science and Technology publishes guides to GMP.

Industries that have adopted the GMPs manufacture safer and of better quality products; decrease consumer complaints; have a better, cleaner, and safer working environment; and present a greater employee motivation and productivity and improved psychological conditions.

GMPs focus on three areas: personnel, buildings, and facilities as well as production and process control.

Personnel should have adequate personal cleanliness and be responsible for disease control by testing themselves for sexually transmitted diseases; wash their hands thoroughly before starting work and after using the toilet; wear gloves and protective clothing, suitable footwear, and hair coverings; avoid smoking, eating, chewing, spitting, sneezing, or coughing in the production area; and remove all unsecured jewelry and other objects that might fall into food. Personnel should also be aware of the infectious nature and transmission routes of food-borne pathogens.

Buildings and Facilities Equipment

They should be located away from environmentally polluted areas or areas subject to flooding or areas prone to infestations of pests; they should have adequate supply of potable water, natural gas, electricity, fuel, waste disposal systems, ventilation system to minimize odors and vapors, air-conditioning, and dust control.

Floors should have non-slip surface and be made of materials that are impervious; durable; resistant to grease, cleaning agents, and biochemical and microbial attack; free from cracks and crevices; and easy to clean. Doors should open automatically or have heavy-duty plastic strips permitting easy access by personnel and forklift trucks.

Roofing is normally flat or slightly pitched and is supported by trusses or beams and should provide adequate natural light.

Finally, pest control should apply focussing on insects, flies, cockroaches, moths, beetles, and rodents.

Equipment should be readily disassembled for inspection and manual cleaning, sanitized with approved sanitizer, and rinsed with potable water if required, equipped with rounded corners and edges. All surfaces in contact with food should be smooth, not porous, inert, visible for inspection, accessible for manual cleaning, made of nontoxic material, and corrosion-resistant.

Production and Process Controls

No raw material or ingredients should be accepted if it is known to contain parasites, undesirable microorganisms, pesticides, veterinary drugs or toxic, and decomposed or extraneous substances.

Quality control of raw materials should take place to decide if deliveries are accepted or rejected. Moreover, inspection of the overall condition of the trucks used to transport low-moisture raw materials or frozen raw materials should take place.

Storage rooms for raw materials should be clean and have adequate space for inspection. They should also have good air circulation, correct temperature, and proper humidity. Raw materials should not be placed on the floor.

Packaging materials should be hygienic, odorless, and not reacting with either the contained food or the surrounding atmosphere. Finished products should be labeled and placed for checks to see their conformity with product specifications. Defective products should be placed on a site waiting for a decision on rework or disposal. Final products approved for release should be taken to the warehouses.

Control Measures

Control measures are grouped into PRPs that manage the basic conditions and activities, operational PRPs that manage control measures that the hazard analysis identifies as necessary to control identified hazards to acceptable levels, and an HACCP plan to manage control measures that the hazard analysis identifies as necessary to ensure control of identified hazards to acceptable levels (CCPs).

Operational prerequisite programs (OPRPs) are PrPs that are essential. They are essential because a hazard analysis has shown that they are necessary in order to control specific food safety hazards. OPRPs are used to reduce the likelihood that products will be exposed to hazards, that they will be contaminated, and that hazards will proliferate. OPRPs are also used to reduce the likelihood that the processing environment will be contaminated and that hazards might occur in that environment.

Critical Control Points

A CCP is a point in a step or procedure at which a control is to be applied to prevent or eliminate a hazard or reduce it to an acceptable level.

CCPs may be located at any point in the food production plant where hazards need to be prevented, eliminated, or reduced to acceptable levels. The identification of CCPs should ensure appropriate control measures that are effectively designed and implemented. In particular, if a hazard has been identified at a step where control is necessary for product safety and no control measure exists at that step, then the product or process should be modified at that step or at an earlier or later stage, to include a control measure. Moreover, a monitoring system per critical point should be established and implemented.

CCPs should be carefully identified and documented. They should be used only for purposes of product safety or their use should be justified by the critical nature of the CCP. CCPs should not be confused with control points that do not control safety but refer to quality issues.

A tree diagram can be used to detect CCPs or PrPs in a food processing plant as shown in Table 1.

OPRPs are PrPs that are essential. They are essential because they are necessary to control specific food safety hazards.

Critical Limits

The maximum or minimum value to which a physical, biological, or chemical hazard should be controlled at a CCP to prevent, eliminate, or reduce to an acceptable level the occurrence of the identified food safety hazard.

The establishment of CLs takes place in parallel or follows the identification of all factors associated with CCPs. CL levels should be determined scientifically and should be related to unacceptable consumer health risks.

HACCP Plan

The HACCP coordinator and HACCP team are responsible for the development of the HACCP plan or plans for specific food products having identified the highest risks to food safety within hazard analysis. The HACCP plan should include the different food safety hazards to be controlled at each CCP, the control of measures, CLs, monitoring of procedures, corrections and corrective actions if CLs are not in control, responsibilities and authorities, and monitoring records.

Table 1 Tree diagram for CCP and OPRP detection in food processing

Procedure step	*Q1 Do preventative control measures exist? (yes/no)*	*Q2 Is the step specifically designed to eliminate or reduce the likely occurrence of hazard to an acceptable level? (yes/no)*	*Q3 Could contamination with identified hazard (s) occur or could this increase to unacceptable levels? Receiving of raw materials	Y	N	N	–	OPRP
Storage of raw materials	Y	N	Y	N	CCP1 (M)

Verification Planning

Verification activities should confirm that PRPs and OPRPs are properly implemented, continually update the hazard analysis, and ensure that the HACCP plan is implemented effectively, hazard levels are within acceptable levels, and FSMS are performing effectively on a daily basis. The food safety team is involved in result evaluation.

Elements of verification include validation, CCP verification activities (calibration of monitoring devices, calibration record review, targeted sampling and testing, and CCP record review), HACCP system verification (observations and reviews and microbiological end product testing), and review by regulatory agencies.

Establishment of a Product Traceability System

A traceability system is mandatory in ISO 22000 but happens to be a common process in the food industry, often as a result of legislation. The auditor should check the batch and/or lot identification in records maintained throughout the process from material receipt to end product dispatch. The organization defines a retention period for traceability records and considers implications for disposition of potentially unsafe products and product withdrawal.

Corrective Actions

Initiation of corrective actions starts when nonconformities have been identified. A documented procedure defines requirements for nonconformities review (including customer complaints), determination of the causes of nonconformities, implementation of corrective action required, recording results of action taken, and review of corrective action taken.

Validation of Food Safety Control Measure Combinations

Validation of control measures relates to the control measures taken to manage hazards. These control measures need to be validated before being implemented. Steps prior to validation include identification of the food safety hazards to be controlled, identification of the necessary control measures, and prioritization of control measures to be validated.

The organization should validate that the selected control measures are capable of achieving the intended control of food safety hazards and that the control measures are effective and capable of ensuring control of the identified food safety hazards to obtain end products that meet the defined acceptable levels.

Validation is the element of verification focussed on collecting and evaluating scientific and technical information to determine if the HACCP plan, when properly implemented, will effectively control the hazards. It involves a scientific and technical review of the rationale behind each part of the HACCP plan from hazard analysis to each CCP verification strategy.

Example of a validation activity for cooked hamburgers is the collection of data to establish that CLs for maximum patty thickness, maximum belt speed, and minimum oven temperature will ensure that the internal temperature of every patty reaches the minimum requirement.

Continual Improvement

Continual improvement is an integral part of every step in environmental management and takes place by conducting routine internal audits and monitoring. Hence, policy, objectives, targets, and plans will have to be modified when nonconformities are identified. Actions for improvement include analysis and identification of areas for improvement; search and evaluation of possible solutions to achieve the objectives for improvement; implementation of the selected solution; measurement, verification, and analysis of implementation results to determine that the objectives have been met; and formalization of changes.

Management should ensure that the organization continually improves the effectiveness of the FSMS through communication, management review, internal audit, evaluation of verification results, analysis of results of verification activities, validation of control measures, corrective actions, and FSMS updating.

The New Standard ISO 22000

ISO 22000 is the new international standard for FSMSs, harmonizing key requirements and overcoming the difficulties of various food safety standards by region, country, activity, organization, and food type. ISO 22000 will help the organization to establish, implement, improve, and update an FSMS in the food plant. This standard promotes conformity of products and services to international standards by providing assurance about quality, safety, and reliability. It was created to gain universal acceptance and recognition by all segments in the food chain.

ISO 22000:2005 includes the following documents:

- ISO/TS 22003, FSMS – Condition for organizations that make certification and inspection of FSMS gives harmonized guidance for the accreditation (approval) of ISO 22000 certification bodies and defines the rules for auditing an FSMS as conforming to the standard. Published in the first quarter of 2006.
- ISO/TS 22004, FSMS – Guide-related practicing of ISO 22000:2005 gives harmonized guidance for the approval of ISO 22000 certification bodies and defines the rules for auditing an FSMS as conforming to the standard. Published in November 2005.
- ISO 22005, monitoring in bait and food chain – General principles and guide for system preparing and design.

The standard has three parts:

- Requirements for GMPs or prerequisite programs
- Requirements for HACCP principles of the Codex Alimentarius
- Requirements for management system

The standard aims at food safety enhancement, consumer protection, consumer confidence strengthening, cost efficiency

improvement throughout the food supply chain, compliance with Codex HACCP principles, alignment with ISO 9001:2008, and provision of auditing guidelines for internal audits and third-party audits.

Relation of ISO 22000 to HACCP

ISO 22000 dynamically combines HACCP principles as described by the Codex Alimentarius Commission with PrPs and HACCP plan using hazard analysis. The adoption of a solid PrP is important with regard to improving the economic viability for HACCP implementation. Representative PrPs are water supply, premises/equipment, transport and storage, sanitation and pest control, personnel hygiene, recall program, supplier evaluation, and approval. The ISO 22000 analysis worksheet for determination of the PrPs for food processing is shown in Table 2. Receiving of raw materials is a PrP, whereas pasteurization is not a PrP, that is, it is a CCP. This analysis worksheet can be used in conjunction with the decision tree or tree diagram shown in Table 1.

Failure Mode and Effect Analysis

In failure mode and effect analysis (FMEA), risk of contamination and its presence at hazardous fraction in the final product are expressed with the risk priority number (RPN), which is defined as follows:

$$\mathrm{RPN} = \mathrm{S} \times \mathrm{O} \times \mathrm{D} \qquad [1]$$

where S is the severity of contamination risk, O the occurrence of contaminated ingredient, and D is the detection probability of contaminated ingredient. S, O, and D are given values out of 10.

Corrective action is carried out when RPN is greater than 130.

The classification of hazardous elements occurs according to the RPN assessment, and corrective actions are proposed per identified hazard. Following calculation of the new RPN (the RPN′ after undertaking corrective actions), a new classification of hazardous elements is shown (Table 3).

Analysis is made based on both best expert opinion and product history (epidemiological studies) for similar items of all the ways that each component or subsystem might fail to comply with its intended function.

Table 2 ISO 22000 analysis worksheet for determination of the prerequisite programs for food processing

Processing step	*Are the technical infrastructure and the preventative maintenance program adequate?*	*Is it feasible to evaluate them?*	*Do they contribute in the control of recognizable food safety hazards?*	*Does the effectiveness of the remaining control measures depend on them?*	*Is it a prerequisite program?*
Receiving of raw materials	Yes	Yes	No	Yes	Yes
Pasteurization	Yes	Yes	No	No	No

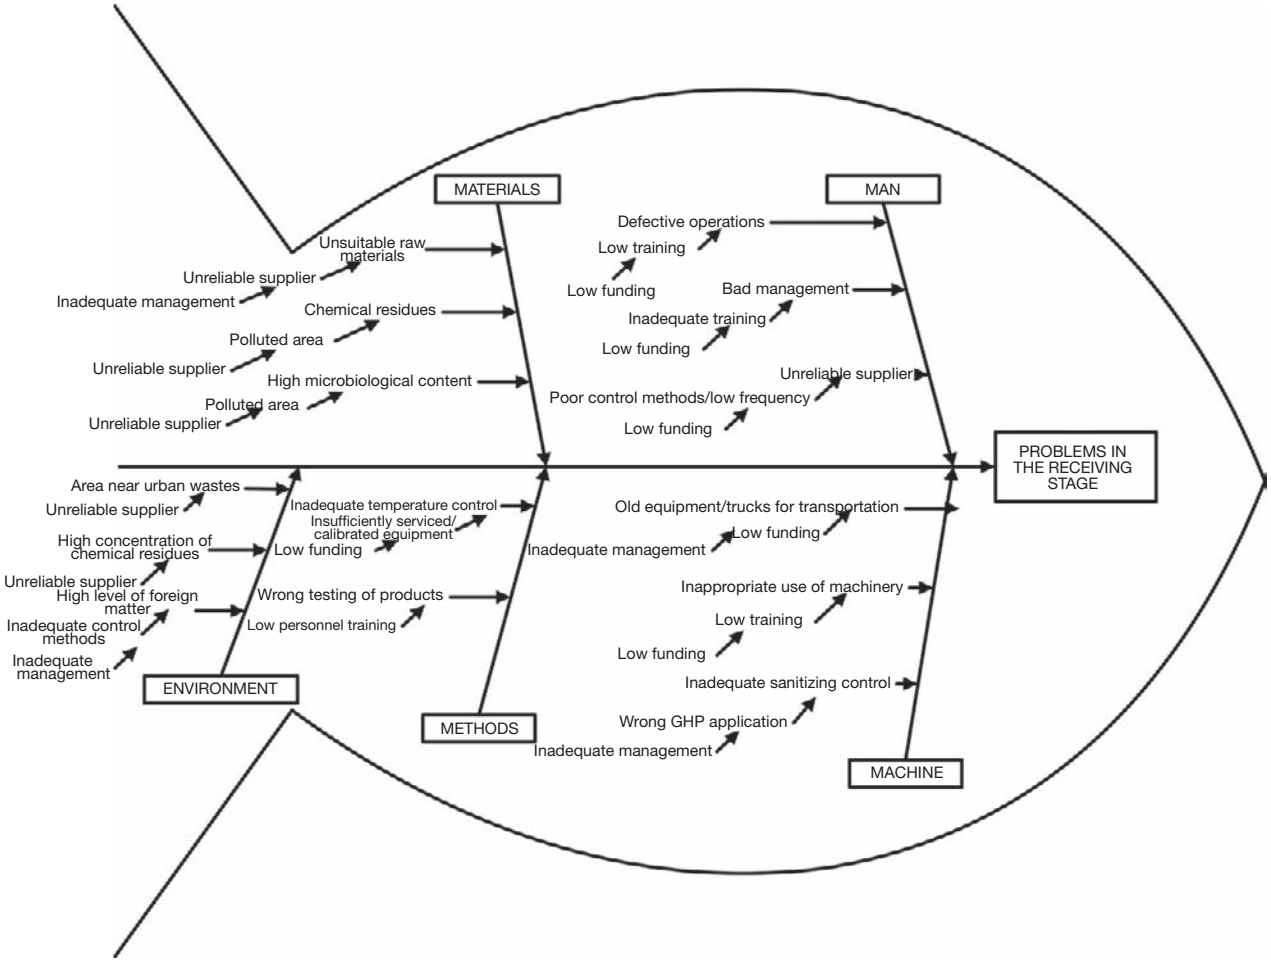

Figure 1 Application of Ishikawa diagram to food processing (CCP receiving of raw materials).

Ishikawa Diagrams

Ishikawa or fishbone diagrams analyze all the dangers at all processing stages where CCPs are incorporated. These diagrams consist of five basic axes: man, machine, materials, methods, and environment. In these axes, the danger is described.

The Ishikawa diagram or fishbone diagram was invented by Ishikawa, a Japanese quality control statistician. Due to its function, it is referred to as a cause and effect diagram, and due to its resemblance to fish skeleton, it is also referred to as a fishbone diagram. This diagram is an analysis tool that provides a systematic way of investigation of causes and effects. Causes create or contribute to those effects.

An implementation of Ishikawa diagram for the CCP of raw materials receiving in any food processing is shown in Figure 1.

Pareto Diagrams

A Pareto diagram is usually constructed aiming at the determination and display of particularly high-risk processing steps and their corresponding corrective actions. Then, a second Pareto diagram is drawn focussing on spinach pie processing aiming at the determination of new risk situation (following the suggested corrective actions) (Figures 2 and 3).

In a Pareto diagram, corrective actions for the 20% of causes of failures with the highest RPN are recommended. Then, further corrective actions are suggested for the remaining causes of failures.

Conclusion

HACCP and ISO 22000 are FSMSs that can be used effectively and proactively by the food industries along with GMPs and GHPs to enhance food safety and respond to food scares. Other food safety tools can be used in conjunction with HACCP and ISO 22000 such as FMEA, Ishikawa diagrams, and Pareto diagrams.

Introduction

Cooked ham is typically a cured piece of pork derived from the hind legs of swine, which is further preserved through processes like cooking and, optionally, smoking. Cooked ham is also known as gammon in the United States. The processing of cooked ham involves the use of brine or curing solutions that are either injected or soaked, followed by the application of thermal treatment. The piece of ham may be intact with bones in or deboned before either curing or cooking. Once the final ham product is manufactured, it can be sold as a piece for slicing by retailers or sliced and packaged under various forms of vacuum or under modified atmosphere for its direct sale to consumers at retail outlets.

There are many variables at play during the manufacture of a cooked ham, and these all impact on the final quality of the final product, but the quality of raw materials and an adequate processing regime, based on minimum temperature–time treatments, are the most important to achieve a product possessing good organoleptic quality. Initially, special care must be taken with respect to the selection and quality of the meat cut chosen, the quality and level of ingredients used in cure formulation, the injected volume of brine or cure used, the rate and extent of tumbling employed, and the cooking time and temperature selected. Cooked ham is sold in many formats: from chilled and sliced formats lasting for several weeks to canned formats lasting for months to years. The consumption of cooked ham is quite relevant in many countries worldwide. The processing technologies employed for the production of cooked ham may change depending on the raw materials and the processing conditions adopted by ham manufacturers in different regions of the world, and these will be discussed in this article.

Types of Cooked Ham

The best cooked hams are achieved when low injection curing volumes are used and no addition of any ingredient, with the exception of salt and nitrite, is utilized in the cure formulation. In general, if excessive levels of water are injected into the ham, then the resulting product quality becomes poor. Water retention in ham products can be facilitated by the addition of processing aids like polyphosphates, carrageenans, alginates, and starches.

There are many types of products that depend on the raw materials used and the type of processing technology employed. Ham products are no exception. Some traditional hams have received the name of the region where they were originally produced, like British Wiltshire and York hams, French jambon de Bourgogne and jambon de Reims, and the Italian prosciutto cotto. For instance, Wiltshire ham is produced according to traditional recipes originating back to the eighteenth century using a wet cure, within which the meat is soaked for 4–5 days and which then could be smoked using oak whisky barrels.

If claims are made for any specific procedure like hickory-smoked ham, then hickory wood must be used for smoking. If the smoke flavor is injected, then the term added smoke flavor must be included on the label. Honey-glazed hams or honey-cured hams can be labeled if honey constituted at least 50% of the sweetener used and comprised at least 3% of the formula and has a discernible effect on flavor. Other sweet cure hams may be produced by using less salt and including sugar in the brine.

Processing Technology

The processing of cooked ham includes some key manufacturing stages, which are receipt and intake of hams, brine injection, tumbling and massaging, cooking, and cooling as shown in Figure 1.

Receipt and Intake

Meat for ham manufacture may be preserved through refrigeration or kept under frozen storage. Once received, they are controlled before processing. The microbiological condition of the hams must meet the microbiological standards and not exceed 5 °C upon arrival and be stored at −2 °C to +4 °C until processing commences. Previously frozen meat for ham manufacture must be completely thawed, taking care that the outer surface of the meat does not exceed +7 °C during the defrosting period. The high pH 6.0–6.5 of dark, firm, and dry leg meat is not a problem for cooked ham manufacture because any microbial risk is eliminated by the heat treatment, and its typically high pH assists in increasing water retention. The fat and its composition in fatty acids in meat are very important for flavor development in the resulting ham. Of course, this strongly depends on the pig crossbreeds used for meat supply, the production systems operated, and the type of feeds received by the pigs. In most cases, hams are boned to facilitate cure injection, cure diffusion, meat molding, and, later, slicing.

Brine Injection

The main ingredients in the brine or cure are salt and sodium or potassium nitrite. The amount of salt varies depending on the type of product to be produced. The salt in the brine or cure assists in the binding of muscles through myofibrillar protein solubilization, and this also results in the enhancement of product yield and final weight. Some carbohydrates, like sucrose, dextrose, and corn syrup, may be added to the brine or cure to impart a pleasant mild taste. Nitrite is added to assure the generation of nitric oxide for preservation purposes, and it also contributes to the typical cooked pink color brought about by

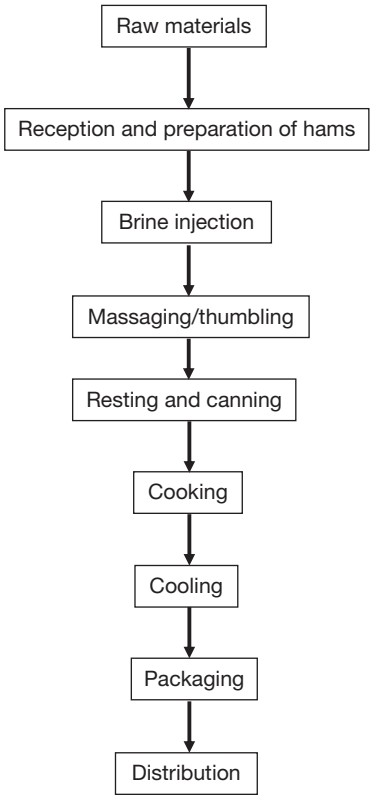

Figure 1 Flow diagram for a typical processing of cooked ham.

the formation of nitrosyl hemochrome. Sodium ascorbate or sodium erythorbate may be added as cure accelerators in order to speed up the conversion of nitrite to nitrous oxide, thus resulting in the disappearance of nitrite and lowering the generation of nitrosamines. Other additives may be added to the brine or curing solution, but this is mostly used for the production of low-quality hams where more water uptake is required to make such products more palatable. Consequently, additives such as alkaline phosphates, polyphosphates, and pyrophosphates elevate pH values to around 6.0–6.5, thereby shifting the pH far from the isoelectric point of muscle proteins (which lies around a pH value of 4.5), and consequently, the water holding capacity is increased and more water is retained within the ham product. Phosphates also enhance the ionic strength within hams and this also results in protein solubilization. The amount of phosphates that is permitted in the curing solution for cooked hams varies from country to country and from product to product, but in general, added phosphate content in cooked ham does not exceed 0.3–05% (as P_20_5). Levels certainly do not exceed 0.6% as higher usage levels will result in the generation of bitter aftertastes, which consumers can easily perceive.

The brine or cure is injected into the ham through a multi-needle system. Pumping speed and volume of injection may be controlled. The injection machines may pump brine into boneless hams or also into bone-in hams. Care must be taken when injecting bone-in meat in order to avoid needle breakage as this would pose a major health risk. When an immersion brine is used to cure hams, it is continually reused, and its composition, temperature, and pH are monitored between uses. A current practice, after brine injection, consists of holding the hams for a brief period of time for resting. This practice assures a full diffusion of salt and additives through the entire piece.

Massaging and/or Tumbling

This is a common operation also performed under refrigeration. Tumbling or massaging hams typically takes a few hours and is carried out in rotational tumblers or mixers under mild agitation to avoid severe physical disruptions or damages. Often, the tumbling process occurs in cycles of starts and stops (i.e., tumbling for 20 min and resting for 10 min, before the cycle starts again). It is very important to maintain a low speed so that the paddles or baffles contained within the tumbler do not destructively damage the muscles as they collide with these structures. The tumbling process is often accompanied by applying a vacuum within the tumbler to remove air and air bubbles within the meat, and this reduces undesirable oxidation reactions. Pulsed vacuum application can be applied to tumbling ham, and the serial application and removal of the vacuum pressure cause the ham to sequentially close and open the meat structure, thereby allowing processing salts to become more interactive with meat myofibrillar proteins.

Cooking

Following the tumbling process, the meat pieces and extracted exudate are often stuffed into metal molds, polymer-based bags, or elasticated polymeric netting and made ready for cooking. The purpose of cooking, apart from achieving an acceptable flavor and texture, is to assist in setting the three-dimensional gel matrix that helps bind meat pieces together and reduces the microbial load on the ham to a level that renders it safe. Endogenous enzymes are also inactivated. The cooking process used for ham manufacture is such that the time/temperature achieved in all parts of the ham is equivalent to 2 min at 72 °C. The actual temperature achieved in the center of the ham may vary between 68 °C and 75 °C, but an internal temperature of 72 °C is targeted typically. Heat treatment is calculated and applied to inactivate pathogens and spoilage microorganisms and requires a rigorous control of time and temperature to achieve the final desired effect and ensure product wholesomeness during the anticipated shelf life. Canned hams are contained in special metallic molds that produce the final product shape or optionally packaged in ham-shaped plastic (zero water loss). Cooking can be considered as a pasteurization process since the internal temperature in the ham can reach around 72 °C after 30–60 min of heating. The way heat is distributed within hams follows two heat transfer mechanisms. The first one is convection by transferring the heat from the heating medium to the ham surface, and the second is by conduction of the heat from the ham surface to the inner part of the ham. The rate of temperature increase during cooking is important. Cooking can be operated in three ways: (1) heating at a fixed temperature, which is a less used approach, (2) heating until a determined temperature inside the ham (usually 68 °C) is reached, and (3) heating through stages so that consistent increases in temperature within the ham are stepwise, not exceeding 25–30 °C during each sequential step, thereby avoiding excessive heating of the ham. The sensory

Figure 2 Example of a cooked ham slice.

characteristics of hams are developed during cooking as a consequence of multiple enzymatic and chemical reactions.

Cooling

This stage must be performed carefully to ensure the wholesomeness and safety of the hams. Ham molds are immersed in cold water or cooled by using cold water showers in order to reduce the temperature to below 5 °C inside the ham. The most hazardous period in the cooling process is the temperature transit between 50 °C and 12 °C where bacteria might grow during the time involved to achieve this, and consequently, this is why it is recommended not to extend the temperature reduction period for more than 10 h.

Final Product

Hams are removed from the molds and may be smoked at the end of the process. The smoking of ham is usually performed by hanging over burning wood chips in a smokehouse, through the use of friction smokers providing smoke to the smokehouse or by spraying atomized liquid smoke on its surface. In all cases, the final product appearance is equivalent. Once finished, the hams are packaged, sometimes with a previous surface heat treatment to avoid any recontamination. Cooked hams can be commercialized as a full piece to retailers or as ham slices packaged under vacuum or modified atmosphere ready to be consumed. For ease and consistency of slicing (thereby preventing ham slices from breaking apart), hams can be placed in a freezer for up to 12 h (usually overnight) to harden the ham surfaces. A typical slice of cooked ham is shown in Figure 2.

Quality Attributes of Ham

Color

During the heating process, the color of ham changes from the initial red pork meat color to the final pink color, typical of cooked ham. This is due to nitrosyl hemochrome, which results from the transformation of nitrosyl myoglobin by heating. The final color of the cooked ham depends primarily on the initial content of myoglobin present in the starting muscles used and, consequently, is dependent upon the biochemical muscle type (whether muscles are more oxidative or glycolytic in nature), age of the animal at slaughter (higher in older animals), and degree of exercise afforded to the pigs during production.

Texture

The extent of heating and the enzymatic proteolysis on myofibrillar and connective tissue proteins will affect the structural breakdown and, thus, its texture. The moisture content and the amount of intramuscular fat also exert a positive influence on some textural and appearance traits. When hams are manufactured using hydrocolloids as part of the curing solution, the final ham products may have distinctive textures as a result of containing more bound water and possessing unique mouthfeel properties.

Flavor

Several biochemical changes, mainly relating to enzymatic reactions (proteolysis and lipolysis) by endogenous muscle peptidases and lipases, contribute to the generation of free amino acids and fatty acids, all substances that influence the taste and aroma of the final product. The high water activity and relatively low salt favor these enzymatic reactions, even though muscle peptidases become rapidly inactivated by heating, especially at temperatures above 50 °C. The release of free amino acids and free fatty acids may increase in hams during a 1–2-day chilled resting period before processing. Such released amino acids and fatty acids will be subject to further chemical reactions (i.e., Strecker reactions) that can generate volatile aromatic compounds. Further chemical reactions, like Maillard reactions, can also proceed during cooking and contribute to the generation of aromatic volatile compounds. So, the final flavor will depend on the time and intensity of heating.

Nutritional Composition

As for other meat products, the nutritional content of cooked ham is variable and is dependent on the initial composition of the raw ham (which is affected by pig physiology, animal production practices, and type and composition of feed) and the type of processing conditions used (brine injected, amount of injected water, other ingredients added, and heating conditions). Therefore, all of these factors will directly impact upon both the macro- and microcomposition of the final ham products.

Lipids, Fatty Acids, and Cholesterol

The fat content in cooked ham varies (5–20%) largely depending on animal genetics (pig crossbreeds used) and the type of feed offered to pigs during production. Triacylglycerols, which are particularly rich in monounsaturated fatty acids (45–50%) and contain a moderate level of saturated fatty acids (SFA) (35–40%), are mainly located in fat cells, while phospholipids, which contain high amounts of polyunsaturated fatty acids (PUFAs) and some cholesterol, are located in cell and organelle

membrane lipids. Free fatty acids (9–20% of total lipids) can also be found in ham products. The PUFA/SFA ratios may range from 0.17 to 0.35. Cholesterol levels in cooked hams are in the range of 50–65 mg/100 g, so that consumption of 100 g of cooked ham would contribute nearly 20% of the maximum recommended daily intake of cholesterol (300 mg).

Proteins, Peptides, and Amino Acids

Cooked ham contains about 25–30 g of protein per 100 g ham. These proteins are considered of high biological value due to their high content of all essential amino acids. Animal proteins in the diet are also known to favor the absorption of minerals like heme iron and trace elements. There are also histidine-based dipeptides, carnosine, and anserine, compounds that all possess antioxidant activity and that are quite resistant to heat treatment, thereby functioning to prevent oxidation-based reactions in cooked ham products. However, their antioxidant properties may only be secondary to those provided by the presence of nitrite in these products.

Minerals

Cooked ham constitutes a good source of highly bioavailable heme iron, zinc, phosphorus, potassium, magnesium, and selenium.

Vitamins

Cooked ham constitutes an excellent source of B-group vitamins like thiamine (B_1), riboflavin (B_2), niacin, vitamin B_6, and vitamin B_{12}, but, as for other meat products, its content in major vitamins A, C, D, and K is rather poor. Vitamin E may be largely increased in hams if pigs have been supplemented with the vitamin in the feed prior to slaughter.

Ham: Dry-cured Ham

F Toldrá, Instituto de Agroquímica y Tecnología de Alimentos (CSIC), Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Dry-cured ham constitutes a type of meat product that has been produced for centuries. These products exhibit a wide variety of flavors and textures. Today, these products still constitute an important part of any local economy, culture, gastronomic heritage, and tradition. Even though the technology used for ham manufacture has evolved and new technologies are introduced, the basic processing procedures still rely on traditional manufacturing processes that are mostly based on salting, drying, and ripening. The dry-cured ham products develop an intense and characteristic texture and flavor, especially during the ripening and drying phases, where endogenous muscle enzymes play an important role in the final character of the product. The drying of dry-cured ham products is a key and common practice in product manufacture and adopted to great effect in the Mediterranean region due to the privileged climatic conditions that exist there. Not surprisingly, this is a region where dry-cured meat products have typically been produced. The primary product types produced and their specific characteristics are described in the succeeding text.

Types of Dry-Cured Ham

Dry-cured ham constitutes one of the main and representative products in Mediterranean countries. Some of the most well-known European products include Spanish jamón ibérico and jamón serrano; French Jambon de Bayonne; Italian prosciutto di Parma, prosciutto San Daniele, and prosciutto Toscano; Belgian jambon d´Ardenne; Portuguese presunto; and Croatian Istrian dry-cured ham. The production of these hams is based on a careful selection of the raw materials (back legs), control of time and processing conditions, and, of course, quality control at the end of the process, especially for color, texture, and flavor attributes (see Figure 1). Minimum processing time for an acceptable quality of those nonsmoked products is usually >9 months, but for the highest-quality products like Iberian hams, the processing time may last up to 24–30 months. The result is a ham with extremely rich flavors that are generated through enzymatic reactions. Dry-cured hams are usually consumed raw and cut into thin slices (see Figure 2), without further smoking or cooking.

Culatello is a derived product from dry-cured ham. It is produced in Italy from the large part of the ham (underside). It is packaged with the pig's bladder and tied using slip knots in order to keep its nice round shape. Then, culatello is salted and dried like hams. The processing is usually between 10 and 14 months. Culatello di Zibello is produced in Parma (Italy).

Certain dry-cured hams have been protected with European Union certifications like the protected designation of origin (PDO), the protected geographical indication (PGI), or the traditional speciality guaranteed (TSG). There are many PDO-classified products in the Mediterranean area. In the case of Spain, there are three for Iberian hams: Guijuelo, Dehesa de Extremadura, and Huelva, and one for non-Iberian hams that is denominated Teruel. Serrano ham has TSG classification; French Bayonne ham has PGI classification, as does Spanish Trévelez ham. The accomplishment of the established requirements is controlled by consortia or local entities that take care of the control of raw materials, processing conditions, and quality of the finished products. For instance, Serrano ham, a TSG ham produced in Spain, is stamped once approved by the Serrano Foundation. In a similar way, the PDO prosciutto di Parma is stamped by the Parma consortium once it has been produced in a state of control and has met all of the requirements and quality attributes expected for the product by the consortium.

Hams in Northern Europe are processed for shorter times, than those in Southern Europe, and manufacture is followed by smoking and cooking before consumption. Some examples are the Norwegian Spekeskinke ham that is ripened for up to 12 or more months, Fenalâr ham produced from lamb or mutton, German Westphalian ham, the cold-smoked Katenschinken ham, and the Finnish 'sauna' ham.

The American country-style ham or country ham is salted, postsalted, and aged for about 1 month. It is usually smoked and cooked before consumption (pan frying, in the oven or roasting). Most relevant country hams are produced in Kentucky, Virginia, Tennessee, Missouri, and North Carolina (see Figure 3).

China has also produced dry-cured hams for centuries. Some of the most important are the Jinhua ham, produced in the Jinhua district; Xuanwei ham, produced in the Yunnan province in the southwest of China; and Rugao ham, produced in the Jiangsu province.

Production of Dry-Cured Ham

The traditional processing of hams was extensively used in ancient times, but today, they are limited in production and restricted to rural regions, which are located in mountainous areas where cool and dry winds are available most of the year. Basically, and focussing on the Mediterranean area, the process consists of rearing pigs at home for about 1 year. These pigs are slaughtered by the end of November to coincide with late autumn or early winter months. Hams are salted by rubbing salt on the surface of the hams, and these are left hanging for a few weeks. Salt diffuses through the whole hams over a period of 3 months, and then, they are hung in large rooms in the uppermost part of buildings for the ripening and drying processes to proceed, which progress during the spring and summer months. Effective drying can be achieved by correct employment of natural air circulation, which is achieved by manual opening of windows. The decision is based on

Figure 1 Image of Spanish dry-cured ham during ripening/drying.

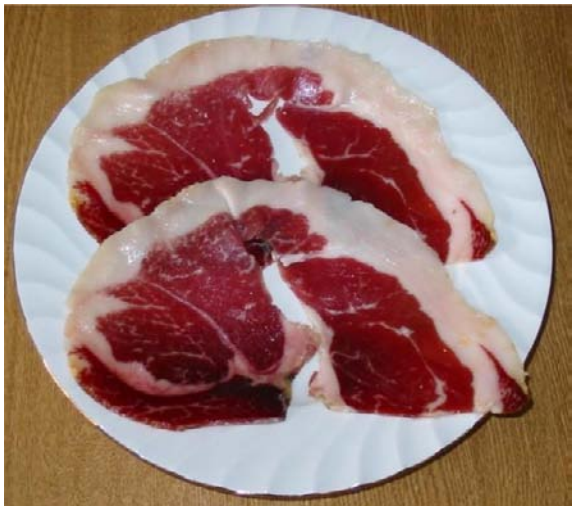

Figure 2 Slices of Iberian dry-cured ham showing typical marbling.

subjective evaluation of ham status. Total processing time takes nearly 1 year to complete.

The current processing technology is based on traditional steps but using modern technology. There is a careful selection of the raw meat materials (back legs from specific crossbreed pigs reared under controlled production regimes). The first stage in the manufacturing process involves meat reception, where hams are weighed and rubbed with curing salt (which is a mixture of sodium chloride and potassium nitrate) on the external surface of the ham. In some ham types, nitrate is not added. Immediately, hams are covered by salt during the salting stage. The main purpose of salting is to allow the

Figure 3 Image of a smoked American country-style ham.

penetration of salt and other curing agents into the meat. After 11–15 days, hams are hung to allow for diffusion of salt and curing agents through the entire meat piece and allow them to reach the inner part of the ham; this postsalting period lasts up to 3 months. Then, hams are ripened and dried to encourage flavor development and water loss for a period of time ranging anywhere from 1 to 18 months or more. Hams may be further ripened in cellars at mild temperatures for long periods of time; up to 24 months at temperatures between 10 and 20 °C in order to assist in the development of exquisite and intense flavors generated through further chemical and enzymatic reactions. The application of smoking is optional and more typically applied in Northern European countries and in the United States for country hams. Weight losses may reach up to 35%. Hams are rigorously controlled at the end of the production process for the quality attributes of color, texture, and flavor.

Traditional commercialization of hams is either as an entire piece (including the bone and foot) or as boned and molded pieces that facilitates its slicing at the point of retailing or directly by consumers at home. In the last few decades, the commercial distribution and retail display of ham slices have been through the employment of vacuum or modified atmosphere packaging systems.

Sensory Characteristics

Dry-cured ham has a typical bright red cured color, which is due to the formation of nitrosomyoglobin; a compound generated through the reaction of nitric oxide with myoglobin. This color is more intense in those oxidative muscles that contain larger amounts of myoglobin and in those hams derived from older animals.

The texture of hams depends on the extent of proteolytic breakdown of myofibrillar proteins and connective tissue and the extent of drying and the content in intramuscular fat, which also increases the juiciness and acceptability of hams.

Flavor of dry-cured ham is very intense, pleasant, and much appreciated. The taste is mainly associated to nonvolatile compounds like free amino acids and small peptides, which are generated in large amounts through proteolytic mechanisms

that take place throughout the entire ripening and drying process, thereby leading to the generation of numerous aromatic volatile compounds. These compounds are generated through different routes like enzymatic proteolysis and lipolysis and chemical reactions like amino acids degradation by Maillard and Strecker reactions.

Nutritional Composition of Dry-Cured Ham

Nutrient composition for dry-cured ham may be quite variable depending on not only factors intrinsic to the raw material, like pig breeding, animal production practices, type and composition of feed, age, and sex, but also factors related to meat processing like salting, drying, and ripening. So, some relevant differences in qualitative and quantitative data may be found in relation to not only macrocompounds, such as water, protein, fat, and salt content, but also microcompounds, like minerals and vitamins. All of these compounds are relevant to the nutritional characteristics of hams and to their potential implications for human health. The primary composition values for dry-cured hams are reported in the succeeding text.

Lipids, Fatty Acids, and Cholesterol

Fat content in dry-cured ham is extremely variable due to the influence of genetics (pig breeds used) and the differences in the type of feed offered to pigs prior to slaughter. For example, Iberian hams are known to contain large amounts of intramuscular fat (>9.5%), while those produced from usual crossbreeds contain much lower amounts: about 4.8% for Serrano hams, 3.6% for Parma hams, and 2.6% for Bayonne hams.

Triacylglycerols, which are rich in monounsaturated fatty acids (MUFA) and, to a lesser extent, in saturated fatty acids (SFA), are mainly located in fat cells, while phospholipids, which contain high amount of polyunsaturated fatty acids (PUFA) and some cholesterol, are located in membrane lipids. There are also free fatty acids that can range from 9% to 20% of total lipids. The main typical ranges for the fatty acid composition of lipids in dry-cured hams from white pigs are within 35–40% of SFA, 45–50% of MUFA, and 10–15% of PUFA. In special cases, and due to the use of particular pig breeds or due to feeds offered, these ranges may increase to 54–58% of MUFA. The most abundant SFAs are palmitic acid (25%), stearic acid (12%), and myristic acid (1.5%). The PUFA/SFA ratios may range from 0.17 to 0.35, which are typical ratios found in hams from white pigs such as Serrano or Parma hams. However, the $n-6/n-3$ ratio in dry-cured hams tends to be too high (reported values from 9 to 30) in relation to the recommended ratio of 6. However, these PUFA/SFA and $n-6/n-3$ ratios may be improved through adequate manipulation of pig genetics and feeding strategies. Cholesterol levels in dry-cured hams have been reported within the range 65–70 mg/100 g for Serrano and Parma hams. This means that consumption of 100 g of dry-cured ham would contribute nearly 25% of the maximum recommended daily intake of cholesterol (300 mg). Some oxidation of unsaturated fatty acids may be observed during the processing of dry-cured hams. This can be followed by determining oxidation-derived volatile compounds like hexanal. In the case of cholesterol, its oxidation products are found at very low concentrations (<1 ppm).

Proteins, Amino Acids, and Peptides

Dry-cured ham contains about 30 g of protein per 100 g ham, but this figure may change substantially depending on the extent of drying and final product fat content. These proteins are considered of high biological value due to their high content and due to their rich possession of all of the essential amino acids. A large proportion of these amino acids are readily available as a result of the extensive proteolysis, which takes place during dry-cured ham manufacture. Some additional for the nervous system from other amino acids like taurine (80 mg/100 g) and glutamine (5 mg/100 g) may be achieved. Animal proteins in the diet are also known to favor the absorption of minerals like heme iron and other trace elements. There are also histidine-based dipeptides, carnosine and anserine, which possess antioxidant activities that can control oxidation through the prevention of lipid oxidation by inactivating catalysts and/or free radicals in the cytosol. In any case, proteins experience some oxidation during processing and storage of dry-cured ham, but the determination of protein carbonyls shows intermediate oxidation when compared to the oxidation in other dry-cured and cooked meat products.

Recently, many peptides resulting from myofibrillar and sarcoplasmic protein degradation have been identified through the use of proteomic tools. Extracts of dry-cured ham and some of the identified peptides, with sequences containing between 2 and 10 amino acid residues, have shown a relevant inhibitory activity against the angiotensin I-converting enzyme (ACE). This enzyme plays an important role in the regulation of blood pressure by converting an inactive angiotensin I to angiotensin II, a potent vasoconstrictor. So, ACE inhibition can reduce arterial contraction and decreased blood pressure. The generation of bioactive peptides has been attributed to the action of muscle dipeptidyl peptidase enzymes, which remain active and stable during the complete processing cycle.

Minerals

Dry-cured ham constitutes a good source of iron (1.8–3.3 mg/100 g), which is highly bioavailable and, thus, provides a high nutritional contribution upon dietary intake. This is an important contribution because iron deficiency produces anemia, one of the main public health concerns that affect a substantial part of the population. In addition, heme iron favors absorption of nonheminic iron from other foods. Other relevant minerals found in dry-cured meat products are zinc, phosphorus, potassium, magnesium, and selenium (see Table 1). Zinc bioavailability also increases during the consumption of animal proteins. Recommended zinc intake levels are not being reached in many countries, and its deficiency considerably affects morbidity, mortality, growth, and development.

The main health concern with the consumption of dry-cured ham is related to its high salt content. Sodium concentrations up to 1200 mg/100 g may be reached in certain hams, but they are too high in relation to the recommended sodium intake that is < 2000 mg/100 g. This large amount of salt limits

ham consumption for a certain section of the population, which has a predisposition toward high blood pressure.

Vitamins

Dry-cured ham constitutes an excellent source of vitamins, especially the group B vitamins like thiamine (B_1), riboflavin (B_2), niacin, vitamin B_6, and vitamin B_{12} (see Table 1). The amount of thiamine that acts as a cofactor in various enzymatic reactions affecting appetite and the nervous system is very high (0.57–0.84 mg/100 g). Folate levels up to 13.5 μg/100 g are found in ham, which can help to reduce homocysteine levels. Levels of α-tocopherol in dry-cured ham usually range from 0.08 to 0.67 mg/100 g. However, its content in major vitamins such as A, C, D, or K is rather poor. Vitamin E may be largely increased in meat products if pigs are supplemented with this vitamin through the diet for several weeks prior to slaughter.

According to EU legislation (Directive 90/496/EEC, 2008), dry-cured ham can be considered a natural source of iron, zinc, phosphorus, selenium, thiamine, riboflavin, niacin, and vitamins B6 and B12, since it contains significant amounts (>15% RDA in 100 g) of these micronutrients (Table 1).

Dry-Cured Ham and Health

Some studies have been carried out in an attempt to relate the influence of the nutritional content of foods upon various pathologies, such as cardiovascular disorders, high blood pressure, various types of cancer, diabetes, and obesity. Few studies are available that assess the effects that dry-cured ham in the diet has on health, but a few studies have reported some beneficial effects of consuming dry-cured ham on atherogenic risk factors like a better lipid profile and a maintained blood pressure in spite of the high salt content.

In summary, dry-cured ham is a well-known product still produced through traditional recipes even in modern factories, giving particular sensory characteristics and a balanced nutritional profile.

Table 1 Minerals and vitamins in dry-cured ham and its contribution to recommended daily allowances (RDA)

Micronutrients	*Amount per 100 g*[a]	*RDA*[b]	*% of RDA*
Ca (mg)	12–35	800	1.5–4.4
Fe (mg)	1.8–3.3	14	13–23
Zn (mg)	2.2–3.0	10	22–30
Mg (mg)	17–18	375	4.5–4.8
K (mg)	153–160	2.000	7.6–8.0
P (mg)	157–180	700	22–26
Se (μg)	29	55	52
Na (mg)	1.100–1.500	–	–
Thiamine (B_1) (mg)	0.57–0.84	1.1	51–76
Riboflavin (B_2) (mg)	0.20–0.25	1.4	14–18
Niacin (equiv.)	4.5–11.8	16	28–73
Vitamin B_6 (mg)	0.22–0.42	1.4	16–30
Folic acid (μg)	Tr-13.49	200	6.7
Vitamin B_{12} (μg)	Tr-15.68	2.5	627
Vitamin E (mg)	0.08–1.5	12	0.7–12

Heat Treatment: Effect on Microbiological Changes and Shelf Life

Introduction

Foods are complex ecosystems constituted by the environment and the microorganisms that live in it. The food environment consists of intrinsic factors such as pH, water activity, and nutritional components and extrinsic factors such as temperature and gaseous composition, among others. By manipulating these, factors microbial growth can be limited and enzymatic degradation can be avoided, achieving the food preservation.

Thermal treatment is one of the most important physical methods for increasing the shelf life of foods. It is a versatile and economical system that can be adapted to almost any foodstuff and package. It can also be combined with other physical or chemical stress factors to achieve the microbiological stability of foods, causing the least possible destruction of quality. Traditionally, foods have been sterilized in hermetically sealed tinplate cans or glass jars. The intensity of the heat treatment applied depends on the type of foodstuff, quality of raw materials employed, pH, transportation and storage conditions, and geographic retail area. If the treatment complies with 'commercial sterilization' standards and no recontamination is allowed, it is clear that foods preserved by sterilization are stable and safe from a microbiological point of view during their shelf life. To avoid recontamination, sterilization relies on the existence of a hermetic package and, in some cases, such as with aseptic packaging, on very strict additional hygiene measures.

Preservation of foods by heat is a relatively old technology that started in 1810 with Nicolas Appert's work. In the development of this technology, there were various steps or milestones. The science application to food preservation by heat really started 85 years after Appert published his work. During those years, millions of canned foods were produced but no significant scientific advance was reported. Until well into the twentieth century, the main form of preservation was heat treatment, although salting, drying, fermentation, cold smoking, and other preservation methods were also used.

The evolution of thermal processes depended mainly on the equipment development and also on knowledge of the biological mechanisms involved in those processes. Isaac Solomon, a canner from Baltimore, modified the technology in 1860. He added calcium chloride to the cooking water, increasing the boiling point to 115 °C, which made it possible to increase the rate of production and also increase the bactericidal efficacy of the process. But the canning industry was revolutionized by A. K. Shriver in 1874, when he invented the pressure cooker. In 1910, Peter Durand patented a process that was, in essence, Appert's procedure but using a metal container instead of glass jars. During the twentieth century, the evolution of thermal processes permitted the development of the aseptic packaging technology, hydrostatic sterilization, and high-temperature short-time (HTST) procedures. These and other developments were, in principle, engineering improvements aimed at more efficient heating of canned products.

At the same time, there were advances on the scientific side related to process calculations. The first mathematical equations for process calculations appeared in 1920 and 1923 and published by Bigelow and Ball, respectively. More recently, the increase of HTST applications has been related to the development of time–temperature integrators for thermal process control and evaluation.

Heat treatment impact on the safety and quality of a product depends on the rate of the heat-induced reactions, and the process time treatment can have a strong and negative impact on the quality of processed foods, which is not desirable, especially nowadays, when the consumer trend is to demand minimally processed products. For preservation purposes, measuring the impact of heat in terms of safety and quality is of the greatest importance in the design, control, evaluation, and optimization of the sterilization process.

Effect of Heat on Microorganisms

Heat treatment is the most efficient and widely used method for destroying microorganisms. However, resistance to heat depends on the type of microorganism. A major problem in discussing mechanisms of heat inactivation and injury is that heat brings about many changes in biological material and therefore identification of 'the event' that causes death or injury is difficult. Moreover, there are differences among strains of the same species, among species, and between spores and vegetative cells.

Effect of Heat on Vegetative Cells

Most vegetative cells are killed at the sterilization temperatures normally used in the food industry, over 110 °C. The most important vegetative cells related to the safety of heat-treated foods are *Salmonella*, *Listeria*, *Campylobacter*, and *E. coli*, microorganisms that can contaminate various foods including meat, milk, vegetables, fish, and eggs and that are a great problem if the products are not properly heat-treated and stored.

Heat resistance to pasteurization temperatures depends on the species and strain and is usually expressed in terms of *D*-values (the time needed to reduce microbial concentration by one $\log_{10}$). Microorganisms are more resistant to dry heat than to wet heat, although, in view of food composition, much attention should be paid to wet heat in food microbiology. Physiological state is also a factor that affects microorganisms' resistance, cells in stationary growth phase being more resistant than cells in exponential phase. Other factors, such as low pH, modification of a_w, and presence of organic acids, also affect microorganism thermal inactivation.

In some cases, microorganisms can be sublethally injured by heat, making them more sensitive to adverse recovery conditions, such as organic acids, low pH, and low water activity. However, under these conditions, some microorganisms activate stress response mechanisms, and as a result, cross-resistance is often seen, leading, for instance, to greater heat resistance among the microbial population

Effect of Heat on Bacterial Endospores

To counteract unfavorable conditions, for instance, nutrient restriction, some microorganism species, especially *Bacillus* and *Clostridium*, activate a specific set of genes involved in sporulation. The bacterial endospore consists of a spore core with a membrane that will later form the vegetative cell. This core is surrounded by a cortex with a peptidoglycan structure and spore coat layers consisting of keratin on the outside. This morphology and the very low water content of the spore core play a crucial role in the high resistance (to heat and other stresses) of the bacterial endospore. When conditions become favorable, the spore starts to geminate and eventually develops into a new vegetative cell.

Since 1986, the year in which Cohn and Koch discovered the bacterial spore, its mechanisms of heat resistance and death have been studied in depth in an attempt to control inactivation processes. The high thermal resistance of spores has been attributed to the unequal distribution of water in the protoplast, providing stabilization to critical molecules such as DNA or RNA. However, this unequal distribution does not account for the extreme resistance of spores of some microorganisms, such as *Bacillus stearothermophilus*; consequently, it appears that there are other additional factors related to the high resistance of spores.

Heat can cause bacterial spore activation or induce deactivation and latency, damage, mutations, or complete inactivation. When the temperature is increased over the optimum for growth, the microorganism is inactivated or suffers some kind of deterioration, inability to initialize germination, or inability to duplicate critical molecules. It is possible that high temperatures affect the germination mechanism by damaging the trigger mechanism or cortex lytic enzymes. It has also been observed that some bacterial spores injured by heat are sensitive to antibiotics that under normal conditions would not affect them. This might suggest that heat affects the membrane, favoring the surface activity of antibiotics. Recent studies have indicated that physical damage of DNA does not take place, which means that in spores, the DNA is protected against heat and that the mechanism of thermal inactivation is something other than damage to those molecules.

There are many factors that can influence the heat resistance of bacterial endospores. The main factors affecting microorganisms can be grouped into four categories:

- Those affecting microorganisms during sporulation
- Those that affect microorganisms during storage of the spores that are produced
- Those that are a consequence of treatments given before, during, or after the treatment and also the nature of the medium
- Those affecting microorganisms during the recovery of survivors

Factors affecting microorganisms during the sporulation process determine the heat resistance of the spores. The presence of metal ions (Ca^{2+}, Mg^{2+}, or Mn^{2+}) in the sporulation medium is the main extrinsic factor contributing to an increase in the heat resistance of spores. If the presence of those ions decreases, the thermal resistance of the spores also decreases. A diminution of certain fatty acids during sporulation can increase the heat resistance of spores, and lack of glucose in the sporulation medium can reduce their heat resistance. The presence or absence of some amino acids makes the heat resistance of spores vary. One of the most important factors affecting the heat resistance of microorganisms during the thermal process is pH. Acidic pH values during the heating process reduce the heat resistance of spores, while at pH values close to neutrality, the thermal resistance does not vary substantially. There is an important interaction between pH and temperature; some studies have shown that the effect of pH diminishes as treatment temperature increases. Other factors that can influence the heat resistance of spores during the heating process are NaCl concentration, water activity (a_w), the presence of sugar or some germinant such as lysozyme that can help to increase the apparent heat resistance, and sublethal heating of spores prior to the thermal process.

Shelf Life

Shelf life is the time after manufacturing, processing, and packaging that a product remains acceptable under defined environmental conditions. It is a function of product characteristics such as composition, pH, water activity and fat content, the package, and the environment in which the product is transported, stored, and sold. It is established primarily not only in terms of microbial stability but also in terms of sensory acceptability.

Shelf life studies should be carried out in the following circumstances:

- Development of new products, processes or packaging, or reformulation or modification of existing ones
- Change of place of production or production team
- When there are no previous studies of shelf life

The starting point for determining shelf life is to obtain the necessary information about the food studied (chemical and physical characteristics, type of packaging, and storage, among other things) to determine the most important pathogenic microorganism that can grow in the product and to examine the relevant scientific literature. If the results of these studies guarantee that the pathogenic microorganism cannot grow in the food, it is not necessary to continue further studies. However, if the results are not clear on the possibility of growth of the organism, then it is necessary to conduct a series of additional studies that may include one or more of the following:

- Historical data for products manufactured
- Predictive microbiology
- Studies of specific laboratory life (durability studies and challenge tests)

Durability Studies

Durability studies assess the growth of a microorganism in a food during storage under reasonably foreseeable conditions without artificial inoculation, considering only natural contamination of the foodstuff. They are realistic and the evolution of the natural product contamination is studied. However, interpretation may be difficult because of the low prevalence of units contaminated with a certain microorganism, the low concentration of microorganisms present in the product under study, and/or the heterogeneity of the microbial distribution in the food. This would imply the need to conduct further studies and perform challenge tests.

Challenge Tests

In general, these tests are used only when other methods for assessing the food safety or its stability cannot be carried out or are not sufficiently clear about the possibility of pathogen growth. They provide information about the behavior of microorganisms inoculated in the food studied under certain conditions in a laboratory environment before storage. International committees have established protocols for conducting challenge tests. They consist essentially in inoculating the food with a defined concentration of the pathogenic microorganism and measuring the changes in the concentration levels during storage time, considering the worst case. This type of test should take into account the variability in food (using different batches) and specific food contamination (inoculation of isolates of food). However, it is difficult to imitate the level and heterogeneity of contamination and the physiological state of the bacteria.

Challenge tests can be performed with two different objectives:

(1) Assessment of growth potential (δ):

The growth potential (δ) is the difference between the $\log_{10}$ cfu g^{-1} at the end of the test and the $\log_{10}$ cfu g^{-1} at the beginning of the test. The experimental results may show a wide dispersion, notably because the lag phase is included. They depend on factors such as the strain(s) inoculated, the physiological state of the strain(s), the intrinsic properties of the food (pH, NaCl content, a_w, nutritional content, associated microflora, antimicrobial constituents, etc.), and the extrinsic properties (time–temperature profile, gas atmosphere, etc.) The main advantages of this method are (i) that it is relatively simple to implement and (ii) that the results can be used directly. Its drawback is the lack of flexibility in the interpretation: the results are only valid for the food studied in the conditions studied, so new experiments have to be performed each time there is a change.

(2) Estimation of growth parameters (μ_{max}):

The drawbacks of the previous approach can be solved by combining predictive microbiology models and challenge tests assessing μ_{max} (growth rates). This approach consists of a laboratory-based study that measures the growth rate of the pathogenic microorganism involved in an artificially contaminated food stored at an appropriate temperature. The temperature used for the experiment is not (necessarily) the one used for predictions since it is possible to predict growth at a temperature other than the one tested or in a time–temperature profile chosen to be representative of the foreseeable conditions of transportation, distribution, and storage. Once the test has been performed, the maximum growth rate is calculated from the growth curve. In the exponential growth phase, plotting the natural logarithm of the number of cells against time produces a straight line, and the slope of this line is μ_{max}. With this test, it is possible to estimate the microorganism concentration on a given day of the shelf life study if the initial concentration is known and/or to estimate the maximum allowable concentration of the microorganism that may be present in a food on the day of production in order to comply with legal limits at the end of its shelf life.

Thermal Process Calculation

Thermal process calculation is a fundamental step in ensuring the safety of thermally processed foods during their shelf life and their optimization. The calculation has two main components: (a) microorganism inactivation kinetics and (b) heat transfer mechanisms in food.

The inactivation kinetic of microorganisms is determined by using mathematical models that describe the rate of inactivation at a specific temperature and the dependence of the rate kinetic parameter on temperature. It has generally been accepted that when a homogeneous microbial suspension of microorganisms (spores or vegetative cells) is subjected to a constant temperature, microorganisms die at a constant rate. This means that, at a defined time, the same percentages of live microorganisms will die in the next time unit. According to these ideas, microbial inactivation by heat (spores and vegetative cells) follows two laws: (a) survivor law and (b) thermal destruction (TD) law.

Survivor Law

This law is based on the assumption that the destruction by wet heat of a pure bacterial culture at a constant temperature follows an exponential negative kinetic. This means that the number of viable cells is exponentially reduced during the time of exposure to a lethal temperature (Figure 1).

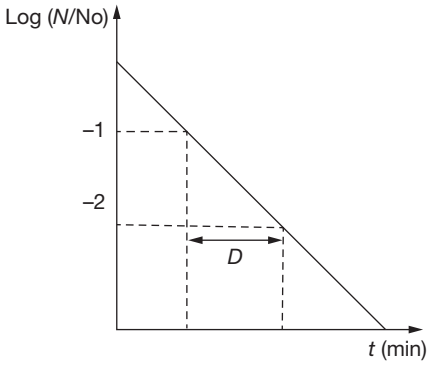

Figure 1 Survivor curve at constant temperature.

The parameter defining the destruction rate is named D_T, and it is defined as the treatment time, usually minutes or seconds, at a specific temperature that is required to reduce the bacterial population by 90%. This parameter is the best one for comparing the thermal resistance of different microorganisms, of the same or different species, at a given temperature, and of the same strain at different temperatures. It is also useful for evaluating the effect that environmental conditions have on the thermal resistance of microorganisms.

However, genetic or phenotypic heterogeneity of the cells in a population, mild or low temperature processes applied in food preservation, or any other stresses that may be applied to a microorganism population may result in nonlinearity. In these cases, shoulders appear, that is, the existence of a critical time before the microorganism is inactivated, or tails, showing a resistant population, or sigmoid curves, which are a combination of these two cases. A number of nonlinear models have been described in the literature, Weibull-like models, the biphasic model, normal distribution models, the logistic model, and Gompertz models being the ones most commonly used.

TD Law

When calculating sterilization or pasteurization processes, it is important to have knowledge of the variation of the rate constant with temperature.

The variation of D_T values with temperature was empirically modeled by Bigelow in 1921. This pioneer of thermal process calculations observed that by representing the logarithm of the rate constant versus temperature, a linear relationship was obtained for the temperature range studied. This curve was named the TD curve (**Figure 2**). The parameter that defines this TD relationship was called 'z,' and it indicated the change in treatment temperature (°C) required to achieve a tenfold increase or decrease in the D_T value.

Heat Penetration Curves and Process Calculation

The response of the product temperature to the temperature of the heating medium, for example, the steam retort temperature applied to a can, is governed by the physical laws of heat transfer and can also be expressed mathematically. Basically, there are two forms of temperature transfer: by conduction and by convection. The mechanism depends on the food; liquid food is usually heated by convection, while solid food is heated by conduction. The evolution of the temperature in the food can be measured by thermocouples installed in the package or in pipes containing the food, or mathematically by a computer model. The heat transport in foods is influenced by various factors including nature of the food, package, retort temperature, and the way in which the heat is applied. Heat penetration curves are obtained by plotting the evolution of food temperature versus treatment time. The parameters defining the heat penetration rate are deduced from heat penetration curves. These parameters, in addition to the microbial inactivation parameters, are used to calculate the thermal process properly.

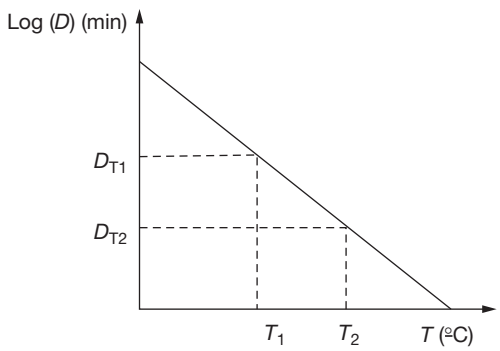

Figure 2 Thermal destruction curve.

There are two traditional ways to calculate the thermal process, the general method and the formula method first used by Ball in 1923 and improved in 1957 by Ball and Olson, known as Ball's formula method. The general method is more versatile and can be applied to almost any type of thermal process situation. However, this method is time-consuming and it soon gave way to the more convenient Ball's formula method. Ball's formula is very practical and rapid for estimating the sterilizing values of the process, although the accuracy of the calculation depends on how heat penetration parameters comply with certain restrictions established in the model.

Heat penetration curves and parameters can also be calculated mathematically, thus avoiding carrying out new experimental heat penetration assays when the retort or the size of the can is changed, for example. The models for carrying out these calculations are known as deterministic models, and they make use of a numerical solution by finite differences in the two-dimensional partial differential equation that describes conduction heat transfer in a finite cylinder.

The evolution of heat treatment procedures encouraged research on new models and tools to develop and validate thermal processes, not only from the point of view of safety but also from the point of view of retention of nutrients and sensory properties. Thus, the main objective of thermal process optimization is to maximize product quality while minimizing undesirable changes and cost. Optimization theory makes use of the different temperature sensitivities of microbial and quality factor destruction rates.

Heat Treatment: Principles and Techniques

OH Campanella, Purdue University, West Lafayette, IN, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Given its practical implementation in both laboratory and industrial scales, heat treatment is one of the most preferred methods used for the destruction of spoilage and pathogenic bacteria. It is usually assumed that, at constant temperature, thermal death of bacteria is exponential with time, and thermal process calculations used in the food processing industry are based on this assumption. Despite the widespread use of the approach, it has been largely recognized that there are situations in which survival curves of many bacteria and other microorganisms after thermal and nonthermal treatments do not follow the exponential relationship.

Survival curves are represented as the decimal logarithm of the ratio between the number of microorganisms at a particular time, $N(t)$, and the initial number of microorganism, N_0, as a function of time t. As early as 1912, four types of survival curves have been recognized; they are illustrated in Figure 1. Since, in a thermal treatment, the number of microorganisms decreases with time, the ratio $N(t)/N_0$ is smaller than 1, so the decimal logarithmic values of that ratio are always negative.

Curve A is the survival curve most typically found and shows an initial lag in the bacterial death followed by an exponential decay (linear logarithmic decay), whereas curve C is similar but it includes a tail, which is hypothesized to be due to the presence of highly resistant populations. Survival curves as that represented by curve D indicate the presence of populations having different heat resistances.

The Linear Case (Curve B)

Curve B is the linear case that is traditionally used for most thermal and nonthermal processing calculations. To mathematically model thermal treatments practiced by the food industry, the thermal death of bacteria at a constant sterilizing temperature is assumed to follow a first-order kinetics expressed by the following equation:

$$\frac{dN(t)}{dt} = -k(T)\cdot N(t) \qquad [1]$$

where T is the temperature and k is a temperature-dependent kinetic constant. For practical reasons, it is convenient to express eqn [1] in terms of a change in the bacterial count after a certain time is elapsed. That is obtained by simply integrating eqn [1] from an initial time arbitrarily chosen to be zero in which the bacterial count is N_0 to a certain time t in which the number of surviving organisms is $N(t)$. If the heating process is carried out under isothermal conditions, integration of eqn [1] yields

$$\log\frac{N(t)}{N_0} = -\frac{k(T)}{2.303}\cdot t \qquad [2]$$

For application in thermal processes, the equation has been rearranged as

$$\log\frac{N(t)}{N_0} = -\frac{1}{D(T)}\cdot t \qquad [3]$$

where $D(T) = \frac{2.303}{k(T)}$ is the decimal reduction time; it has units of time (e.g., seconds or minutes) and represents the time necessary to treat a given food, at constant temperature T, in order to reduce its microbial count by 90% (i.e., when $N(t)/N_0$ is a factor 1/10). Thus, microorganisms with higher $D(T)$ values are more resistant to heat treatments than microorganisms with lower $D(T)$ values. Equation [3] clearly shows that by fitting the experimental data, obtained from a thermal treatment at constant temperature, the value $D(T)$ can be estimated from the slope of the straight line (Figure 2).

For calculation purposes, it is necessary to describe the relationship between $D(T)$ and temperature, which is usually done assuming that the death rate constant $k(T)$ varies with temperature following an Arrhenius-type relationship:

$$k(T) = \frac{2.303}{D(T)} = ae^{-E/RT} \qquad [4]$$

which after rearrangement in terms of $D(T)$ yields

$$D(T) = \frac{2.303}{a}e^{E/RT} = Ce^{E/RT} \qquad [5]$$

where C is an empirical constant. Equation [5] clearly shows that a plot of log $D(T)$ as a function of $1/T$ (where T is expressed as an absolute temperature) is a straight line. However, in some cases, experimental data plotted as log $D(T)$ versus T (either Fahrenheit or Celsius) over a small range of temperature yield a straight line. Figure 3 illustrates a typical log $D(T)$ versus T plot, from which a kinetic parameter known as z-value can be obtained from the slope of the line. From that relationship, an equation to determine the value of the decimal reduction time $D(T)$ at a given temperature T is obtained:

$$D(T) = D_{121}\cdot 10^{\frac{T-121}{z}} \qquad [6]$$

In eqn [6], T is expressed in degree Celsius (or Fahrenheit), as well as the z-value, and $D_{121.1}$ is decimal reduction time at the reference temperature considered to be 121.1 °C (250 °F). The decimal reduction at the reference temperature and z-values for some spore-forming microorganisms are given in Table 1.

A similar kinetics has been used to describe the destruction of nutrients and enzymes, some of which are given in Table 2. It is important to note that the values given in Tables 1 and 2 depend on the food and conditions such as concentration, pH, and processing temperatures.

For specific situations, the values of D and z including other reference temperatures can be found in several references. By combining eqns [3] and [6], an equation to estimate the

processing time t to achieve a given level of microorganism inactivation in the product (defined by the ratio $N(t)/N_0$) at a constant temperature T is obtained:

$$t = -D_{121.1} \cdot 10^{-\frac{T-121.1}{z}} \log \frac{N(t)}{N_0} \qquad [7]$$

A similar equation can be used to relate processing time with destruction of food nutrients, and for that case, the number of microorganism is replaced by concentrations of the respective nutrients or other components such as enzymes. By comparing z-values for microorganisms and food nutrients, it can be noted that the latter are significantly larger, which in a log t versus T plot yields straight lines with small negative slopes, which is schematically illustrated in Figure 4. For a given temperature, times on or over the respective lines indicate either sterility or oversterility. Concerning the food nutrients' destruction line, times on or above the line would indicate only nutrient or overnutrient destruction. Since the current trends and goals in thermal processing are to reduce the level of microbial contamination in the food while preserving its nutrients, flavors, appearance, and overall quality, Figure 4 clearly shows that high temperatures and short processing times are required to achieve these objectives.

Peleg et al. discussed and challenged the suitability of the classic Arrhenius and other relationships (e.g., the William-Landel-Ferry (WLF) equation, also known as the WLF model) used to describe rate–temperature relations in food and biological systems. Although these models have had some

applicability on chemical kinetics, food and biological systems exhibit a particular behavior as microbial inactivation of cells and spores is not done at ambient temperatures so the equal weight to rate deviations at low- and high-temperature conditions provided by the Arrhenius-type model is not appropriate to describe food and biomaterial-related kinetics. More details are discussed in the next section.

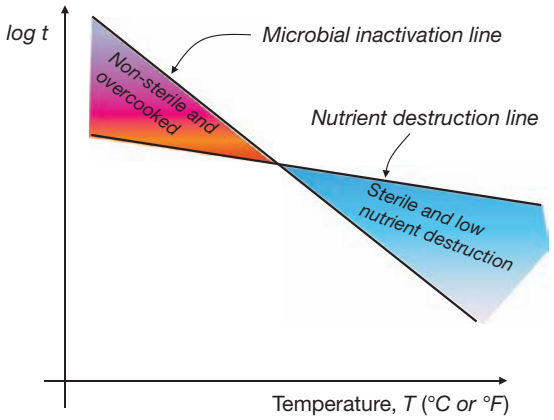

Figure 4 Schematic diagram illustrating the logarithm of the processing time as a function of temperature to achieve a given level of microbial inactivation and nutrient destruction.

The Nonlinear Case

Different mathematical models have been employed to describe nonlinear survival curves as those illustrated in Figure 1. Among them, the Weibull model has been extensively used. Alternative models that do not require the isothermal survival curves' log-linearity assumption have been also used and described in the literature.

The Weibull model can be written as

$$\log_{10}\frac{N(t)}{N_0} = -b(T)t^{n(T)} \qquad [8]$$

where $b(T)$ and $n(T)$ are temperature-dependent coefficients. Unlike the log-linear survival model, eqn [8] entails that even under isothermal conditions, the exponential inactivation rate can be time-dependent ($n \neq 1$) and the log-linear model is just a special case of eqn [8] when $n = 1$. Thus, the Weibull model can be applied to the traditional log-linear model but not vice versa.

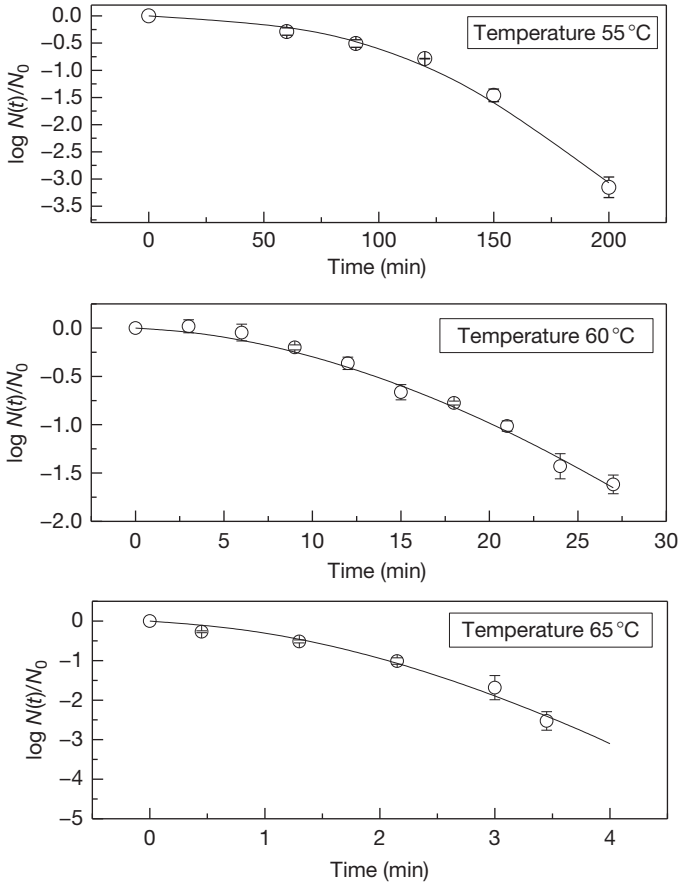

Figure 5 Experimental survival curves of *Listeria monocytogenes* inoculated on ready-to-eat meat after postpackage pasteurization at 55 °C, 60 °C, and 65 °C. Symbols are experimental points and lines are the fit of the Weibull model. Weibull parameters $b(T)$ and $n(T)$ can be obtained from fitting the experimental values, which for this particular case are plotted as a function of temperature and represented in Figure 6. Data extracted from Selby, T. L., Berzins, A., Gerrard, D. E., Corvalan, C. M., Grant, A. L. and Linton, R. H. (2006). Microbial heat resistance of *Listeria monocytogenes* and the impact on ready-to-eat meat quality after post-package pasteurization. *Meat Science* **74**, 425–434.

Figure 5 shows the heat inactivation of *Listeria monocytogenes* inoculated on ready-to-eat meat after postpackage pasteurization in a temperature range of 55–65 °C. It is clear from the figure that for all temperatures, the survival curves do not follow a first-order kinetics and the Weibull model provides a good description of the experimental data.

As shown in Figure 6, the parameter $b(T)$ is very small and becomes significant only when the postpasteurization temperature reaches a value that induces mortality to the bacterial population. The parameter $n(T)$ however has a very weak dependence on temperature (Figure 6(b)). In many instances, the coefficient n is practically constant over a considerable temperature range, that is, $n(T) = n$, further simplifying the use of eqn [8]. It has been shown that eqn [8] also applies to food components degradation.

Regardless of whether $n(T)$ is assumed to be constant constant or not, Figure 6 shows that there is a strong dependence of the parameter $b(T)$ with temperature. Campanella and Peleg found that for several bacterial cells and spores, *Clostridium botulinum* included, the dependence of $b(T)$ with temperature could be described by the log-logistic model given by the following equation:

$$b(T) = \ln\left(1 + \exp\left(m(T - T_c)\right)\right) \quad [9]$$

where T_c is a threshold temperature beyond which the inactivation becomes significant and m is a measure of the acceleration rate above T_c. It has been shown that eqn [9] is a better description of the effect of temperature on the parameter $b(T)$ than the traditional Arrhenius model because it provides a qualitative difference between the effects of temperature on microbial inactivation (or nutrient degradation) at low- and high-temperature ranges, which is defined by the value of T_c. To compare this approach with the traditional Arrhenius model given by eqn [6], the effects of temperature on the parameter $b(T)$ could be rewritten as

$$b(T) = Ae^{B \cdot T} \quad [10]$$

where A and B are empirical parameters and, in this case, T is the absolute temperature. After applying logarithm, eqn [10] yields

$$\ln b(T) = \ln A + B \cdot T \quad [11]$$

so a linear regression on $\ln b(T)$ versus T data will yield values of the parameters A and B. Figure 7(a) shows a comparison between the two approaches used to describe the effect of temperature on $b(T)$, whereas in Figure 7(b), the linear regression of the data expressed as eqn [11] is presented.

Determination of Survival Curve Kinetic Parameters

In order to design a thermal treatment, it is important to know how the kinetic parameters describing the survival curve change with temperature: specifically the parameters $D(T)$ and z if the traditional approach is used and the parameters $b(T)$ and $n(T)$ if the survival curve is better described by the Weibull model. Regardless of the model utilized to describe the survival curves, the traditional approach to determine these parameters is schematically described in Figure 8, which for the traditional approach is known as the thermal death time (TDT) method. As illustrated in Figure 8, one of the requirements of the procedure is that the thermal process be isothermal. That is practically achieved using small quantities of the sample inoculated with the microorganism under study using a variety of methods.

The use of small samples brings practical problems since the sample may not be representative of the whole food, in particular when the food consist of solids of different sizes suspended in a liquid phase (e.g., in a soup). The requirement of a constant temperature during the procedure to estimate the

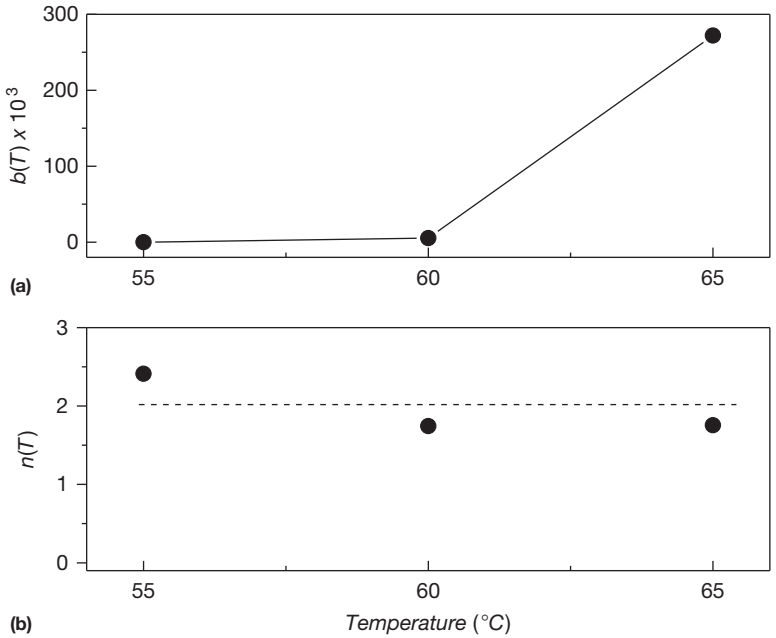

Figure 6 Weibull parameters $b(T)$ and $n(T)$ as a function of temperature derived from fitting the experimental data illustrated in Figure 5. (a) $b(T)$ versus T data and (b) $n(T)$ versus T data.

microbial resistance parameters $D(T)$ is also practically challenging as, in many situations, it becomes difficult to achieve a true isothermal process. That concern also holds when nonthermal treatments are used. For instance, for a chemical treatment, it is necessary to avoid dissipation of the chemical agent, and for high-pressure treatments, the come-up time is one of the main problems that may affect the determination of the microorganism resistance to the treatment. A methodology to estimate survival parameters under nonisothermal conditions has been proposed by Peleg et al. for the linear case, whereas for the nonlinear case, it was proposed by Peleg and Normand. For inactivation processes that are not isothermal, Peleg and Penchina demonstrated that the local slope of nonisothermal curve is a function of the momentary temperature $T(t)$. Thus, the corresponding survival of the microbial population at a given time t can be determined by integrating the following differential equation:

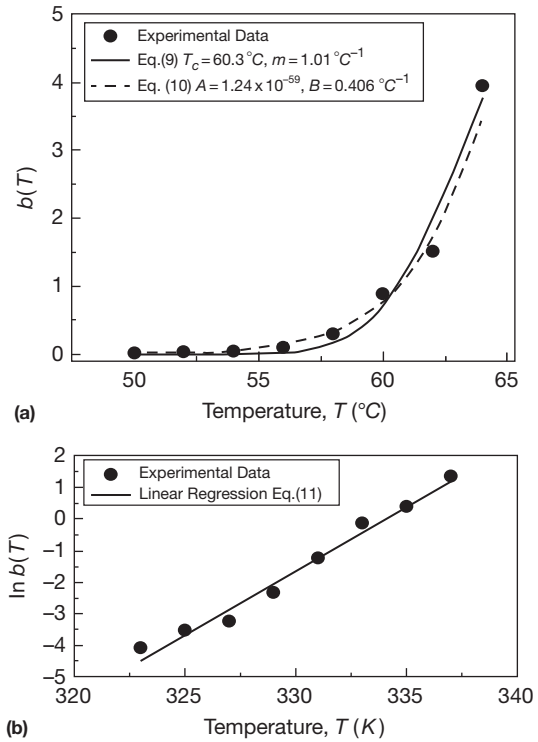

Figure 7 (a) Effect of temperature on the parameter $b(T)$ using the log-logistic equation and an Arrhenius-type equation. (b) Arrhenius equation expressed in logarithm form linear regression of experimental data. Experimental data from Stephens, P. J., Cole, M. B. and Jones, M. V. (1994). Effect of heating rate on the thermal inactivation of Listeria monocytogenes. *Journal of Applied Bacteriology* **77**, 702–708.

$$\begin{cases} \dfrac{\mathrm{d}\left[\log\left(\dfrac{N(t)}{N_0}\right)\right]}{\mathrm{d}t} = -b[T(t)]\cdot n[T(t)]\cdot\left[\dfrac{-\log\dfrac{N(t)}{N_0}}{b[T(t)]}\right]^{\dfrac{n[T(t)]-1}{n[T(t)]}} \\ \log\dfrac{N(t)}{N_0} = 0 \quad \text{at} \quad t = 0 \end{cases} \qquad [12]$$

The solution of eqn [12] can be obtained from a numerical integration algorithm using specialized software such as Mathematica® and Mathcad or by programming a numerical integration routine in a computing language such as MATLAB or other languages. The solution of that equation can also be implemented in a spreadsheet such as Microsoft Excel.

Online integration of eqn [12] using either Mathematica® or Microsoft Excel is also posted in Professor Peleg's websites, http://people.umass.edu/aew2000/ExcelLinks.html and http://people.umass.edu/aew2000/WolframDemoLinks.html.

In order to perform the integration of eqn [12], the relationship between the parameters $b(T)$ and $n(T)$ and temperature must be known as well as the temperature evolution in the thermal process indicated as $T(t)$. Although, as shown in previous section, the relationships between the kinetic parameter $b(T)$ and temperature can be expressed as either an Arrhenius-type equation or log-logistic model expressed by eqn [9], the experimental data shown in **Figure 6** clearly show that a model including differences between sublethal and lethal temperature ranges is preferred. Furthermore, Peleg et al. showed that a more simplified equation to describe the relationship between $b(T)$ and temperature could be used:

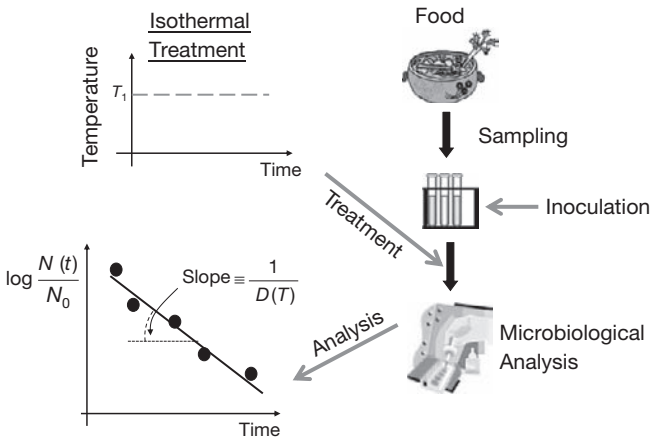

Figure 8 Schematic of the typical experimental procedure TDT to estimate the decimal reduction time at a constant temperature T_1.

$$\begin{cases} b(T) = 0 \quad \text{If } T < T_c \\ b(T) = m(T - T_c) \quad \text{If } T > T_c \end{cases} \qquad [13]$$

The relationship indicates that when processing temperatures are lower than the threshold temperature T_c (sublethal temperatures), there is no inactivation of the microbial population, whereas microbial inactivation is observed when processing temperatures are larger than T_c (lethal temperatures). After T_c, the dependence of $b(T)$ with temperature is linear (see Figure 6). By assuming that n is independent of temperature and substituting eqn [13] into eqn [12], the following equation is obtained:

$$\begin{cases} \dfrac{d\left(\log \dfrac{N(t)}{N_0}\right)}{dt} = 0 \quad \text{for } T < T_c \\ \dfrac{d\left(\log \dfrac{N(t)}{N_0}\right)}{dt} = -m[T(t) - T_c] \cdot n \cdot \left[\dfrac{-\log \dfrac{N(t)}{N_0}}{m[T(t) - T_c]}\right]^{\frac{n-1}{n}} \quad \text{for } > T_c \\ \log \dfrac{N(t)}{N_0} = 0 \quad \text{at } t = 0 \quad \text{initial condition} \end{cases} \qquad [14]$$

Equation [14] shows that provided the Weibull parameter n, the survival parameters T_c and m, and the temperature evolution are known, microbial inactivation at any given time can be estimated by integration of eqn [14].

Determination of Kinetic Parameters m and T_c

In a direct approach, integration of eqn [14] results in the survival curve corresponding to the parameters m and T_c associated to the specific microbial population and the food being treated as well as the temperature evolution of the thermal treatment $T(t)$. However, an inverse approach can also be used to estimate the parameters m and T_c provided the nonisothermal treatment and the resulting survival curve are known; Figure 9 illustrates a schematic of the steps needed in each approach.

The inverse approach mainly consists in solving a nonlinear regression algorithm in which the fitting parameters are T_c and m and the model to be fitted is the survival curve, which is mathematically described by the differential equation given by eqn [14]. The solution of the problem involves the use of a nonlinear regression approach to search for the parameters T_c and m that minimize the error between the experimental data (survival curve) and the model given by eqn [14]. Thus, every time the model is evaluated, eqn [14] must be integrated. Although a priori it could be thought that the approach involves a formidable computational task, current software is able to deal with this algorithm without major complications. Software like Mathematica®, used to introduce the approach, Mathcad, and MATLAB incorporate numerical solutions of differential equations and nonlinear regression algorithm that can be effortlessly integrated to estimate the fitting parameters T_c and m provided the temperature evolution of the nonisothermal thermal treatment and the resulting survival curve are known (see Figure 9 – inverse problem). Spreadsheets like Microsoft Excel that has minimization functions like 'Solver' could be also used if the numerical solution of an ordinary differential is incorporated in the spreadsheet. Thus, the function *Solver* is used to minimize the sum of squared errors (SSE) defined as the square of the difference between the experimental data (survival curve) and the model function (numerical solution of eqn [14]). The incorporation of numerical methods is an active area of research and teaching, and there is an extensive collection of articles and books dealing with this subject. Applications on the use of the Visual Basic language

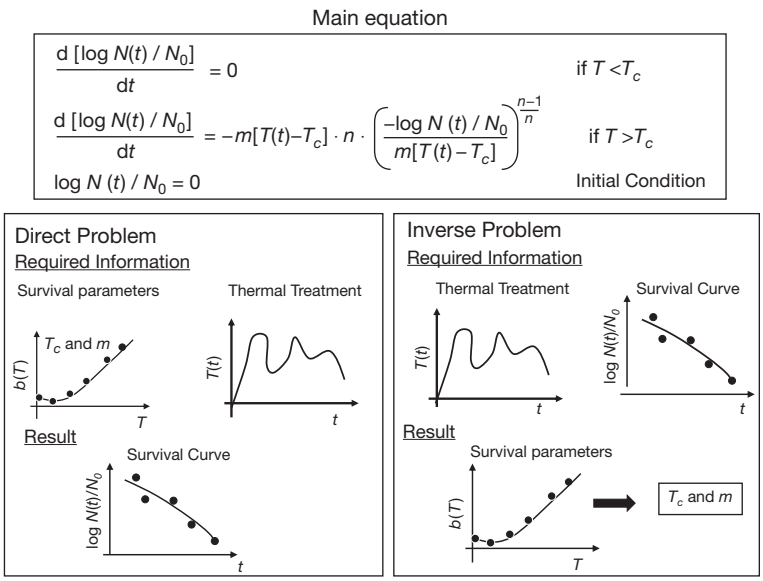

Figure 9 Schematic of the approach followed to determine the survival curve provided the parameters m and T_c and the nonisothermal temperature evolution are known (direct problem). In the inverse approach, the parameters m and T_c are determined from information of the survival curve obtained from a known thermal evolution.

to integrate numerical methods with minimization functions like *Solver* or *Goal Seek* can be also found in the web.

Testing the approach: The linear case

For the linear case, $n=1$, so eqn [14] simplifies to

$$\begin{cases} \dfrac{\mathrm{d}\left(\log \dfrac{N(t)}{N_0}\right)}{\mathrm{d}t} = 0 \quad \text{for } T < T_c \\ \dfrac{\mathrm{d}\left(\log \dfrac{N(t)}{N_0}\right)}{\mathrm{d}t} = -m[T(t) - T_c] \quad \text{for } T > T_c \\ \log \dfrac{N(t)}{N_0} = 0 \quad \text{at } t = 0 \quad \text{initial condition} \end{cases} \qquad [15]$$

which after integration yields

$$\begin{cases} N(t) = N_0 \quad \text{for } T < T_c \\ \log \dfrac{N(t)}{N_0} = -\displaystyle\int_0^t m[T(t) - T_c] \quad \text{for } T > T_c \end{cases} \qquad [16]$$

Equation [16] is the model that contains the parameters m and T_c to be determined from the nonlinear regression applied to the experimental survival curve. The question that immediately arises is whether the proposed method can be used to predict, or estimate, inactivation parameters of organisms on the basis of experimental survival data originating from nonisothermal heat treatments that have significant scattering data.

Since it was not possible to find that kind of experimental information in the literature, to test the practicality of the approach, the recovery of survival parameters was done from data generated with the proposed model on which a random noise was superimposed. Using *L. monocytogenes*' survival parameters, $T_c = 60.3\ ^\circ\mathrm{C}$ and $m = 1.01\ ^\circ\mathrm{C}^{-1}$ (see Figure 7) survival curves, with a superimposed random noise of 50%, corresponding to different nonisothermal heating processes were generated with eqn [16]. This generated survival data along the corresponding nonisothermal temperature profile were then employed to retrieve the original survival parameters T_c and m. Figure 10 shows that for a linear heating profile, the parameters T_c and m obtained were reasonable estimates of the generation parameters despite the considerable scattered data used. These results indicate that nonisothermal survival curves can be used to estimate an organism's survival parameters.

Testing the approach: The general case with n constant but different than 1

It was demonstrated in the previous section that the survival parameter n can be considered constant for *L. monocytogenes* and other microorganisms, whereas the parameter b depends strongly on temperature; it is almost zero at sublethal temperatures (identified with the parameter T_c) and then rises sharply with a rate defined by the parameter m when the temperature passes the lethal level. As shown earlier in the text, such a temperature dependence can be described by the log-logistic model defined by eqn [9]. A simplified version of eqn [9] was used in the previous section to demonstrate the applicability of the inverse approach to solve the linear problem. The method for nonlinear survival curves and n values is independent of T, whereas dependence of the parameter b with temperature described by eqn [9] can be extended and the differential equation to be integrated is

$$\begin{cases} \dfrac{\mathrm{d}\left(\log \dfrac{N(t)}{N_0}\right)}{\mathrm{d}t} = 0 \quad T < T_c \\ \dfrac{\mathrm{d}\left(\log \dfrac{N(t)}{N_0}\right)}{\mathrm{d}t} = -\ln\left[1 + \exp\left(m(T(t) - T_c)\right)\right] \cdot n \cdot \left[\dfrac{-\log \dfrac{N(t)}{N_0}}{\ln\left[1 + \exp\left(m(T(t) - T_c)\right)\right]}\right]^{\frac{n-1}{n}} \quad T > T_c \log \dfrac{N(t)}{N_0} \\ = 0 \quad \text{at } t = 0 \quad \text{initial condition} \end{cases} \qquad [17]$$

The model defined by eqn [17] containing the survival parameters T_c and m and the temperature profile of the nonisothermal treatment, $T(t)$, was numerically integrated for a set of guess initial parameters T_c and m, which were adjusted to minimize the SSE defined in the preceding text. The minimum of SSE, was obtained using the simplex algorithm, which can be easily implemented in software such as Mathematica®. Experimental survival curves from nonisothermal treatments of broth samples inoculated with *Salmonella* were used to estimate the survival parameters. Figure 11 illustrates the nonisothermal heating profiles used in the heat treatment as well as the resulting experimental survival curves (symbols) and the fitting of the data (lines) with the model defined by eqn [17].

The values of the survival parameters obtained from the approach are given in Table 3. As noted, they do not differ significantly from the different applied thermal treatment. The results also show that the Weibull parameter n was not affected by the temperature profile.

Estimation of Processing Time

Isothermal Conditions

If $T = 121.1\ ^\circ\mathrm{C}$ (250 °F) is substituted in eqn [7], the processing time is defined as the F_0 value for the process, which represents the value of a processing time that will produce the same degree of inactivation as the given process at its temperature T. Thus,

$$F_0 = -D_{121.1} \cdot \log \frac{N(t)}{N_0} \qquad [18]$$

By combining eqns [7] and [8], the following is obtained:

$$F_0 = t \cdot 10^{\left(\frac{T-121.1}{z}\right)} \qquad [19]$$

Equation [19] is used to estimate the value of F_0 of the thermal process at a given constant temperature T (°C) and a given processing time t.

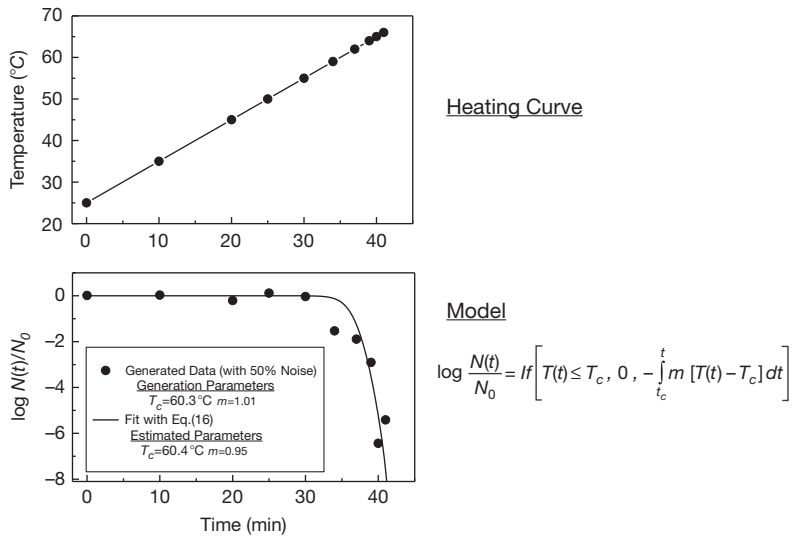

Figure 10 Determination of the survival parameters T_c and m from a known nonisothermal heat treatment and the resulting survival curve using the inverse approach.

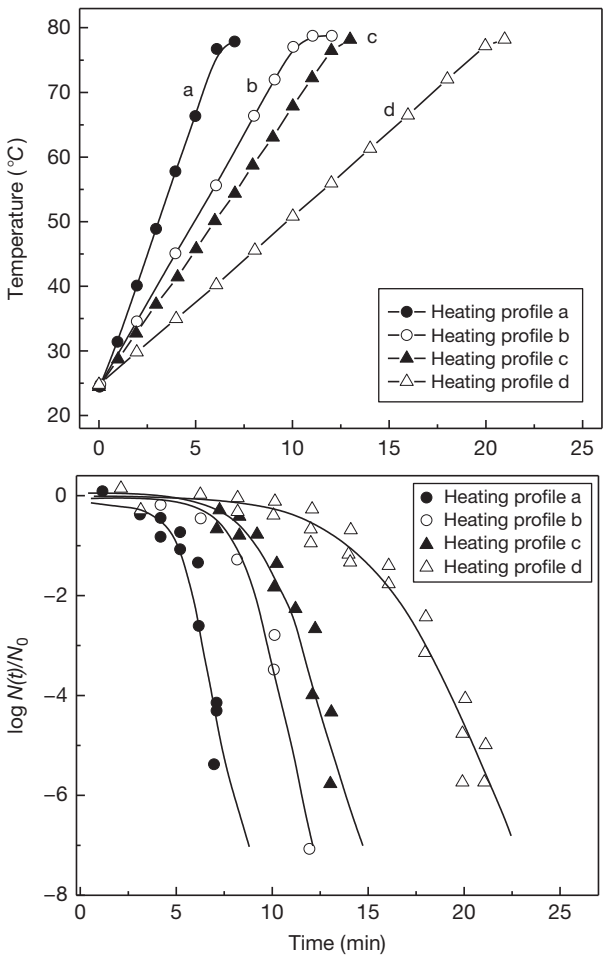

Figure 11 Experimental survival curves of *Salmonella* heat treated in a broth under four temperature profiles (top graph). In the bottom graph, symbols represent experimental data and lines, the model given by eqn [17] for the corresponding survival parameters T_c and m. The averaged survival parameters obtained from the different heating profiles are listed in **Table 3**. Adapted from Peleg, M. and Normand, M. D. (2004). Figure 12 Hypothetical thermal process consisting of successive isothermal heat treatments.

Nonisothermal Conditions

Figure 12 schematically illustrates a thermal treatment consisting of successive processes having different processing times and different temperatures. By assuming that these successive thermal processes are additives, the F_0 of the entire treatment could be calculated by the following equation:

$$F_0 = t_1 \cdot 10^{\left(\frac{T_1 - 121.1}{z}\right)} + t_2 \cdot 10^{\left(\frac{T_2 - 121.1}{z}\right)} + t_3 \cdot 10^{\left(\frac{T_3 - 121.1}{z}\right)} \quad [20]$$

When the food material is being thermally processed with a processing time of duration t_f, the temperature at different locations of the product varies continually during the process (see Figure 13). As indicated in the figure for foods subjected to external heating and cooling using, for example, steam and cooling water, respectively, temperatures at locations close to the surface (identified as $T_s(t)$) respond faster to temperature changes in the heating/cooling media than temperatures close to the center of the food (identified as $T_c(t)$).

The value of the thermal process in a given location of the product for this general case can be calculated as

$$F_0 = \int_{t=0}^{t=t_f} 10^{\left(\frac{T(t) - 121.1}{z}\right)} dt \quad [21]$$

By calculating the F_0 value for a thermal process, two aspects concerning the temperature profile in the processed material must be taken into account. First, the complete temperature evolution, $T(t)$, at each location of the processed material must be known in the entire process. Second, different locations in the product receive different thermal treatments. This is important especially when the heat is transferred to the product by conduction because the slowest rate of this heat transfer mode increases temperature differences between the center and the surface of the product leading to significant differences in the product heat treatment, leading to serious quality concerns. By using a finite-difference algorithm, the heat conduction equation for a cylindrical can of finite length containing a homogeneous solid food with a constant thermal diffusivity α, which is given by the following equation, can be solved:

$$\frac{\partial T}{\partial t} = \alpha \left[\frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial T} + \frac{\partial^2 T}{\partial h^2} \right] \quad [22]$$

where T is the local momentary temperature at a given location, t is the time, and r and h are the radial and vertical coordinates of a location in the material, respectively. Given suitable boundary conditions, for example, the temperature of the retort temperature, the solution of eqn [22] yields temperature–time relationships at any given point (r, h) within or on the surface of the cylindrical-shaped food.

Although experimental measurements and simulations clearly show significant temperature gradients during conductive thermal treatments, the calculated process' lethality (traditionally defined by the F_0 value) is based on the product's coldest point. However, if the temperatures at all locations of the product are known, an 'overall lethality' of the entire food could be calculated by summing up local lethalities. To compare the calculated 'coldest point' and the 'overall' lethalities for linear and nonlinear inactivation kinetics, simulated processes using parameters that match realistic process conditions used in the food canning industry were performed. The processing time was adjusted to achieve 12 decades' reduction (F_0) at the coldest point of the can as judged by the traditional criteria of thermal processing. Figure 14(a) shows a simulated retort processing temperature and the corresponding temperature profile at the product's coldest point. Temperatures at other locations were also calculated (for the sake of clarity, it is not shown in the figure). The corresponding survival curves, calculated with the linear and the Weibull models, are shown in

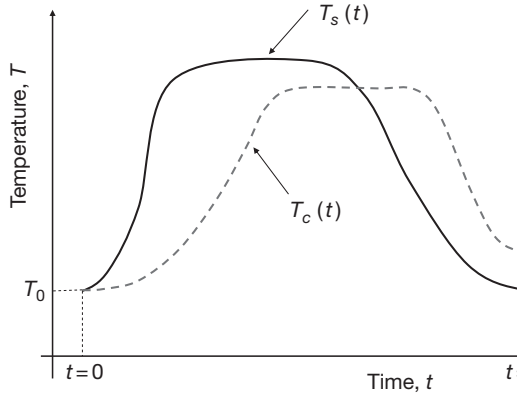

Figure 13 Typical temperature profile in different locations of a food product subjected to a heating/cooling process. $T_s(t)$ indicates temperature at locations close to the surface, whereas $T_c(t)$ indicates temperatures close to the center of the food.

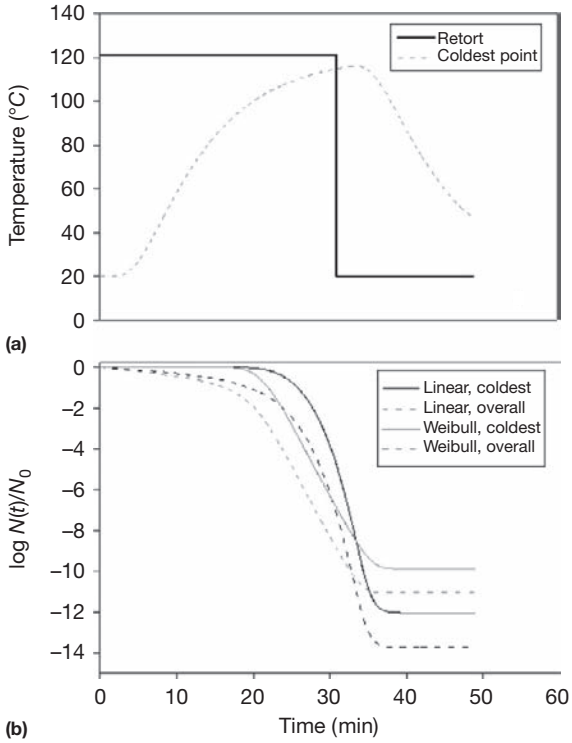

Figure 14 (a) Coldest temperature profile and (b) comparison between the lethality calculated at the coldest point of the product and the overall process calculated for both the traditional linear and the Weibull models. Conditions and parameters used for the simulations were as follows: can dimensions $H = D = 76.2$ mm, thermal diffusivity of the product $\alpha = 3.3 \times 10^{-7}$ m^2 s^{-1}, product's initial temperature $T_i = 20$ °C, retort temperature $T_p = 121.1$ °C, and cooling water temperature $T_w = 20$ °C. Survival parameters used in the simulation are reported in Table 4. Adapted from Chen, G., Campanella, O. H. and Peleg, M. (2011). Calculation of the total lethality of conductive heat in cylindrical cans sterilization using linear and nonlinear survival kinetic models. *Food Research International* **44**, 1012–1022.

Figure 14(b). Thermal inactivation parameters used in the simulations were those for *C. botulinum* spores, which are reported in **Table 4**.

Simulations involving the coupling of the numerical solution of the heat transfer equation (eqn [22]) with the rate model (eqn [17]) are able to generate a number of relationships that can be used to analyze many *what-if* scenarios. For instance, **Figure 15** shows the lethality distribution throughout one-fourth of the can, calculated by eqn [21] at the end of the thermal process depicted in **Figure 14**. Values show that 50–150 decades of reduction in microbial population warrants that sterility is accomplished in the outer regions of the can despite that in the center, the lethality achieved is just the recommended 12-log reduction. However, the potential value of such plots is not only to assess microbial survival but also to monitor the effects of heat treatments on the product's quality, for example, survival of nutrients and pigments or the accumulation of harmful and toxic compounds generated by excessive heat treatments.

Other 'what-if' scenarios discussed in the simulations involve effects of container shape, initial temperatures, or initial temperature distribution in the can (for the case that the product comes from a preheating or precooling process) and practical situations implying deviations in the retort temperature and during cooling stages. The particular importance for conductive heat transfer is the effect of the thermal diffusivity (α) on both temperature profile and survival curves because it provides a quantitative estimation of process requirements for different products and in addition sets margins for products having variable or nonuniform composition. Examples of simulated temperature profile and corresponding survival curves of *C. botulinum* spores are shown in **Figure 16** for three different values of thermal diffusivity α, selected to highlight the effect of the product's physical properties on the length of the process needed for its sterilization.

Industrial Aspects of Thermal Treatments

Thermal processing applications at the industrial scale have relied for many years on batch processing, and although the basic principles of the process have not changed significantly, improvements have been brought mainly through changes on automation and control of the operation. Innovations on the technology have included more flexibility in handling lighter-weight containers, better options for process optimization, and the introduction of fully automated retort operations. Due to important implications of food safety on public health, processors must

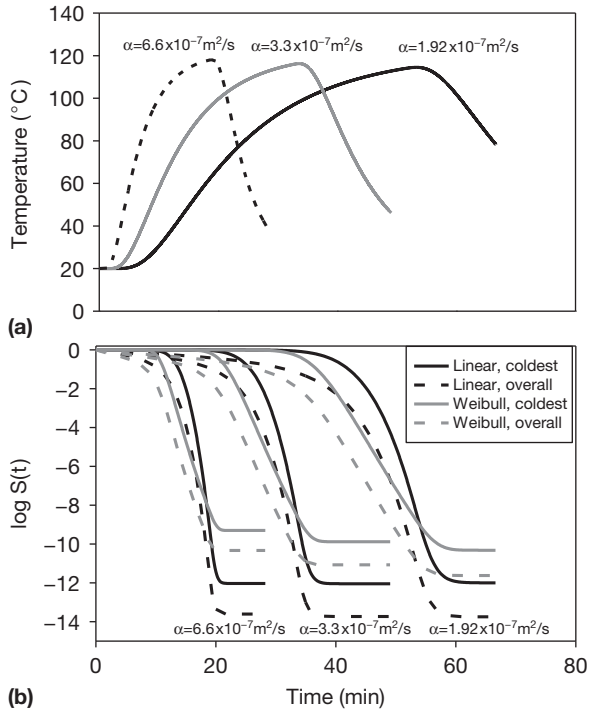

Figure 16 (a) Effects of thermal diffusivity α on the coldest temperature profiles and (b) microbial inactivation at the coldest and the overall inactivation calculated for the traditional and the Weibull approaches. Values of thermal diffusivity are indicated in the figure. Other parameters used in the simulations were as follows: $H = D = 76.2$ mm, product's initial temperature $T_i = 20$ °C, retort temperature $T_p = 121.1$ °C, and cooling water temperature $T_w = 20$ °C. Adapted from Chen, G., Campanella, O. H. and Peleg, M. (2011). Calculation of the total lethality of conductive heat in cylindrical cans sterilization using linear and nonlinear survival kinetic models. *Food Research International* **44**, 1012–1022.

operate in strict compliance with food regulations in particular in regard to low-acid canned foods. In United States, those regulations are controlled by the Food and Drug Administration who are requesting food processors to keep documentation and records of all critical control points during the sterilization of foods. Thus, a typical batch retort system included the following components: a loader/unloader product tracking and systems including control strategies for control points such as the initial temperature of the product, retort temperature, retort pressure, processing time, water flow, water level, and rotation speed, the latter to increase convective heat transfer during the processing of liquid products or products that contain particles, for example, soups. Mathematical models describing convective heat transfer and experimental and predictive models have been developed for liquid products containing particles, but the physics of the problem is complex and may result in less accurate prediction so process optimization for these products still strongly relies on experimental approaches.

Continuous processing including aseptic packaging is finding more application and uses, mainly focusing on the increase of productivity and improvement on product safety and quality while reducing operating cost and safety risks. Some of most widely used systems are nonagitating and agitating continuous retorts that include hydrostatics (e.g., JBT FoodTech Hydrostat) and rotary retorts (e.g., JBT FoodTech Sterilmatic).

Deviations in temperatures and pressures of the steam supply during thermal treatment in continuous processes are often unavoidable and present a challenge to food processors and equipment manufacturers. When a deviation from the temperature–time prescribed process schedule occurs and is not handled properly, it may not only compromise the sterility of the canned food but also lead to subsequent spoilage. Although considerable efforts have been directed toward the development of 'intelligent' online batch retort control systems capable of rapid evaluation, online correction, and printed documentation of any process deviations occurring during a thermal process, these types of algorithms have not been applied to continuous retorts due to the lack of suitable methodologies capable of providing accurate and fast evaluations of product temperature and lethality in response to process deviations. However, methodologies that would allow food processors and equipment manufacturers to employ residence time control through the use of variable conveyor speed in order to accommodate thermal process deviations in continuous retorts have been developed.

Heavy Metal Toxicology

WR Snodgrass, University of Texas Medical Branch, Galveston, TX, USA

© 2016 Elsevier Ltd. All rights reserved.

This article will address a few of the more clinically relevant heavy metals, mercury, cadmium, and arsenic, with regard to exposure via food intake as a source of toxicity. Most other metals pose a lower toxicity risk via food exposure and will not be discussed.

Mercury

Mercury, as inorganic mercury (elemental mercury oxidation state is 0; mercuric cation oxidation state is 2+), originates from the Earth's crust by a natural process of degassing into the atmosphere. Human actions also contribute to atmospheric mercury, for example, coal-fired power plant facilities. Mercury in food, mostly as organic methylmercury, originates from the aquatic food chain including plankton, fish, and sea mammals. The bioconcentration of fish tissue methylmercury can be as much as one thousand times or more the surrounding water mercury concentration. Fish eliminate methylmercury very slowly with a halftime of a few hundred days. In fish tissue muscle, methylmercury occurs as a water-soluble protein-bound form that does not degrade by cooking. Methylmercury in the past has been used as seed dressing (e.g., wheat) as a fungicide. The food content of inorganic mercury is much less than the methylmercury content. Mercury exposure through drinking water typically is quite low. Ionized mercury forms covalent bonds with sulfhydryl groups; this is considered one of the major biochemical mechanisms for mercury toxicity.

Methylmercury is a human teratogen. Health advisories for pregnant women regarding avoidance of certain seafoods (e.g., predatory fish such as pike, tuna and swordfish, shark, tilefish, and king mackerel) due to methylmercury content are based on both animal data that the mammalian fetal brain is adversely affected at low levels of methylmercury exposure and human cases of severe fetal brain malformations and severe fetal brain malfunction (Minamata disease; Minamata Bay disaster) (mental retardation, spasticity, blindness, visual field constriction, dysphagia, nystagmus, strabismus, dysmetria, chorea, athetosis, limb deformities, and seizure disorders and autopsy findings of brain cortical atrophy, cerebellar atrophy, corpus callosum hypoplasia, and demyelination of the pyramidal tract). Other seafood are not considered a risk by the FDA, that is, less than one kg per week of shrimp, catfish, salmon, flatfish, pollack, scallops, cod, clams, crabs, and tuna (nonalbacore). Mammalian animal fetal tissue concentrations of alkyl mercury compounds are about twice that of maternal tissue with fetal erythrocytes (greater fetal hemoglobin affinity for methylmercury) containing about one-third more alkyl mercury compared with maternal erythrocytes. Human (breast) milk contains methylmercury, ranging 5–30% of the maternal blood concentration; so, breast-feeding is not recommended for women with high methylmercury exposure. An estimate of methylmercury exposure in adult humans to cause the lowest observed adverse health effect (paresthesias) is 300 μg per day (adult) (about 4 $\mu g\,kg^{-1}$ per day), resulting in a blood concentration of about 200 $\mu g\,l^{-1}$ (nonexposed persons' background blood mercury concentration is less than 10 $\mu g\,l^{-1}$) (most blood methylmercury is in the erythrocytes). A group of adult persons self-reporting high seafood consumption had blood mercury concentrations of approximately 20–50 $\mu g\,l^{-1}$; they had no increased cognitive complaints. The human fetus is considered to be at risk at lower exposure doses compared with adults. The lower limits of tissue or blood concentrations of methylmercury causing specific human fetal adverse effects are not known.

Methylmercury human gastrointestinal absorption is about 90% or more, with about 90% of methylmercury excretion occurring via the feces. Once absorbed into the tissue, methylmercury is slowly enzymatically cleaved to its inorganic mercuric (divalent cation) form; this enzymatic cleavage is much more rapid and complete for long-chain alkyl and aryl organic mercury compounds compared with methylmercury. The human biologic halftime (half-life) of methylmercury is about 6–10 weeks (about 1% per day of body burden). A greater portion of methylmercury compared with inorganic mercury distributes to the brain, that is, about 10% of body burden of methylmercury distributes to the brain. Adverse neurocognitive and encephalopathic toxicity is a major risk and concern for excessive organic mercury exposure, both acute and chronic. Chronic oral doses of 10 $\mu g\,kg^{-1}$ per day may produce such adverse effects. US government advisories include less than 0.1 $\mu g\,kg^{-1}$ per day of methylmercury intake from fish (EPA reference dose) and less than 0.3 $mg\,kg^{-1}$ of fish tissue (FDA). Also, an FDA action level of one ppm (part per million) of mercury in fish was set to limit methylmercury intake to less than one-tenth of blood concentrations found in persons with adverse toxic effects. Within cells, mercuric (divalent cation) mercury becomes localized in lysosomes where it may persist for long periods of time. Inorganic mercury preferentially binds covalently to sulfhydryl groups. Methylmercury in the liver combines with glutathione in soluble complexes that undergo enterohepatic cycling. A cysteine–methylmercury complex crosses the blood–brain barrier via an amino acid transporter.

Neurotoxic adverse effects of methylmercury in humans may include (1) paresthesias, for example, the fingers, toes, lips, and mouth; (2) ataxia, dysarthria, and impaired swallowing; (3) impaired vision and/or hearing; (4) neurasthenia; (5) tremor and/or spasticity; (6) and even coma and death. Adverse cognitive neuropsychological effects were found in children in the Faroe Islands (whale meat mercury 1.6 $\mu g\,kg^{-1}$) and New Zealand (shark meat mercury 2.2 $\mu g\,kg^{-1}$), but not in Seychelles (fish mercury 0.3 $\mu g\,kg^{-1}$); perhaps, the threshold for chronic adverse neuropsychological effects may be somewhere in this range 0.3 $mcg\,kg^{-1}$ to 1.6 or 2.2 $mcg\,kg^{-1}$. The adverse neuropsychological effects persisted in children tested again at age 14 years in the Faroe Islands.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00373-1

Therapy of methylmercury poisoning (converted in the body to inorganic mercuric mercury), which is usually chronic exposure, is limited due to the lack of a large treatment effect (low effect size). Chelation with succimer (an oral hydrophilic analog of BAL) (succimer is the most superior treatment in decreasing mouse brain mercury after methylmercury administration), DMPS (dimercaptopropanesulfonate), or a nonabsorbable polythiol resin may be tried. British anti-Lewisite (BAL) or dimercaprol should not be tried due to some data showing redistribution of mercury into the brain, that is, increasing brain mercury concentration after administration of dimercaprol.

Cadmium

Cadmium (the most common oxidation state is 2+) exposure via food intake is a lower dose of chronic exposure typically compared with industrial exposure, the latter more often being exposure by inhalation. However, the major source of cadmium exposure for the general population is via food. Higher daily intakes of cadmium exposure via food and water occur in areas of cadmium contamination. Such areas most often are near mining sites; cadmium is a common constituent in many ores being mined. An estimate of daily oral intake of cadmium in the general population (food, water, and air) is approximately 10–50 μg per day. Only approximately an estimated 5% (some estimates of 5–20%) of oral cadmium is absorbed, although greater absorption may occur with iron-deficiency anemia or low-calcium diets or low-protein diets. Plants take up cadmium when grown in soils that have been exposed to cadmium-containing fertilizers, cadmium-containing water, or deposition from the air. Human waste sludge is another source of cadmium. Cadmium content varies – sludge up to 1500 mg cadmium per kg dry weight; shellfish (mussels, scallops, and oysters) 100–1000 μg kg^{-1}; meat, fish, and fruit 1–50 μg kg^{-1}; and grains 10–150 μg kg^{-1}. In the past, acidic contents, such as fruit juices packaged in cadmium-plated containers, were a source of higher-dose oral cadmium exposure.

Cadmium human kinetics reveal a long body halftime of 20–30 years. Absorbed cadmium is distributed rapidly and taken up mostly by the liver and kidneys. An estimated 50–75% of body burden of cadmium is in the liver and kidneys. Over time, there is a progressive accumulation in the human kidneys up to approximately age 50–60 years, after which there is a slow decline in tissue concentrations. A renal cortex cadmium concentration of 200 μg g^{-1} of cortex results in kidney tubular dysfunction in 10% of adults and 300 mcg g^{-1} tubular dysfunction in 50% of adults, as measured by increased urine excretion of low molecular proteins such as beta-2 microglobulin, that is, tubular proteinuria. Whole blood cadmium concentrations in nonexposed adults typically are less than 10 μg l^{-1}, and 24 h urine cadmium concentrations typically are less than 3 μg g^{-1} of urine creatinine. About 95% of adults in the United States have a urine cadmium concentration of less than 2 μg l^{-1} of urine and less than 1% of adults excreting 4 μg l^{-1} of cadmium in their urine; most urine cadmium is in the form of the cadmium–metallothionein complex.

Metallothionein is a protein that forms a low-molecular-weight complex with cadmium; the affinity of cadmium for metallothionein is very high. The cadmium–metallothionein complex accumulates with time in the kidneys in proportion to cadmium concentration. This complex appears to be nontoxic and somewhat protective until high cadmium tissue levels are reached and then kidney toxicity occurs.

The adverse toxic effects of cadmium (chronic exposure via oral intake) include renal toxicity (usually tubular dysfunction but may include glomerular dysfunction), skeletal toxicity including bone pain (itai-itai or ouch-ouch disease), osteomalacia and/or osteoporosis; carcinogenicity; and hypertension/cardiovascular disease. Carcinogenicity and hypertension/cardiovascular disease have been implicated from inhalation exposure, primarily from animal studies, with human data being weak. However, human renal and bone diseases are generally accepted as risks from chronic cadmium toxicity. Human skeletal disease with excessive oral cadmium exposure is associated with low serum 1,25-dihydroxyvitamin D concentrations perhaps due to inhibition of formation by cadmium. The result is decreased calcium absorption and decreased bone mineralization producing osteomalacia.

Chelation therapy for cadmium typically is not effective. This appears to be related to the rapid increase in metallothionein and binding of cadmium to form an intracellular cadmium–metallothionein complex resulting in cadmium not being available for chelation. Some experimental dithiocarbamates have been shown in animal studies of chronic cadmium exposure to reduce total body cadmium burden; however, these compounds are lipid-soluble and redistribute cadmium to the brain, an undesirable and unacceptable drug action.

Arsenic

Arsenic (trivalent arsenite cation oxidation state is 3+; pentavalent arsenate cation oxidation state is 5+) occurs widely in the environment. Natural sources include arsenic-containing mineral ores and groundwater. Pentavalent arsenic exists as the predominant form in the environment. Pentavalent inorganic arsenic is less toxic than trivalent inorganic arsenic. Industrial arsenic processes encompass smelting and refining of ores and metals, semiconductor manufacturing, metallurgy, and burning of wood treated with arsenic preservatives. Commercial products may include herbicides, insecticides, fungicides, animal feed additives, and wood preservatives. Past use of arsenic-containing chemical warfare agents illustrates the degree of widespread use of arsenic compounds. Food sources of arsenic vary such as seafood, kelp, and wine. Water, food, and soil contaminations are the main sources of the general population's exposure to arsenic. Foods grown in arsenic-contaminated soils, for example, rice and produce, may pose a risk of arsenic toxicity, but generally, food contains low concentrations of inorganic arsenic. Organic arsenic compounds include methylarsonic acid, dimethylarsinic acid (cacodylic acid), arsanilic acid, and arsenobetaine. Marine sources of arsenic include algae, fish, and shellfish. Seafood contains relatively large amounts of nontoxic organic arsenic in the form of arsenobetaine (a trimethylated compound), arsenocholine, and arsenosugars.

Inorganic arsenic (both 3+ and 5+ cations) is metabolized by the liver in humans to monomethyl arsenic (MMA) and

dimethyl arsenic (DMA). These methylated arsenic metabolites until recently were considered to be less toxic than inorganic arsenic; however, trivalent methylated arsenicals are more toxic than inorganic arsenite due to an increased affinity for sulfhydryl groups. Ionized arsenic compounds form a covalent bond with sulfhydryl groups. Methylated arsenic compounds are excreted to a greater extent in the urine compared with inorganic arsenic. Ingested pentavalent inorganic arsenic is converted to a significant extent in the human body to trivalent arsenic that then undergoes methylation. Ingested inorganic arsenic is well absorbed in the gastrointestinal tract, about 60–90% absorption. Ingested inorganic arsenic's biologic halftime is reported to range from about 10 h to 4 days, with the latter figure likely more representative of the true beta-phase halftime; some estimates are that by about 3 days, approximately 50–80% is excreted after a single-dose ingestion. Methylated arsenic's halftime approximates 30 h. Arsenobetaine (alpha phase about 7–11 h; beta phase about 75 h) and arsenocholine are largely cleared in about 2 days, being excreted unchanged in the urine. Because of the relatively large amount of essentially nontoxic organic arsenic forms in seafood, urine arsenic concentrations (measuring only elemental arsenic by atomic absorption spectroscopy or similar methods) transiently may be highly elevated after consuming seafood, for example, urine arsenic concentrations exceeding 1000 $\mu g\,l^{-1}$ of seafood nontoxic organic arsenic compounds. For comparison, unexposed (no seafood intake) persons' background urine inorganic arsenic concentrations typically are in the range of 5–50 $\mu g\,l^{-1}$. The diagnosis of increased inorganic arsenic exposure can be made with a 24 h urine collection with an inorganic urine arsenic concentration of 50 $\mu g\,l^{-1}$ or more, 100 μg per gram of urine creatinine or more, or 100 μg of total urine inorganic arsenic or more. Arsenic whole blood concentrations are elevated only for a short time after ingestion due to the short halftime of arsenic compounds in the blood; thus, whole blood concentrations (unexposed persons less than 10 μg of arsenic per l whole blood) typically are not useful in the assessment of arsenic exposure. Hair and nail arsenic concentrations have limited interpretive utility due to possible external contamination.

Seafood contains considerably more arsenic (nontoxic organic arsenic) compared with other foods. Market basket studies by the FDA in the 1990s in the United States showed a daily intake of arsenic from food of less than 10 μg per day. Drinking water estimates are that another 10 μg per day of arsenic is consumed, but this assumes 2 liters per day of drinking water per adult containing 5 μg arsenic per liter of drinking water. The majority of persons in the United States consume drinking water that contains less than 5 $\mu g\,l^{-1}$ of arsenic. In the early 1990s, it was estimated that about 350 000 persons in the United States drank water containing more than 50 $\mu g\,l^{-1}$ of arsenic (mostly in the states of California, Arizona, and Nevada). EPA mathematical modeling shows that 50 $\mu g\,l^{-1}$ of arsenic in drinking water is associated with an increased lifetime risk of lung and bladder cancers. It has been estimated that the daily inorganic arsenic intake in the diet ranges from about 8 to 14 μg per day (adults). Examples of food-related arsenic toxicity include episodes of multiple person exposures, for example, more than 12 000 Japanese children reported in 1972 consumed arsenic-contaminated dry milk with 130 deaths; nearly 400 persons in Hong Kong in 1857 became ill following consumption of arsenic-contaminated bread; approximately 6000 beer drinkers in England in 1900 were ill, and 70 died after drinking beer made with sugar that utilized arsenic-contaminated sulfuric acid; more than 60 persons in Japan in 1998 became ill after eating arsenic-contaminated curry; and 15 persons in the United States in 2003 were hospitalized, and one additional person died after consumption of arsenic-contaminated coffee.

The adverse toxicological effects of arsenic are many and varied. Target organs include the bone marrow, skin, and nervous system after either acute or chronic excessive exposure. Malignant and nonmalignant skin adverse effects, peripheral vascular disease (e.g., blackfoot disease (gangrene of extremities) in Taiwan), diabetes mellitus, hypertension, lung cancer, bladder cancer, and liver cancer may occur with chronic exposure to drinking water with elevated arsenic concentrations. Aplastic anemia, agranulocytosis, and acute myelogenous leukemia may occur after chronic exposure. In Bangladesh, where there is extensive excessive well-water arsenic chronic exposure, cohort studies show a small but statistically significant increased risk of birth defects and fetal demise. Cross-sectional evidence shows an association of persistent neurocognitive deficits in children following *in utero* excessive arsenic exposure or early childhood excessive arsenic exposure. These latter data need to be confirmed by long-term prospective randomized cohort studies.

For chelation therapy of subacute or chronic arsenic toxicity, the drug of choice that is available and marketed in the United States is oral succimer (only the oral formulation is available). DMPS (dimercaptopropanesulfonate) (not marketed in the United States) also is an effective arsenic chelator. DMPS is distributed both intracellularly and extracellularly, a theoretical advantage for effectiveness; DMPS also binds/chelates MMA. A monoisoamyl ester of succimer has increased intracellular distribution compared with succimer and increases survival in arsenic-poisoned laboratory rats.

In summary, food (and water) sources of mercury, cadmium, and arsenic remain a potential route of exposure and possible poisoning by these heavy metals. Poisoning by these metals via food and water has been lessened because of increased regulations, increased awareness, and actions to mitigate such exposure. Continued international efforts will be needed to further decrease and maintain lowered exposure to these metals via food and water consumption.

Introduction

Herbs are the natural food additives that contribute immensely to the taste and flavor of our foods. These mysterious herbs are used for thousands of years in different foods and have been recognized to possess beneficial health properties and effectively used in the indigenous systems of medicine. Generally, the leaves used in cooking may be referred to as culinary herbs, for example, the green leaves of rosemary, oregano, coriander, basil, and parsley are used in Western and Continental cuisines for their aromatic flavors. The other parts like dried fruits (pepper), bark (cinnamon), and rhizomes (turmeric) are the important spices in Indian kitchen. Herbs are important for their disease prevention and health promotion properties, with an emphasis on diet. Regular use of culinary herbs in diet causes beneficial health effects, such as rosemary for jaundice, arthritis, and high blood pressure; oregano for stomach and respiratory ailments; turmeric as alternative to antibiotics; coriander as antioxidant, diuretic, expectorant, laxative, antibacterial, and antipyretic; basil to protect the heart; parsley as antioxidant; pepper for inflammation; and cinnamon to stimulate circulation. Dietary herbs could supply reasonable quantities of nutrients as well. The various aspects studied on these herbs can include safety of consumption, digestive stimulant action, influence on lipid metabolism, fat absorption, and antioxidant potential. Since each of the herbs possesses more than one beneficial health properties and there is a possibility of synergy among them in their action, a herbal diet is likely to make life not only more 'spicy' but also more healthy.

Cinnamomum zeylanicum

Cinnamomum zeylanicum (family Lauraceae), popularly known as cinnamon, is indigenous to Sri Lanka and southern parts of India and is used as an important spice in Indian kitchen in almost every delicious dish. Cinnamon has gained more importance in the Ayurvedic and folklore medicine in India, as remedy for the treatment of respiratory, digestive, and gynecologic ailments. A preclinical and clinical study confirmed anti-inflammatory and antimicrobial properties of cinnamon, which also reduces cardiovascular diseases and risk of colonic cancer, improves cognitive function, and reduces hypertension. Every part of the cinnamon tree has medicinal use including the leaves, bark, flowers, fruits, and roots. In addition, the *C. zeylanicum* is used for the treatment of dyspeptic conditions, flatulence, loss of appetite, abdominal pain, diarrhea, inflammation of the eye, leukorrhea, vaginitis, rheumatism, neuralgia, wounds, and toothache. *In vitro* studies evaluating antimicrobial properties of *C. zeylanicum* confirm its effectiveness against a wide variety of bacteria (Gram-positive and Gram-negative), fungi, and human rotavirus.

The volatile oils obtained from the different parts of the plant possess the same array of hydrocarbons in varying proportions with constituents such as cinnamaldehyde (bark), eugenol (leaf), and camphor (root). Three of the main bark oil components, *trans*-cinnamaldehyde, eugenol, and linalool, represent near 85% of the oil total composition. The *C. zeylanicum* leaf oil is rich in eugenol and the root bark oil in camphor, while the fruit oil is known to have varying major oil constituents depending on its origin (α- and β-pinenes, β-caryophyllene, *trans*-cinnamyl acetate, etc.). The essential oils obtained from the bark and important oil constituent, eugenol, express very powerful antioxidant activities by decreasing 3-nitrotyrosine formation and inhibiting the peroxynitrite-induced lipid peroxidation *in vitro* assays.

In vitro studies demonstrate various antidiabetic effects of *C. zeylanicum* extracts achieved in the following mechanisms: (1) reducing postprandial intestinal glucose absorption by inhibiting the activity of enzymes involved in carbohydrate metabolism (pancreatic α-amylase and α-glucosidase), (2) stimulating cellular glucose uptake by membrane translocation of GLUT-4, (3) stimulating glucose metabolism and glycogen synthesis, (4) inhibiting gluconeogenesis by effects on key regulatory enzymes, and (5) stimulating insulin release and potentiating insulin receptor activity. *In vivo* beneficial antidiabetic effects of *C. zeylanicum* include (1) attenuation of associated weight loss, (2) reduction of fasting blood glucose, (3) reduction of LDL and increase of HDL cholesterol, (4) reduction of HbA1c, and (5) increase in circulating insulin levels. In addition, this plant species also possesses valuable effects against diabetic neuropathy and nephropathy.

C. zeylanicum extract is known to have antisecretagogue and antigastric ulcer effects, as it effectively inhibits gastric hemorrhagic lesions induced by ethanol, NaOH, and NaCl. It has induced a dose-dependent analgesic protective effect against both thermal stimuli and the writhing syndrome, in addition to the evidence that it also shows an anti-inflammatory effect against chronic inflammation induced by cotton pellet granuloma indicating antiproliferative effects.

Piper longum

Piper longum L. (family Piperaceae), commonly known as 'long pepper,' is a climbing shrub, widely distributed in the tropical and subtropical regions of the world, throughout the Indian subcontinent, Sri Lanka, Middle Eastern countries, and the Americas. It is used as an important culinary spice, and although it is a very rare ingredient in European cuisines, it can be found in Indian vegetable pickles, some North African spice mixtures, and Indonesian and Malaysian dishes. In addition, it has gained importance in traditional system of medicine, such as Ayurveda, as an alternative to tonic.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00376-7

Traditionally, unripe fruits and roots of the plant are used for the treatment of bronchitis, cough, and cold; as antidote in snake biting and scorpion sting; and as contraceptive. In the northwestern Himalayan regions, it is used as a root decoction in ethnoveterinary medicine, for swellings of the joints of cattle. The fruits and the roots of *P. longum* contain a number of alkaloids and related compounds, the most abundant one being piperine, followed by methyl piperine, iperonaline, piperettine, asarinine, pellitorine, piperundecalidine, piperlongumine, piperlonguminine, refractomide A, pregumidiene, brachystamide, brachystamide A, brachystine, pipercide, piperderidine, longamide, tetrahydropiperine, terahydropiperlongumine, dehydropipernonaline, piperidine, piperine, terahydropiperlongumine, trimethoxycinnamoylpiperidine, and piperlongumine. Essential oil extracted from the fruits of *P. longum* is a complex mixture, excluding the volatile piperine; the three components of the oil are β-caryophyllene, pentadecane, and bisabolene. Apart from these, sesamin, pulvuatilol, fargesin, thujone, terpinolene, zingiberene, *para*-cymene, *p*-methoxyacetophenone, and dihydrocarveol are also present in the fruit oil of *P. longum*. The plant contains essential oil, which consists of sesquiterpene hydrocarbons and ethers (bisabolene, β-caryophyllene, β-caryophyllene oxide, and α-zingiberene) and saturated aliphatic hydrocarbons such as pentadecane, tridecane, and heptadecane. With respect to its medicinal importance, *P. longum* is well investigated pharmacognostically, chemically, and pharmacologically.

Various studies have revealed that the root has a weak opioid but potent NSAID type of analgesic activity, in addition to cardioprotective, antiarthritic, anticonvulsant, immunomodulatory, and anti-inflammatory activities. Various *in vitro* and *in vivo* models demonstrate effects of the plant extracts on angiogenesis by regulating the cytokines and growth factors in angiogenesis-induced animals. *P. longum* extract demonstrates anticancer properties due to antioxidant and its inhibitory action on inflammatory mediators like cytokines and TNF-α. At a higher dose, the extract of *P. longum* also shows hepatoprotective and antifibrotic activities. Alcoholic extract of the plant fruits and its constituent piperine is studied for possible immunomodulatory and antitumor activities; following their administration, bone marrow cellularity and esterase positive cells proved to be increased. Guineensine, isolated from chloroform extract, inhibited activity of acyl CoA:cholesterol O-acyltransferase in a dose-dependent manner, and dehydropipernonaline demonstrates vasorelaxant activity. Pharmacological inhibition of acyl CoA/diacylglycerol acyltransferase by alkamides isolated from *P. longum* emerged as a potential therapy for the treatment of obesity and type 2 diabetes.

Curcuma longa

Curcuma longa L. (family Zingiberaceae), known as turmeric, is the rhizomatous herbaceous perennial plant, native to tropical South Asia, and now widely cultivated in the tropical and subtropical regions of the world. The rhizome, which is yellow in color, is commonly used as a spice in many Indian dishes and as a medicine in traditional system of medicine in India. In Ayurvedic medicine, turmeric is primarily used for the treatment of inflammatory diseases such as arthritis and cancer, while in traditional Chinese medicine, it is used as stimulant, aspirant, carminative, cordial, emmenagogue, astringent, detergent, and diuretic; also for the treatment of flatulence, jaundice, menstrual difficulties, hematuria, hemorrhage, and colic; or as an ointment to treat many skin diseases. The main components of turmeric include curcumin (curcumin I), demethoxycurcumin (curcumin II), and bisdemethoxycurcumin (curcumin III), together referred to as curcuminoids. Curcumin is a low-molecular-weight polyphenol responsible for the bright yellow color of turmeric; it is the active principle of turmeric that comprises 2–8% of most turmeric preparations. Preclinical and clinical studies confirm that curcuminoids achieve anti-inflammatory activity by inhibiting LOX, COX, phospholipases, leukotrienes, prostaglandins, thromboxane, nitric oxide elastase, hyaluronidase, collagenase, monocyte chemoattractant protein-1, interferon inducible protein, TNF, and interleukin-12. They also decrease prostaglandin formation and inhibit leukotriene biosynthesis via the lipoxygenase pathway. Water- and fat-soluble extracts of turmeric and its constituent curcumin exhibit strong antioxidant activity. Curcumin is found to inhibit cyclosporine A-resistant phorbol myristate acetate anti-CD28 pathway of T-cell proliferation. In addition, it reduces the testicular damage caused by exposure to di-*n*-butylphthalate (DBP), by increasing glutathione (GSH), testosterone levels, and glucose-6-phosphate dehydrogenase (G6PD) activity and decreasing malondialdehyde (MDA) levels. These properties are probably due to intrinsic curcumin's antioxidative abilities.

Animal research demonstrates that this compound inhibits all three stages of carcinogenesis, namely, initiation, promotion, and progression. During initiation and promotion, curcumin modulates transcription factors controlling phase I and II detoxification of carcinogens; downregulates proinflammatory cytokines, free radical-activated transcription factors, and arachidonic acid metabolism via COX and LOX pathways; and scavenges free radicals, and in progression stage, curcumin inhibits papilloma production, induces apoptosis of cancer cells, and inhibits angiogenesis.

Curcuminoids also prove the antidiabetic effects by stimulating following mechanisms: (1) cellular glucose uptake by GLUT-4, (2) glucose metabolism and glycogen synthesis, and (3) insulin release and insulin receptor activity potentiation.

In vitro and *in vivo* studies also demonstrate that turmeric extract and *C. longa* essential oil are active against various microorganisms and inhibit the growth of a variety of pathogenic bacteria, parasites, and fungi. Chronic administration of curcumin modulates the dysfunction of the hypothalamic–pituitary–adrenal axis, through selective increase in brain-derived neurotrophic factor in the frontal cortex and the hippocampus of the animals, showing its activity against anxiety and depression. Turmeric's protective properties of the cardiovascular system include lowering cholesterol and triglyceride levels, decreasing susceptibility of low-density lipoprotein to lipid peroxidation, and inhibiting platelet aggregation.

Coriandrum sativum

Coriandrum sativum L. (family Apiaceae) is herb indigenous to southern Europe and cultivated for its edible seeds and leaves. *C. sativum* seeds are known for over 5000 years and were found in the tombs of Egyptian pharaoh Ramses II and used in ancient Egypt as 'secret of happiness' (an aphrodisiac), and in history of Hebrews, the seed was considered as a gift from God

and was added to drinks during Passover and was used by Hippocrates as a healing herb.

C. sativum leaves, which are larger at the base and smaller on the top, have distinct powerful aroma, and the seeds, flowers, and roots are used in flavoring of rice, sausages, soups, stews, and ratatouille, in pickling, and in baked foods and are an important ingredient of the famous Belgian wheat beer. The coriander leaves have high contents of vitamin C, vitamin A, vitamin K, iron, manganese, thiamine, zinc, and dietary fiber. The fresh juice of the *C. sativum* leaves is helpful in curing deficiencies related to vitamins and iron. The seeds are very rich source of potassium, calcium, phosphorus, magnesium, sodium, and zinc. The finest flavor of *C. sativum* is associated to the plants grown in England, while those cultivated in Russia and Germany proved to be the richest in essential oil.

Fruits and leaves of *C. sativum* are traditionally used for digestive and gastric complaints, coughs, chest pains, bladder complaints, fever, dysentery, headaches (externally), oral and pharyngeal disorders, halitosis, and many other complains. Its crushed seeds can be applied externally for rheumatism and painful joints. *C. sativum* fruits demonstrate antibilious, antispasmodic, aphrodisiac, appetizer, aromatic, carminative, diaphoretic, diuretic, refrigerant, antirheumatic, stimulant, stomachic, and tonic properties; show antihypertensive potential and sedative, hypolipidemic, and vermifuge activities; and also influence loss of appetite, convulsion, and insomnia.

Essential oil from the *C. sativum* fruits contains high percentage of linalool, camphor, α-pinene, γ-terpinene, and limonene. Due to the high linalool content in the essential oil, coriander seeds demonstrate the analgesic activity through an opiate-mediated mechanism. The oil extracted from *C. sativum* leaves demonstrates strong antifungal, antiadherent, and antiproteolytic activities against *Candida* spp. through the synergistic effect of its mono- and sesquiterpene hydrocarbons and modulation of gene expression in chemokine and mitogen-activated protein kinase pathways of *Candida* spp. and expression of adhesion proteins.

C. sativum leaves, which have high content of carotenoids, show higher hydroxyl radical scavenging potential in comparison with its seeds. The ethyl acetate extract of the plant roots inhibits activity in MCF-7 cells by affecting antioxidant enzymes and cell cycle arrest at the G2/M phase and apoptotic cell death by the death receptor and mitochondrial apoptotic pathways. *C. sativum* is also widely used for the management of CNS disorders and demonstrates a high curing potential for Alzheimer's disease in the rat experimental model, through protection and improvement of functions in pyramidal cells in the cerebral cortex.

Ocimum basilicum

Ocimum basilicum L. (family Lamiaceae) is a commonly and widely cultivated European and Asian plant with intense distinctive herbal spicy and sweet aroma (from the Greek 'basileus king,' royal fragrance) and has its origins from the Greek mythology. In ancient Egypt, the so-called Odium basilicum has been used in combination with other essences and oils, during religious ceremonies and for mummification. *O. basilicum* was introduced in England in the sixteenth century. *O. basilicum* is widely used in medicine and for culinary and perfumery purposes all over the Europe, particularly in France. The leaves and the essential oil distilled from the flowering plants are used as powerful flavoring agents. The main *O. basilicum* exporters for the European market are France, Italy, Morocco, Egypt, and the United States (California).

In traditional medicine, *O. basilicum* has been intensively used for the treatment of gastric and respiratory diseases, anxiety, headaches and migraines, inflammation, cough, cold, digestive disorders, chest and lung complaints, fever, insect bites, menstrual cramps, and sinusitis and demonstrates carminative, stimulant, diaphoretic, diuretic, antiseptic, anesthetic, antispasmodic, anthelmintic, antidiarrheal, analgesic, and antitussive properties.

The *O. basilicum* essential oil has several chemotypes (linalool, methyl chavicol (estragole), eugenol, etc.). Basic chemical composition of the linalool chemotype of the *O. basilicum oil* is linalool, epi-α-cadinol, c-cadinene, germacrene D, and camphor. Methyl-chavicol chemotype of *O. basilicum* essential oils contains high percentage of methyl chavicol, 1,8-cineole, *trans*-ocimene, etc. Due to its richness in linalool (oxygenated monoterpene), the *O. basilicum* essential oil exhibits potent antimicrobial activity that is comparable to amoxicillin and flumequine. Phenolic components are the main contributors to the oil antimicrobial properties, causing the leakage of intracellular ATP and potassium ions of bacterial cells, which leads to the death of bacterial cell. Significant antibacterial activity of the oil is documented against Gram-positive and Gram-negative bacteria (*Staphylococcus aureus*, *Escherichia coli*, *Bacillus subtilis*, *Pasteurella multocida*, *Salmonella enteritidis*, *and Proteus vulgaris*), though some Gram-negative bacteria proved to be resistant, probably due to their hydrophilic outer membrane, which protects penetration of hydrophobic compounds into the cell.

The methyl chavicol, which is typical for *O. basilicum* methyl-chavicol essential oil, shows a broad spectrum of antifungal activities (*Aspergillus niger*, *Mucor mucedo*, *Fusarium solani*, *Botryodiplodia theobromae*, *Rhizopus solani*, *Candida albicans*, *and Microsporum gypseum*), which are achieved by disruption of fungal membrane. Methyl chavicol (estragole), one of the major *O. basilicum* oil constituents, is extensively used as a flavoring, antimicrobial, antioxidant, antiedematogenic, and anti-inflammatory agent. It has been shown to block neuronal excitability by direct inhibition of Na^+ channel conductance activation in peripheral nerves due to a local anesthetic mechanism.

The ursolic acid presented in the aqueous extract of sweet basil interferes with postinfectious replication mechanism of CVB1 group of Coxsackie virus. Phenolic compounds of *O. basilicum* plant essential oils and extracts also play an important role in stabilizing lipids against peroxidation and inhibiting various types of oxidizing enzymes. The hydroalcoholic extract of *O. basilicum* contains a range of potent oxygen scavengers (terpenoids, flavonoids, and tannins), which could be useful clinically in the improvement and retrieval of memory via reducing brain cells oxidative damage. Caffeic acid found in the leaf of the *O. basilicum* demonstrates antioxidant, anti-inflammatory, and cancer chemopreventive properties.

Aqueous leaf extract of *O. basilicum* demonstrates cytotoxicity against nasopharyngeal cancer cell line (KB), human liver hepatocellular carcinoma cell lines HeLa and HEp-2, and NIH 3T3 mouse embryonic fibroblasts. *O. basilicum* aqueous extract

has been shown to protect the testis against toxicity induced by one of the most known toxic heavy metals cadmium (Cd).

Petroselinum crispum

Petroselinum crispum (Mill.) Nym. (family Apiaceae) is a vegetable, a medicinal herb, and a spice, widely cultivated for more than 2000 years in the southeastern Europe and western Asia. Its name *Petroselinum* derives from the Greek term referring to the plant's habit to grow in rocky places. *P. crispum* is native to the central Mediterranean region and is cultivated all over the Europe. As a great flavoring to any salad and meet dish, the plant was introduced from Sardinia to England in the sixteenth century.

There are three different varieties of *P. crispum*: var. *crispum* (curles parsley) with a sharp peppergrass-like taste and cultivated in warmer climate; var. *neapolitanum* (flat leaf purslay) with a sweeter and smoother flavor and grown in a colder conditions characterized by dryness and snow (Italian and eastern European parsley); and the less known var. *tuberosum* (Humburg parsley), primarily grown for its roots.

P. crispum has bright green, fragrant leaves, it adds color and flavor to any food we eat, and it is used to soothe various digestive complaints, such as indigestion, flatulence, and loss of appetite, and may prevent stomach ulcers. Fresh *P. crispum* herb is widely used in Middle Eastern, European, Brazilian, and American cooking. French *persillade* (a sauce made of mixture of chopped garlic and parsley) is well known all over the world, and Italian and Spanish cuisines use the herb in delicious *salsa verde*.

In addition to its culinary use, *P. crispum* possesses many medicinal properties, first mentioned by the ancient Greeks. *P. crispum* plant is rich in ascorbic acid, carotenoids, flavonoids, apiole, terpenoic compounds, coumarin, phenylpropanoids, phthalides, tocopherol, and furanocoumarins. The leaves hold high content of vitamins (A, C, and K), β-carotene, and also lutein, zeaxanthin, folate, choline, niacin, and pantothenic acid. Together with leaves, the plant roots are wonderful source of a range of minerals (Ca, K, Mg, B, P, Fe, Na, Zn, F, Mn, and Se). High concentration of boron and fluoride in parsley leaves might help against bone thinning and osteoporosis, and its great combination of calcium and fluorine supports teeth health.

P. crispum essential oils and extracts demonstrate antioxidant, anti-inflammatory, calcium channel-blocking (in the intestine and uterus muscle), cancer preventive, laxative, and diuretic properties. Due to its essential oil content, *P. crispum* has great insect repellent potential and is always a good companion plant, repelling insects from nearby plants. The major constituent of the *P. crispum* leaf oil is *p*-1,3,8-menthatriene, followed by β-phellandrene, myristicin, and β-myrcene, while the major root oil constituent is apiole, followed by myristicin and terpinolene. In addition, the *P. crispum* leaf oil has immunomodulatory effect on mitogen-activated splenocytes and peritoneal macrophages apart that the seed oil is used as a fragrance in soaps, cosmetics, and perfumes and demonstrates strong diuretic activity. However, it is important to remember that *P. crispum* essential oils can also be phototoxic and abortifacient and should never be consumed or applied to the skin without caution.

The methanol extracts of *P. crispum* contain coumarins and express great antimicrobial activity against *B. subtilis*, *P. aeruginosa*, *S. epidermidis*, *S. aureus*, *E. coli*, *Klebsiella pneumoniae*, and *Saccharomyces cerevisiae*, while hydroalcoholic extract of the same plant demonstrates a significant inhibition of the standard *P. aeruginosa strain*. The aqueous extracts of parsley had bactericidal effects against *Helicobacter pylori* and inhibited adhesion of the bacteria to animal stomach section. Daily consumption of *P. crispum* in salad significantly reduces the blood glucose potentially via inhibition of gluconeogenesis and direct stimulation of glycolysis.

In general, fresh *P. crispum* plant and its oils and extracts are widely used as antiaging, anticarcinogenic, antifungal, anti-inflammatory, digestive aid, laxative, diuretic, and aphrodisiac; help soothe arthritis pain; and are used for bronchitis, bruises, burns, itching, common cold, itching, menstrual cramps, bad breath, goiter, edema, swollen glands, bed-wetting, fluid retention, jaundice, asthma, fever, gas, swollen breasts, snakebites, dropsy, worms, obesity, and expulsion of the gravel and kidney stone.

Rosmarinus officinalis

Rosmarinus officinalis (family Lamiaceae) is one of the oldest Mediterranean shrubs with powerful pungent aroma and dark green elongated leaves and white or purple flowers. The rosemary herb was used as a food seasoning and natural medicine for over a million years. The name *Rosmarinus* derives from the Latin term that translates to 'dew of the sea.' Rosemary is a symbol of remembrance, since ancient Greece and Rome. Greeks used the herb to help their memory, to expel negativity by placing the sacred herb under the pillow, and to prevent nightmares. Dioscorides, Theophanus and Conrad Gesner, and ancient healers recognized the beneficial effects of rosemary in dealing with brain, liver, heart, and eye problems. According to legend, when Mary, Joseph, and the baby Jesus were fleeing to Egypt, Mary laid her cloak on a rosemary bush, and since that time, rosemary bush was called the 'Rose of Mary' in honor of the Virgin Mary. Rosemary plants were placed in the tombs of Pharos in ancient Egypt to remember the dead and were used to embalm them. During Medieval times in France, rosemary was burned for church incense and used to purify the air in the hospitals. Famous Napoleon's Eau de Cologne was made with rosemary oil.

R. officinalis leaves added to vinegar (marinade) make a great flavoring component in preparation of meat, shellfish, and vegetables. Rosemary plant is rich in vitamin A, vitamin C, thiamin, riboflavin, vitamin B_6, and folate, as well as such important minerals like Ca, Mg, iron, phosphorus, potassium, and copper. Carnosic acid and carnosol (rosemary polyphenol) pose chemopreventive, antioxidant, and anticancer activities against prostate, skin, breast, leukemia, lung, urinary bladder, and colon cancers through genes that encode antioxidant phase II enzymes. As anti-inflammatory, carnosol has ability to reduce leukotrienes, inhibit 5-lipoxygenase, antagonize the intracellular Ca^{2+} mobilization, and inhibit the secretion of leukocyte elastase. Triterpenoid compound ursolic acid has been shown to have anti-inflammatory and even antidepressant effects.

R. officinalis and its components were reported to possess chemopreventive properties in skin and breast cancers *in vivo*

by inhibiting genotoxicity (7,12-dimethylbenz(a)anthracene (DMBA)–DNA adduct formation). Polyphenolic preparation from R. officinalis in combination with low calcemic vitamin D_3 analogs demonstrates antileukemic activity *in vivo* in six- to eight-week-old female Balb/c mice.

R. officinalis leaf essential oil is composed mainly of α-pinene, 1,8-cineole, and camphor and when used in massage increases blood pressure and respiratory rates and has stimulatory effect on the autonomic nervous system through sympathetic activity. *R. officinalis* essential oil exhibits free radical scavenging activity and excellent hepatoprotective properties by limiting the lipid peroxidation. The 1,8-cineole from *R. officinalis* essential oil is a lipid-soluble compound that facilitates passage across the blood–brain barrier, producing neuronal effect on the receptor sites or impacting enzyme activity of neurons in brushtail possum.

R. officinalis essential oil has excellent antioxidant and antimicrobial activity and is capable to extend the shelf life of food and skin care products during the storage as natural preservative.

Origanum vulgare

Origanum vulgare, also called wild marjoram (family Lamiaceae), whose name comes from Greek *origanon*, is typical to North America, originating from Mediterranean, and have a long history of use as food and a medicinal plant. Oregano is a perennial herb (up to 80 cm in height), with dark oval fragrant leaves and white, pink, or purple flowers formed in spikes. In ancient times, oregano symbolized happiness, is used to combat sadness and bring luck, and is thought to be precious to the Greek goddess Aphrodite. In ancient Egypt, oregano was used as both a preservative and an antidote to poison, and Greeks used *O. vulgare* herb internally and externally as a fomentation to treat skin irritations and infections, dropsy, and convulsions and as an excellent poison antidote. Traditional Chinese healers have also used oregano for generations to treat a variety of complaints. In Shakespearean times, oregano was used for just about anything. It is said to encourage good luck and good health. Oregano gives a slightly bitter flavor to poultry, fish, sauces, eggs, and other dishes. This dried herb is also used in processed foods (alcohol beverages, snack foods, meat, and milk products). The charcoal-roasted lamb *souvlaki* is usually sprinkled with oregano. All the varieties of oregano are interchangeable in food preparation soups, herb bread, and tomato dishes. *O. vulgare* is also used as a fragrance component in perfumes, detergents, cosmetics, flavorings, soap, and pharmaceuticals.

The major constituents of *O. vulgare* leaves essential oil are carvacrol, p-cymene, c-terpinene, limonene, terpinene, ocimene, caryophyllene, β-bisabolene, linalool, and 4-terpineol. Oregano oil has antibacterial, antifungal, antiparasitic, antimicrobial, and antioxidant properties. The antifungal activity of *O. vulgare* essential oil against *A. parasiticus*, *A. niger*, *A. flavus*, and *A. ochraceus* through inhibition of growth and aflatoxin production is well documented. *O. vulgare* essential oil and extract are highly effective against *C. albicans*, *S. aureus*, *and Pseudomonas aeruginosa*.

The bioactive constituents of *O. vulgare* leaves extract are rosmarinic acid, linalool, thymol, carvacrol, tannins, flavonoids, triterpenes, phenol carvacrol, and thymol. Oregano also contains iron, vitamins, calcium, copper, niacin, magnesium, and thiamine. Oregano has been used in the treatment of cancer, muscular degeneration, and heart disease. Oregano taken as a tea or used as a salve inhibits bacterial growth and parasitic microorganisms. The herbal tea also helps to alleviate headaches, urinary problems, diarrhea, nausea, lung disorders, vomiting, and jaundice and is used as a mouthwash to help with tooth infections and sore throat. Oregano is a great cold and flu remedy and aids in the treatment of indigestion, bloating, flatulence, and menstrual symptoms.

Conclusion

As interest in the potential use of herbs in diets for health benefits increases, it will become more important to monitor the progress of the clinical findings and to communicate these in literatures. Modern research on the impact of the bioactive properties of culinary herbs has shed some light on their potential health benefits. However, advance research is required to fully understand the health-promoting mechanism of such herbs from different diets. Furthermore, there is very little knowledge about the impact of combining herbs in different cuisines and their bioactivity. Ultimately, it is determined that the dietary herbs possess true health benefits because of the presence of nutrients, vitamins, and polyphenols.

Histidine-containing Dipeptides: Properties and Occurrence in Foods

M-C Aristoy, L Mora, and F Toldrá, Instituto de Agroquímica y Tecnología de Alimentos (CSIC), Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Histidine-containing dipeptides carnosine, anserine, and balenine (also known as ophidine) are endogenous dipeptides in mammalians, which are described to have important bioactive functions. The main properties of these dipeptides are based on their chemical structure consisting in an imidazole group belonging to the amino acid histidine, 1-methylhistidine, or 3-methylhistidine, respectively, linked by a peptidic bond to the amino acid β-alanine. These dipeptides are widely distributed in the animal body being especially abundant in the skeletal muscle where they exert their main action consisting of buffering effect for contributing to the maintenance of the acid–base balance. This allows rapid recovery of muscle that can continue working after intense exercise. Other locations are the central nervous system, brain, cardiac muscle, liver, kidney, and sense organs like eyes where they exert a combination of antioxidant and cell protective activities for those considered as 'antiaging' peptides. For all these reasons, they are used to prevent and treat diseases such as diabetes, neurodegenerative diseases, cancer, and diseases of the sense organs like cataracts. Carnosine has been demonstrated to have some effect in cell heart contraction via calcium-dependent mechanisms, thus opening a door for discovering alternative ways for treating heart failure. Also, a role as preventive agents, acting as a barrier against influenza virus infection, has been described.

The pool of carnosine in the body comes from endogenous and exogenous sources. Carnosine is synthesized in the organism by carnosine synthase from their constituent amino acids, β-alanine and histidine, when they are available, but it can also be directly ingested in the diet. Indeed, higher carnosine levels are found in people consuming diets rich in meat in comparison to vegetarians. The level of carnosine in tissues is controlled by a number of enzymes that reversibly transform carnosine into other carnosine-related compounds, such as anserine or balenine by methylation, carcinine (β-alanylhistamine) by decarboxylation, or *N*-acetylcarnosine by acetylation. Apart from these, carnosinase, a dipeptidase (2 isoforms) present in the cerebrospinal fluid, serum, and kidney, is able to cleave carnosine into histidine and β-alanine. Carnosinase preferably acts against carnosine, while anserine and balenine are hydrolyzed much more slowly (by 20%) and *N*-acetylcarnosine is not hydrolyzed at all. Another carnosine derivative also present in the animal body, which is homocarnosine (γ-aminobutyryl-histidine), has a strong, competitive inhibitory effect on carnosine turnover mediated by carnosinase. Therefore, the presence of homocarnosine or the metabolic transformation of carnosine to their derivatives can protect it against enzymatic hydrolysis as a spare way. Indeed, *N*-acetylcarnosine has been used as a substitute of carnosine in the treatment of cataracts, because of its same beneficial properties, while showing resistance against hydrolytic action of serum carnosinase.

The histidine-containing dipeptides content in the body is also dependent on age and gender. The activity of carnosinase tends to increase with age, leading to lower levels of carnosine in older people; higher carnosine content has been reported in males than in females.

Presence in Animal Species and Types of Muscle

The presence of histidine-containing dipeptides in muscle mainly depends on animal species and type of muscle. These dipeptides are more abundant in white muscles than in red ones that seem to be due to a kind of adaptation to the requirements of the muscles. Type IIB muscle fibers are fast-twitch glycolytic fibers prone to rapid responses. In fact, it has been observed that sprinter animals like thoroughbred horses or greyhound dogs or animals that need to escape from predators have a higher percentage of fast-twitch glycolytic fibers, which are richer in dipeptides that exert the buffering effect.

Figure 1 shows the content of dipeptides in some common animal muscle foods. It is interesting to highlight the big differences among them. Carnosine is predominant in terrestrial animals, except in those moving by jumping like kangaroo, rabbit, deer, goat, and, also, sheep that have more anserine or equal amounts of anserine and carnosine (see the contents in lamb shown in Figure 1). On the other hand, anserine is predominant in poultry with a very high content in chicken breast.

Migratory fish and birds have muscles rich in anserine to maintain posture and instantaneous power. As occur in birds, anserine is the predominant histidine-containing dipeptide, but, as in the case of fish, carnosine is almost negligible in comparison to the anserine content. Fish muscle contains two functionally and spatially distinct fiber types, red (dark) and white. In general, fish white muscle contains much higher (four to ten times more) amounts of anserine than red one, especially in migratory marine fishes such as mackerel, tuna, and bonito that use anserine to overcome fatigue. On the contrary, deep-sea and demersal fishes, like sole, halibut, code, and hake, contain less anserine. Nevertheless, there is a high variability in the amounts of histidine-containing dipeptides in fish due to the large number of fish species, and they can also vary even for a same species living in different climatic or environmental conditions.

Stability

The availability of these dipeptides through the diet is possible thanks to their good stability during processing (e.g., cooking, fermentation, and drying) and storage. Furthermore, the

ingested histidine-containing dipeptides are absorbed intact because of its resistance to the digestive tract peptidases.

Stability Against Heat Treatments

Different cooking methods for meat have different effects on its histidine-containing dipeptide content. Carnosine losses when using methods like boiling seem to be related to its solubilization in the water boiling medium more than to its degradation. Further, with higher-temperature treatments like those used for broiling meats, less degradation of carnosine was reported. Even higher-temperature broiling (200 °C) led to less reduction in the carnosine content than medium temperature (140 °C), probably due to the higher crusting when using high temperature and thus preventing drip losses and consequently carnosine depletion. Microwave cooking methods were reported to preserve the highest amounts of carnosine in beef meat (losses near 10%) and the total amount of anserine in turkey. These facts indicate that these dipeptides are quite heat-resistant, and therefore, high content of histidine-containing dipeptides may exist in commercial cooked meat products. Table 1 shows the content of dipeptides found in pork loin after different heating treatments. In this case, samples were packaged into a plastic bag and then submitted to different heat treatments. The drip loss was homogenized together with the meat sample to avoid losses in the drippings. At temperatures up to 75 °C, losses were, if any, less than 5% for the three dipeptides at any time of treatment (see Figure 2). Maximum losses were between 20% and 30% of both, carnosine submitted to 95 °C and anserine to 105 °C, after 120 min treatment.

Resistance to Muscle Endogenous Proteases

Endogenous proteases in the living muscle are important in the regulation of some physiological and cellular processes as well as in the prevention of the accumulation of unwanted or abnormal proteins in cells. After slaughter, peptidases start to degrade all proteins in the livestock or poultry muscles in a sequential chain in which endo- and exopeptidases like aminopeptidases are involved. Nevertheless, during meat aging under cold storage (14 days for beef or 7 days for pork), carnosine and anserine contents do not change. Different processes like dry-curing or fermentation and ripening are used for

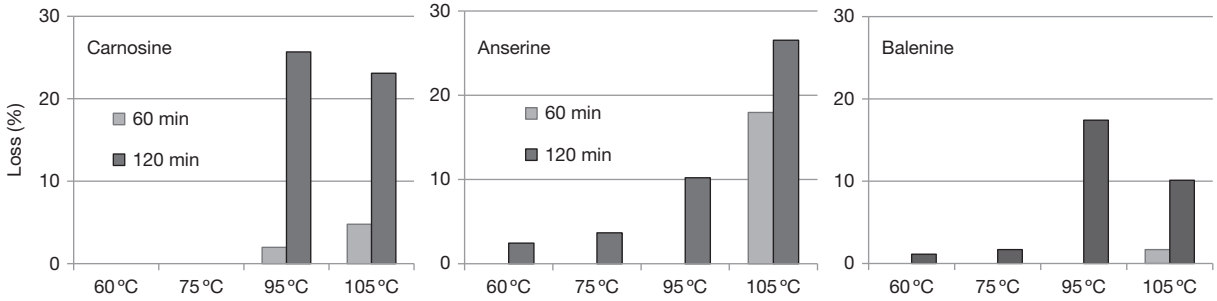

Figure 2 Losses, expressed as %, of carnosine, anserine, and balenine in pork loin after different heat treatments (temperature and time). Raw loin content (in mg/100 g muscle): carnosine, 491.0; anserine, 24.5; and balenine, 35.6. Pieces of loins were vacuum-packaged in plastic bags and submitted to different heat treatments for different times. Afterward, samples were homogenized together with the exudates and analyzed. Adapted from Aristoy, M.-C., Soler, C. and Toldrá, F. (2004). A simple, fast, and reliable methodology for the analysis of histidine dipeptides as markers of the presence of animal origin proteins in feeds for ruminants. *Food Chemistry* **84**, 485–491.

long processing times. Proteolytic enzymes are then the main responsible for the development of relevant sensory characteristics like texture and flavor.

High levels of the histidine-containing dipeptides have been reported in fermented meat products. Proteolysis in fermented sausages is mainly conducted by bacterial peptidases, while in dry-cured ham, muscle endogenous peptidases are responsible for these reactions. This explains the differences found in dipeptide content in both types of products. Muscle endogenous peptidases are not able to hydrolyze the peptidic bond of these dipeptides, while some bacteria (*Lactobacillus*, *Escherichia*, or *Salmonella*) have been described to contain carnosinase, an enzyme with the ability to hydrolyze this bond. So, different concentrations of carnosine and anserine are found in fermented meats depending on the bacterial flora. This flora is composed by the native microbiota together with different starter strains with more or less carnosinase activity and thus different abilities to metabolize the histidine-containing dipeptides. This factor will influence dipeptides amount to a larger extent than processing conditions. Nevertheless, high amounts of carnosine, about 1/3 and 1/2 of the initial concentration, remain intact in all the studied processes.

Figure 3 shows the evolution of carnosine in two types of fermented sausages: two from Spanish sausages and two from Italian salamis.

The very large amount of the histidine-containing dipeptides in dry-cured ham, similar to that from the raw pork ham, indicates a very reduced hydrolysis of the peptidic bond in the dipeptides. Further, carnosinase is not present in muscle. Table 2 shows the carnosine and anserine contents in several dry-cured hams from Spain, France, and Italy. Differences in breed, sex, or age of the animals should explain the differences among them, besides that in processing conditions (temperature, ripening length, etc.).

Figure 4 shows the evolution of carnosine content during a typical Spanish serrano ham process. The slight decrease of carnosine between 3.5 and 5 months of processing is in coincidence with a slight increase of β-alanine and anserine occurring in the same time and may be due to both mechanisms: a hydrolysis of carnosine into the constituent amino acids and a partial carnosine conversion into anserine by methylation.

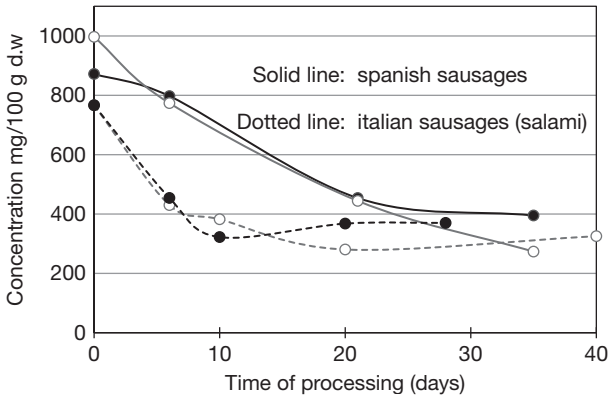

Figure 3 Evolution of the carnosine content in Spanish and Italian dry-fermented sausage processing. Adapted from Cassaburi, A., Aristoy, M. C., Cavella, S., Di Monaco, R., Ercolini, D., Toldrá, F. and Villani, F. (2007). Biochemical and sensory characteristics of traditional fermented sausages of Vallo di Diano (Southern Italy) as affected by the use of starter cultures. *Meat Science* **76**, 295–307; Durá, M. A., Flores, M. and Toldrá, F. (2004). Effect of Debaryomyces spp. on proteolysis of dry-fermented sausages. *Meat Science* **68**, 319–328.

Resistance to Digestive Peptidases

The resistance of these peptides to peptidase digestion has been assessed by analyzing them in plasma and urine after ingesting beef, breast chicken, and breast chicken broth. Anserine increased in plasma after chicken or chicken broth ingestion, while the presence of carnosine in plasma depended on the carnosinase, present in the small intestine and in the human plasma, which acts preferably on carnosine. The cleavage of carnosine can be detected in urine by analyzing its constituent amino acids. In any case, these findings confirm the intact absorption of both peptides.

Analysis of Histidine-Containing Dipeptides

The analysis of these dipeptides is relatively easy. They are soluble molecules and thus can be easily extracted from the

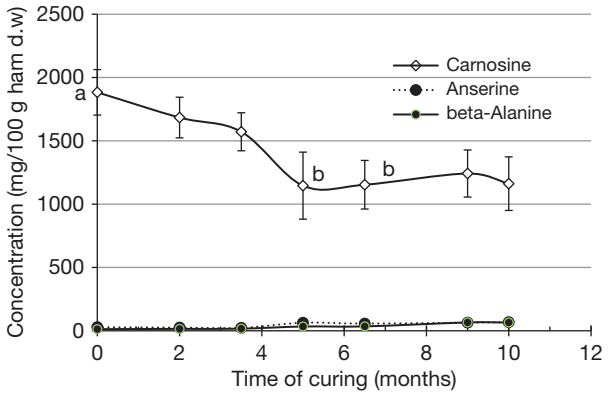

Figure 4 Evolution of carnosine, anserine, and β-alanine contents during a traditional dry-curing ham processing. Adapted from Marušić, N., Aristoy, M. C. and Toldrá, F. (2013). Nutritional pork meat compounds as affected by ham dry-curing. *Meat Science* **93**, 53–60.

matrix with either water or aqueous solvents. Afterward, proteins from the matrix should be eliminated by adding strong acids (perchloric or trichloroacetic acids) or organic solvents (acetonitrile, methanol, etc.) and, after centrifugation to eliminate the precipitated protein, sample is ready for separation by chromatography or micellar capillary electrophoresis.

Chromatography is the most used technique to analyze the histidine-containing dipeptides. These dipeptides are polar and ionic at physiological pH, and thus, they can be separated based on their charge by cation exchange chromatography (CEC) or by hydrophilic interaction chromatography (HILIC). Another interesting alternative is to increase the hydrophobicity of the histidine-containing dipeptides by making them react (derivatization) with a hydrophobic molecule (o-phthalaldehyde, OPA; phenyl isothiocyanate, PITC; dansyl chloride; or 2,4-dinitrofluorobenzene, DNFB, are the most used) that should also confer ultraviolet or fluorescent-absorbing properties. Derivatized dipeptides will then be separated by reversed-phase chromatography (RP-HPLC), which is a more efficient chromatography technique.

Several methods to detect the separated peptides are used. The UV absorption of the peptidic bond at 214 nm is used when no derivatization has been performed, which is the case of CEC or HILIC separations. Nevertheless, when derivatizing the molecule with a chromophore like PITC, OPA, dansyl chloride, or DNFB, more sensible and selective detection at higher UV wavelength or by fluorescence can be used. The derivatization can be achieved before separation by RP-HPLC method or after CEC or HILIC separations by means of a postcolumn reaction. This last method requires the derivatization reaction to be very rapid in order to avoid any spoiled separation. In this sense, OPA would be a very good choice. The use of mass spectrometry as a detection method to analyze histidine-containing dipeptides has become more popular in recent years. This detection does not need any previous derivatization and works very well after HILIC separations because of the good compatibility of both techniques with regard to the solvents used as mobile phases. When using the dansyl chloride derivatization and RP-HPLC coupled to single quadrupole mass spectrometry for the detection, very complex samples of nitrogen-based compounds (amino acids, nucleosides, carnosine, etc.) can be analyzed. Nevertheless, the high cost of this technique may not always be justified for the exclusive analysis of histidine-containing dipeptides because they are found in high concentration in foods.

Introduction

Human immunodeficiency virus (HIV) infection is a worldwide problem of great magnitude. The World Health Organization (WHO) estimates that about 35 million adults and children were living with HIV in 2013, the majority of whom are in developing nations. In 2013, HIV and its related complications were the cause of death in 1.5 million people worldwide. However, the number of individuals infected with and dying from HIV has been steadily declining in the last 15 years. This trend reflects the expansion of services to prevent the transmission of HIV from mother to child, the wider use of antiretroviral therapy (ART), and the improved prophylactic regimens worldwide. In developed nations, HIV has become a chronic illness with highly active antiretroviral therapy or now what is currently called combination antiretroviral therapy (cART) as the mainstay of treatment. With more individuals living with HIV, the necessity of appropriate supportive care is paramount.

Clinicians who care for those with HIV should be aware of potential nutritional and metabolic problems and their consequences. In the past, and currently in some subpopulations, wasting syndrome is the primary nutritional concern for HIV-infected individuals. Malnutrition can have additive destructive effects on the immune system and host defense mechanisms. T cell-mediated immune responses are targeted primarily and have been termed the nutritionally acquired immune deficiency syndrome. It has been long thought that aggressive nutritional rehabilitation can combat and potentially reverse these effects. However, as we approach 20 years since the advent of cART, expanding cardiometabolic and related nutritional issues often prevails that can also alter immune responses and produce additional comorbidities. Knowledge and implementation of effective nutritional therapies are important to improve medical outcomes and quality of life. The problem of malnutrition in patients with the acquired immunodeficiency syndrome (AIDS) is multifactorial, and proper nutritional support will replenish body cell mass in these patients, which is associated with functional improvement. With appropriate combinations of ART, nutritional and other supportive care, many HIV-infected individuals are now able to lead relatively normal lives.

HIV and Gastrointestinal Tract: Nutrient Absorption

Gastrointestinal malabsorption can lead to malnutrition and a dysfunctional gastrointestinal tract can produce clinical symptoms that contribute to both morbidity and mortality in those with HIV-1 infection. The etiology of gastrointestinal malabsorption is multifactorial and includes gastrointestinal mucosal abnormalities, which in turn can lead to macro- and micronutrient malabsorption. These mucosal changes can be due to local HIV infection of the gut or secondary enteric infections. Villous atrophy and gastrointestinal tract dysfunction are coincident with high levels of HIV-1 viral load in the gut. There is evidence that certain gastrointestinal epithelial cells bind and selectively transfer HIV from the cells' apical to basolateral surface, where viral translocation across the epithelium encounters lamina propria macrophages and T cells.

The gastrointestinal tract has substantial CD4 T-cell depletion in all stages of HIV disease that is discordant with systemic CD4 T-cell repletion with effective ART. This immune derangement may contribute to altered epithelial permeability thereby permitting translocation of microbes and generalized immune activation leading to localized cytokine production and further replication of HIV. High systemic levels of lipopolysaccharides (LPS) as a result of bacterial translocation are associated with marked systemic immune activation that increases metabolic rate and sustains HIV infection. ART decreases the levels of LPS and promotes CD4 T-cell reconstitution and may subsequently decrease the systemic immune activation, although not completely.

As a result of either local HIV infection with associated bacterial translocation (which induces proinflammatory changes in the gastrointestinal mucosa and systemically) or the injury caused by a secondary infection (this is most typical when CD4 T cells drop below 200 cells per mm^3), mucosal function can be compromised resulting in gastrointestinal malabsorption, diarrhea, and malnutrition that may eventually contribute to excess morbidity and mortality, especially in developing nations.

Body Composition and Energy Expenditure

The interest in body composition of HIV-infected individuals grew as early as the onset of the HIV epidemic. The importance stems from the physiological and metabolic changes that have been attributed to HIV. HIV was initially described as a wasting disease, and since 1987, the wasting syndrome is considered a case definition of AIDS. The Centers for Disease Control and Prevention defines AIDS wasting syndrome as an involuntary weight loss of greater than 10% baseline body weight during the previous 12 months or a 5% loss of weight during the previous 6 months. However, establishing a single definition of wasting has been difficult for individuals of all ages. Even in the era of cART, wasting continues to be prevalent. Some have used the term cachexia as a more relevant description of body composition changes in HIV. Wasting is associated with weight loss while cachexia is related to loss of lean body mass. Some studies found the prevalence of wasting in patients who are cART-naive to be 48.4%.

The use of cART has become a standard practice in developed and, now with increasing frequency, developing nations and is the first line of care for many with HIV infection.

However, cART has been linked to body composition changes. Lipodystrophy, the redistribution of body fat characterized by the combination of lipoatrophy (loss of fat tissue) in the extremities and lipohypertrophy (excess accumulation of fat, usually in the trunk, dorsocervical region, and breasts), is associated with cART and in many situations specifically with protease inhibitor (PI) use. Fat can also accumulate in the abdominal viscera (usually the liver and mesentery) and heart. The prevalence of lipodystrophy is reported to occur in sometimes over 50% of cohorts with over 5 years of ARV exposure. However, with the advent of newer classes of antiretrovirals, fat redistribution for many individuals with HIV is less prevalent.

Mortality, accelerated disease progression, and impairment of functional status have all been associated with wasting. In one study, every 1% weight loss resulted in an 11% increase in the risk of death. Additionally, when weight loss exceeded 10% from baseline, there was a sixfold increase in relative risk for mortality. This highlights the importance of preventative measures needed to obviate the potential effects of wasting in HIV. Recent studies have assessed the effects of nutritional supplementation, physical activity (specifically resistance training), and the use of pharmacological methods on wasting and weight loss.

Chronic viral infections can influence energy utilization and potentially alter nutritional status. These infections can increase or shunt the effective use of energy substrates from normal, healthy anabolic patterns to energy pathways associated with inflammatory processes. The chronic viral activity of HIV is likely no different. Small studies of energy expenditure have shown few differences in resting energy expenditure (REE) or total energy expenditure (TEE) between HIV-infected children with growth failure and those with normal rates of growth. However, adults with HIV-1 infection show REE increases with severity of illness, especially with secondary infection and more advanced HIV disease, yet TEE is similar, suggesting a compensatory response with reduced physical activity. As HIV-infected individuals are treated with cART, previously noted increases in protein catabolism decrease to more normal rates, suggesting that chronic viral activity leads to increased protein catabolism and can be brought to more normal levels with successful viral suppression.

Macronutrients

Although the WHO has played a prominent role in efforts to fully integrate food and nutrition in all aspects of prevention, care, and treatment of HIV and AIDS, nutrition-specific recommendations for this patient group are limited. Knowledge about the nutritional needs of people infected with HIV over and above those required by uninfected people remains limited. This section discusses existing macronutrients recommendations for people living with HIV.

Patient groups vary in terms of their response to the virus, stage of the disease, susceptibility and exposure to opportunistic infections, nutritional status, and individual response to the various treatments received. Although compelling evidence exists for the direct association between BMI < 18 kg m^{-2} and accelerated disease progression, limited data exist regarding the role of macro- and micronutrients in disease progression.

Existing energy and macronutrient recommendations for this population based on HIV disease progression are summarized in Table 1. In addition to nutrient-specific recommendations, the nutritional interventions for the amelioration of growth and weight gain and for the prevention or management of metabolic complications of HIV disease for all age groups are discussed in the subsequent sections.

The energy and protein needs of HIV-infected individuals depend on their age, nutritional status, degree of gastrointestinal dysfunction, and the long-term effects of HIV disease such as acute/chronic infection or other complications. Some nutrient-specific recommendations for people living with HIV have been established for all age groups and pregnant and lactating women.

Current knowledge with regard to energy supports the existing WHO recommendations (i.e., calories increased by 10% for asymptomatic children, adolescents, and adults). The additional energy helps children to maintain normal growth, development, activity, and bodily functions. In terms of specific recommendations for HIV-infected adolescents, overall dietary goals are consistent with those in uninfected adolescents and include meeting the needs of normal growth. Most adults maintain body weight through a reduction in physical activity and/or an increase in caloric intake, so energy intake above the 110% of that recommended for uninfected population has not been advised. In those with chronic malnutrition, caloric needs will be greater, depending on the degree of malnutrition and other factors such as demands for physical activity.

In resource-rich settings, asymptomatic HIV infection is unlikely to significantly affect the energy requirements of pregnancy and lactation. Recommendations with regard to energy intake for pregnant women should be population-based because of differences in body size. To achieve optimal pregnancy outcomes, energy needs for women with healthy baseline body weight are no higher than the Estimated Energy Requirement for nonpregnant women until the second trimester; thereafter, the extra energy need per day is 340 and 452 kcal in the second and third trimesters, respectively. The 10% increase in REE currently recommended (above those of nonpregnant adult females) is likely reasonable for asymptomatic HIV-positive pregnant and lactating women. For pregnant and lactating women in resource-limited settings, some recommendations have been established, and they vary according to condition (pregnant and breastfeeding), HIV stage (stratified by CD4 T-cell count), age (14–20, >20–30, and >30–50 years), weight or BMI, food security score, micronutrient status including hematologic status (presence of anemia), and treatment status (ART or other drugs).

For all age groups, macronutrient (protein, carbohydrate, and fat) should be consumed at recommended amounts, with additional adjustments made that are consistent with the energy needs (i.e., if calories are increased by 10%, the macronutrient content should be increased proportionately). Although some studies in adults have suggested that protein requirements may be higher with HIV infection, as yet there is no consistent evidence that increasing protein intake above the required amounts for uninfected populations is beneficial.

During periods of acute/chronic infection, during weight loss, or when metabolic complications become more evident consequent to prolonged ART exposure, energy and nutrient

Table 1 Energy and macronutrients needs in HIV infection

Nutrient	*HIV infection factors* *Clinical situations*	*Nutrition recommendations*
Energy	When secondary infections are absent and growth is adequate in children and weight is stable in adults	*Children, adolescents, and adults*: target energy intake of 110% of that recommended for uninfected population (based on actual weight rather than on expected weight for age) (WHO 2009) *Pregnant and lactating women*: the 10% increase in REE currently recommended is likely reasonable for asymptomatic HIV-positive pregnant and lactating women. Energy requirements may be higher for pregnant adolescents (Raiten et al., 2011) Standard methods of assessing energy needs – calorie levels based on the Estimated Energy Requirements (EERs) and activity levels from the Institute of Medicine Dietary Reference Intakes (DRIs) (Macronutrients Report, 2002)
	During illness, decreased appetite, poor growth, weight loss	*Children*: energy requirements can increase by up to 20–30% during infections and recovery (WHO, 2009). Equations for estimating catchup growth requirements for both calories and protein can be used *Adults*: increase energy intake by 600–960 kcal day^{-1} in adults with weight loss may increase body weight (Grobler et al., 2013), which is better achieved by providing a balanced nutritional supplement *Pregnancy and lactation*: the energy needs may be even greater than 10% above those of nonpregnant adult females for women with inadequate rate of weight gain during pregnancy, excessive weight loss postpartum, or other ongoing health issues (Raiten et al., 2011)
	Advanced disease	Up to 50–100% additional energy to recover and regain weight (WHO 2003) For critically ill patients: energy requirements may be calculated by predictive equations or measured by indirect calorimetry (Singer, 2009), with special attention to the prevention of complications related to under- or overfeeding (Fraipont and Preiser, 2013) This is best achieved through enteral or parenteral (if enteral has failed) feeding
	Overweight or obesity	*Weight management*: Counseling on changing eating habits and patterns Regular exercise: physical activity counseling or physical activity program participation
Protein	During periods of well-being	As in asymptomatic children, protein should contribute about 10–15% of the energy intake and there is no need for additional protein other than what is present in a balanced diet (WHO, 2009) Acceptable Macronutrient Distribution Ranges (AMDRs) can be used to ensure sufficient intakes of essential nutrients (Food and Nutrition Board, 2005)
	Period of catchup growth	Use equation for estimating catchup growth requirements
Fat	During periods of well-being	Provide anticipatory guidance regarding the importance of a low-fat, low-saturated-fat, low-cholesterol diet for all otherwise healthy HIV-infected patients older than 2 years and their families due to increased risk of CVD in HIV-infected populations AMDR: Food and Nutrition Board (2005) 1–3 years: 30–40% of total calories 4–18 years: 25–35% of total calories *Pregnancy and lactation*: essential fatty acid needs are 30% higher than those of nonpregnant women, and adequate fatty acid intake should be ensured in a manner consistent with recommendations for uninfected women (Raiten et al., 2011)
	Fat malabsorption (due to HIV GI enteropathy or secondary infections)	In these cases, dietary modification of fat may be required Supplemental MCT and enteral formulas containing MCT can be used to supplement caloric intake
	Dyslipidemia	Dietary intervention with NCEP Therapeutic Lifestyle Changes (NCEP 2002) and exercise have been shown to reduce triglycerides in both HIV-infected (Stradling et al., 2012) and HIV-uninfected (Kelley et al., 2011) populations and to reduce LDL cholesterol in the general population (Yu-Poth et al., 1999) Counseling on changing eating habits and patterns per AHA/AAP
Carbohydrate	During periods of well-being	AMDR: Food and Nutrition Board (2005), 45–65% of total calories Added sugars should comprise no more than 10% of total calories consumed
Fiber		A reasonable intake is 0.5 g kg^{-1} day^{-1} to a maximum of 35 g daily

BMR, basal metabolic rate; EER, Estimated Energy Requirement; FTT, failure to thrive; DRI, dietary reference intake.
Acceptable Macronutrient Distribution Range (AMDR) is the range of intake for a particular energy source that is associated with reduced risk of chronic disease while providing intakes of essential nutrients.

needs are greater than that recommended for uninfected population. As for uninfected individuals, the estimation of energy requirements for critically ill patients may be calculated by predictive equations or measured by indirect calorimetry, with special attention to the increased risk of overfeeding during the early phase of acute illness and the increased risk of underfeeding during the late phase. Once the secondary infections are successfully treated and energy intake is increased sufficiently, patients are able to regain weight and remain weight-stable.

Micronutrients

In addition to macronutrient intake, careful attention to micronutrient status (vitamins and minerals) is a critical component in the nutritional treatment and care of people living with HIV infection. The WHO has long taken the lead in the establishment and dissemination of specific requirements for micronutrient consumption among people living with HIV throughout all stages of the life cycle. The importance of the role specific micronutrients serve in the maintenance of immune system function and in the reduction of morbidity and mortality from disease- and treatment-related symptoms has been well established. However, a general consensus of the long-term effects, optimal composition, and dosing of both single and multiple micronutrient (MMN) supplements has yet to be reached. This section provides an overview of current micronutrient guidelines for people living with HIV. Table 2 provides a summary of micronutrient guidelines for HIV-infected populations throughout the life cycle.

Table 2 Micronutrient recommendations in HIV infection

Population	*Current micronutrient recommendations*	*Comments*
Children and adolescents	*Maintain current WHO recommendations*: ● Ensure one Recommended Dietary Allowance (RDA) for all essential nutrients, preferably through a well-balanced diet ● When dietary intakes are insufficient, the use of micronutrient supplements at RDA levels is supported *Vitamin D intake*: ● Children on antiretroviral treatment (ART) should be given two to three times more vitamin D than the RDA for their age group	– Currently, there exists insufficient evidence to support a general policy encouraging the use of daily oral nutrient supplements – Careful attention to dietary quality and adequacy of micronutrients is critical; important factors to consider include high food insecurity or poor dietary diversity – Additional attention may be justified for specific nutrients (e.g., vitamin A, vitamin D, calcium, and iron) either in terms of dietary intake and poor exposure or in the context of potential treatment interactions
Adults	● Insufficient evidence to support a change from 2003 recommendations of one RDA for essential micronutrients, preferably from dietary intake ● Adults on ART should be given two to three times more vitamin D than the RDA for their age group	– Given the vast diversity of variables and study design throughout various studies investigating micronutrient supplementation in this population, it is not possible to recommend anything other than the current RDA or a routine multivitamin. However, there still remain safety concerns for potential harm from higher doses of selected micronutrients (e.g., vitamin A and multiple micronutrient (MMN) supplements, which may promote increased viral replication and increased shedding of virus in genital secretions, thus potentially increasing risk of transmission of HIV). Further research into optimal composition and dosing is warranted
Pregnant and lactating women	● Supplementation of one RDA amount of micronutrients for all HIV-positive pregnant and lactating women is recommended due to the high likelihood of food insecurity, the fact that micronutrient needs are higher during pregnancy and lactation and that deficiencies appear to be more common in HIV-infected women ● Supplements should contain the 14 core micronutrients provided in the UNICEF UNIMMAP (UN international multiple micronutrient preparation) supplement. These micronutrients include vitamins A, D, and E; thiamine; riboflavin; niacin; folic acid; vitamins B_6, B_{12}, and C; and minerals including zinc, iron, copper, selenium, and iodine ● In areas of endemic vitamin A deficiency, WHO recommends that a single high dose of vitamin A (200 000 IU) be given to women as soon as possible after delivery, but no later than 6 weeks after delivery ● Pregnant and lactating women require at least 600 IU day^{-1} of vitamin D; at least 1500–2000 IU day^{-1} of vitamin D may be needed to prevent/treat deficiency	– Supplementation at amounts above the RDA is not advised at this time as some studies have shown that they may in fact be harmful (e.g., vitamin A, vitamin D (25), and iron) – Iron supplementation is recommended at the RDA amount for HIV-positive pregnant women – Iron supplementation is not recommended in lactating HIV-positive women unless the presence of iron deficiency is clinically confirmed

Micronutrient deficiencies are often observed in conjunction with a wide range of impaired immune responses and clinical manifestations including increased susceptibility to infection, inadequate intake, malabsorption, diarrhea, and subsequently increased morbidity and mortality among various groups of people living with HIV. Although malnutrition likely plays a role in disease outcomes, current data regarding the role of micronutrients in disease progression remain limited. In conjunction with cART, inexpensive micronutrient supplements could provide several cellular and clinical benefits, ranging from the prevention of mitochondrial toxicity and oxidative stress to facilitation of immune reconstitution. Per the established WHO guidelines, HIV-infected children and adults should consume diets that provide micronutrient intakes at the Recommended Dietary Allowance (RDA). These recommendations state that in cases where dietary intakes are insufficient, the use of micronutrient supplements at the RDA in HIV-infected individuals of all ages is supported.

Low levels of vitamins, minerals, and other micronutrients are often observed among HIV-infected children. This may frequently be the result of inadequate nutritional intake from their diet or their bodies may demand increased micronutrient levels for the purpose of fighting the HIV infection itself or opportunistic infections. Vitamin A supplements, as in children without HIV infection, reduce diarrheal morbidity and mortality especially in young children. As stated in the 2003 WHO guidelines, HIV-infected 6–59-month-old children living in resource-limited settings should be given periodic (every 4–6 months) vitamin A supplements (100 000 IU for infants 6–12 months and 200 000 IU for children >12 months) in order to reduce all-cause mortality and diarrhea morbidity. This level is consistent with WHO recommendations for the prevention of vitamin A deficiency in children. Furthermore, studies have shown that vitamin A supplements are beneficial and safe and can half mortality overall in an analysis of three trials in different African countries.

Micronutrient supplements in adults are also shown to reduce the metabolic and cellular complications of cART. A greater intake of vitamin E and vitamin A in those on cART was associated with fewer metabolic complications, dyslipidemia, and insulin resistance. In addition, a daily supplement of vitamins C and E for 3 months reduced oxidative stress baseline CD4 counts <100 cell per μl.

Zinc is another important nutritional factor for HIV-infected individuals. Zinc supplements have been shown to help HIV-infected children recover from diarrheal illnesses, are safe, and appear to have similar benefits on diarrheal morbidity in children with HIV as in children without HIV infection. Long-term (18-month) zinc supplementation potentially reduces the likelihood of opportunistic infection in adults and children and improves CD4 counts in adults.

There has been considerable growth in clinical interest and research with respect to vitamin D deficiency and its effects on the progression of HIV infection. With mounting evidence that vitamin D deficiency can exacerbate immune dysfunction, contribute to skeletal fractures, and increase cardiovascular disease (CVD) and metabolic risk, there has been a great focus on how this nutrient contributes to disease progression in HIV. A number of clinical studies among populations in both developed and developing nations have associated vitamin D deficiency with a variety of poor health outcomes such as atherosclerotic CVD, increased viral load, and immune suppression. Up to a third of perinatally HIV-infected children can be vitamin D-deficient. As a result of the current data, the National Endocrine Society recognizes that ART increases the catabolism of 25-hydroxy vitamin D and 1,25-dihydroxy vitamin D levels, therefore recommending that children on ART be given two to three times more vitamin D for their age group.

As recommended for children and adolescents, HIV-infected adults should also consume well-balanced diets in order to reach micronutrient intakes of one RDA for essential micronutrients. In the event that RDA amounts of micronutrient intakes cannot be reached through dietary sources, evidence from current studies on this topic taken collectively indicates that there is a role for multivitamin supplements at the level of the RDA in most HIV populations, adults included. Furthermore, for adults on ART, it is recommended they be given two to three times more vitamin D than the RDA for their age group to treat deficiency and potentially mitigate the effects of ART on calcium balance and bone metabolism.

A well-balanced diet certainly remains the gold standard for micronutrient intake for all HIV-infected populations. However, the high prevalence of food insecurity, the increased metabolic and micronutrient demands of pregnancy and lactation, and the observation that deficiencies appear to be more common in HIV-infected women necessitate micronutrient supplementation at one RDA for all HIV-positive pregnant and lactating women. In general, supplements should provide the 14 core micronutrients that comprise the UNICEF UNIMMAP (UN international multiple micronutrient preparation) supplement: vitamin A, vitamin D, vitamin E, thiamine, riboflavin, niacin, folic acid, vitamin B_6, vitamin B_{12}, vitamin C, zinc, iron, copper, selenium, and iodine.

Since nutrient deficits are often observed during pregnancy and lactation and specifically among HIV-infected pregnant women, current guidelines continue to address specific instances of common vitamin and mineral deficiency states. In the case of anemia prevention, the WHO recommends daily iron–folate supplementation (400 μg of folate and 60 mg of iron) during 6 months of pregnancy and, in the case of clinically confirmed severe anemia, twice-daily supplements. Hence, these levels of iron and folate are incorporated into the UNICEF UNIMMAP supplement. In accordance with the 2003 WHO guidelines, vitamin A intake by HIV-infected women during pregnancy and lactation should not exceed the RDA levels as it may be harmful in some cases; in areas of endemic vitamin A deficiency, a single high dose of vitamin A should be given to women as soon as possible after delivery, but no later than 6 weeks after delivery. As for vitamin D, the National Endocrine Society suggests that pregnant and lactating women require at least 600 IU day^{-1} of vitamin D; at least 1500–2000 IU day^{-1} of vitamin D may be needed to prevent/treat deficiency. When taken collectively, available evidence suggests that the approach to caring for HIV-infected women is the same as that for uninfected women with special attention to HIV-specific factors such as viral load, CD4 T-cell count, and ART status.

Although there have been some advances in the study of MMN and positive clinical outcomes in HIV, the impact of specific micronutrient supplements as determined through

randomized, controlled trials remains few and less clear. Additional research is warranted to determine the long-term clinical advantages, potential adverse effects, and optimal composition of micronutrient supplementation among more diverse groups of HIV-positive research participants.

Cardiometabolic Complications

Obesity and Cardiometabolic Disease

Obesity is an emerging health problem among adolescents and adults living with HIV/AIDS. With the institution of cART, the immune and disease status of HIV-infected individuals has improved and eating patterns (healthy or not) often parallel those in healthy uninfected individuals. Poverty and food insecurity are among other factors that can contribute to childhood obesity that influence both HIV-infected and HIV-uninfected populations equally. Immigrant families are particularly vulnerable. As the prevalence of obesity increases among patients with HIV, the cumulative risk for CVD also increases.

Fat Redistribution

Coincident with the introduction of cART, a clinical syndrome of body fat redistribution and metabolic changes was first described initially in adults, but is now commonly reported among children. HIV-infected patients receiving cART regimens have developed a syndrome of peripheral insulin resistance, hyperlipidemia, and lipodystrophy (truncal obesity, dorsocervical fat pad, and extremity and facial wasting). Clinical and biochemical abnormalities associated with the fat redistribution syndrome or commonly termed, lipodystrophy syndrome, are shown in Table 3. Risk factors associated with developing the fat redistribution syndrome in adults include female gender, increasing age, family history of premature CVD, higher pretherapy body weight, and behavioral patterns such as tobacco and alcohol use. Complications associated with the fat redistribution syndrome include higher rates of diabetes mellitus and premature CVD. Lipodystrophy is almost exclusive to patients receiving ART and can improve after PI and NRTI switching. Medical compliance with drug therapy may be poorer owing to the cosmetic side effects of therapy.

Table 3 Clinical and biochemical abnormalities of the fat redistribution syndrome

Clinical features	*Laboratory features*
Increased abdominal (visceral) fat	Hyperlipidemia
Increased waist-to-hip ratio (more reliable in adults)	Increased triglycerides Increased total cholesterol
Buffalo hump	Increased LDL-C
Fat atrophy	Decreased HDL-C
Wasting of extremities	Insulin resistance
Wasting of buttocks	Normal to increased serum glucose
Loss or thinning of facial fat, prominence of nasolabial fold	Increased insulin Increased C-peptide
No change to increased weight	
Fatigue and weakness	

Lipodystrophy is described in children, as well. Early studies showed a beneficial nutritional effect of cART in both adults and children. Early initiation of cART is associated with more rapid restoration of growth in children of developing nations. Growth hormone levels are significantly lower in lipodystrophic HIV-infected adults with visceral adiposity. In addition to the positive improvement in growth and lean body mass, however, cART is also associated with abnormalities in fat distribution though some studies report similar lean mass in HIV-infected and HIV-uninfected individuals. Both peripheral lipoatrophy and central obesity occur in both HIV-infected adults and children. Fat redistribution can develop fairly rapidly after initiating a cART regimen and changes can progress over time. Metabolic abnormalities are associated with specific classes of drugs with many NRTIs and PIs implicated. Newer agents often have less impact on fat redistribution and are the preferred therapy if the virus is sensitive to the therapy.

Cardiometabolic Risk

Atherosclerotic CVD is a leading comorbidity and cause of mortality among HIV-infected adults. Several studies show that HIV-infected children, compared to healthy peers, have higher rates of CVD risk factors, including dyslipidemia, insulin resistance, obesity, and central adiposity. HIV infection also results in prolonged chronic inflammation, thereby increasing CVD risk. In adults with cART-related fat redistribution, several studies have suggested an increase in the risk of myocardial infarction relating to the level of viral control (increased inflammation) or to ARV exposures (including PIs and certain NRTIs). Exogenous obesity, common among all individuals with HIV, can also contribute to CVD risk. Children, compared to adults with HIV, may be at even greater risk of developing premature CVD as the lifetime exposures to factors associated with CVD risk are longer in children.

Dyslipidemia

Prior to the introduction of any ART, elevated triglycerides and LDL cholesterol and lower HDL cholesterol were reported and associated with HIV infection. This profile persists in the current era and suggests that chronic immune activation can influence lipid metabolism. Proinflammatory cytokines (as a response to the chronic viral infection) may affect lipid pathways. After PI therapy became widespread, several investigators in the United States and abroad reported a 20–50% rise in lipid levels of HIV-infected individuals. In hepatocyte cell lines, PIs have been shown to interfere with cholesterol synthesis by the inhibition of the proteasome, a potent regulator of apolipoprotein B production, among other mechanisms. Other factors associated with dyslipidemia include successful viral suppression, better CD4 T-cell counts, and demographic factors. The impact of PIs on lipid levels, independent of HIV, is effectively described in HIV-seronegative volunteers who developed dyslipidemia following PI treatment.

Insulin resistance and type 2 diabetes mellitus

Abnormal glucose homeostasis was documented in HIV-infected adults with lipodystrophy well before it was reported in children. The etiology of insulin resistance is multifactorial and has been linked with PI, NRTI, or nonnucleoside reverse

transcriptase inhibitor (NNRTI) use both singly and in combination, although exact mechanisms have not been well defined. HIV-uninfected adults treated with indinavir (a PI) showed a rapid onset of insulin resistance but not hyperlipidemia or body shape changes. Leptin, a hormone secreted by adipocytes, is low in congenital and HIV lipoatrophies. These patients also tend to have increased intramyocellular lipid in direct correlation to their degree of insulin resistance. A possible mechanism by which cART causes insulin resistance is by direct inhibition of the transport function of glucose transporter type 4 (GLUT4), which is responsible for insulin-stimulated glucose uptake into the muscle and fat. Other potential causes of insulin resistance include NRTI or NNRTI therapy associated with mitochondrial DNA (mtDNA) mutations or depletions. Although there are limited data in adults, there are striking similarities between rare mitochondrial disorders, such as multiple symmetric lipomatosis (MSL), a condition that is phenotypically very similar to cART-associated lipodystrophy. These mtDNA mutations in MSL lead to an impaired function of cytochrome c oxidase and a subsequent decrease in fat turnover. Inflammatory cytokines have been linked to both insulin resistance and diminished adiponectin, which affects insulin signaling and glucose homeostasis. The adipose tissue is a major determinant of insulin sensitivity and changes associated with lipodystrophy can alter the secretion of adiponectin. In one study, patients with PI-induced lipodystrophy had increased levels of circulating inflammatory cytokines.

Vascular inflammation and atherosclerosis

Vascular endothelial dysfunction, a process that is associated with atherosclerosis, may occur as a result of chronic inflammation and injury in the endothelium. Oxidative stress due to cART and direct cytopathic effect of the virus are likely causative agents in HIV. In addition, dyslipidemia, insulin resistance, and chronic inflammation due to ongoing immune activation in HIV-infected individuals also contribute to endothelial damage. The levels of proinflammatory cytokines are higher in HIV-infected individuals compared to contemporary controls. These vascular inflammatory biomarkers are positively correlated with clinical markers including higher viral load, lipids, and waist circumference. Furthermore, Wolf found that not only were levels of vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1), and von Willebrand factor higher in untreated patients with HIV infection, but also they decreased significantly after treatment with a regimen containing either one PI or one NNRTI.

Preatherosclerotic lesions can be defined by imaging studies of the arterial structures. Common ways of evaluating CVD risk are through measurements of the carotid intima, brachial artery reactivity, or pulse wave velocity. Both adults and children with HIV have evidence of increased CVD risk when their measures are compared with controls.

Nutritional Interventions

People living with HIV are faced with many obstacles that challenge their ability to sustain proper nutritional status. Decreased energy intake, increased energy expenditure, and accelerated protein turnover are common in people with HIV. Promoting and supporting adequate nutrition and food security are critical for this population. Presently, there are a number of different strategies to improve nutritional outcomes for people living with HIV. Regardless, nutritional interventions in HIV should be designed under the premise that (1) ARVs are essential to prolong life and to halt the spread of HIV and (2) food and sound nutrition are essential to human health. Table 4 shows the gastrointestinal and nutritional side effects of current ARVs.

Overall dietary goals for HIV-infected individuals are consistent with those for non-HIV-infected and include meeting the needs of normal growth of children and adolescents, meeting the needs of adequate weight gain of pregnant women, consumption of a high-quality, nutrient-dense diet, building good eating habits, avoiding obesity through limiting intake of energy-dense but nutritionally poor foods, engaging in physical activity, and avoiding cigarettes, alcohol, and drugs. The diet plan should be individualized based on the patient's nutritional status, age, symptoms, and ability to meet nutrient requirements. Regular nutritional assessments are necessary in order to determine the appropriateness and effectiveness of the interventions. This assessment should include a review of the medical and dietary history, nutrient analysis of usual intake, anthropometric measurements, body composition, and measurement of biochemical values. In order to guarantee optimal nutrition care, the team should be multidisciplinary and be composed of a physician, nurse specialist, social worker, and dietician.

Consumption of a well-balanced diet remains the optimal choice for achieving adequate nutritional status for all HIV-infected individuals regardless of age for overall health and wellness, as well as growth and development in pediatric and pregnant populations. However, the increased metabolic demands of HIV infection and symptomatic HIV often present significant challenges for achieving or maintaining healthy body weight and immune system function. In circumstances where malnutrition and food insecurity are present, supplemental food sources and/or enteral nutrition supplements may be necessary to achieve positive health outcomes and are often effective when given in the appropriate amounts. Some data suggest that body weight and lean body mass tend to increase with nutritional support. Food-based interventions can treat malnourished HIV-infected patients and are necessary in order to address both the individual needs of the patients and the food security of their households. Ready-to-use therapeutic foods effectively treat malnutrition of HIV-infected individuals in developing nations.

Incentives provided through food supplements can be a helpful method to improve clinical adherence. There is limited evidence regarding the use of balanced nutritional supplements (consisting of 50–60% carbohydrate, 15–30% protein, and 20–30% fat) for improving energy intake and protein among HIV-infected adults with weight loss, but no effects on anthropometric or immunologic parameters. It is likely that decreased energy intake, not changes in energy expenditure, plays a major role in the weight loss experienced by those with HIV and secondary infection. Therefore, with appropriate treatment and nutritional resources, most patients with HIV-related weight loss will gradually increase ad libitum caloric intake and gain weight.

Table 4 HIV-related medications and common gastrointestinal and metabolic side effects

Medication	*Action*	*Side effects*
Abacavir	NRTI	Nausea, vomiting, diarrhea, abdominal pain, pancreatitis, abnormal liver function
Aciclovir	Antiviral	Nausea, abdominal pain, diarrhea, abnormal liver function
Atazanavir	PI	Nausea, diarrhea, abdominal pain, hyperbilirubinemia
Atripla (tenofovir, emtricitabine, and efavirenz)	Combination	Nausea, vomiting, diarrhea, abdominal pain, hepatitis, bone loss, pancreatitis, lactic acidosis
Azithromycin	Antibacterial	Nausea, vomiting, melena, jaundice
Ciprofloxacin	Antibacterial	Ileus, jaundice, bleeding, diarrhea, anorexia, oral ulcers, hepatitis, pancreatitis, vomiting, abdominal pain
Clarithromycin	Antibacterial	Nausea, diarrhea, abdominal pain, abnormal taste
Combivir (zidovudine–lamivudine)	Combination	Nausea, vomiting, abdominal pain, abnormal liver function, pancreatitis, lactic acidosis
Complera (rilpivirine, tenofovir, emtricitabine)	Combination	Nausea, vomiting, abnormal liver function, lactic acidosis
Darunavir	PI	Nausea, vomiting, diarrhea, abdominal pain, pancreatitis, hepatitis, constipation
Didanosine (ddI)	NRTI	Nausea, vomiting, abdominal pain, pancreatitis, abnormal liver function
Edurant	NNRTI	Abnormal liver function, lipodystrophy
Efavirenz	NNRTI	Nausea, vomiting, abnormal liver function, hyperlipidemia
Emtricitabine	NRTI	Lactic acidosis, hepatomegaly, diarrhea, nausea
Epzicom (zidovudine, abacavir)	Combination	Nausea, vomiting, abdominal pain, abnormal liver function, lactic acidosis, pancreatitis
Erythromycin	Antibacterial	Nausea, vomiting, abdominal pain
Etravirine	NNRTI	Nausea, vomiting, diarrhea, abdominal pain, hepatitis
Fosamprenavir	PI	Nausea, diarrhea, vomiting, abdominal pain
Enfuvirtide	FI	Nausea, diarrhea, abdominal pain, hepatitis, pancreatitis, dry mouth, anorexia
Ganciclovir	Antiviral	Nausea, vomiting, diarrhea, anorexia, abnormal liver function
Indinavir	PI	Nausea, vomiting, abdominal pain, diarrhea, changes in taste, jaundice, abnormal liver function
Ketoconazole	Antifungal	Hepatotoxicity
Lamivudine	NRTI	Nausea, diarrhea, decreased appetite, vomiting, abdominal pain, pancreatitis, abnormal liver function
Lopinavir/ritonavir	PI	Diarrhea, nausea, vomiting, abdominal pain, lipodystrophy, hyperlipidemia
Maraviroc	EI	Nausea, constipation, diarrhea, flatulence, abdominal pain, hepatitis, dysgeusia, stomatitis
Nelfinavir	PI	Nausea, diarrhea, fatigue, abnormal liver function, exacerbation of chronic liver disease
Nevirapine	NNRTI	Stomatitis, nausea, abdominal pain, raised gamma-glutamyl transpeptidase level, hepatotoxicity
Pentamidine	Antiparasitic	Abdominal pain, bleeding, hepatitis, pancreatitis, nausea, vomiting
Raltegravir	II	Gastritis, hepatitis, nausea, vomiting, abdominal pain, diarrhea, hyperbilirubinemia
Rifampin	Antibacterial	Abdominal pain, nausea, vomiting, diarrhea, jaundice
Rilpivirine	NNRTI	Lipodystrophy
Ritonavir	PI	Nausea, vomiting, diarrhea, abdominal pain, anorexia, pancreatitis, abnormal liver function
Saquinavir	PI	Mouth ulcers, nausea, abdominal pain, diarrhea, pancreatitis, abnormal liver function, exacerbation of chronic liver disease
Stavudine	NRTI	Nausea, vomiting, abdominal pain, diarrhea, pancreatitis, abnormal liver function, hepatic failure, lipodystrophy, hyperlipidemia, insulin resistance
Stribild (elvitegravir, cobicistat, emtricitabine, tenofovir)	Combination	Lactic acidosis, severe hepatomegaly with steatosis, and posttreatment acute exacerbation of hepatitis B
Sulfonamides	Antibacterial	Hepatitis, pancreatitis, stomatitis, nausea, vomiting, abdominal pain
Tenofovir	NRTI	Nausea, vomiting, diarrhea, abdominal pain, hepatitis, bone loss, pancreatitis, flatulence
Tipranavir	PI	Hyperlipidemia, nausea, vomiting, diarrhea, abdominal pain, pancreatitis, hepatitis
Tivicay	II	Gastritis, hepatitis, nausea, vomiting, abdominal pain, diarrhea, hyperbilirubinemia
Trizivir (abacavir–lamivudine–zidovudine)	Combination	Nausea, vomiting, abdominal pain, pancreatitis, abnormal liver function
Triumeq (abacavir, dolutegravir, lamivudine)	Combination	Lactic acidosis, abnormal liver function
Truvada (emtricitabine, tenofovir)	Combination	Lactic acidosis, nausea, vomiting, diarrhea, abdominal pain, hepatitis, bone loss, pancreatitis
Tybost	PE	Nausea, jaundice
Vitekta	II	Diarrhea
Zidovudine (ZDV)	NRTI	Nausea, vomiting, abdominal pain, abnormal liver function

HBV, hepatitis B virus; FI, fusion inhibitor; II, integrase inhibitor; EE, entry inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, nonnucleoside reverse transcriptase inhibitor; PI, protease inhibitor; PE, pharmacokinetic enhancer of PIs.

Since the advent of cART, much of the wasting seen since the pre-cART era has been diminished in developed countries. HIV-infected patients are now faced with metabolic consequences of their ART regimen. Obesity, dyslipidemia, lipodystrophy, insulin resistance, and central adiposity are common cART-related complications due to increases in fat rather than lean mass.

HIV infection also results in prolonged chronic inflammation, thereby increasing CVD risk. Even though the mechanisms for these effects are likely multifactorial, care must be taken to avoid unwarranted weight gain and many nutritionally related components should be targeted. However, there are no specific guidelines that address lipid abnormalities or insulin resistance specific to HIV-infected patients. A recent meta-analysis has demonstrated a comparable clinical benefit of dietary intervention or omega-3 supplementation in reducing triglycerides, but no effects on other lipids in patients without concurrent lipid-lowering medication. Dietary intervention with the National Cholesterol Education Program (NCEP) Therapeutic Lifestyle Changes and exercise have been shown to reduce triglycerides in both HIV-infected and HIV-uninfected populations and to reduce LDL cholesterol in the general population. Treatment of these complications should, therefore, follow nutrition and lifestyle interventions guidelines recommended for the general population. Higher-intensity dietary interventions may also be required in the HIV population for LDL cholesterol reduction. Mediterranean-style diet plans, which promote the importance of healthy fats generally found in nuts, seeds, and olive and canola oils, have recently been shown to be effective in improving the lipid profiles and CVD risk factors in HIV-infected and HIV-uninfected adults. These diet plans are similar to other heart healthy eating regimens, emphasizing the consumption of fruits, vegetables, and whole grains.

It is well known that HIV and its treatment impact bone mineral density, so bone health must be considered when addressing the nutritional needs of HIV-infected individuals. Baseline bone assessments are recommended (typically evaluated with dual-energy x-ray absorptiometry), with periodic follow-up. It is important to ensure adequate intake of vitamin D and calcium and to emphasize the importance of weight-bearing exercise and avoidance of alcohol and tobacco, especially during adolescence, when peak bone mass is achieved.

Addressing food security is essential in the prevention, care, and treatment of HIV and AIDS. Food insecurity has been associated with worse ART adherence in low- and middle-income settings as a consequence of negative feedback (e.g., ART leads to improved appetite, which, in the absence of food, leads to poor adherence), worse virological and immunologic outcomes, worse physical and mental health status, and increased risk of mortality. Thus, interventions to ensure provision of food with assessment of food security and appropriate referrals to food assistance programs should be well integrated with HIV care programs. Health providers should be familiar with locally available resources that can be offered to this nutritionally vulnerable population.

For HIV-infected individuals who suffer from malnutrition and food insecurity, nutritional supplements can be effective if administered in adequate amounts. HIV populations at higher risk include those with increased metabolic demands such as pregnant and lactating women and children and those with active infections. Otherwise, with appropriate treatment and nutritional resources, most patients with HIV-related weight loss will gradually increase ad libitum caloric intake and gain weight. Future intervention efforts should quantify HIV-specific requirements across all ages/sexes so that supplements can be dosed in adequate amounts or administered by meal replacements. In developing nations, where malnutrition is of great concern, research should focus on locally based and sustainable foods. Food supplements that are economically feasible and efficient have the potential to improve nutritional intake, curtail weight loss, and alleviate HIV-associated symptoms. Future research efforts should analyze the long-term effects of nutritional interventions on LDL and HDL cholesterol and triglycerides in children and adults.

In addition to nutritional interventions involving diet, per se, other strategies to improve the nutritional status of HIV-infected individuals include progressive resistance training and hormone therapy. Exercise is a valuable option to increase lean tissue mass. Several studies in children/adolescents and adults have shown an increase in lean muscle mass as well as strength and cardiorespiratory fitness. Pharmacological treatments have also shown some benefit. Growth hormone-releasing hormone can improve central adiposity, while metformin has been reported to improve glucose homeostasis.

Summary

The multidimensional nature of nutritional problems associated with HIV infection is a microcosm for most nutritional disorders that span a vast array of both acute and chronic disease states in humans. With improved therapies and survival of HIV-infected individuals, the state of nutrition will continue to evolve. Future research and treatments in this field will focus on using nutrition to augment and optimize the clinical care of those chronically infected with HIV.

Introduction

Meat is normally regarded as the edible part (muscle and offal) of livestock animals. Meat consumption practices vary based on geographic disposition, availability of animals, religious practices, and rituals and customs of the population. Conventional food of one community may not be same for the other. For example, global attitudes to the consumption of flesh derived from dog, elephant, hippopotamus, rhino, seal, whale, frog, and horse are extremely varied. Several works have demonstrated that horses from heavy breeds are well adapted to meat production. In some countries like Kazakhstan and Kyrgyzstan, horse meat (HM) is considered as an alternative to beef. HM has been historically obtained from animals that were slaughtered at the end of their working life. Horse carcasses have high dressing percentages and meat yields. HM is regarded as more digestible than that from sheep or cattle. Horse bones have also been used as a traditional medicine for treatment of bone fracture and arthritis in Korea. The consumption of HM is known as hippophagia and is very common in countries, such as Denmark, Belgium, Holland, and Germany. The top eight HM-consuming countries consume about 4.7 million horses a year. HM has been described as slightly sweet, tender, and low in fat. The slaughter weight of male and female horses is about 504.8 kg and dressing percentage is ~70%. The most important difference between male and female horses is in the degree of fatness, which is highest in females. Horses today are slaughtered at ages ranging from 16 to 24 months.

Pattern of HM Consumption

HM gained widespread acceptance in French cuisine during the later years of the Second French Empire. The high cost of living in Paris prevented many working-class citizens from buying meat such as pork or beef. In 1866, the French government legalized the eating of HM, and the first butcher's shop specializing in HM opened in eastern Paris, providing quality meat at lower prices. During the Siege of Paris (1870–71), HM was eaten by anyone who could afford it, partly because of a shortage of fresh meat in the blockaded city and also because horses were eating grain, which was needed by the human population. Many Parisians gained a taste for HM during the siege, and after the war ended, it remained popular. Likewise, in other places and times of siege or starvation, horses were viewed as a food source of last resort. Despite the general Anglophone taboo, horse and donkey meats were eaten in Britain, especially in Yorkshire, until the 1930s, and in times of postwar food shortage, HM consumption surged in popularity in the United States and was considered for use in hospitals. Horses are poor converters of meat; hence, they are not generally raised for meat production.

As indicated previously, the consumption pattern of HM is common in Europe and Central Asia. Some of the reasons for increased interest in HM consumption have arisen due to concerns pertaining to the occurrence of dioxins, bovine encephalopathy, and foot-and-mouth disease problems in conventional meat-producing farm animals. Therefore, consumers began to look for alternative red meats from other nontraditional species. The killing of horses for human consumption is widely opposed in countries such as the United States, the United Kingdom, Ireland, and Australia. In these countries, horses are generally considered to be companion and sporting animals only. HM consumption is forbidden by Romanian and Jewish cultures because horses do not have hoofs and do not chew cud (owing to the fact that horses are not ruminant animals). HM is generally not widely consumed in Spain (with the exception being that in the north of the country), although the country exports horses both 'on the hoof and on the hook' for the French and Italian markets.

HM is consumed in some North American and Latin American countries, but deemed illegal for consumption in some countries. For example, the Food Standards Code of Australia and New Zealand's definition of 'meat' does not include horse. Under Islamic law, the consumption of HM is forbidden. In north Africa, HM has been occasionally consumed, but almost exclusively by the Christian Copts and the Hanafi. Nowadays, consumption of HM is common in Iceland, wherein horses are mainly raised for this purpose. HM is generally considered by ethnic Russians to be a low-quality meat with poor taste, and it is rarely found in stores. It is popular among nomadic peoples of Eastern Russia such as Tatars and Yakuts and Central Asia such as Kyrgyzs and Kazakhs.

Production of HM

The Republic of Croatia is modest in production and consumption of HM. Geographic position, underutilization of great pasture grounds, and breeding structure of horse population in Croatia give good chances for a profitable production of HM with the possible export orientation. In Kazakhstan, HM is a large part of the diet, due mainly to the nomadic roots of the population. In Japanese cuisine, raw HM is called *sakura* or *sakuraniku*. In 2013, HM and traces of horse DNA were found in some food products where horse was not labeled as an ingredient, sparking the 2013 meat adulteration scandal across

Table 1 Major horse meat-producing countries

Country	*HM production (metric tons)*
Mexico	78 000
Argentina	57 000
Kazakhstan	55 000
Mongolia	38 000
Kyrgyzstan	25 000
Australia	24 000
Brazil	21 000
Canada	18 000
Poland	18 000
Italy	16 000
Romania	14 000
Chile	10 000
France	7500
Uruguay	8000
Senegal	9500
Colombia	6000
Spain	5000

Source: British Agriculture Industry Website (2009).

Europe. The major HM-producing countries and their production are depicted in Table 1.

Physical Characteristics of HM

HM has a soft consistency and is dark red in color. Following exposure to light, it becomes brown or black with a bluish tinge due to light-induced changes. Generally, horse fat is yellow in color and soft and greasy in consistency. Intermuscular fat is absent, and also, the large fatty adipose tissue is absent. Low level of adiposity appears in subcutaneous fat. Fat depots of flank and kidney are relatively lean. Horse is a lean and muscular animal as the whole body contains on average 69.6% muscle, 10.4% saturated fat, and 17.4% bone. It is high and at least ten times higher when compared to other muscle-based foods. Therefore, HM is a suitable meat source for those suffering from anemia or hypercholesterolemia, dieters, or those seeking an alternative to beef. Myoglobin content in HM is at a maximum (0.7%) compared to other food animals. The refractive index for horse fat is 53.5, which in pork fat is <50 and for beef fat is <40. HM has the highest iodine number (70–85) of all meats. For the lard, iodine number is 50–70 and ox and sheep fat 35–46. Horse fat contains 1–2% linoleic acid, whereas all other animal-derived fats contain $<0.1\%$.

Changes Occurring after Slaughter of Horse

There are a series of reactions that take place during the transformation of muscle to meat. Factors such as preslaughter care, mode and duration of transport, lairage conditions, and injury and stress of any other form on the animal awaiting slaughter all impact significantly this transformation. As biophysical and biochemical changes continue to take place in HM following slaughter and exsanguinations for several hours to several days, the conversion of muscle to meat is a complex process.

Palatability Characteristic of HM

Aroma and Flavor Development

The basic flavor of meat is primarily due to the presence of inosinic acid, and HM is no exception. In the process of heating, inosinic acid reacts with glycoprotein containing alanine. The inosinic acid reacts on heating with a glycoprotein containing alanine and glucose producing a basic meat flavor and odor. The breakdown of proteins and fats during aging also contributes to flavor by producing H_2S, acetaldehyde, ammonia, acetone, and diacetyl, but at the same time, prolonged aging is associated with loss of flavor.

Color

In living condition, horse muscle with sufficient oxygen becomes bright red in color. After slaughter, oxygen is used up by the muscle, and the tissue becomes dark purplish red in color. In the living animal, muscles with sufficient O_2 supply have a bright red appearance. In the postmortem muscles, as the O_2 is used up, the muscles become dark purplish red in color.

Firmness

Living muscles maintain certain amount of tone. Since they are attached at both ends directly or indirectly to some part of the skeleton, they are relatively firm. After rigor mortis, the muscle becomes firm and stiff; due to denaturation of protein and enzymatic degradation, it becomes more tender. This is same as in case of other meats.

Water-Holding Capacity

Moisture content of HM muscle is 65–80%. The capacity of meat to retain its own water or added water after the application of several forces is called as water-holding capacity of meat. It gives juiciness to the meat. HM is less juicy as compared to beef and carabeef.

Meat Composition

The intramuscular fat content in mutton is the highest (13%) and in buffalo meat the least (1.0%). Beef contains 2.5%, goat meat 3.5%, and pork 4.5%. Vitamin A content is significant in beef and mutton but highly insignificant in buffalo meat, chevon, and pork. The glycogen content is high in HM, by at least ten times compared with other food animals. Myoglobin content in HM is maximum (0.7%) compared with other food animals.

Body Fat Composition

The refractive index value for horse fat is 53.5, while in pork fat, it is <50, and in beef fat, it is <40.

Iodine Number

The iodine number of horse fat (70–85) is the highest compared to lard (50–70), ox, and sheep fat (35–46).

Linoleic Acid Content

Horse fat contains 1–2% linoleic acid, whereas all other fats contain $<0.1\%$.

Nutritive Value

Fatty acid composition of different game animals is given in Table 2. The fatty acid profile of HM is positive from a nutritional point of view and in line with health recommendations. However, health-conscious consumers tend to avoid red meat because of the public perception of the adverse effects of saturated fatty acids that have been linked to coronary heart disease. Among red meat varieties, HM is considered more dietetic because it contains less fat and cholesterol. The $N-6/N-3$ ratio is more favorable in HM than from other ruminant-derived meats. Among red meats, HM is known to contain high levels of unsaturated fatty acids such as α-linolenic (18:3 $n-3$), monounsaturated fatty acids (MUFAs), vitamin B_{12}, and heme iron (4 mg/100 g), thereby making HM one of the healthiest forms of red meat available for consumption.

Palmitic, stearic, and oleic acids are predominant in HM and contribute for 3–18% of total MUFA levels. The wide range is attributed to the feeding practices adapted. HM is considered an important source of minerals, especially iron, magnesium, and copper. Regarding Ca content, equine meat has relatively low values. The Mg content in HM is 21.00–43.31 mg/100 g. It is low in cholesterol. Glycogen content is ten times higher as compared with other foods. Myoglobin content is at maximum (0.7%) compared with other food animals. The refractive index is 53.5, while for pork fat, it is <50, and for beef fat, it is <40.

The HM is known to contain high levels of unsaturated fatty acids like α-linolenic (18:3 $n-3$) and MUFAs, indicating that it is more beneficial for health than beef. Retinol content is the highest, riboflavin is similar as in beef, but thiamine is higher than beef. Regular consumption of HM may contribute to reduced LDL and cholesterol and improve omega-3 index and docosahexaenoic acid (C22:3$n-6$) and iron status. Energy value of HM of medium fatness is 472 KJ, that is, 110 kcal per 100 g. The proteins from HM are better than the proteins from veal, pork, or beef by their quantity and quality (because of a smaller content of connective tissue, it is easier to digest).

Examples of Specific HM Products Found Internationally

Kazy and Shuzhuk

Kazy and shuzhuk are types of sausage found in Kazakhstan and are made from HM and the intestinal lining used as a natural casing. Another product known as *Zhaya* is made from hip meat, which is smoked and boiled. *Zhal* is made from neck fat, which is again smoked and boiled, while *Karta* is made from a section of the rectum, which, similarly, is smoked and boiled. Sur-yet is derived from HM and is produced as a dried meat.

Horse Satay

In Indonesia, chunk cuts of grilled HM are served with spicy sauce known as horse satay. More details about satay are not available in the literature.

Sakura

In Japanese cuisine, raw HM is called *sakura* or *sakuraniku* (sakura means cherry blossom and *niku* means meat) because of its pink color. It can be served raw as sashimi in thin slices dipped in soy sauce, often with ginger and onions added. In this case, it is called *basashi*, which is popular in some regions of Japan. Fat, typically from the neck, is also found as *basashi*, though it is white, not pink. HM is also sometimes found on menus for *yakiniku* (a type of barbecue), where it is called *baniku* literally 'HM' or *bagushi* ('skewered horse'); thin slices of raw HM are sometimes served wrapped in a shiso leaf.

Table 2 Fatty acid (%) content of intramuscular fat of final dry-cured products

Fatty acids	*Deer*	*Wild boar*	*Horse*	*Bovine*	*Goat*

Kumamoto, Nagano, and Ōita are famous for *basashi*, and it is common in the Tohoku region as well. Some types of canned 'corned meat' in Japan include HM as one of the ingredients. There is also a dessert made from HM called *basashi* ice cream. The company that makes it is known for its unusual ice cream flavors, many of which have limited popularity.

Kazy

It is a type of salted sausage that is produced as a regional delicacy by the Mongolian Kazakhs. In modern times, they prefer beef and mutton, though during the extremely cold winter, however, many people prefer HM due to its low cholesterol. It is kept nonfrozen, and traditionally, people believe that HM helps generate body heat. Other Asian nations import processed HM from Mongolia.

Tonga

In Tonga, HM is much more than just a delicacy. Consumption of HM is generally only reserved for special occasions. These special occasions may include the death of an important family member or community member or celebration during the birthday of an important family member or perhaps the visitation of someone important like the king of Tonga.

In Tonga, a horse is one of the most valuable animals a family can own because of its use as a beast of burden. Therefore, the slaughter of one's horse for the purpose of consumption becomes a moment of immense homage to the person or event the horse was slain for. Despite a diaspora into Western countries like Australia, United States, and New Zealand where consumption of horse meat is generally tabooed, Tongans still practice the consumption of HM perhaps even more so because it is more readily available and more affordable.

Lukba or Tapang Kabayo or Kabayo

In the Philippines, HM is commonly sold in wet local markets. HM is a famous delicacy. The method of preparation is very common, which includes marinating the meat with lemons, toyo (soy sauce), and patis (fish sauce). It is then fried and served. It is usually dipped into vinegar to give the meat a sour taste. It is known throughout the country as 'lukba,' 'tapang kabayo,' or just simply 'kabayo.'

Conclusion

The HM is soft, delicious, easily digestible, and favorable to health-conscious consumers. Its nutritional compositions, like proteins, fat, glycogen, essential amino acids, and macro- and microelements, rate better than beef. HM's high content of proteins, vitamin B_{12}, and iron and its low content of cholesterol make it the best and cheapest alternative for red meat.

Human Milk: Composition and Nutritional Value

MH Monaco, J Kim, and SM Donovan, University of Illinois, Urbana, IL, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Human milk (HM) is a complex and dynamic fluid that has evolved to meet the nutritional needs of the infant. As such, the nutritional composition of HM changes continuously with the infant's development, which differs markedly from infant formula that is designed to be appropriate for the first year of life and does not change in composition. Unlike infant formula, HM contains a variety of bioactive proteins, lipids, oligosaccharides, and immunomodulatory components that facilitate the infant's transition to extrauterine life. This article will review the content and composition of HM, with a particular focus on the bioactive components in HM and their potential role in infant development. The factors that influence HM nutrient composition, such as maternal genetics, diet, stage (e.g., prematurity), and route of delivery, will be highlighted.

Breastfeeding

Health Benefits

HM is the optimal form of nutrition for the infant. Epidemiological studies have shown that compared with formula feeding, breastfeeding protects against common infectious diseases in infancy (otitis media, respiratory syncytial virus, and urinary tract infection), necrotizing enterocolitis (NEC) in preterm infants, and immune-mediated disorders in later childhood, including allergy, asthma, atopic dermatitis, inflammatory bowel disease, celiac disease, type 1 and type 2 diabetes mellitus, and leukemia. The reduced risk of immune-mediated diseases may be due in part to differences in the gut microbiota of breast-fed (BF) and formula-fed (FF) infants. Additional evidence support improvements in cognitive development and reduced risk of childhood obesity.

Breastfeeding Recommendations and Rates

Due to these health benefits, exclusive breastfeeding is recommended for the first year of life, with exclusive breastfeeding in the first 6 months, by the World Health Organization and leading pediatric societies, including the American Academy of Pediatrics (AAP). However, the rates of breastfeeding vary widely throughout the world, and only 14% of infants are exclusively BF for 12 months in the United States. Thus, most infants receive formula either exclusively, or in combination with breastfeeding, during the first year of life. For this reason, HM and infant formula composition will be compared throughout the article, where appropriate.

HM Composition

HM is initially synthesized as colostrum, which persists for ~72 h, followed by transitional and then mature HM. Colostrum contains low concentrations of lactose and fat, but is rich in immunoprotective and trophic compounds. After 72 h, milk production increases considerably and transitional milk composition changes, including increases in lactose and fat, to support the rapid growth and motor and cognitive development of the infant. By 15 days postpartum, milk is considered mature and its composition remains relatively stable until weaning. In addition to changes with duration of lactation, HM composition varies within feeding and between breasts in a few selected milk components. For instance, the lipid content of hind milk is twice that of milk secreted at the beginning of the feeding (foremilk). Similarly, vitamin A and E contents are higher in hind milk than foremilk. Differences in HM composition between breasts have been observed, although these differences tend to be more sporadic. More recent studies suggest that infant gender affects nutrient composition, with higher lipid content in milk of women breastfeeding male infants.

Nutrients in HM are derived from three major pathways: (1) secretion of components endogenously synthesized in the mammary gland, such as lactose, milk proteins, lipids, and oligosaccharides; (2) transport of substances from the maternal circulation to milk, such as immunoglobulins, other immune factors, and hormones; and (3) nonspecific entry of serum and interstitial components into HM during the process of milk synthesis, including urea, free amino acids, and other low-molecular-weight compounds. The nutrients in HM are compartmentalized based on their chemical structures. Water-soluble components are found in the whey (aqueous phase of milk), while the major protein components, such as casein, are found in the colloidal phase. Fat and hydrophobic components are emulsified in droplets surrounded by the milk-fat globule membrane (MFGM).

Colostrum and mature milk are approximately 88% water and have an osmolality of 286–319 mOsm l^{-1}, compared with 185–374 mOsm l^{-1} for infant formulas. Milk comprises 120 and 128 g l^{-1} solids in mature milk and colostrum, respectively. Milk solids are composed of 70 g l^{-1} carbohydrate, 40 g l^{-1} fat, 10 g l^{-1} protein, and 2 g l^{-1} mineral ash. The compositions of colostrum and mature milk are shown in Table 1. Colostrum has higher protein and lower fat and carbohydrate concentrations relative to mature milk. Despite the differences in protein and lipid content between colostrum and mature milk, they have similar energy content, which is less than that of formula (670 kcal l^{-1}).

Carbohydrates

The predominant carbohydrates in milk are lactose and HM oligosaccharides (HMO). Lactose is the least variable HM macronutrient throughout lactation. In addition, lactose is the major osmol in HM, and its concentration is highly correlated to milk production. Lactose is digested almost entirely by

Table 1 Energy and macronutrient composition of colostrum and mature human milk[1]

Constituent (l^{-1})	*Colostrum*	*Mature milk*
Energy (kcal)	536	577
Total carbohydrate (g)	50–70	70–85

[2]Data not reported.

intestinal lactase, although a small proportion of undigested lactose may contribute to softer stools and increased absorption of minerals. HMOs are the third most abundant component in milk and are found in higher concentration in colostrum than mature milk (Table 1). HM is unique compared with that of other species in its high content and composition of HMO. Up to 200 structures of HMO have been identified in HM, of which ~70% are fucosylated. In contrast, oligosaccharide concentrations in cow's milk and cow's milk-based infant formulas are predominantly sialylated, and their concentration is negligible compared with HM.

Proteins

The HM protein content is lower than that of cow's milk (35 g l^{-1}) or cow's milk- (13–15 g l^{-1}) or soy-based infant formula (18–20 g l^{-1}). These proteins provide essential amino acids to support infant growth; however, many HM proteins are relatively resistant to digestion and are involved in immune protection, improvement of nutrient digestion (e.g., enzymes), and enhancement micronutrient availability (e.g., mineral binding proteins).

Milk proteins are broadly classified into casein and whey fractions. Colostrum has a whey-to-casein ratio of 90:10 compared with 60:40 in mature milk. Whey is composed of over 150 proteins. The most abundant whey protein is alpha-lactalbumin (α-LAC), which contains higher levels of tryptophan, lysine, and cysteine than other proteins in HM. α-LAC serves a critical functional role as a component of the lactose synthase complex. In addition, peptides released during α-LAC digestion have antimicrobial and prebiotic activities that stimulate beneficial bacterial colonization of the gut, while inhibiting the growth of pathogenic bacteria. Other HM whey proteins are lactoferrin, immunoglobulins, and lysozyme, which are related to the immune protection of the neonate and will be discussed later in this article.

The HM casein fraction differs from bovine milk with lower casein concentration in HM (3–5 vs. 26 g l^{-1}, respectively), and it is composed of β- and κ-casein, while bovine milk is predominantly composed of α-casein. Glycosylation of casein, particularly of κ-casein, is associated with protection against infection and increased micronutrient absorption.

Fats

Fat is the second most abundant macronutrient in HM and is an important energy source for the infant. Approximately 98% of the fat in HM is in the form of triglycerides, which are synthesized in the mammary alveolar cells from fatty acids derived from maternal diet or adipose tissue, or *de novo* synthesis. Of the fatty acids in mature HM, 32–52% are saturated, 30–50% are *cis*-monounsaturated, and 2.5–13.8% are *trans*-monounsaturated. The remaining are polyunsaturated fatty acids (PUFA). Compared with bovine milk, HM has a lower percentage of short-chain fatty acids and considerably more long-chain fatty acids in the form of arachidonic acid (AA) and docosahexaenoic acid (DHA) than bovine milk. The HM AA content is relatively constant, whereas HM DHA content is sensitive to maternal diet. Dietary DHA and AA benefit infant visual and cognitive development, which has led to their supplementation into infant formula.

The fat in HM is surrounded by the bipolar MFGM, which originates from the mammary apical plasma and mature Golgi vesicle membranes. The MFGM also contain a diverse group of proteins, including mucin and lactadherin, which act as antimicrobial agents. Other molecules present in MFGM that may be involved in brain development and myelination are sphingomyelin, gangliosides, sialic acid, and cholesterol.

Vitamins

In most cases, HM contains all essential vitamins in adequate concentrations to meet the nutritional requirements of the growing infant. Their content is, however, dependent on maternal nutritional status and dietary habits. Vitamin supplementation during lactation is recommended to compensate for

any dietary insufficiency. The content of fat-soluble and water-soluble vitamins in HM is summarized in Table 2.

The fat-soluble vitamins in HM are contained within the MFGM, with the exception of vitamin D, which is present in whey attached to vitamin D-binding protein. Vitamin A includes retinol, β-carotene, and carotenoids, which have roles in vision, growth, healing, reproduction, cell differentiation, and immune function. HM is enriched with retinol esters and contains 1.8 μmol l^{-1} carotenoids, with α-and β-carotenoids and cryptoxanthin accounting for 50% total carotenoids. The vitamin A content of HM is sensitive to maternal diet and decreases from colostrum to mature milk (Table 2).

Table 2 Vitamin composition of human milk[1]

Constituent (l^{-1})	*Colostrum*	*Mature milk*
Fat-soluble vitamins		
Vitamin A and carotenoids

Effect of pantothenic acid status on the content of the vitamin in human milk. *American Journal of Clinical Nutrition* **40**, 317–324.

Vitamin D is present in its hydroxylated form or as 25-hydroxyvitamin D (25(OH)D) in HM, and its content is dependent on maternal vitamin D status, diet, and sun exposure. Vitamin D is involved in calcium and phosphorus metabolism, bone formation, and modulation of the immune system toward a more tolerogenic behavior. The HM vitamin D content (20–80 UI l^{-1} or 0.5–2 μg l^{-1}) is not sufficient to meet the AAP recommendation of 400 IU (100 μg) per day in exclusively BF infants who have limited exposure to sun. Infant formula is fortified to 270–670 UI l^{-1}. Maternal supplementation with cholecalciferol increases HM 25(OH)D to levels that are sufficient to avoid deficiency in BF infants. Vitamin D can also be directly supplemented to exclusively BF infants.

Vitamin E refers to a family of eight tocopherols that function as antioxidants in cell membranes and the development of the nervous system, skeletal muscle, and retina. The alpha-tocopherol form is the most abundant in HM, and it is higher in colostrum than mature milk and four times higher in hind milk compared with foremilk.

Vitamin K is important for blood coagulation, cell cycle regulation, and cell adhesion and bone metabolism. HM contains both forms of vitamin K: phylloquinone (K_1) and menaquinone (K_2) with an additional form, melaquinone-4 (MK-4), that is synthesized in the body from dietary phylloquinone by bacteria. Vitamin K is not readily transported through the placenta and is low in HM. Therefore, the AAP currently recommends a single intramuscular injection of vitamin K (0.5–1.0 mg) immediately after birth.

The other major class of vitamins is the water-soluble vitamins, which include vitamin C and eight B vitamins: thiamin (B_1), riboflavin (B_2) niacin (B_3), pyridoxine (B_6), biotin, pantothenic acid, folic acid, and cyanocobalamin (B_{12}). The concentration of the water-soluble vitamins is dependent on maternal diet and vitamin supplement use.

Vitamin C is critical in collagen synthesis and synthesis and activation of neuropeptides and is an important antioxidant. The concentration of vitamin C in milk does not vary greatly from colostrum to mature milk and ranges from 40 to 100 mg l^{-1}. The B vitamins are important components or cofactors in intermediary metabolism. The concentration of B vitamins in HM increases from colostrum to mature milk with the exception of B_{12} and riboflavin, whose content decreases as lactation progresses (Table 2). HM concentration of B vitamins is adequate to fulfill the needs of exclusively BF infants; however, concentrations of folate, B12, and B6 in HM may be compromised if maternal intake of these vitamins is inadequate.

Minerals

The mineral and trace element concentrations in HM change over the course of lactation and are higher in colostrum than mature milk (Table 3). The transport of minerals and trace elements is highly regulated, and there is typically no association between maternal serum mineral concentration or dietary intake and HM content, with the exception of selenium, fluorine, and iodine. Many minerals in HM are bound to proteins, which increases their bioavailability. Minerals in infant formula, whether cow's milk- or soy-based, are found in higher concentration than HM to compensate for lower availability and absorption rates.

Table 3 Macromineral and micromineral composition of human milk[1]

Constituent (l^{-1})	*Colostrum*	*Mature milk*
Macrominerals		
Calcium (mg)	250	200–250
Chloride (mg)	600–800	400–450
Magnesium (mg)	30–35	30–35
Phosphorus (mg)	120–160	120–140
Potassium (mg)	600–700	400–550
Sodium (mg)	300–400	150–250
Microminerals		
Boron (μg)	30	28
Chromium (μg)	17	25–75
Copper (mg)	0.5–0.8	0.1–0.3
Fluoride (μg)	5–20	4–15
Iodine (μg)	40–50	140–150
Iron (mg)	0.5–1.0	0.3–0.75
Manganese (μg)	5–12	3–4
Selenium (μg)	25–32	10–25
Zinc (mg)	5–12	1–3

The major HM macrominerals are calcium, phosphorus, magnesium, sodium, potassium, and chloride. Calcium concentration in HM is markedly lower than that of bovine milk and formula (250 vs. 1250 and 500 mg l^{-1}, respectively). Most HM calcium is found in whey, while 15% is bound with phosphorus in casein micelles. The linkage between calcium and phosphorus occurs in a 2:1 ratio resulting in high calcium availability. The concentration of sodium, potassium, and chloride in milk is mostly determined by electrochemical gradient, as HM should be iso-osmolar with plasma. Sodium levels have been reported to vary significantly between women in the early phase of lactation. This variation decreases by 50 days postpartum. Magnesium content of HM is relatively stable due to tight regulation of serum concentration.

Trace elements in HM include iron, zinc, manganese, selenium, copper, chromium, boron, fluorine, and iodine (Table 3). The concentration of iron in HM is low and averages 0.5–1.0 mg l^{-1} in colostrum and 0.3–0.7 mg l^{-1} in mature milk. However, exclusively BF infants rarely develop iron deficiency or anemia in the first 6 months of life, most likely due to high iron bioavailability. Lactoferrin and vitamin C may facilitate the uptake of these elements from HM. Iron in infant formula has a bioavailability of 4–7%; thus, most formulas are iron-fortified. By 6 months, BF infants should be gradually introduced to iron-fortified foods, such as cereals to prevent iron deficiency. Zinc and manganese in HM follow similar patterns as iron, as both decrease after the first days of lactation but present higher availability than those found in infant formula.

Maternal iron, zinc, and manganese intake does not affect HM concentration even when mineral supplementation is taken. On the other hand, minerals such as selenium, fluorine, and iodine in milk are associated with maternal intake and vary with geographic location and supply of mineral-rich foods. Milk selenium tends to be lower in areas with limited grass and cereal such as Finland and New Zealand compared with other areas. Likewise, milk fluorine varies greatly geographically, with higher levels in areas where fluorine is added to the water supply (4.5–50.7 vs. 4.3–14 μg l^{-1}, respectively). APP recommends no fluorine supplementation to BF infants in the first 6 months of life, but suggests fluorine supplementation from ages 6 months to 3 years in areas where water supply has limited concentration. Iodine concentration in milk is affected by maternal intake and has a strong correlation with maternal milk intake since cow's milk is a rich source of iodine. In addition, salt iodization increases milk iodine; the milk iodine levels rose from 70 to110 μg l^{-1} between 1950s to 1985 in the United States.

Bioactive Components of HM

HM contains a multitude of biologically active compounds that are likely to have a key role in the health benefits of HM. Many of these components are proteins and are thought to modulate immune function, response to infection, intestinal bacterial colonization, and development. In addition, the HMOs, which are not digested by the infant, act as prebiotics and stimulate gut colonization and have antiadhesive properties against pathogenic bacteria. Infant formulas do not contain many of these bioactive components, and it may explain differences between disease incidence between BF and FF.

Hormones and Growth Factors

An array of hormones and growth factors are present in HM. Although their role for the newborn is still unclear, many may contribute to the healthy development of the immune and neurological systems and maturation of the gastrointestinal (GI) tract. Hormones in HM include adrenal gland hormones (e.g., corticosteroids, glucocorticoids, cortisol, and corticosteroid), gonadal hormones (e.g., estrogen and progesterone), brain–gut hormones (e.g., gonadotropin-releasing hormone, somatostatin, growth hormone-releasing hormone, and thyrotropin-releasing hormone), insulin-like growth factors (e.g., IGF-I and IGF-II), epidermal growth factors, transforming growth factors (α, β1, and β2), growth hormones (e.g., insulin, relaxin, growth hormone, and prolactin), neurotrophic factors (e.g., brain-derived neurotrophic factor (BDNF), glial cell line-derived neurotrophic factor (GDNF), and ciliary neurotrophic factors), and hormones that regulate metabolism (e.g., leptin, adiponectin, resistin, ghrelin, apelin, nesfatin-1, copeptin, and adropin). Hormone and growth factor concentrations vary by

the stage of lactation. For instance, colostral IGF-I, vascular endothelial growth factor, adiponectin, and insulin contents are higher in transitional than mature HM.

Adipokines are cytokines that are released from adipocytes with hormone-like activities. Adipokines in HM include leptin, adiponectin, resistin, ghrelin, and apelin. They are purported to regulate energy homeostasis, glucose homeostasis, food intake, and energy balance, but the bioactivity of these factors in HM has not been directly tested. Other proteins involved in energy metabolism that are present in HM include nesfatin-1, copeptin, adropin, irisin, and obestatin. It is hypothesized that adipokines and hormones in HM may contribute to the differences in body composition seen in BF versus FF infants in early life.

Among the most studied bioactive components in HM are insulin, IGF-I, and EGF. Animal studies have demonstrated that all three proteins given orally are most likely not absorbed, but act locally within the GI tract, resulting in small intestine maturation and decreased gut permeability. While the insulin concentration in HM remains constant throughout lactation, IGF-I and EGF are higher in colostrum than mature HM.

Transforming growth factor β (TGF-β) family constitutes the major cytokines in HM, with TGF-β2 being the most abundant. TGF-β2 is proposed to stimulate the maturation of the infant's intestinal immune system. Recent studies suggest that TGF-β1 and TGF-β2 survive the low pH of the infant's stomach and are absorbed by the infant's intestine. TGF-β may influence the immunity beyond modulating the GI tract.

Lastly, neurotrophic factors such as BDNF and GDNF may reduce the risk of NEC by modulating the function and integrity of the infant's gut. Specifically, BDNF helps with enteric nervous system development, enhances peristalsis, and protects against intestinal infections. GDNF is involved with the development of the enteric nervous system and maintenance of the intestinal epithelial barrier integrity.

Immunological Factors

HM contains factors that stimulate the development of the infant's immune system, including immunoglobulins, cytokines, maternal mammary epithelial cells, maternal immune cells (e.g., macrophages, neutrophils, natural killer cells, T cells, B cells, and progenitor cells), nucleotides, chemokines, long-chain PUFA, and compounds that promote microbial intestinal colonization. Secretory IgA is the most abundant and biologically active immunoglobulin found in HM. It resists proteolytic digestion in the stomach, and its abundance may compensate for the infant's inability to produce sufficient levels of sIgA in the first month postpartum. Specifically, sIgA binds to microbial antigens, blocks adhesion of pathogens to epithelial cells, enhances phagocytosis, and modulates local immune function. Other immunoglobulins such as IgG and IgM are present in much smaller quantities in breast milk.

Cytokines are multifunctional peptides or glycoproteins that bind to receptors on immune and nonimmune cells to produce various actions in the immune system, including stimulating the development of the infant's immune and GI systems. Many cytokines are present in HM, including IL-1β, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IL-13, TGF-β, INF-γ, TNF-α, and granulocyte-colony stimulating factor, with IL-6, IL-8, IL-10, TGF-β, and TNF-α being the most abundant. Evidence suggests that cytokines are produced in the mammary gland. Osteopontin is a multifunctional protein with cytokine-like activity that has been shown to regulate the development and maintenance of the immune system and enhance host resistance to infection.

Antimicrobial Peptides

Among the antimicrobial peptides detected in HM are cathelicidin (LL-37), human β-defensin 1 and 2, lactoferrin, sIgA, lactoperoxidase, and lysozymes. The presence of antimicrobial peptides in HM has been associated with protection against mastitis in the mother while simultaneously acting as immunomodulators for the infant. Antimicrobial peptides from the cathelicidin and defensin families have been shown to protect the epithelial surfaces of the infants' intestine, lung, and skin from bacterial colonization and modulate the potency of neutrophils, macrophages, and mast cells.

Lysozyme and lactoferrin are antimicrobial whey proteins that also give rise to potent antimicrobial peptides during the process of digestion by the infant. Lysozyme is secreted by polymorphonuclear leukocytes and degrades the peptidoglycan cell walls associated with most bacteria. The high concentration of lysozyme found in HM ($0.3–0.5\ g\ l^{-1}$) may play a role in local protection of the infant's GI tract. Lactoferrin is an iron-binding antimicrobial protein that produces a potent antimicrobial peptide lactoferricin after being hydrolyzed by pepsin in the stomach. Lactoferricin's antimicrobial property is associated with its high affinity for iron. Other mechanisms of bactericidal activity include increased permeability of the cell membrane, thereby impairing the function of the cell, and inhibition of DNA, RNA, and protein synthesis after incorporation of lactoferricin into the bacterial cytoplasm. Lactoferrin-derived peptides share common characteristics with antimicrobial peptides such as the positively charged region of the peptide that contribute to its antimicrobial effects.

Conclusions

Health organizations worldwide support breastfeeding as the optimal form of nutrition for the human infant. HM is a living fluid that meets the nutritional needs and contains many bioactive components that likely foster early postnatal development and contribute to the demonstrated benefits in health outcomes associated with breastfeeding.

Hunger

J Pickering and J Halford, University of Liverpool, Liverpool, UK

© 2016 Elsevier Ltd. All rights reserved.

Glossary

Hedonic hunger A drive to consume palatable food, which is driven by pleasure and not a need for energy.

Homeostatic hunger The drive to restore the body to a state of homeostatic equilibrium. That is, when the body is in energy-deficit (more energy has been expended than energy that has been taken in), the body will respond by creating a strong motivational drive for the individual to seek and consume food.

Hunger A motivational force to find and consume food, which often (but not necessarily) precedes an eating episode.

Satiation The process that develops during eating that generates negative feedback to end the eating episode. This determines meal size (energy, weight, or volume).

Satiety A state of noneating, characterized by the absence of hunger, that follows at the end of a meal and that arises from the consequences of food ingestion. This determines the length of time between eating episodes.

Definition

The term 'hunger' is used in many different ways. It can be used figuratively as a motivational driver (e.g., 'She's hungry for success'), to refer to cravings for specific foods (e.g., something sweet), and to refer to malnutrition and starvation (i.e., 'world hunger'). In a scientific sense, hunger has a more precise definition. Here, we refer to hunger as the motivational force that drives people to seek and consume food. There are two forms of hunger: firstly, homeostatic hunger, which is the body's drive to increase energy intake in response to an energy deficit, in order to restore energy balance or equilibrium (this is an important biological expression of the body's need for energy to sustain growth and life) and secondly, hedonic hunger, a powerful psychological driver to eat foods known to be pleasurable and rewarding. These expressions of hunger are not always distinct and it is not always possible to identify which type of hunger a person may be experiencing. For example, a person who has not eaten for several hours and whose upper digestive tract is empty may experience not only homeostatic hunger but also hedonic hunger triggered by others nearby eating palatable foods.

Hunger can be inferred in two distinct ways within nutritional science. Firstly, it can be inferred through directly observable behavior, such as the willingness to work for food or through observable events such as a long period of food deprivation (this is the method used in animal studies). In this sense, hunger becomes a mediating concept or an intervening variable. Secondly, subjective feelings or sensations of hunger can be measured through rating scales and other measurement devices. The subjective perception of hunger is often accompanied by easily identifiable bodily sensations in the stomach, mouth, throat, and head, for example, increased saliva production, stomach rumbling, and preoccupation with food-related thoughts.

It is worth noting at this point that eating food ordinarily decreases the sensation of hunger and increases the sensation of fullness. However, although hunger and fullness are related concepts, they are not opposite dimensions of the same concept. For example, fullness can be increased via gastric distention (e.g., by inflating a balloon in the stomach or through ingesting large quantities of water) but these methods only marginally reduce hunger. This suggests that physical sensations of emptiness within the gastric tract are only one aspect of hunger sensations.

Measurement of Hunger

Hunger is an internal subjective state and there is not an objective 'standard' by which internal experiences can be calibrated. There are therefore several difficulties in attempting to objectively quantify and measure hunger. Firstly, there is an inherent mistrust of subjective reports of appetite, which are often varied, and therefore, the accuracy of which is often doubted. Another difficulty is that the term 'hunger' is not only a scientific concept but also a commonly used colloquial word and people may have their own individual interpretations of what the word refers to. These difficulties are somewhat illustrated by the large amount of between-subject variation in hunger reports.

Measurement Scales

The two most common methods for quantifying hunger are fixed-point rating scales and visual analog scales (Figure 1). Fixed-point rating scales are quick and simple to use and provide numeric data, which are easy to analyze. These scales can be affected by the word choice and the number of points chosen. Furthermore, past examples of these scales show that they vary considerably in complexity. In considering the appropriate number of points to be included in this type of scale, the freedom to make a range of possible responses must be balanced against the precision and reliability of the device. Research indicates that scales with an insufficient number of fixed points can be insensitive to subtle changes in subjective experience. In addition, the fixed points affect how people interpret the scales and distribute their ratings. One way of overcoming some of these failings is to remove these points.

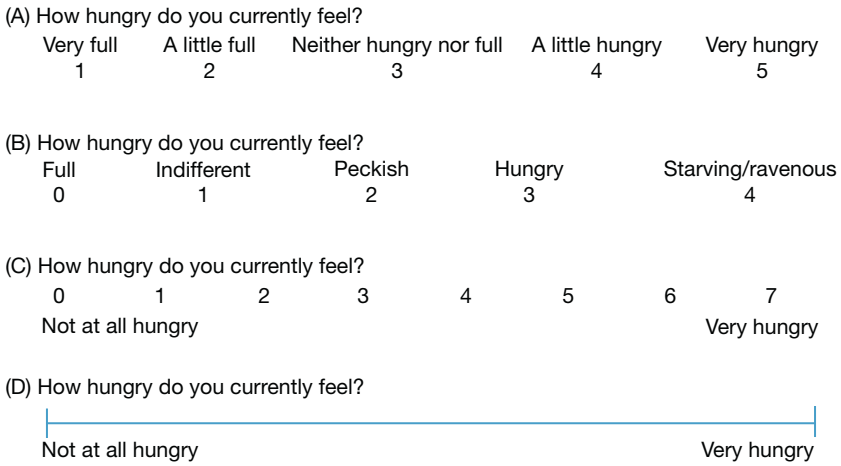

Figure 1 Examples of different types of scales used to determine hunger: fixed-point scales with points defined (a and b), fixed-point Likert scale (c), and visual analog scale (d).

Visual analog scales are normally 100 mm horizontal lines, which allows data to be easily converted into percentage scores (they can be longer to allow more freedom of responses). Participants are asked to mark the line at the point that most accurately reflects their current feelings of subjective hunger. The researcher then measures the distance from the negative end of the scale (not hungry) to the participant's mark, yielding a score of 0–100 (in the case of 100 mm lines). The scales are unbroken and unmarked, which has the advantage of making it difficult for participants to remember exactly where they may have marked the line in previous hunger questions or assessments. This helps to reduce a cross-checking response bias, whereby participants amend some question answers to be consistent with previously answered questions, which can overly inflate the reliability of some scales.

Scales can be computerized or presented via pen and paper. Computerized scales remove human error in recording the data and can ensure that scales are completed at precise time points in the day. By removing verbal labels (except the end anchors), visual analog scales retain the advantages of fixed-point rating scales while avoiding many of the problems with uneven response distributions and are therefore often the preferred scale in many experiments.

It is important to interpret these scales' results properly. For example, it cannot be assumed that the difference between 20 and 30 mm on a visual analog scale is perceptually the same as the difference between 80 and 90 mm. Nor can a hunger rating of 80 mm be said to represent a feeling of hunger that is twice the intensity of one rated as 40 mm. The variation of scores on these scales represents fluctuations in hunger perception and not absolute change of some physical commodity. Individuals will use these scales idiosyncratically (each individual may interpret the scale and gauge their response differently). For example, a minority of subjects are reluctant to make ratings away from the upper or the lower end points of the scale, despite clear instructions. This leads to the problem of 'end effects.' However, participants are generally consistent on repeated occasions (participants will use their own parameters, producing a reliable record of alterations in an individual's appetite). Despite their limitations, data from such scales are often analyzed using parametric statistics, such as analysis of variance, and in general, this appears to be satisfactory.

Hunger and Eating Behavior

The subjective experience of hunger is a biologically useful indicator of a depleted nutritional state and often precedes an eating episode. However, hunger and eating behaviors, although closely linked under many circumstances, are not always entirely dependent upon each other. Hunger is neither a necessary nor sufficient condition for eating to occur. There are many examples of people who are hungry but do not eat, for example, those who fast for political or moral reasons, those who deliberately restrict their energy intake for weight loss, or even those who do not want to spoil their appetite before a planned evening meal. Hunger is therefore not a sufficient condition to cause food intake, even when food is readily available. People can, and regularly do, resist the drive to consume. Hunger is also not a necessary condition to cause food intake. Often, people will overeat at special occasions such as weddings and Christmas, will eat a desert despite having just consumed a filling meal, and finish a large meal in the spirit of economic prudence.

Laboratory-based research notes that increasing the palatability and variety of food can encourage eating beyond the limits of normal satiety. It takes longer to achieve sensory-specific satiety (where one becomes bored of a particular flavor) with highly palatable and energy-dense foods. It is also easy to overconsume energy-dense foods because they can be eaten more quickly. As satiety signals are not instantaneous, eating quickly makes it more likely that a person will overconsume. Therefore, it is misplaced to criticize the validity of hunger ratings due to a discrepancy with recorded food intake, as the previous examples show that in certain circumstances, the two can be disengaged.

Proximity to food cues can have dramatic, instantaneous effects on appetite expression. For some individuals,

responsiveness to food cues overwhelms normal appetite control and the normal rhythm of hunger. For others, eating in the 'absence of hunger' is a component of their natural eating repertoire. It is clear that hunger ratings cannot be used simply as a proxy measure for food intake. Equally, when such factors are taken into account, there is good evidence that self-report ratings of hunger correlate statistically and meaningfully with eating.

By questioning the relationship between hunger and eating, we are also forced to place the action of hunger within a broader context of social and psychological variables that moderate food choice and eating behavior. Eating patterns and food intake are affected by habits, attitudes, and opinions about the value and suitability of foods and an overall liking for them. Food can be avoided, even when an individual is hungry, for health, moral, or political reasons: for example, reducing sugar intake to protect against diabetes, eating a vegetarian diet in support of animal rights, and avoiding palm oil to reduce the impact of deforestation. These factors, derived from the cultural ethos, largely determine the range of foods that people consume and sometimes the timing of consumption. In addition, recent research suggests that social modeling and mimicry can have an important impact upon food intake. Laboratory research suggests that a participant's *ad libitum* food intake can be manipulated by how much a stooge eats and that even food-deprived participants will eat less if a stooge only eats a little. Fluxes in hunger are therefore only one aspect of the range of eating determinants.

Hunger, Satiation, and Satiety

Hunger is a motivational driver to seek and consume food. When a meal is initiated, the process of satiation will begin, which generates negative feedback to end the eating episode. Hunger declines as satiation develops and usually reaches its lowest point at the end of a meal. Satiation therefore determines meal size (energy, weight, or volume). Satiation can be measured via eating rate within a meal. Satiety is defined as a state of noneating, characterized by the absence of hunger, which follows at the end of a meal and arises from the consequences of food ingestion. This determines the length of time between eating episodes. The intensity of satiety can be measured by the duration of time until the next eating episode, by the amount consumed at the next meal, or by how long hunger is suppressed.

Satiety does not refer to a single event or process, but rather an interconnected series of sensory, cognitive, postingestive, and postabsorptive signals. By definition, satiety is not an instantaneous event but occurs over a considerable time period. In the very short term, hunger is inhibited by sensory effects generated through the smell, taste, temperature, and texture of food. Hunger is inhibited for a little longer by cognitive beliefs about the properties of foods and appropriate portion sizes. Hunger is increasingly suppressed by postingestive processes such as gastric distension, rate of gastric emptying, and the release of hormones such as cholecystokinin and peptide YY. These factors will inhibit the rebound of hunger during the early postprandial period. In the postabsorptive phase of satiety, metabolites are absorbed from the intestine into the bloodstream. These signals will continue to suppress hunger late into the postprandial period.

Hunger and satiety are affected by the nutritional composition and structure of foods; therefore, some foods have a greater capacity to maintain suppression over hunger than others. This will depend on the food's sensory impact, physical characteristics, energy density, and macronutrient composition. The satiating potential of foods is often tested via a preload design, whereby isocaloric 'preloads' (usually soup or milk shakes) are consumed before an *ad libitum* meal and their effects on intake are assessed.

Research suggests that per unit of energy proteins are the most satiating macronutrient, then carbohydrate, and then fat. The satiating effect of protein may depend on the preabsorptive factors of elevated cholecystokinin and glucagon-like peptide-1 release and the postabsorption of circulating amino acids. The satiating effects of protein are prevalent in short-term studies in both lean and obese participants. Emerging evidence suggests that high-protein diets can have medium-term effects on satiety. Current research is investigating the long-term satiating effects of high-protein diets. Fats are the most energy-dense of the macronutrients at 9.5 kcal per gram and high-fat diets (in comparison with low-fat and high-carbohydrate diets) have a disproportionately weak action on satiety.

Dietary fiber is highly satiating for several reasons: It takes longer to chew (sensory satiety), soluble fiber binds to water and swells causing bulk (mechanical satiety), it slows down gastric emptying and remains in the stomach longer (mechanical satiety), and soluble fiber prolongs the intestinal phase of nutrient digestion and absorption (thereby prolonging the postabsorptive satiety signal). Fiber-rich foods can therefore suppress hunger for longer. Hunger is also reduced more by solid foodstuffs than energy-loaded drinks. Sugar-sweetened beverages provide energy without many of the cues for satiety (such as mastication, bulk, and cognitive beliefs about the drink being filling).

Hunger: Physiological Determinants

Hunger often begins with signals from the environment, such as the sight and smell of food and learned contextual cues such as location and time of day. Environmental cues of highly palatable foods can instigate hedonic hunger, which is a drive to consume for pleasure and not energy. Hedonic hunger is underscored by the endogenous opioid system, such as beta-endorphins released in the hypothalamus. Research suggests that opioid antagonists, such as naltrexone, reduce food intake by lowering the perceived pleasantness of foods. It should therefore be noted that the biological mechanisms critical to the expression of hunger are not independent of psychological ones. Indeed, the sensory and cognitive cues that stimulate hunger produce physiological changes that anticipate the ingestion and metabolism of energy and subsequently aid these processes. This gives rise to the psychological factors critical in the expression of appetite.

The ability for external stimuli to incite an anticipatory hunger is known as the cephalic response, which prepares the body for digestion. The cephalic response is expressed in several parts of the gastrointestinal tract and acts to anticipate food ingestion and optimize nutrient absorption. Cephalic

responses include increased release of saliva, stomach acid, and digestive enzymes. Upon food intake, stomach distension and the detection of macronutrients within the gut act as powerful satiety cues, bringing a meal to an end and temporarily inhibiting further consumption. Eventually, hunger again prevails and food intake follows. The flux between hunger and satiety is episodic and underpins the expression of our eating behavior throughout the day.

In addition to episodic hunger signals, tonic signals such as a reduction in blood glucose levels (glucoprivation or hypoglycemia) or low levels of the hormone leptin (produced by the adipose tissue) indicate a deficit in available energy and stored energy reserves and therefore promote feelings of hunger. Other tonic factors that indicate the body's energy status, such as adiponectin, cytokines, and gonadal hormones, appear to act on energy regulator centers within the brain, particularly the hypothalamus, mainly to suppress hunger. Again, their absence serves to promote appetite.

However, not all physiological signals, episodic or tonic, inhibit hunger. The peptide hormone ghrelin is a potent stimulator of food intake. It is released by the stomach and the brain and is detected by receptors in the upper intestine, the mesolimbic system, and various orexigenic circuits in the hypothalamus. Blood levels of ghrelin increase with fasting, reduce after meals, and are correlated with self-reported hunger levels. Further studies demonstrate that ghrelin infusions increase food intake. It may be due to this hormone's role in appetite that most people have a three meal per day macrostructure of food intake, as an individual's preprandial ghrelin levels tend to be similar before breakfast, lunch, and dinner, suggesting that this hormone is a major instigator of meals. The rare disorder Prader–Willi syndrome is a genetically determined conditioned characterized by chronically high ghrelin levels and insatiable hunger. Most people with the disorder are obese and their excessive levels of food intake are associated with both a delayed reduction in hunger while eating and a more rapid return to premeal states when eating has finished. However, mice with a knockout of the ghrelin gene eat almost normally, suggesting that appetite is too important to entrust to only one mechanism.

Other hunger signals from the digestive tract include the lack of satiety hormones (such as cholecystokinin, peptide YY, amylin, and glucagon-like peptide-1). Finally, in further support of the assertion that the body's energy regulatory system is far too important to be entrusted to any singular mechanism, many neurotransmitters and neuropeptides have been identified that stimulate appetite, including neuropeptide Y, agouti-related peptide, melanin-concentrating hormone, orexin A, melanocortin-concentrating hormone, glucocorticoids, endocannabinoids, and galanin. It should be noted that the hypothalamus is a key location for the release of such appetite-promoting neuropeptides (particularly the lateral hypothalamus and the arcuate nucleus of the hypothalamus) and the ventrolateral medulla is important for receiving hunger signals transmitted to the brain via the vagus nerve from the rest of the body.

Hunger: Cognitive and Affective Consequences

It is a common observation among the lay public that hunger affects concentration, attention, and memory. Recent research supports these observations. Systematic reviews indicate that children who eat breakfast have superior cognitive function and academic performance in comparison with those who do not eat breakfast. Such research has led to health and well-being initiatives introducing breakfasts in schools.

Furthermore, bodily sensations of hunger often accompany diffuse feelings of restlessness and excitability. The consumption of food changes both the pattern of physical sensations and the accompanying emotional feelings. Classic drive reduction theory suggests that hunger is associated with unpleasant feelings, and food consumption eases these. Thus, for example, after eating, an aching stomach becomes relaxed and feelings of excitement and irritability become contented. People frequently make judgments regarding their own hunger state using these sensations. However, there is much within- and between-subject variability. In other words, not every person sitting down to eat nor every act of eating by an individual will necessarily be accompanied by bodily sensations of hunger or aversive emotional states.

Conditioned Hunger

As the classical work of Pavlov demonstrates, hunger responses can be easily entrained to specific stimuli. Omnivores, like carnivores, are meal eaters (in contrast to grazers); however, their dietary decisions are more complex. One of the essentials for an omnivore faced with a variety of new and different foods is the capacity to learn. It is not possible for an innate preference or aversion to guide the choice of every possible food. Therefore, we learn which foods are beneficial (and which are not) through experience.

Emerging research suggests that some food preferences can be acquired prenatally and during lactation. This is because flavonoids from the pregnant woman's food are passed to the fetus via the amniotic fluid and to infants via breast milk. Babies are often averse to bitter-tasting vegetables (which is an evolutionary advantage, as many bitter alkaloid plants are poisonous to humans). However, babies who are exposed to high levels of bitter vegetables in the womb are more likely to find vegetable juices pleasant in comparison with babies who were exposed to lower levels. This emphasizes how exposure to different flavors is essential to developing our taste preferences. This principle extends throughout our lifetimes.

Through our experiences, we learn that ingesting food creates pleasant postingestive sensations of satiety that serve as a positive experience, leading to learned preferences, as studied by Birch. Alternatively, if consumption leads to an association between a food and negative gastrointestinal consequences such as nausea, then a conditioned aversion to that food (or even other similar tastes and flavors) is likely to develop. The learning process involves the association between the sensory and the postabsorptive characteristics of foods. In this way, the sensory characteristics of foods act as cues and come to predict the impact that foods will later have. Consequently, these cues should suppress hunger according to their relationship with subsequent physiological events. The potency of taste aversions following vomiting or illness indicates the strength of cue–consequence learning. Food intake depends upon the stability and reliability of the

relationship between the taste (sensory cues) and physiological effect (metabolic consequences) of food.

It is possible to demonstrate experimentally how human beings adapt their eating to a food's energy content. A distinctively flavored food that contains 'extra' hidden energy, presented on several occasions, will result in a change in eating and in preference. When deprived of food, the subjects' preference for the taste increases with gained experience. If presented when satiated, preference for the taste decreases. This process is also observable in young children, who eat smaller meals following a taste previously associated with a high-energy snack and larger meals following a taste previously associated with a low-energy snack. Our hunger can thereby be potently reduced by the learned associations of satiety. This relates to the cognitive factors discussed earlier regarding a person's beliefs about foods and their satiating potential.

In environments where food sources remain limited and dietary variety is controlled, learned responses may effectively control subjective feelings of appetite. However, in wealthy countries where there is an abundance of food, there is distortion, variation, and extreme complexity in the relationship between sensory characteristics and nutritional properties. The conditioned control of hunger is therefore weakened or lost in such rich environments. In such a scenario, hunger may become less controllable. The variety of foods available has many different sensory characteristics. Furthermore, some ingredients preserve sensory qualities while altering the nutritive value (such as diet products that substitute sugar for sweeteners or that remove certain ingredients and replace them with artificial bulking agents). Learned hunger therefore is a relatively less important factor when the food supply contains many food items with identical tastes but differing metabolic properties.

In addition to learning associations between the sensory properties of foods and their satiating potential, people also learn association between food cues and future food intake. Food cues are plentiful and researchers have found that food intake increases after television viewing when food adverts are shown and also after playing advert games (online games often designed and produced by food manufacturers, where food products are highly prominent). Some individuals are more receptive to the effects of food cues than others and demonstrate an attentional bias toward them (their attention is more easily 'grabbed' and maintained by food-related stimuli). Reactivity to food cues emphasizes the importance of conditioned hunger and how associating cues with the naturally rewarding properties of energy intake serves to promote hunger and eating behaviors.

The naturally rewarding properties of food consist of two distinct psychological components, wanting and liking, that are controlled by separate neurobiological systems. Wanting is primarily mediated by dopamine, whereas liking is mediated by opioids in hedonic hot spots. Some research has noted that obese individuals are more sensitive to the rewarding properties of food than lean individuals, promoting greater hunger. While other research suggests that obese individuals have greater hunger to compensate for reward deficiency due to reduced dopamine function; more research is needed to resolve this debate.

Disorders of Hunger

The clinical eating disorders anorexia nervosa and bulimia nervosa are commonly believed to encompass major disturbances of hunger. Yet the role that hunger may play is not entirely clear. Contrary to the literal meaning of the term, 'anorexia' is not experienced as a loss of appetite. Rather, clinicians recognize that anorexics may endure intense periods of hunger during their self-restricted eating. For some, their strength in resisting intense episodes of hunger provides a feeling of self-mastery and control that is absent in other areas of their lives. Research suggests that restricting anorexics (compared with those who binge) have the greatest blunting of hunger responses and that this disturbance in hunger is not a product of other areas of perceptual confusion.

There is evidence that under conditions of total starvation, hunger may become temporarily diminished. This circumstance is extremely rare and obviously relatively brief. Once eating is recommenced, hunger returns rapidly and with extreme intensity. The accounts of the male volunteers who submitted to a 6-month period of semistarvation during World War II (the 'Minnesota Starvation Experiment') are a testament to the extreme power of hunger. Referred to as semistarvation neurosis, the behavior of these men was shaped by their need for food, and their hunger experience was extreme. Nearly two-thirds reported feeling hungry all the time and a similar proportion experienced physical discomfort due to hunger. Participants described a marked increase in what was referred to as 'hunger pain.' For some, this was mildly discomforting and vaguely localized in the abdomen. For others, it was extremely painful. This account is especially useful in reminding us why energy-reduced diets aimed at achieving weight loss are often difficult to maintain and easy to abandon.

Bulimia literally means 'ox hunger'; however, the term is imprecise. Close analysis of the precursors of binge episodes shows hunger to be lower than it is before a typical meal. In addition, although the urge to eat may be strong during a binge, the large amount of food consumed implies some defect in satiation rather than in hunger. Moreover, binging is often a well-practiced behavior that develops and changes with time. Similarly, binge-eating disorder (binging without the purging behaviors that are present in bulimia) is characterized by binging even in the absence of hunger and continuing until uncomfortably full. For all three of these disorders, it is likely that a stable eating pattern is necessary in order to normalize the experience of hunger, a process that may take a long time to establish. The question of whether obesity reflects a disorder of hunger is now regarded as largely redundant. Obesity is strictly a disorder of energy balance and partitioning. There is limited evidence that heightened hunger contributes to excessive energy input.

Why Do We Care About Hypertension and Diet?

Hypertension is a chronic medical condition in which the blood pressure (BP) in the arteries is elevated. Untreated, hypertension increases the risk for coronary heart disease (CHD) and stroke (Figure 1).

After poor diet and tobacco use, hypertension is the third leading risk factor for premature death in the United States, and approximately one in three US adults (78 million) suffer from this condition. It affected ~972 million people worldwide in 2000, and global prevalence is projected to almost double, to 1.56 billion, by 2025. Hypertension is responsible for ~450 000 deaths annually and contributes ~8% to disability-adjusted life years (DALYs). Worldwide, hypertension is responsible for an estimated 9.4 million premature deaths and accounted for 7% of DALYs in 2010. These estimates are based on the World Health Organization (WHO)'s global burden of disease study, which compares a theoretical minimum risk exposure distribution (TMRED) to estimates of the actual population distribution. For example, the TMRED for tobacco use would be the distribution of the population that has never smoked in the past. For hypertension, the TMRED is defined as a systolic BP (SBP) distribution curve with a mean of 110–115 mmHg and a standard deviation of 6 mmHg.

A 2011 study by the American Heart Association (AHA) estimated that the direct medical costs of hypertension in the United States would triple from ~$70 billion in 2010 to $200 billion in 2030 and indirect costs associated with lost productivity would increase from $23.6 billion to $39.8 billion. A 2009 study by Gaziano and colleagues estimated global health-care costs attributed to hypertension among adults to be $370 billion in 2001, about 10% of all health-care expenditures. The authors estimated that over a 10-year period, hypertension could cost nearly $1 trillion globally in increased health spending and $3.6 trillion annually in indirect costs. Each year, excess sodium consumption, a significant risk factor for hypertension, is estimated to kill between 40 000 and 90 000 Americans and cause up to $20 billion in medical costs.

Hypertension is a significant public health priority, because it is very common and largely preventable. Early detection and effective treatment can reduce morbidity and mortality significantly. Poor nutrition, especially high salt consumption, is a significant contributor to high BP, and a low-sodium diet has been shown to reduce a person's risk of developing hypertension. Only 82% of US adults with hypertension are aware of their condition, and three-quarters are using antihypertensive drugs; however, only about half of these individuals are controlling their condition to target BP levels.

Definition

Although there is no evidence of a BP threshold that separates healthy people from people with hypertension, guidelines have been established to diagnose and treat hypertension in clinical practice. In the United States, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) defined BP as comprising four categories ranging from 'normal' to 'stage 2 hypertension' (Table 1).

In December 2013, the Eighth Joint National Committee (JNC8) published their '2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults.' The controversial guideline proposed less restrictive BP targets for adults 60 years of age and older and for people with diabetes and chronic kidney disease. JNC8 set goals for SBP and diastolic BP (DBP) at $<$150/90 mmHg, a sizable increase from the JNC7 goal of $<$140/90 mmHg. The recommendations were based on a different methodology from that used for JNC7. For example, unlike JNC7, JNC8 restricted the scope of evidentiary review to published randomized controlled trials.

Contrary to previous practice, the US National Heart, Lung, and Blood Institute (NHLBI) did not publish the JNC8 guideline; rather, it declined to endorse the new recommendations. Furthermore, none of the national scientific organizations, including the AHA, the American College of Cardiology (ACC), and the American Society of Hypertension, have accepted all of the JNC8 recommendations, particularly the less restrictive goals for BP treatment and control for older adults. The AHA and ACC issued a statement endorsing JNC7 as the national standard, and proposals are under way to develop a new AHA/ACC guideline. An independent study by Navar-Boggan and colleagues found that compared with JNC7, JNC8 was associated with a reduction in the proportion of US adults recommended for antihypertensive treatment and a substantial increase in the number of adults, primarily older adults, considered to have achieved goal BP.

The somewhat arbitrary nature of BP classification is also demonstrated by the fact that the European Society of Hypertension and the European Society of Cardiology define BP differently than does the US system. 'Optimal' BP is SBP $<$120 mmHg and DBP $<$80 mmHg, whereas 'normal' BP is defined as 120–129 mmHg SBP and/or 80–84 mmHg DBP. The European classification does not have a category for prehypertension and defines three grades of hypertension.

For children, hypertension is not defined by absolute levels but on the relative rank of a child within the BP distribution. Reference distributions for sex, age, and height are used to determine the 90th, 95th, and 99th percentiles (Table 2). The

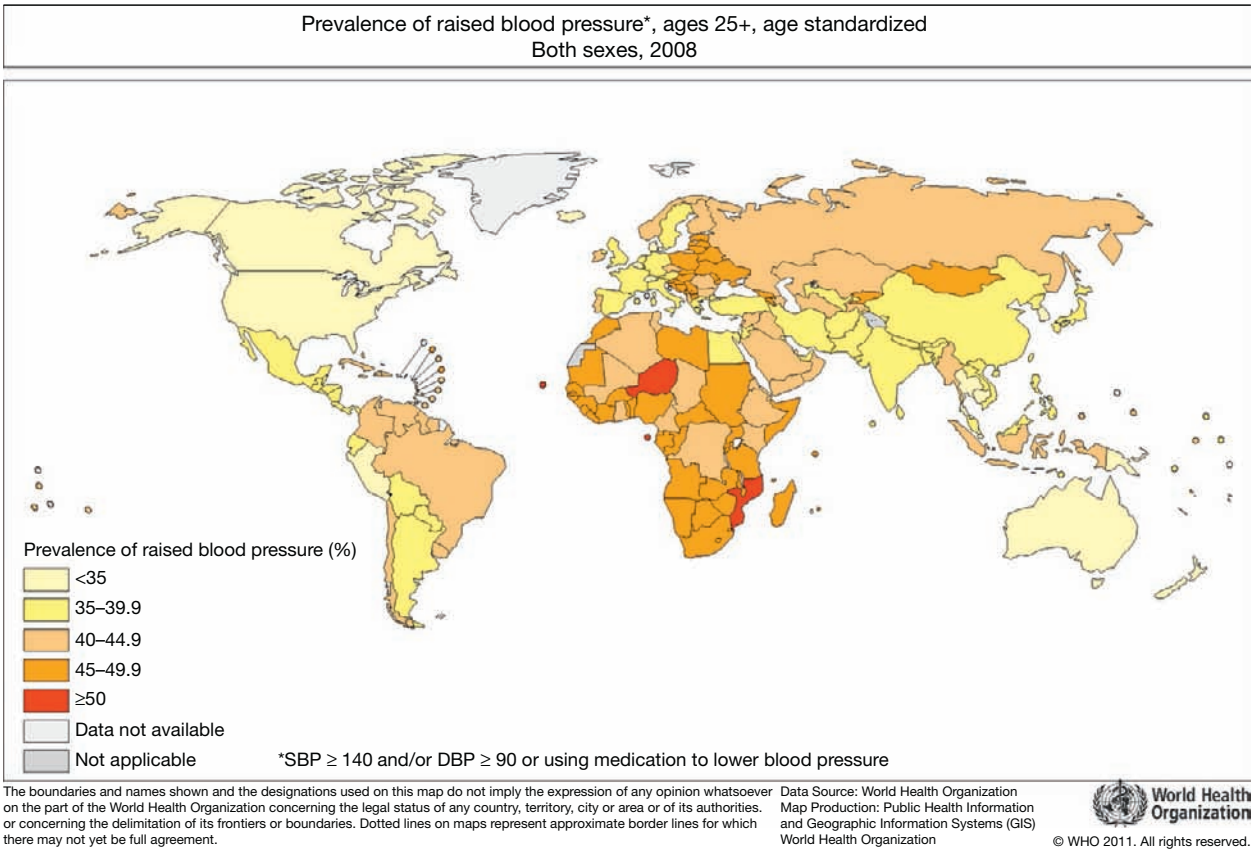

Figure 1 Prevalence of raised blood pressure ages 25+, age standardized. Both sexes 2008.

Table 1 Classification of blood pressure in adults (JNC7)

Classification	*SBP (mmHg)*	*DBP (mmHg)*	*Treatment*
Normal	<120	and <80	Encourage lifestyle modification to keep to goal No antihypertensive drug therapy unless for compelling indications such as diabetes
Prehypertension	120–139	or 80–89	As earlier, but initiate lifestyle modifications
Stage 1 hypertension	140–159	or 90–99	Lifestyle modifications Thiazide-type diuretics for most patients Also consider ACEI, ARB, BB, CCB, or combination For compelling indications, drug therapy as needed
Stage 2 hypertension	≥160	or ≥100	Lifestyle modifications Two-drug combination for most (usually thiazide-type diuretic + ACEI, ARB, BB, or CCB) For compelling indications, drug therapy as needed

SBP, systolic blood pressure; DBP, diastolic blood pressure; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB, beta blocker; CCB, calcium channel blocker.

NHLBI released an updated evidence review through 2008 for high BP among children and adolescents, including an algorithm and flow diagram to help clinicians identify hypertension. From a population-based, health-promotion perspective, the AHA defines cardiovascular health as the product of seven science-based risk factors (Life's Simple Seven™), which include ideal BP defined as <120/80 mmHg in adults and below the 90th percentile in children.

Determinants of Hypertension and the Role of Diet

Although demographic factors such as age, gender, and race/ethnicity, as well as genetics and family history, are associated with BP, diet plays an important role in the development of hypertension. Studies comparing BP among Japanese people living in Hawaii with that of Japanese people living in Japan found higher BP among those living in Japan despite lower

Table 2 Classification of hypertension in children and adolescents

Classification	*SBP or DBP percentile*	*Treatment targets*
Normal	<90th	Recheck at next scheduled physical exam Encourage healthy diet, sleep, physical activity
Prehypertension	90th to <95th or if BP exceeds 120/80 mmHg even if <90th percentile up to <95th	Recheck in 6 months Weight-management counseling if overweight Introduce physical activity and diet management No pharmacotherapy unless compelling indications such as diabetes, chronic kidney disease, or heart failure
Stage 1 hypertension	95th to 99th + 5 mmHg	Recheck in 1–2 weeks if patient is symptomatic If persistently elevated, evaluate or refer within 1 month Weight-management counseling if overweight Introduce physical activity and diet management Initiate pharmacotherapy if needed or if compelling indications as previously mentioned
Stage 2 hypertension	>99th + 5 mmHg	Evaluate or refer within 1 week or immediately if patient is symptomatic Weight-management counseling if overweight Introduce physical activity and diet management Initiate pharmacotherapy

SBP, systolic blood pressure; DBP, diastolic blood pressure.

R. (2011). *Epidemiology and prevention of cardiovascular diseases: a global challenge* (3rd ed.). Sudbury, MA: Jones and Bartlett Learning.

body weight, which may be related to higher salt and lower potassium intake. The Japanese are at higher risk of stroke and have higher rates of hypertension than American and European populations. Ueshima and colleagues concluded that this may be explained by higher sodium and lower calcium and animal protein in the diet and higher alcohol intake among men in the Japanese population than in the Western population. Studies conducted in South Africa in the 1980s showed significant differences between the prevalence of hypertension in urban Zulu populations and that in rural Zulu populations: 25% versus 9.4%, respectively. The age-associated increase in hypertension seen in the urban population was not observed among rural Zulus. This suggests that environmental and dietary patterns may affect BP more than genetic or age-related factors. Increased physical activity and more traditional dietary patterns in the rural Zulu population may have affected BP favorably. Lower levels of obesity among rural Zulus and less exposure to the stresses of urban life, including detribalization, are factors thought to contribute to these differences. Similar rural–urban differences in hypertension rates were observed among the Xhosas of South Africa and the Haryana population of India.

Within the United States, non-Hispanic blacks are at higher risk than are other groups. Younger women also tend to have lower levels of hypertension than do older women or men. These patterns among adults have been observed across the world. Among children and adolescents, statistically significant differences between sexes, ages, and races have been observed. By age 12, boys have higher SBP than girls, and black boys have higher DBP than nonblack girls. The underlying causes of these differences are not yet well understood.

Family history is another important risk factor for hypertension. In one study of Utah students, adults 20–49 years old who had at least one first-degree relative with high BP at any age had a relative risk of high BP 2.3 times higher than that among students with no family history of hypertension. Several genotypes have been identified that influence renal salt handling via the renin–angiotensin–aldosterone axis.

Dietary Factors Affecting BP

High intake of fruits and vegetables and certain diets such as the DASH (Dietary Approaches to Stop Hypertension) diet have strong evidence of antihypertensive effects and are recommended by the Academy of Nutrition and Dietetics and the AHA. A systematic review of dietary factors associated with hypertension reports fair evidence for the antihypertensive effects of potassium, calcium, magnesium, and polyunsaturated fatty acids. The Nurse's Health Study of 41 541 US women found that age, body weight, and alcohol intake were significant predictors of hypertension, whereas calcium, dietary fiber, potassium, and magnesium were inversely associated with BP. These results suggest that diet contributes to BP regulation and a diet rich in fruits, vegetables, whole-grain bread, and rice may reduce BP.

Salt

There is a direct dose–response relationship between salt consumption (sodium or sodium chloride) and high BP: the greater the amount of salt in one's diet, the higher one's risk of hypertension. There is strong evidence from experimental studies that adopting a diet low in sodium lowers BP and reduces the risk of hypertension. A review by He and colleagues found that a reduction in salt intake of 6 g day^{-1} predicts a BP decrease of 7.11/3.88 mmHg in individuals with hypertension and 3.57/1.66 mmHg in those without hypertension. Reducing sodium intake to reduce BP is recommended by the Dietary

Guidelines for Americans, the WHO, the World Heart Federation, and other international groups.

Salt increases water retention, raising BP and affecting the kidneys, arteries, heart, and brain. High salt intake reduces the ability of the kidneys to remove excess water effectively. Over time, this additional stress can cause kidney disease, which hampers the kidneys in removing waste products from the body. As BP increases, artery walls become thicker to handle the strain, which increases BP further. Over time, the arteries can rupture or become blocked, preventing blood flow to the heart and other tissues and causing angina. Arterial damage can lead to reduced blood flow to the brain, resulting in vascular dementia.

Recommendations for sodium intake include <2300 mg day^{-1} (one teaspoon of salt) in the US Dietary Guidelines and <2000 mg day^{-1} for adults by the WHO. All national guidelines recommend reducing sodium consumption. In 2005–06, US men consumed an average of 10.4 g day^{-1} of salt, and women consumed 7.3 g day^{-1}. The majority of the sodium in the American diet – 75% – comes from processed foods. Only 6% is added at the table and 5% during cooking; the remaining 12% occurs naturally in foods. Bread can contain more than 200 mg sodium per slice, and deli turkey can contain more than 1000 mg per 3 oz. In China, 76% of sodium is added in home cooking, whereas 63% of sodium intake in Japan comes from soy sauce. In the United Kingdom, an estimated 95% of sodium comes from processed foods.

Weight

Maintaining a healthy weight helps normalize BP levels. High BP can be controlled with a weight loss of 5–10 pounds. Overweight and obesity are associated directly and indirectly with hypertension. Weight loss reduces BP in individuals with and without hypertension. In addition, hypertension predicts overweight. The Framingham Heart Study found that the relative risk for developing obesity was 1.62 among men with hypertension and 0.79 among men with normal BP. Among women, the relative risk for developing obesity was 1.45 for those with hypertension and 0.75 for those with normal BP. A maximum body mass index of 25 kg m^{-2} is recommended.

Alcohol

Excessive alcohol intake can increase BP. The risk for high BP increases for people who have more than two alcoholic drinks per day, and this relationship is independent of other risk factors such as age, obesity, and salt intake. The AHA recommends a maximum of two drinks per day for men and one per day for women, as well as at least two alcohol-free days per week. Hypertension risk increases by 57% among men and 81% among women who consume more than 3.5 standard drinks per day and by 147% among men and 181% among women who consume more than seven standard drinks per day. A standard drink is defined as 12 oz of beer, 5 oz of wine, and 1.5 oz of spirits.

Potassium

Potassium lowers BP through its vasodilating action and its natriuretic effects: the more potassium consumed, the higher the volume of sodium excreted in urine. Dietary potassium exerts a dose-dependent inhibitory effect on sodium sensitivity. The AHA recommends 4.7 mg day^{-1} of potassium to help control BP, and several guidelines recommend food sources of potassium (beans, dark leafy greens such as spinach, yogurt and milk, bananas, and winter squash) rather than supplements. Systematic evidence reviews suggest that potassium is associated with lower BP among individuals with hypertension, but estimates of the BP-lowering effect for individuals with BP in the normal range are mixed.

Fish oil

Omega-3s and fish oil are included in several national recommendations to address hypertension. Meta-analyses of the effect of fish oil intake on hypertension have been conducted, and consistent evidence suggests that fish oil supplements reduce BP in individuals with hypertension, although fairly high doses (more than 3 g) are generally required.

DASH diet

In addition to the specific issues discussed earlier, research on whole dietary patterns has shown promising results in the management of hypertension. The DASH trial was a multicenter randomized trial that tested the effects of different dietary patterns on BP. The study focused on three patterns – a control diet with nutrient composition typical of the American diet, a diet high in fruits and vegetables, and a 'combination' diet that emphasized fruits, vegetables, low-fat dairy products, whole grains, poultry, fish, and nuts and limited red meat, sweets, and sugar-containing beverages. It was also lower in saturated fat and cholesterol than the typical Western diet and provided higher amounts of calcium, potassium, magnesium, fiber, and protein. The sodium content was kept constant in all three diets, with an intake of 3 g day^{-1}.

The study showed that the DASH diet was the most effective in reducing BP among both normotensive and hypertensive individuals. The DASH diet reduced SBP and DBP by 3.5 (5.3–1.6) mmHg and 2.1 (3.6–0.5) mmHg, respectively, in normotensive people. In hypertensive individuals, the diet reduced SBP by 11.4 (15.9–6.9) mmHg and DBP by 5.5 (8.2–2.7) mmHg.

Reductions in BP were seen within 2 weeks of diet initiation and maintained for 6 weeks following cessation of the trial. Dietary adherence rates were high, with low participant dropout rates, suggesting that DASH is a feasible long-term diet.

The DASH diet is recommended in guidelines as a key lifestyle choice for the management of hypertension. The reduction in BP observed among people with normal BP also suggests that following the DASH diet might be helpful in preventing hypertension. The DASH diet recommends 8–10 servings of fruits and vegetables per day, far exceeding the recommended 5–7 servings per day for the general population. Recommendations for dairy products are consistent with those for the general population: 2–3 servings per day of predominantly low-fat dairy foods. The DASH diet is nutritionally balanced and can be adopted by the general population. However, because of its relatively high potassium, phosphorus, and protein content, it is not recommended for individuals with stage 3 or 4 chronic kidney disease.

The exact mechanism by which the DASH diet lowers BP is unknown. It is likely the combination of beneficial nutrients it provides rather than the effect of individual factors. Because of the high proportion of fruits, vegetables, and low-fat dairy products, the DASH diet is low in sodium and high in potassium and calcium. Some benefits may be due in part to its

more close resemblance to a vegetarian diet, which has a positive impact on BP, than a traditional Western diet. Further studies have shown that when combined with a low sodium intake, DASH results in even further reductions in SBP and DBP. The DASH sodium study observed stepwise decreases in BP with successive decreases in sodium intake of 150, 100, and 50 mmol day^{-1}. Reductions in BP were of similar magnitude to those yielded by antihypertensive drug therapy for people with mild hypertension. For this population, following the DASH diet is a feasible alternative to medication, and doing so may delay the need to begin using medication.

Observations of older populations suggest that the DASH diet in combination with reduced sodium intake may lessen the effects of age-related increases in BP. Greater reductions in BP due to the DASH diet have been seen among adults more than 45 years of age than among younger people. The DASH diet has also been shown to benefit African Americans by 1.5- to 2-fold more than it does white Americans. African Americans are a high-risk group who experience higher rates of hypertension than do white Americans. Wide adoption of the DASH diet at a population level could reduce the occurrence of cardiovascular disease (CVD) caused by hypertension. It is estimated that a population-wide reduction in BP through the intake of a DASH-like diet would decrease CHD incidence by 15% and stroke incidence by 27%. Consumption of a DASH-like diet is also associated with lower all-cause mortality and mortality from stroke among adults with hypertension. In addition, because it is consistent with dietary patterns recommended for the prevention and management of other cardiovascular risk factors such as hyperlipidemia and type 2 diabetes, the DASH diet may well be effective in preventing CVD caused by factors unrelated to hypertension.

Behavioral Strategies to Address Hypertension

Behavioral strategies that address lifestyle modifications have long been recommended as first-line or adjunctive treatment for hypertension. Following a healthy diet, reducing sodium intake, moderating alcohol intake, and exercising regularly are some of the lifestyle modifications that have been shown to lower BP. However, achieving and sustaining the necessary diet and lifestyle changes to manage hypertension can be challenging.

A number of studies have used behavioral strategies to encourage adherence to diet and lifestyle recommendations. These strategies have been based on a variety of behavioral theories and models such as social cognitive theory, the transtheoretical model, behavioral self-management theory, and the relapse-prevention model. Typically, the strategies are incorporated into interventions that emphasize skills training, motivational interviewing, self-monitoring, and self-regulation. The type of intervention implemented and its efficacy depend heavily on the target population and the chosen setting.

The social cognitive theory-based 'DASH-dinner with Your Nutritionist' trial showed significant improvements in BP management. Participants were African American adults from low-income areas who had poorly controlled BP. The intervention was a joint university and neighborhood initiative conducted at local health-care centers with the aim of promoting adoption of the DASH diet. Participants were divided into groups of 12–15 that met for 1–2 h weekly for 8 weeks. The courses were based on building knowledge and self-efficacy for following the DASH diet and included a range of behavioral strategies such as incentives, role-playing, and engaging social support. The sessions began with a nurse measuring BP and weight; this was followed by a brief nutrition education presentation from a nutritionist, meal service and 'table talk,' and recipe demonstrations and taste testing. BP was significantly lowered among participants who attended at least six of the eight sessions. This style of intervention could be applied to other at-risk groups as an effective community-based technique for achieving behavior change.

A culturally tailored behavioral intervention for improving hypertension-related health behaviors among Hispanic adults conducted at a community health center in North Carolina consisted of six weekly group sessions based on principles derived from social cognitive theory and techniques of behavioral self-management. It emphasized the importance of the individual's ability to regulate behavior by setting goals and attaining the skills necessary to achieve them. Motivational interviewing was used to help participants move through different stages of change. Participants were encouraged to monitor their daily intake of fruits, vegetables, dairy, and fat and to record physical activity; were provided with education on the DASH diet, food preparation, and weight loss; and took part in exercise sessions and cooking demonstrations. Cultural adaptations included conducting the study in a familiar place (a community health center), using a Spanish-speaking interventionist, and incorporating culturally appropriate food choices and physical activity. At the end of the intervention, all physiological, diet, and exercise outcomes were more favorable, with the exception of fat intake.

Home-based behavioral interventions, delivered via telephone or over the Internet, offer effective strategies for managing hypertension for those in remote areas or with difficulty accessing health-care facilities. Combined BP monitoring and a tailored behavioral telephone intervention were shown to improve BP over a 24-month period compared with standard clinical care involving antihypertensive medication. The telephone intervention centered on self-management strategies including adhering to a DASH-style diet, moderating alcohol intake, stopping smoking, and increasing physical activity.

Overall, evidence suggests that behavioral interventions are effective in managing hypertension in the short term, usually up to 6 months. A review of three common education-based behavioral interventions for managing hypertension – counseling, a structured training course, and self-monitoring of BP – showed that counseling about diet and lifestyle modifications was the most effective and offered significant improvements in BP compared with standard medical care. Long-term effectiveness has not yet been demonstrated. Despite this, behavioral interventions should be part of a comprehensive approach to managing hypertension that includes addressing environmental and cultural factors that encourage poor dietary and lifestyle habits.

Lifestyle Versus Medication for Hypertension

According to the AHA, reducing hypertension requires adopting seven key lifestyle modifications: eating a healthy diet, engaging

in regular physical activity, maintaining a healthy weight, managing stress, not smoking, adhering to prescription medication regimens, and limiting alcohol intake. Improving diet means eating higher nutrient quality foods and decreasing portion sizes if weight loss is needed. There are many options for medications to treat hypertension, including diuretics, antiadrenergics, direct-acting vasodilators, calcium channel blockers, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers. The most common hypertension drugs act on the renin–angiotensin–aldosterone system, which affects blood volume, arterial pressure, and heart function.

The major challenge to pharmacotherapy is poor adherence. Nonadherence was observed among 28% of US patients with hypertension, with similar rates for hyperlipidemia and diabetes. Developing effective strategies to improve adherence is critical to preventing stroke and death. A Finnish study found that the relative risk for fatal and nonfatal strokes was 4.5 for patients with adherence rates of 30% or below compared with patients with adherence rates of 80% or above.

Innovations to improve adherence can be patient-focused or integrated into the health-care system. Data to support the use of electronic medication packaging devices are limited and variable. Devices with digital displays and audible alarms were found to be most useful in improving adherence; in addition, interventions integrated into the health-care system with greater complexity were often associated with improved adherence. For example, an Internet-connected packaging and feedback intervention called Glowcaps has been found to improve medication adherence by 27%. Lottery-based financial incentives have also shown promise. Volpp and colleagues found that the proportion of incorrect pills taken over 3 months decreased to 2.3% (with a \$5 day^{-1} expected lottery value) and 1.6% (with a \$3 day^{-1} expected value) compared with a historic mean of 22%.

Innovations to Address Hypertension

Individual-level interventions such as education campaigns that promote the DASH diet or drug therapy can reduce the prevalence of hypertension; however, only population-based strategies that target the underlying causes of high BP have the potential to reduce incidence and shift the distribution of hypertension. The WHO recommends adopting comprehensive national evidence-based policies to combat hypertension such as lifestyle modification, reductions in alcohol and sodium consumption, and increased physical activity and including more systems-based approaches such as food policy, voluntary reformulation of processed foods by industry, regulation, and improvement of the quality and consistency of medical care for patients. Over the last few decades, there have been many examples of communities' adopting comprehensive strategies to reduce heart disease and stroke and improve BP control.

The North Karelia Project

The North Karelia Project in Finland is perhaps the most widely cited example, serving as a model that has been replicated in communities throughout the world. In the 1960s, CHD mortality among Finnish men was the highest in the world. In 1972, a pilot program was launched in North Karelia province to reduce the prevalence of risk factors such as smoking, high serum cholesterol, and BP. Several interventions were implemented in collaboration with multiple stakeholders such as health service providers, nongovernmental organizations, businesses, and the media. After 5-year results showed a significant decline in risk factors in North Karelia compared with a control province, a national prevention strategy was gradually implemented based on the same principles. Recent analysis of 35-year trends in cardiovascular risk factors in Finland have shown an 80% decline in coronary mortality since the 1960s and continued reductions in most risk factors including BP, although obesity rates are on the increase.

Million Hearts™

Million Hearts™ is a national US campaign launched in September 2011 with the goal of preventing 1 million heart attacks and strokes by 2017. More specifically, Million Hearts™ sets targets for improving BP control (by 65% from a baseline of 45%) and reducing sodium intake (a 20% reduction from a baseline of 3.5 g day^{-1}). The campaign is an innovative public–private partnership created by the Centers for Disease Control and Prevention and the Centers for Medicare and Medicaid Services in partnership with more than 100 private sector and nonprofit organizations to focus, coordinate, and enhance CVD prevention activities. Partner organizations include the AHA, the American Pharmacists Association, the YMCA of the United States, the retail pharmacy group Walgreens, the insurance company UnitedHealthCare, and many others. The strategic approach involves both primary CVD prevention (empowering Americans to make more healthy lifestyle choices by reducing tobacco use and sodium and trans fat consumption) and secondary CVD prevention by emphasizing the widespread and consistent use of the *ABCs* (*a*spirin for people at risk, *b*lood pressure control, *c*holesterol management, and *s*moking cessation). Tactically, Million Hearts™ targets both clinical and community prevention services and systems by

- implementing education campaigns to increase awareness of modifiable risk factors;
- using health information technology to increase access to and delivery of timely, evidence-based care;
- promoting community efforts to discourage smoking and reduce sodium in the food supply.

Examples of Innovative Partnerships to Implement These Tactics

Sodium reduction

The California Department of Public Health and eight independent restaurants in northern California worked together to reduce sodium content in meals, achieving an average 26% reduction across 15 meals offered at the restaurants.

BP risk reduction

Measure Up/Pressure Down is a partnership with the American Medical Group Foundation to support hypertension control in

medical groups and health systems. To date, 30 participating medical groups have helped 30 000 people reduce their risk for heart attack and stroke.

Heart360

Heart360 is a home BP-monitoring program implemented by pharmacists in which participants upload their home BP measurements three to four times per week to the AHA's Heart360 Web site. Clinical pharmacy specialists monitor the patients' BP readings and adjust medication as needed. This program has led to improved BP control, increased reductions in BP, and greater patient satisfaction with care.

Government salt regulation

Because community efforts to reduce hypertension have existed for decades and prevalence remains high, public health officials and academics have increased their requests that governments use tools such as regulation to improve population health. The US Food and Drug Administration does not regulate salt, because it is currently classified as 'generally recognized as safe.' Sodium content is, however, one of those that manufacturers of packaged and processed foods are required to disclose on the Nutrition Facts panel. Given persistent high levels of sodium consumption and the fact that ~75% of consumed salt comes from packaged, processed, and restaurant food, interventions such as regulation aim to reduce the availability of sodium in the food chain and, thus, reduce consumption; improve public health; and reduce health-care costs. Several countries, including the United Kingdom, Finland, Portugal, and Japan, have reduced population-wide salt consumption successfully through a combination of consumer education and government regulation.

He and colleagues estimated the effect of a salt reduction program in the United Kingdom initiated in 2003–04 and found that sodium consumption decreased by 1.4 g day^{-1} between 2003 and 2011. During the same period, deaths from heart attack declined by 40% and deaths from stroke by 42%. Although other factors could account for these improvements, such as increased fruit and vegetable consumption and greater BP control, the study still found a significant decrease in BP among untreated individuals (i.e., people not on antihypertensive medication) even after adjustment for several factors, including fruit and vegetable consumption and body mass index. This suggests that salt intake reduction played a significant role. According to the UK government, the program saved an estimated £1.5 billion year^{-1} in health-care-related costs. Despite this positive outcome, a sobering finding of the study is that average salt intake in England was still 35% higher than the recommended daily level.

A study by Bibbins-Domingo and colleagues estimates that a 3 g day^{-1} reduction of salt in the United States would reduce annual deaths from all causes of CVD by between 44 000 and 92 000 and save $10 billion to $24 billion each year in avoided health-care costs. All segments of the population would benefit, and the regulatory intervention would be cost saving even at a more modest salt reduction of 1 g day^{-1}. Despite the public health need, estimated health-care cost savings, and calls from the Institute of Medicine for the Food and Drug Administration to regulate salt, there is political resistance to government regulation of the food industry.

Australia has proposed a stepwise reduction in salt based on a responsive regulatory approach. Food manufacturers are challenged to meet 'legislative scaffolds' in reducing salt via product reformulation. This model supports industry collaboration and innovation. Phase 1 allows food manufacturers to negotiate reformulation targets. Phase 2 requires companies that have failed to reformulate products to include high-salt warning labels on these products; this would occur concurrently with media and marketing campaigns encouraging reduced salt intake and release of company compliance data. Finally, phase 3 imposes court-enforced penalties on companies that continue to fail to reduce salt. This approach encompasses several components that predict success: industry collaboration, stepwise reductions that allow companies to reformulate and consumer taste to adjust, and incentives for compliance.

Industry efforts to reduce sodium

Voluntary commitments have been made by eight packaged-food companies that collaborate in the International Food and Beverage Alliance. These companies met or exceeded their sodium reduction targets in 2011 (Table 3). Large-chain restaurants have also made efforts to reduce sodium. McDonald's

Table 3 Sodium reduction targets

Company	*Territory*	*Target*
General Mills	United States	−20% across top 10 product categories (2015)
Grupo Bimbo	United States/ Mexico	−30% across bread portfolio and −15% in snacks key brands (2015)
Kellogg	Global	Continue responsible sodium reduction globally
Kraft Foods	Global	Continue sodium reduction efforts, in addition to region-specific goals
	Latin America	−10% across cheese and biscuit portfolio (by end 2013)
	North America	−10% across product portfolio (by end 2012)
Mars	Global	−15% across entire global food portfolio (2015)
Nestlé	Global	−25% in products with a sodium content >100 mg/100 kcal (2005–10). Continue reducing sodium levels by an average of 10% in products that can best contribute to reducing sodium intake (e.g., soups, recipes, and pizza portfolio) (2012–15)
PepsiCo	Global	−25% in key global brands in key countries (2015)
Unilever	Global	The first milestone was to reduce salt levels to an interim target of 6 g day^{-1} by the end of 2010. This required reductions of up to 25%. Unilever aims to reduce levels by a further 15–20%, on average, to meet the target of 5 g of salt per day. The company's goal is to help consumers meet the recommended 5 g of salt per day based on globally recognized dietary guidelines

has pledged to cut sodium by 15% across US menu items by 2015 and already has reduced salt in fries by 20% in Europe.

Internationally, especially in developing countries where informal food sector calorie intake is high, large companies are challenged with maintaining the taste profile of products that adhere to regulation, while informal sector products that fall below regulation continue to have high salt content. Since regulations are only as strong as their enforcement, which is weak in many countries, the government must consider alternative ways of encouraging industry from reducing sodium in products aside from only regulation. Companies reducing sodium often do not market this change due to consumer bias against products labeled low sodium. Rather, companies often reduce sodium without changing their marketing – known as stealth reduction – and consumers must compare the old and new Nutrition Facts panel to know the change.

Conclusion

Hypertension is a significant burden worldwide, increasing the risk for CHD and stroke. Poor diet is a leading contributor to hypertension risk, and improving diet is a key factor for primary and secondary prevention of hypertension. Several dietary factors contribute to hypertension risk, including sodium consumption and alcohol intake, whereas intake of potassium and fish oil reduces hypertension. Overall, the DASH diet has strong antihypertensive effects. Medications exist to support hypertension control, although poor adherence is a challenge. Behavioral strategies that address lifestyle modifications are recommended to treat hypertension. Innovations have been developed to address hypertension through comprehensive community-level strategies. In addition, the food industry has made significant progress in reducing sodium in packaged foods.

Hypovitaminosis A

NW Solomons, Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM), Guatemala City, Guatemala

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Hypovitaminosis A is the deficiency of vitamin A, a fat-soluble vitamin discovered simultaneously in 1913 by two groups of North American scientists, McCollum and Davis in Wisconsin and Osborne and Mendel in Connecticut. It has been endemic in most parts of the world at one or another time in history, and its complications and consequences can greatly increase the risk of mortality, especially in childhood. For this reason, it has been considered one of the most prioritized public health problems to be addressed by the World Health Organization and health authorities of countries in which hypovitaminosis A is endemic. A WHO map of nations with endemic vitamin A deficiency is shown in Figure 1.

The Vitamin

Vitamin A belongs to a class of compounds known as retinoids. The circulating form in blood is as the alcohol form: retinol. Retinol has a molecular weight of 286.5 kDa. In biological systems, however, it is more often found in other chemical forms. In foods of animal origin, the vitamin is part of a retinyl ester, that is, with the retinoid bound to a fatty acid. This is also the form of the vitamin in storage in human tissues. In the retina of the eye, where it participates in both daylight vision and nocturnal vision, it is the retinaldehyde (retinal) form that is active in the visual signal of the retinal rods and cones. The most important among the vitamin's physiological functions is its regulation of transcription at the level of the cell nucleus. The chemical form of the retinoic acid (RA) participates with specialized nuclear receptor sites that act as transcription factors.

Because of its size as an organic molecule with only a limited number of exposed oxygen groups, retinoids are better soluble in lipids (fat soluble) and less soluble in water. Retinol and its derivatives are relatively stable to heat but are degraded by exposure to white light.

Vitamin A Transport

Vitamin A can be transported to and from the different sites in the body by various ways. One involves the transport of the recently absorbed vitamin from the intestine to the liver. This involves transport within the lipoproteins formed in the intestinal cells to export newly absorbed lipids (chylomicrons). These travel from the lymph into the bloodstream and are transformed into increasingly smaller sizes until they are completely cleared by the liver. Once in the liver, vitamin A is stored for a short term in the hepatocytes and for a longer term in special stellate fat-storage cells of the liver. To be mobilized for transport to the peripheral tissues, vitamin A in the hepatocyte is attached to a molecule of a specialized transport protein, retinol-binding protein (RBP) (molecular weight = 21.1 kDa). This, in turn, couples with transthyretin (prealbumin, molecular weight = 55.0 kDa) for transport in the systemic circulation.

The exact mechanism of transfer of vitamin A across the placenta from the mother to the developing fetus is not known. What is established is that, as a fat-soluble vitamin, the movement is much slower than that of water-soluble vitamins. This has implications for preterm infants, who will be born before having the chance to accumulate appropriate body stores of the vitamin. Once born, the infant ideally will be fed with breast milk exclusively for the first 6 months of life. The transport and delivery of vitamin A to human milk appear to be more closely dependent on recently ingested vitamin A than on the maternal liver stores. Rather than moving to the mammary glands from the liver on RBP, it is taken up directly from the chylomicrons for its incorporation into milk.

Consequences of Vitamin A Deficiency

The essence of a discussion of hypovitaminosis A revolves around the consequences of vitamin A deficiency. These include metabolic and functional consequences that may not express themselves in a clinical manner. For the practitioner, however, the clinical signs and symptoms of more advanced deficiency are an important concern.

Metabolic and Functional Role of Vitamin A

Vision and the eye

Vitamin A is instrumental in vision both in its neurosensory mechanism and for the structural integrity of the ocular structure. Vitamin A is part of the classical visual cycle, which involves not only the rod structures of the eye's retina for vision in dim light but also the cone structures for daylight color vision. 11-*cis*-Retinal is linked to an opsin protein. Exposure of this unit to a photon of light produces a decoupling accompanied by the transduction of a signal via the optic nerve interpreted as vision. The all-*trans*-retinal released is converted to all-*trans*-retinol and then regenerated to the 11-*cis* form for recoupling to the opsin to await another cycle. Vitamin A is also important for vision, supporting the anatomical integrity of the eye. Ocular mucins, a secretory variety from the goblet cells of the conjunctival cells of the eye, and another membrane-spanning mucin from both conjunctival and corneal lining cells are exquisitely sensitive to vitamin A deficiency. It is extrapolated, moreover, that there is probably similar mucin-regulatory process at play within the oropharyngeal, gastrointestinal, and urinary tracts as well. It is assumed that the transcription of the peptide skeleton of the mucin glycoprotein is suppressed by the absence of or deficiency in nuclear RA.

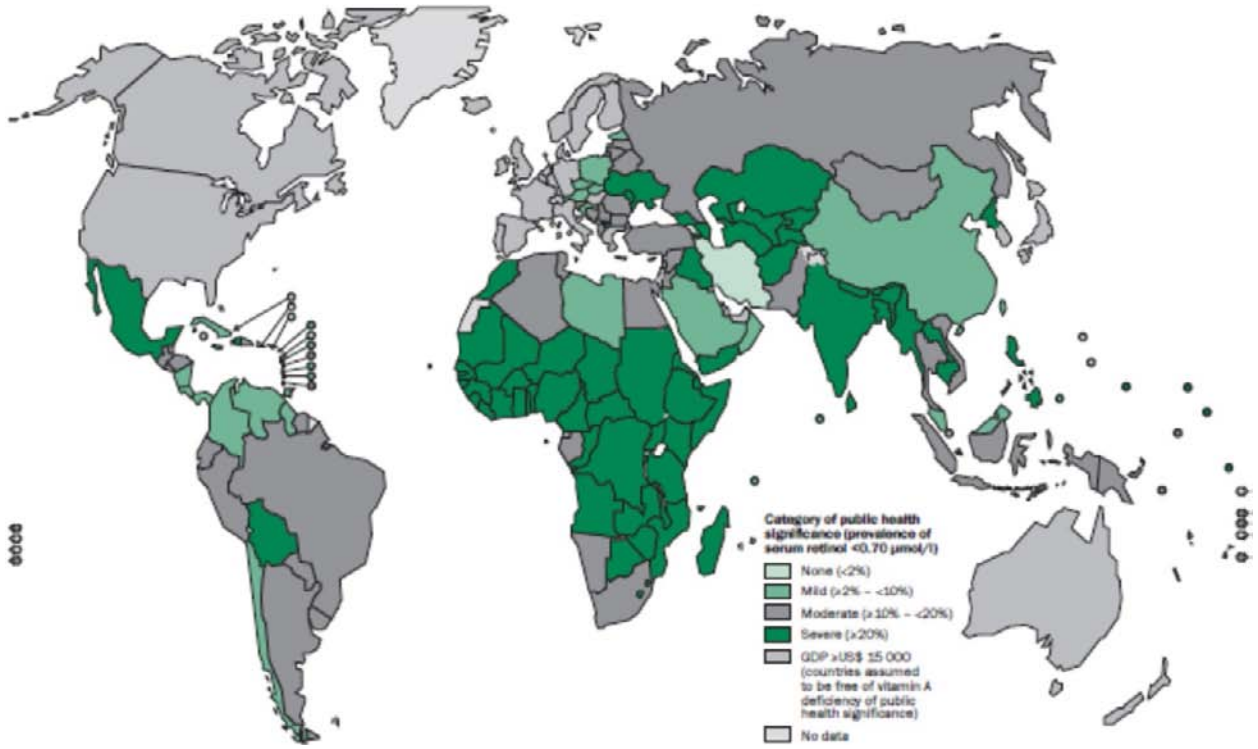

Figure 1 Countries and areas with survey data and regression-based estimates: preschool-age children. Reproduced from the WHO Summary tables and maps on global prevalence of vitamin A deficiency 1995–2005.

The cell cycle

RA, derived from vitamin A, is a pivotal signaling molecule, interacting with RA receptors in the nuclei of all cells. It can either enhance or inhibit transcription depending on the configuration of the nuclear receptor. As such, it is instrumental in regulating all aspects of the cell cycle from maturation and differentiation to proliferation and programmed cell death (apoptosis). RA is instrumental in the expression of the delta-5 desaturase enzyme, working with elongating enzymes to form the long-chain essential fatty acids of both the omega-3 and omega-6 series. In one aspect, they participate with RA in the transcriptional regulation. Yet another function is in modulating inflammation.

Immunity and host defense

The immune response is a final function worthy of mention. Recently, several lines of evidence have converged to show that RA, a major oxidative metabolite of vitamin A, plays a key role in the differentiation of T-cell subsets, the migration of T cells into tissues, and the proper development of T cell-dependent antibody responses.

Clinical Manifestation of Human Vitamin A Deficiency

Night blindness

This symptom manifests as the inability to adapt to vision under dim light. Sufferers may stumble into objects at night. It relates to the disruption of the visual cycle by depriving the retinal rods of the precursor of 11-*cis* retinal.

Xerophthalmia and nutritional blindness

These manifestations are not related to the biochemistry in the retina, but rather to the decline in mucus production across the surfaces of the eye. Xerophthalmia literally derives from ancient Greek for *dry eye*. It evolves in stages from dryness of the conjunctiva, to the formation of foamy deposits of debris on the lateral aspect of the conjunctiva (Bitot's spots), to drying of the cornea itself. Depending on the extent of corneal damage, degrees of visual impairment range from scarring to complete perforation into the ocular globe. The latter produces full blindness.

Skin changes

A number of skin changes have been described in vitamin A deficiency, but the thickening to mounds around the hair follicles (follicular keratosis), probably due to cell-cycle dysregulation, is the most common.

Gastrointestinal dysfunction

Dry mouth, swallowing difficulties, and diarrhea have been described in vitamin A-deficient individuals. The specific interference with the production and secretion of mucin for the normal maintenance of the mucus membranes is the putative origin of clinical manifestations, perhaps in conjunction with altered renewal of the epithelial lining.

Decreased infectious disease resistance and resilience

Vitamin A supplementation has been shown to retard the emergence of a recurrent childhood infection following the resolution of pneumonia or diarrhea. This may be a

pharmacological effect, however, as the epidemiology does not recognize dramatically increased incidence rates in the context of hypovitaminosis A.

Assessment of Vitamin A Status

Most nutrient deficiencies pass from a milder, subclinical phase on the way to a more severe, clinically evident stage, in which signs, symptoms, or both become manifest to the patient, the family, or the health practitioner. The consequence is that deficiency in the subclinical stage can only be revealed by some form of laboratory or functional test. This is notably true for vitamin A. Moreover, the assessment of vitamin A status can proceed for two qualitatively distinct goals. One is to determine the status of a given *individual* in the clinical setting; the other is to assess the risk of a *population* for endemic hypovitaminosis A.

Assessment of Individual Status

In a conceptual manner, in order to identify vitamin A deficiency in an individual, one would ideally need standards of what constitutes an adequate amount of vitamin A in a body of a given size or the concentration of vitamin A in the human liver, which constitutes the main reserve. Due to its invasive nature, liver biopsy can only be used in exceptional circumstances (e.g., when primary liver disease is suspected) or in the postmortem state.

Because circulating levels of retinol are homeostatically regulated, serum or plasma retinol is a poor indicator for an individual. In an experimental setting, such as evaluating an intervention, total body dilution studies with stable isotope-labeled vitamin A can give a quantitative estimate of body stores.

In a clinical setting, quantitative dark-adaptation testing can be used to confirm indications from clinical chemistry. Of course, with advancing deficiency, the symptom of night blindness and the ocular manifestations of xerophthalmia provide diagnostic evidence.

Collective Epidemiological Assessment of Status

Population-level public health assessment addresses one primary question: is there an indication of an endemic hypovitaminosis A that would warrant a public health intervention? In an official manner sanctioned by the WHO, the prevalence of retinol concentrations is below 20 dl^{-1} in a nationally or regionally representative sample of children aging 6–59 months. Additionally, the symptom of night blindness in the same population sample is an alternative indicator of population risk.

As discussed, the circulating retinol level is problematic due to its homeostatic regulation. It is also susceptible to distortion by the presence of inflammation or infection, which decreases circulating concentrations. A functional test of hepatic handling of newly absorbed vitamin called the modified relative dose response (MRDR) has been shown to classify low liver stores from normal ones; the MRDR technology, however, is expensive and confined to a very limited number of centers around the world, and it cannot detect elevated stores. Interestingly, given the growing concern for excessive vitamin A exposure as the result of confluent interventions, in Guatemala, the isotope dilution approach is being introduced into the epidemiological domain.

Dietary Sources of Vitamin A

Two diet-related determinants are imposed upon the public health occurrence of hypovitaminosis A as well as the geographic distribution of its endemicity (see Figure 1). One is the variety and abundance of vitamin A-rich foods and the other is the economic, cultural, and physiological issues relating to their accessibility and acceptability of these sources. The most active and available form of the vitamin, preformed vitamin A in a retinyl ester form, is only found in foods of animal origin; these are expensive and often consumed only selectively for cultural or religious regions. As discussed, plants are a source of a less biologically available form of provitamin A carotenoids. Even in this domain, the richer (orange-colored) sources may be more expensive than the less bioconvertible forms in dark-green leafy vegetables (DGLVs) and herbs. The primary, but not exclusive, contributor to hypovitaminosis A is the chronic consumption of a diet that does not fulfill on an average daily basis the recommended intakes to satisfy requirements. The recommended amounts, arrayed by age, sex, and physiological condition, are provided in Table 1.

Expression of Vitamin A Content in Foods and in the Diet

The expression of vitamin A in foods and in pharmaceutical preparations has evolved over the years. The options are international units (IUs, original), retinol equivalent (RE, 1967), and retinol activity equivalent (RAE, 2001). They are not entirely mutually interconvertible, which is a source of considerable confusion.

International units

The initial system was the IU. It was an expression for food analysis, but for dietary purposes, it has fallen into disuse. It persists today only in the pharmaceutical domain. Medicinal supplements are expressed in IU. One IU vitamin A is approximately the biological equivalent of 0.3 μg retinol, or of 0.6 μg beta-carotene. The IU system cannot account for provitamin A sources other than beta-carotene.

Retinol equivalents

This system dates back to 1967, but it is still the standard of the UN system: WHO and FAO. One retinol equivalent is equal to

- 1 μg of retinol,
- 6 μg of all-*trans* beta-carotene,
- 12 μg of other provitamin A carotenoids.

Retinol activity equivalents

As it was recognized that provitamin A carotenoids were more bioconvertible when dispersed in oil but less convertible when consumed from foods than what is considered in the RE, the

Table 1 Recommendations for daily intake of vitamin A as derived from the United Nations system (WHO/FAO) and the US–Canada consultation (Institute of Medicine)

	United Nations system (WHO/FAO)		*US and Canada dietary reference intakes*	
	Estimated average requirements[a]	*Recommended nutrient intakes*	*Estimated average requirements*	*Recommended dietary allowances*
Population	*RE per day*		*REA per day*	
0–6 month	–	375	–	400 AI[b]
7–12 month	–	400	–	500 AI
0–1 year	290	400	–	–
1–3 year	320	450	210	300
4–6 year	320	450	–	–
4–8 year	–	–	275	400
7–9 year	360	500	–	–
9–13 year	–	–	445[c],420[d]	600
10–18 year	430	600	–	–
14–18-year-old males	–	–	630	900
14–18-year-old females	–	–	483	700
Adult males	430	600	625	900
Adult females	360	500	500	750
Pregnant	570	800	550	770
Lactating	610	850	900	1300

[a]EAR retrofitted a posteriori from RNI values after Allen et al. (2006) and rounded off to zero.
[b]AI, adequate intake.
[c]Males.
[d]Females.

Dietary Reference Intakes (DRIs) for the United States and Canada reformed the expression to RAE. One RAE is equal to

- 1 μg of retinol,
- 2 μg of all-*trans* beta-carotene,
- 12 μg of all-*trans* beta-carotene,
- 24 μg of other provitamin A carotenoids.

If the vitamin A source in question is entirely preformed vitamin A, then the three expressions do become mutually interconvertible; otherwise, they diverge substantially.

Dietary Vitamin A of Animal Source Origin

Cod-liver oil, goose liver pate, beef liver, and chicken liver would rank among the four richest sources commonly consumed. Per 100 g portion, these would range from 1000 to 30 000 RAE, primarily as retinyl esters. Eggs and dairy items are also dietary sources, at lower specific contents. It should also be noted that provitamin A carotenoids also form part of flesh foods and milk. Intact carotenes are the pigment that gives the yellow tinge to animal fat; as such, this can supply vitamin A to the consumer. Beef liver also has provitamin A carotenoids as a minor storage component.

Vitamin A in human milk is primarily preformed retinyl esters, with a variable amount of provitamin A, depending on the carotene content of the maternal diet. Human milk should contain from 300 to 700 $\mu g\,l^{-1}$ to be both nourishing and safe for the exclusively breast-fed infant. This compares with 450 $\mu g\,l^{-1}$ in unfortified bovine milk and 900 $\mu g\,l^{-1}$ in fortified commercial milk.

Dietary Vitamin A of Plant Source Origin

The other major domain of vitamin A intake generally constitutes from 40% of total vitamin A intake in industrialized countries and up to 100% in societies that are totally vegetarian by religious practice or economic necessity. Exotic and regional sources of provitamin A include unrefined red palm oil (*Elaeis* spp.) and oil from the buriti fruit (*Mauritia vinifera*) from Brazil, and other parts of Latin America were reported to have ~6000 and ~50 000 RE per 100 g of oil, by using the 1967 conversion factors. As oil suspensions, the newer conversion-efficiency norms of the DRI would revalue these amounts to ~18 000 and 150 000 RAE per 100 g.

For Western societies, dehydrated forms of orange vegetables, such as carrot or sweet potato chips, can provide over 1000 RAE per 100 g. Carrots, sweet potato, and pumpkins as well as kale and other DGLVs can exceed 700 RAE in a 100 g portion when cooked and prepared. Most other edible DGLVs have important quantities of provitamin A as do other orange fruits and tubers.

Provitamin A carotenoids and their conversion to active vitamin A

A series of plant pigments, including beta-carotene, alpha-carotene, and alpha-cryptoxanthin, among others, can be converted into active (retinoid) vitamin A by enzymatic activity in the small intestine. The responsible enzyme uses molecular oxygen to cleave the carotenoid molecule in the center of the chain, yielding either two (in the case of beta-carotene) or one (with other provitamin A carotenoids). The enzyme has been termed carotene-15,15′-monooxygenase (CMO I), and it is

located inside the intestinal cells. A certain amount of fat is required in a meal containing provitamin A to evoke the intestinal mechanisms of fat digestion and absorption and make its intestinal handling most efficient.

Genetic traits govern the efficiency of action of the carotene oxygenase enzyme in the intestine. Conversion efficiency for plant precursors to the active vitamin has a genetic component with different assortment of alleles conveying distinct extents of bioconversion. Ethnic groups with historically more vegetarian-type diets seem to have conserved the more efficient cleavage constitution. An important caveat is the fact that the conversion of provitamin A to the active form in the intestine is homeostatically regulated and self-limited.

There is no example of developing *hyper*vitaminosis A from excessive intake of provitamin A sources. The only consequence is a yellowish discoloration of the skin (carotenodermia), which can be unsightly but is harmless to health and reversible upon reduction of carotene intake.

Nondietary Mechanisms for Vitamin A Deficiency

Dr. Victor Herbert sagely pointed out that, beyond an insufficient intake of a nutrient, mechanisms that impaired its intestinal uptake, interfered with its internal utilization, or accelerated its excretion would also contribute to poor nutritional status. With respect to vitamin A, we can identify important instances of these factors. Cystic fibrosis and other diseases of the liver or pancreas that impair fat digestion will impair vitamin A uptake, as will small intestinal diseases such as celiac disease, persistent diarrhea, or environmental enteric dysfunction. Since its mobilization is dependent on a hepatic transport protein (RBP), protein deficiency and certain liver diseases will impair the utilization. During fever, excessive amounts of vitamin A are lost in the urine. Acute or chronic febrile illness, therefore, can reduce or deplete vitamin A reserves. Finally, certain internal threadworms (filarial) have a high specific requirement for vitamin A. Patients with high body burdens of these parasites in their tissues might suffer from the competition if dietary sources are also marginal.

Prevention of Hypovitaminosis A

There is a generally accepted hierarchy of behaviors and measures that can be applied, alone or in combination, to prevent hypovitaminosis A in vulnerable populations. These include dietary diversification, food fortification and periodic oral supplementation, and general health measures. They differ with respect to the time frame for onset of effect, popular acceptability and long-term sustainability, economic cost, and risk of adverse consequences. On the dietary side, they would include consumption on a daily basis of the amounts of vitamin A recommended on an age-specific basis. The recommendations from two authoritative sources are provided in Table 1.

Dietary Diversification for the Prevention of Hypovitaminosis A

Dietary diversification is a somewhat euphemistic term for a strategy to improve the nutritional quality of a population by enabling them to substitute foods of lower micronutrient density for foods of higher nutrient content. In the present context, it would mean increasing the percentage of the required energy from the rich sources of preformed vitamin A or provitamin A than are currently in the diet. One example would be the substitution of red palm oil for the refined variety; the red staining of traditional dishes, however, generally deters its adoption.

Fortification for the Prevention of Hypovitaminosis A

Several countries with background endemic conditions for hypovitaminosis A have opted to mandate the fortification of one or another staple food that is consumed widely throughout a population. Table sugar and edible oils with added retinyl esters are the prime examples. Wheat and maize flours have also been vitamin A-fortified.

Fortification of commercial products

More and more, commercial products, such as ready-to-eat cereals or precooked gruels. This category of fortification has been termed 'market-driven' fortification. Problems of overconsumption may arise when this combines with publically mandated programs; this has been documented in preschool and school children in Guatemala.

Biofortification of plants

The amount of provitamin A in plants can be enhanced either by crossbreeding of high-carotenoid plants (i.e., hybridization) or by genetic modification, that is, the insertion of carotene-regulating genes from another organism. Orange-fleshed sweet potatoes are an example of the former. Golden rice is an example of the latter.

Home fortification for complementary food

A mode of adding vitamin A, along with a multiple host of companion micronutrients, directly to complementary foods to enrich the dietary intake of infants and toddlers during the weaning process has arisen. It is in response to the generally low micronutrient density of traditional paps and gruels of natural cereal grains. Foodlet, a crushable tablet, was developed during the first the International Research on Infant Supplementation meeting in 1999, with weekly periodicity. Sprinkles® was the first in the series of currently expanding microencapsulated micronutrients in a sachet. The major thrust has been combating iron deficiency anemia, but it contains 300 RAE per sachet. Lipid nutrient spreads such as Nutributter®, derived from Plumpy'Nut®, generally supply 400 RAE per 20 g sachet.

Supplementation for the Prevention of Hypovitaminosis A

Periodic supplementation is recommended for children in the appropriate settings aged 6–59 months. The periodicity is once every 4–6 months; the latter is the standard. The dosage is 100 000 IU between 6 and 11 months and 200 000 from 12 months onward. The trigger public health condition for implementing the program is a prevalence of night blindness in children of this age range of 1% or greater or a prevalence of 20% low serum or plasma retinol concentration ($<20\ \mu g\ dl^{-1}$)

in a representative survey of under-fives. When such survey data are unavailable, severe poverty or unsanitary conditions often instigate the adoption of the program *under an abundance of caution* motivation. Poor sustainability and low coverage rates among the most rural populations have been documented as common operational problems in high-dose supplementation. The official WHO recommendations for supplementation, revised in 2011, are shown in Table 2.

General Health Measures for the Prevention of Hypovitaminosis A

The failure to absorb vitamin A has the equivalent negative effect on vitamin A status as the failure to have consumed it in the first place. Treatable small bowel diseases such as celiac disease and Crohn's jejunoileitis will respond to remission therapy with normalization of vitamin A uptake. In irreversible pancreatic insufficiency, such as in cystic fibrosis, meals accompanied by oral pancreatic enzymes will improve absorption of lipids including fat-soluble vitamins. In the tropics, recurrent and persistent diarrhea, intestinal protozoan infections, helminthes, and environmental enteric dysfunction are treatable small bowel afflictions that can interfere with uptake of dietary vitamin A. Immunizations to prevent enteric illness contribute to gut resistance. Decreased exposure to parasites through environmental sanitation, appropriate hygienic practices, and periodic deparasitization can reduce the rates of protozoan and helminthic parasitosis, which have been associated with lower vitamin A status.

Febrile illnesses lead to urinary wasting of vitamin A. Vaccinations are available from many severe infectious. Malaria and dengue fever can be prevented in part with the use of insecticide-impregnated bed nets. Appropriate treatment with antimicrobials and antipyretic medicines can limit the ravages of fever and reduce vitamin A loss.

Treatment of Hypovitaminosis A

With the exception of clinical situations, the prophylactic regimens discussed earlier in the text would restore – at least transiently – a normal vitamin A status in a child with depleted vitamin A stores. The clinical situations of note, both considered to be a medical emergency, are (1) acute xerophthalmia and (2) measles with a medical complication.

Any child reported to have night blindness or having ocular manifestations of xerophthalmia should immediately receive an oral dose of 200 000 IU of vitamin A and an equal dose on the following calendar day. If the conjunctival and corneal lesions are severe, direct care for the integrity of the eye should accompany vitamin A dosing.

The eradication of measles has been retarded in recent years by resistance in certain populations to vaccination. It has become recrudescent in many areas of the world. When hospitalization for a complication of measles such as pneumonia or encephalitis occurs, even in an area not certified as endemic for hypovitaminosis A, it is prudent to provide high-dose oral vitamin A in the schedule described in the preceding text: 200 000 IU immediately, repeated on the following day.

Hypervitaminosis A as a Consequence of Combating Hypovitaminosis A

One can have too much of a good thing and this is becoming potentially and actually true in current efforts to eradicate and prevent endemic hypovitaminosis A. Concerted efforts to increase the intake of vitamin A – both mandated and voluntary – can tip the pendulum of dietary exposure to the vitamin from deficit to excess. Under certain circumstances, and in certain dosages and forms, too much vitamin A can be as bad as or worse than an insufficiency.

Table 2 The 2011 World Health Organization guidelines on vitamin A supplementation

Population category	*Guideline for vitamin A supplementation*
Neonates	The WHO does not recommend vitamin A supplementation for neonates as a public health intervention
Infants 1–5 months of age	The WHO does not recommend vitamin A supplementation for infants 1–5 months of age as a public health intervention. Mothers should continue to be encouraged to exclusively breast-feed infants for the first 6 months to achieve optimal growth, health, and development
Infants and children 6–59 months of age	The WHO does recommend high-dose vitamin A supplementation every 4–6 months for infants and children 6–59 months of age, as a public health intervention to reduce child morbidity and mortality
Pregnant women	The WHO does not recommend vitamin A supplementation during pregnancy as part of routine antenatal care. However, in areas where there is a severe public health problem of vitamin A deficiency, the WHO recommends giving vitamin A supplementation during pregnancy for the prevention of night blindness
Postpartum women	The WHO does not recommend vitamin A supplementation for postpartum women as a public health intervention for the prevention of maternal and infant morbidity and mortality
During pregnancy for reducing the risk of mother-to-child transmission of HIV	Currently, the WHO does not recommend vitamin A supplementation in HIV-positive women as a public health intervention for the prevention of mother-to-child transmission of HIV

The WHO standard for 'high-dose' vitamin A supplementation refers to an oral dose of 100 000 IU (30 303 RE) for 6- to 12-month-old infants and 200 000 IU (60 606 RE) from 1 year onward, including adults. These are also the age-specific dosages for specific therapeutic indications for oral vitamin A supplementation.
Modified from the guidelines for routine immunizations of the World Health Organization. Available at: http://www.who.int/nutrition/publications/micronutrients/guidelines/en/index.html.

Acute exposure to massive amounts of preformed vitamin A can produce a series of consequences leading to death. These include blurring of vision; headaches and coma, due to increased intracranial pressure; and acute liver failure due to hepatotoxicity. Various skin rashes can also occur. The visceral organs of marine mammals, such as seals, walruses, narwhals, and polar bears, have enormous concentration of retinyl esters. The food culture of traditional inhabitants of arctic climes evolved to recognize the hazards of the organ meats of these species, and they were consumed in moderation. Arctic explorers were unaware of the danger and avidly consumed whole polar bear liver, which contains upward of 350 000 IU per 100 g, succumbing to the aforementioned syndrome and alerting the medical community of acute hypervitaminosis A. In lower chronic dosages, that is, above 8000 μg daily, usually due to self-prescribed oral retinol supplements or daily cod-liver oil, a more indolent presentation of hypervitaminosis A can occur. This includes headaches and visual disturbances, fibrosis of the liver leading to cirrhosis, and softening and weakening of the bones.

The periodic supplementation of retinyl palmitate involves dosage forms of 200 000 IU (~60 000 RAE), generally spaced at 4- to 6-monthly intervals in children between 12 and 59 months of age. For children between 6 and 11 months, a single dose of 100 000 IU (~30 000 RAE) is recommended (see Table 2). At this dosing, the exposure is generally safe. In the medical emergencies of xerophthalmia and complicated measles, the standard dose is repeated twice to a dosage of 400 000 IU within 48 h for therapeutic purposes. The threat from the primary diseases far outweighs any consideration of vitamin A toxicity in these sight- and life-threatening circumstances. Lower doses of both 50 000 and 100 000 IU have been used in trials and public health practice in infants below 6 months of age. These children still have not sealed the seams of the cranial bones. Administration of these doses in the first semester of life produces an overt increase in intracranial pressure, manifested by transient bulging of the fontanels of the scalp. The very existence of this anatomical 'escape valve' and the failure to document sequelae convinced the public health community of the safety of the practice. Administration in this age group is currently not recommended.

In periodic-supplementation setting, however, in which multiple agencies address the same population of children without common clinic-visit controls, eligible children can be dosed more frequently than the prescribed intervals. Moreover, a notorious instance of alleged overdosing comes from Assam, India, in 2001, where the local preparation of a supplement syrup was used, rather than the imported capsules. Through miscommunication to field workers, five times the intended volume of syrup was administered in a regional campaign, and deaths attributed to acute overdose with retinyl esters were alleged. Measures were instituted to prevent subsequent occurrences, but the reputation of high-dose supplementation remains damaged in the Indian community.

Conclusion

Of all the micronutrient deficiencies of public health interest, that of vitamin A has had both the most intensive investigation and the most aggressive investment. The role of periodic high-dose supplementation as a measure against child mortality – but not as a means of sustained adequate vitamin status – has confused the discourse. Because vitamin A deficiency tracks with the extremes of poverty, the most needy are often not reached by the attempts to reduce the deficiency. Biofortification of plant sources holds promise to improve sustainability in a fortification form that does not risk excessive superimposition of sources of provitamin A. The lesson from contemporary Guatemala should be a cautionary tale regarding the uncoordinated offering preformed vitamin A across the population. More effort, therefore, is needed to develop sustainable formats to keep the pendulum of vitamin A status away from the extreme of either severe deficiency or inadvertent overload.

Introduction

Ice cream is a frozen dairy product made by freezing the ice cream mix with agitation. It is composed of a mixture of food ingredients like milk products, sweetening materials, stabilizers, colors, flavors, and egg products. Ice cream mix is the unfrozen mixture of the ingredients, consisting of all the ingredients of ice cream with the exception of air and flavoring materials. The composition of ice cream is usually expressed as a percentage of its constituents, for example, the percentage of milk fat, milk solids not fat, sugar, egg solids, stabilizers (which are the compounds added in very small quantities to strongly influence the formation and growth of ice crystal in the ice cream so as to render the product with desired body and texture), and the total solids. Ice cream and related products are classified as frozen desserts, which include ice cream, frozen custard, frozen confections, ice milk, sherbets, water ices, and mellowing products.

Ice cream had its origins in Europe and was introduced later in the United States where it developed into an industry. It is widely believed that ice cream evolved from iced beverages and water ices. Ice cream probably came to the United States with the early English colonists. In 1851, the first wholesale ice cream industry in the United States was established in Baltimore, Maryland. Ice cream plants were also established in New York, Saint Louis, Chicago, Washington, and Cincinnati. The development of condensed and dried milks and the introduction of the pasteurizer and homogenizer, improved freezers, and other preserving equipments accompanied a slow growth in the industry only after 1900. The ice cream soda was introduced in 1879, and ice cream cone and Eskimo Pie were introduced in 1904 and 1921, respectively.

Drivers of Extensive Development of the Ice Cream Industry

It was around 1920 that the value of ice cream as an essential food was recognized and the product was immensely popular since then. The following developments have made ice cream widely available to the consumer:

- Improved manufacturing technologies and development of automated operating systems, refrigeration, and transportation
- Ingredients of better quality and enhanced knowledge of their usage
- Establishment of product standards
- Quality assurance in the ice cream industry
- Widespread academic programs, research, and extension activities in ice cream technology
- Attractive packaging and efficient distribution network
- Extensive advertising and merchandising programs

In India, an initiative was taken by the Ministry of Food Processing Industries (Goverment of India) by recommending the Cooperative and Public Sector milk plants to produce ice cream. It enabled the production of a range of low-cost ice creams for those who cannot afford it and frozen novelties that dominate the market. At the same time, this step widened the product mix of the cooperative dairy plants and improved their efficiency and viability. Already, encouraging results have been reported from field trials of ice cream production by the Cooperative Sector. The entry of the Cooperative Sector resulted into a boom in the production and sales of ice cream.

Composition of Ice Cream

Ice cream is frequently considered as a 'fun food,' which is undeserving consideration, and even was considered as a 'junk' food. These depreciatory statements have affected industrial development virtually from its inception. In reality, ice cream is a relatively well-balanced, wholesome, easily digestible, and delicious food. It is because ice cream is a nutritious element of the diet that is frequently used as a meal component for hospital patients. The energy value and nutrient content of ice cream depends upon the food value of the products from which it is made. Ice cream contains about four times as much carbohydrates as milk. The milk products that go into the ice cream mix convey the constituents of milk, but in different amounts. In developing a formulation of satisfactory composition, some of the factors that need to be considered are personal preference of company management or customer demands for flavor, body and texture, and color characteristics of the finished product, that is, natural or fortified flavor with artificial flavoring; chewy to heavy, higher overrun; or more cooling body and texture characteristics. Composition standards are also influenced by demands of customers, volume

Table 1 Composition of plain ice cream (per 100 g edible portion)

Constituents	Good/average ice cream	For different fat (%)			Ice milk	Ice cream cones	Water ices
		~10	~12	~16			
Water (%)	61.7	63.2	62.1	62.8	66.7	8.9	66.9

of operation, quality of ingredients, and ingredient costs. Detailed composition of ice cream is given in Table 1.

Ice cream contains three- to fourfold more fat than milk and about 15% more protein than milk. It also contains other food products such as fruits, nuts, eggs, dry fruits, and sugar, which boost its nutritive value. The milk solids in ice cream are usually subjected to higher heat treatments than those of pasteurized milk, they are also subjected to lower temperatures in the freezing process, and they are stored longer before consumption. It is an excellent source of food energy due to its enhanced fat content than that of milk, and 50% of its total solids content is sugar, including lactose, sucrose, and corn syrup solids. The fact that these constituents are almost completely assimilated makes ice cream an especially desirable food for growing children and persons who need to put on weight. For the same reason, its controlled use finds a place in the diet of persons who need to reduce or who do not wish to gain weight. Like milk, ice cream is not a good source of iron and some of the trace elements. The nutritive value of commercial ice cream and related products is depicted in Table 2.

Proteins in Ice Cream

The milk proteins contained in ice cream are of excellent biological value, because they contain all the essential amino acids. Milk proteins are important sources of essential amino acids like tryptophan and lysine. Proteins in the diet supply the amino acids required for the growth of infants and children and for the maintenance of tissues in adults. Not only are milk proteins known to be complete, but also the assimilation of ingested milk proteins is 5–6% more complete than other proteins in general. Milk proteins also have high chemical quality and high net protein utilization (NPU) values. The chemical quality of a protein is determined by comparing its amino acid content with that of hen's egg protein, which is recommended as a reference protein. It is difficult to obtain NPU values using man as a test animal, but relatively easy using the rat. The values for protein are calculated from determinations of the nitrogen content in the food. Early analysis of proteins showed that they have close to 16% nitrogen. The general practice then was to multiply the nitrogen content by 6.25, the conversion factor for the protein content. For milk proteins, the conversion factor is 6.38. The glycosylated proteins make the ice cream more compact and smooth and tend to prevent a weak body and coarse texture. However, excessive amounts result in a salty or cooked flavor and soggy or sandy body and texture defect.

Carbohydrates in Ice Cream

Carbohydrates provide a significant amount of energy in all human diets. These are synthesized by plants from carbon

dioxide and water with the liberation of oxygen under the influence of sunlight. The chief products are the sugars, which are a convenient source of energy for the cells. These include starch, dextrin, cellulose, pectin, gums, and related substances. Sugars of several kinds may be used in the manufacture of ice cream. The commonly used sugar is sucrose. It may come from either cane or beet, as these are identical in composition. Corn sugar, now used extensively, is predominantly glucose or is converted to maltose or fructose. Invert sugar, a mixture of equal amounts of the monosaccharide fructose and glucose, is used at times. Lactose constitutes over one-third of the solid matter in milk and ~20% of the carbohydrates in ice cream, which makes this product suitable for lactose-intolerant people. Furthermore, it is readily hydrolyzed into glucose and galactose. It enhances the utilization of calcium and phosphorus in the human body. Additionally, ingestion of higher amounts of lactose is conducive to the growth of lactose-fermenting *Lactobacillus acidophilus*, which produces acidic condition in the intestine, thereby creating unfavorable conditions for the growth of putrefactive bacteria. A sandy body and texture defect is caused by a high concentration of lactose.

Fat in Ice Cream

Fats are a rich source of energy. It is of major importance in ice cream. It contributes a rich flavor and is a good carrier for added flavor compounds and promotes desirable texture qualities. It is essential to use the correct percentage of milk fat to balance the mix properly as also to satisfy legal standards. Milk fat is in the form of an emulsion; hence, it does not lower the freezing point as it is not a true aqueous solution. It tends to retard the rate of whipping. High fat content limits consumption, will increase the cost, and increase calorific value. Generally, the fat content of a good average ice cream is considered to be 12%. The best source of milk fat is fresh cream. Other sources are frozen cream, plastic cream, butter, butter oil, and condensed milk blends. Fats are present in foodstuffs and storage depots of most animals, mainly in the form of triglycerides. Milk fats have both saponifiable matter and nonsaponifiable matter. The saponifiable fraction includes the glycerides, phospholipids, and other esters, such as those of cholesterol and minor acid components. Milk fat contains at least 60 fatty acids. Milk fat contributes significantly to the nutritive value of ice cream. It is a rich source of energy, serves as a carrier of fat-soluble vitamins A, D, E, and K, and contains a significant amount of essential fatty acids, for example, linoleic and arachidonic acids. The amount of saturated and unsaturated fatty acids and cholesterol in ice cream, ice cream cones, and ice milk is given in Table 3.

Minerals in Ice Cream

A variety of inorganic elements are essential for growth and performance. Those needed in substantial amounts, such as calcium, phosphorus, magnesium, sodium, potassium, and sulfur, are termed as major minerals or macronutrients. Those needed in small amounts, such as copper, cobalt, iodine, manganese, zinc, fluorine, molybdenum, and selenium, are termed as trace elements. The inorganic nutrients are interrelated and should be in particular proportions in the diet. Calcium and phosphorus are of vital concern, since they are very closely related. Milk and products like ice cream are the richest sources of calcium, phosphorus, and other minerals essential in adequate nutrition. It has been proved by research workers that additional amounts of lactose in the diet favor the assimilation of calcium. As ice cream is a rich source of lactose, it favors the assimilation of greater quantities of the calcium content of diet, which is needed by growing children and some adults. The calcium contents of milk and ice cream are 0.118 and 0.132 g/100 g, respectively; the corresponding phosphorus contents are 0.093 and 0.105 g/100 g, respectively. The minerals impart a slightly salty taste, which rounds out the flavor of the finished ice cream.

Vitamins in Ice Cream

Vitamins are organic substances, which are required in small amounts by the body for its metabolism and cannot be synthesized in sufficient quantities by the body. These do not contribute appreciable amounts of energy. Vitamins are divided into two groups: fat-soluble and water-soluble vitamins. The fat-soluble vitamins include A, D, E, and K; the water-soluble vitamins include B_1 or thiamine, B_2 or riboflavin, B_6, and B_{12}. Like milk, ice cream is a rich source of many of the essential vitamins without which normal growth and health cannot be maintained. A brief description of the better-known vitamins may help to emphasize the importance of milk and ice cream in the diet.

Fat-soluble vitamins in ice cream

Vitamin A: Ice cream is an excellent source of this anti-infective vitamin (492 IU 100 g^{-1}). It is the principal milk fat vitamin. It is essential for growth and normal functioning of the retina. Its deficiency results in night blindness and follicular keratosis, a skin disorder.

Table 3 Selected fatty acids and cholesterol in ice cream and related products (per 100 g edible portions)

	Fatty acids				
Item	*Total (g)*	*Total unsaturated (g)*	*Unsaturated oleic (g)*	*Linoleic (g)*	*Cholesterol (mg)*
Ice cream	12.5	7.0	4.0	Trace	45.0
Ice cream cones	2.4	1.0	1.0	Trace	0.0
Ice milk	5.1	3.0	2.0	Trace	21.6

Source: Arbuckle, W. S. (1986). *Ice cream* (4th ed.). New York: AVI Publishing

Vitamin D: Ice cream contains little quantities of this antirachitic vitamin (4 IU 100 g^{-1}). Its deficiency results in decreased growth rate and lowered calcium and inorganic phosphorus levels in the blood. Vitamin D-enriched ice creams can be prepared from fortified milk.

Vitamin E: Ice cream is a fair source of this antisterility vitamin, containing about 3 mg kg^{-1}. This vitamin helps to maintain normal health and reproductive organs in laboratory animals. This vitamin is found in all cell membranes. It acts as an antioxidant for polyunsaturated fatty acids and prevents a large number of degenerative disorders.

Vitamin K: This vitamin has been found necessary for the formation of prothrombin, which prevents bleeding by clotting the blood. The concentration of this vitamin is very low in milk, and pasteurization and evaporation destroy it.

Water-soluble vitamins

Vitamin B_1 (thiamine): Ice cream contains an average of 0.48 mg kg^{-1} of this vitamin, with a range of 0.38–0.65 mg kg^{-1}, which is essential for proper metabolism and health. Its deficiency causes beriberi, which is manifested by loss of appetite, anxiety, exhaustion, and irritability. In some cases, it can cause nervous disorders or dilation of the heart.

Vitamin B_2 (riboflavin): Riboflavin is a dietary essential vitamin for humans. Ice cream is a fairly good source of riboflavin, containing an average of 2.3 mg kg^{-1}, with a range of 2.0–2.6 mg kg^{-1}. Its deficiency causes lesions of the eye and mouth and reddening of the lips.

Vitamin B_6 (pyridoxine): It is an important coenzyme in the metabolism of amino acids. Its deficiency can cause anemia, convulsions, decreased growth rate, and dermatitis. Ice cream contains an average of 0.0047 mg kg^{-1} of this vitamin, with a range of 0.0026–0.0078 mg kg^{-1}.

Vitamin B_{12} (cyanocobalamin): It is one of the anemia-preventing vitamins and is unique among vitamins, as it is not found in any plants. This vitamin has the most complex structure of all vitamins. It is an essential metabolite for a wide variety of organisms. Ice cream contains an average of 0.0047 mg kg^{-1} of this vitamin, with a range of 0.0026–0.0078 mg kg^{-1}. Its deficiency can produce anemia and degeneration of the spinal cord.

Vitamin C (ascorbic acid): It is widely distributed in the tissues of all plants and animals. It is abundantly found in fruits, fruit juices, and green leafy vegetables. These vitamins act as an antiscorbutic factor in the prevention of scurvy. Fruit ice creams are excellent sources of this vitamin. On an average, ice cream contains 3 mg kg^{-1} of this vitamin, with a range of 0–11 mg kg^{-1}.

Stabilizers

Stabilizers are used to prevent the formation of objectionable large ice crystals in ice cream. They have high water-holding capacity; in addition, they prevent ice crystal formation in storage, give uniformity of product, give desired resistance to melting, and improve handling properties. The effect of stabilizers on flavor is indirect. They increase viscosity, have no effect on the freezing point, and generally decrease whipping ability. The amount of stabilizers to use varies with its properties, with the solids content of the mix, with the type of processing equipment, and other factors.

Generally, stabilizers are added at the rate of 0.2–0.3% of the mix. Stabilizers commonly used are sodium alginate, sodium carboxymethyl cellulose (CMC), guar gum, locust bean gum, carrageenan, gelatin, and pectin. It is not necessary to age the mix when alginates are used. CMC produces a chewy characteristic in the finished product. Gelatin produces a thin mix and requires an aging period. Pectin is used alone or in combination with gums as a sherbet or ice stabilizer. The addition of excessive amounts of stabilizers results in soggy or heavy body and high resistance to melting in the finished product.

Emulsifiers

Emulsifiers are used to produce ice cream with a smoother body and texture, to impart dryness, and to improve whipping ability of the mix. Emulsifiers extensively used are monoglycerides or diglycerides, sorbates, and polysorbates and are added at the rate of 0.1–0.4% of the finished product. Egg yolk solids are also used as emulsifiers. Excessive amounts of emulsifiers produce slow melting characteristics and body and texture defects in the product.

Flavors

Flavor is generally considered as one of the most important characteristics of ice cream. The kind of flavoring material influences the quality of the ice cream mix since slight off-flavor in it can obscure the delicate flavor of the flavoring material to be added. Local preference of the consumers determines the type and intensity of flavor to be added. Natural and synthetic flavor substances are available for the flavoring of ice cream.

Colors

Ice cream should have a delicate, attractive color that can be readily associated with the flavor. Most colors are of chemical origin. Colors are available in liquid or powder form. Most ice cream manufacturers prefer to purchase dry colors since these are more economical and can be dissolved in boiling water as needed.

Digestibility and Palatability of Ice Cream

Ice cream is considered as an ideal food for people suffering from stomach or throat ailments when other foods cannot be taken. There are several reasons to support this viewpoint. Its sweet, pleasant flavor, smooth texture, and characteristic coolness make it a highly palatable food. Its high palatability stimulates the flow of digestive juices, which enhances digestion. Moreover, homogenization employed in its manufacture facilitates digestion as it happens with homogenized milk, as the digestive juices readily act upon the fat globules broken into small globules. Many experiments show that homogenized milk is more digestible than milk not so treated. The same holds true for the fat in ice cream mix when it is forced through the homogenizer, as is now the practice in commercial ice cream plants.

Health Effects of Ice Cream

To combat osteoporosis

Dairy products like ice cream contain 0.122 g calcium per 100 g. It is beneficial for strong and healthy bones. According to the Office of Dietary Supplements (ODS), 99% of the body's calcium can be found in the bones and teeth where it is used to help function and structure. When the body is not receiving a sufficient amount of calcium daily, it can take calcium from where it is stored. Regular calcium intake from ice cream and other dairy products can also reduce the risk of osteoporosis, a disease related to an increase in bone fractures. Not only is calcium good for the bones and teeth, but also it plays a part in weight loss. Studies have shown a correlation between reduced weight and weight gain prevention with an adequate daily intake of calcium. When the body is not receiving an adequate amount of calcium, it causes fat cells to enlarge by storing fat. The lack of calcium is correlated to the creation of fat-producing hormones and a slowing effect of fat breakdown leading to weight gain.

In women's reproductive health

It is very strongly advocated by the researchers that ice cream is helpful in maintaining the reproductive health of women. A recent investigation comprising 18 000 women of 24–42 years suggests eating ice cream increases chances of ovulating. The study looked at the eating habits of the women under the feeding trials. After accounting for other factors, like smoking and drinking, the researchers found that women who ate full-fat ice cream two more times a week had a 38% lower risk of ovulation-related infertility. That is compared to women who had full-fat ice cream less than once a week. So what about low-fat foods? The study found that women who ate at least two servings of low-fat milk products a day were 85% more likely to have problems ovulating than women who only ate one serving. The researchers suggest women trying to get pregnant keep a careful eye on calories, but eat full-fat until conception.

Improvement of immunity

As ice cream is rich in lactoferrin and cytokines, it improves the immunity against various diseases, including influenza. Ironically, there is a misapprehension that ice cream is regarded as a cause of colds and coughs. In fact, when we eat ice cream, melting ice cream that goes into the mouth is affected by body temperature, so at that point, the temperature of ice cream is not so low any longer.

Ice cream as a delivery medium for probiotics

Probiotics are distinct live microorganisms that, when administered in sufficient amounts, exert a health benefit on the host. In recent years, probiotic bacteria have increasingly been incorporated into dairy foods as dietary adjuncts. This is an ideal way to reestablish the balance of intestinal microbiota. Probiotic ice cream can be produced by the incorporation of probiotic bacteria in both fermented and unfermented mixes. Ice cream is an ideal vehicle for the delivery of these organisms in the human diet. *Lactobacillus* and *Bifidobacterium* are the most common species of lactic acid bacteria used as probiotics for this purpose. Among the frozen dairy products with live probiotics, probiotic ice cream is also gaining popularity for its neutral pH. The high total solids level in ice cream including the fat and milk solids provides protection for the probiotic bacteria. Because the efficiency of added probiotic bacteria depends on dose level, type of dairy foods, presence of air, and low temperature, their viability must be maintained throughout the product's shelf life and they must survive the gut environment. Live probiotic bacteria are more than unviable cells; therefore, the International Dairy Federation (IDF) recommends that a minimum of 10^7 probiotic bacterial cells should be alive at the time of consumption per gram of product. Studies indicate, however, the bacteria may not survive in high enough numbers when incorporated into frozen dairy products unless a suitable method is used against freeze injury, and oxygen toxicity represents factors affecting probiotic survival in ice cream.

Another way is to adjust the conditions of production and storage for more survival rates. The physical protection of probiotics by microencapsulation is a new method for increasing the survival of probiotics. Encapsulation helps to isolate the bacterial cells from the adverse environment of the product and gastrointestinal tract, thus potentially reducing cell loss. Selecting suitable probiotic strains depends on their ability to survive simulated conditions of ice cream (high sucrose concentrations, high oxygen, freezing, and storage temperatures), acidic (to simulate gastric conditions) and alkaline conditions (to simulate intestinal conditions). Microencapsulation of probiotics can further protect these bacteria from the mentioned conditions.

During the last two decades, several studies have shown that ice cream has a good ability as a medium for delivery of probiotics into the human gut. Frozen dairy products create ideal conditions for probiotic bacteria to survive for a long term of production, distribution, and storage. Ice cream provides good conditions for probiotic growth in large numbers and their survival during storage. Low-fat ice cream in comparison with regular ones provides better conditions for the survival of probiotics. Incorporation of probiotic bacteria in ice cream does not create any problem because ice cream pH (6.6–6.5) is ideal for survival of these microbes.

It could be concluded from the ongoing discussion that ice cream is particularly valuable for its content of high-quality protein and easily assimilated calcium. It provides many nutrients and can make a useful and enjoyable contribution to the daily intake of energy in a healthy and balanced diet. The future success of functional probiotic ice creams in marketplace depends on its consumer acceptance. The development of probiotic ice cream is a key research priority for food design and a challenge for both industry and science sectors. Especially, ice cream is a good vehicle to transfer probiotics to the human intestinal tract. An additional way to keep the levels up of the probiotic cells in the gut is to consume this frozen dessert on a regular basis. More studies are needed to further investigate the probiotic survival in harsh conditions of ice cream formulation and manufacturing.

Introduction

Ice cream is a frozen dairy product made by freezing the ice cream mix with agitation. It is composed of a mixture of food ingredients like milk products, sweetening materials, stabilizers, colors, flavors, and egg products. Ice cream had its origins in Europe and was introduced later to the United States where it developed into an industry. It is widely believed that ice cream evolved from iced beverages and water ices. Ice cream probably came to the United States with the early English settlers. In 1851, the first wholesale ice cream industry in the United States was established in Baltimore, Maryland. Ice cream plants were then established in New York, St. Louis, Chicago, Washington, and Cincinnati. The development of condensed and dried milks and the introduction of the pasteurizer and homogenizer, improved freezers, and other preserving equipments accompanied the growth of this industry after 1900. The ice cream soda was introduced in 1879, and ice cream cone and Eskimo Pie were introduced in 1904 and 1921, respectively.

Global *per capita* consumption of ice cream and related products is presented in Table 1. The US ice cream market in 2007 was $23 billion. The global value of the ice cream industry is US$59 billion, growing on an average by 4% per annum with a growth rate of 7–9%. More than 90% of American households purchase ice cream. Global market share, according to point of manufacture/consumption, take-home, impulse, or artisanal products, is shown in Table 2. The take-home category is defined as grocery store purchases and home consumption, the impulse category is categorized by hand-held, single-serving eat-on-the-spot products (sometimes referred to as novelty products), and the artisanal category is defined as being manufactured at the site of purchase and consumption or sold directly by the manufacturer to the consumer (e.g., ice cream parlors and street vendors). There are very large differences globally, impacted in large part by the presence of home freezers.

Ice creams are unique frozen food because they are consumed in the frozen state, usually as a scooped product or as a single-serving item, sometimes on a stick and often with other confectionery items. These products rely on a concomitant freezing and whipping process to establish the desired structure and texture. The manufacturing process for most of these products is similar. It involves the preparation of a liquid mix, which is prepared by blending the desired ingredients, followed by pasteurization, homogenization, and aging. It is followed by whipping and freezing this mix dynamically under high shear to soft, semi-frozen slurry. The flavoring ingredients are then incorporated in this partially frozen mix. It is then placed in molds for desired shaping and packaging the product. It is further subject to freezing (hardening) under static, quiescent conditions. Swept-surface freezers are used for the first freezing step, while forced convection freezers, such as air blast tunnels or rooms, or plate-type conduction freezers are used for the second freezing step.

A wide variety of ingredients are used to produce ice creams. Even any one kind of ice cream can be made by combining the ingredients in any of several different combinations of ingredients. Ice cream mix is the unfrozen mixture of the ingredients, consisting of all the components of ice cream with the exception of air and flavoring materials. The composition of ice cream is usually expressed as a percentage of its constituents, for example, percentage of milk fat, milk solids-not-fat, sugar, egg solids, stabilizers, and the total solids.

Ice Cream Mix

Ice cream mix comprises milk fat, milk solids-not-fat (MSNF), sweeteners, stabilizers, colors, emulsifiers, and water. Dairy and other ingredients used to supply these components are chosen on the basis of their cost, availability, and quality of the finished product. An account of composition of various frozen dairy desserts is presented in Table 3. The source of fat that is derived from milk ingredients (e.g., cream and butter) is common in North America and many other parts of the world, while fat derived from nondairy sources (e.g., coconut oil and palm kernel oil) is more common in parts of Europe and Asia. The triglycerides in milk fat have a wide melting range of 40 to −40 °C. Consequently, at refrigeration temperatures, there is always a combination of liquid and crystalline fat within the globules. The resulting solid–liquid ratio at freezer barrel temperatures is important for formation of ice cream structure, as crystalline fat is required for partial coalescence. Nondairy fat sources must also be chosen to provide a suitable solid fat content.

The Milk Solids-Not-Fat

It comprises lactose, casein, whey proteins, minerals, vitamins, and other minor components of the milk or milk products from which they were derived (e.g., skim milk powder, condensed milk, and whey protein concentrate ingredients). Proteins contribute much to the development of the structure of ice cream, including emulsification, whipping, and water-holding capacity. Whipping of proteins in ice cream contributes to the formation of the initial air bubbles in the mix. Emulsification of proteins in the mix arises from their adsorption to fat globules due to homogenization. Viscosity of mix is enhanced due to water-holding capacity of proteins, which imparts a desired body to the ice cream, increases the meltdown time of ice cream, and contributes to reduced iciness.

Table 1 *Per capita* consumption of ice cream and related products in selected countries (2002, unless otherwise noted)

Country	*Consumption*
New Zealand	22–23 (2006)
The United States	18.3 (2007)
Australia	18 (2006)
Finland	14 (2006)
Sweden	12
Italy	9.2
Ireland	9.0
Denmark	8.7
Canada	8.7 (2007)
The United Kingdom	6 (2007)
Chile	5.6

Sweeteners

Sweeteners improve the texture and palatability of the ice cream, impart sweet taste, and enhance flavors. They also lower the freezing point of the mixture, which imparts a measure of control over the temperature–hardness relationship. In determining the proper blend of sweeteners for an ice cream mix, the total solids required from the sweeteners, the sweetness factor of each sugar, and the combined freezing point depression of all sugars in solution (including lactose from the dairy ingredients) must be calculated to achieve the proper solids content, the appropriate sweetness level, and a satisfactory degree of hardness. The most common sweetening agent used is sucrose. It provides sweetness, depresses freezing point, affects freezing performance, affects body and texture, enhances flavor, and contributes bulk or total solids and impacts on economics. Generally, the equivalent of 15% sucrose is considered optimal sweetness in ice cream. Substitute sweeteners derived from starch hydrolysate syrup (glucose syrup) for all or a portion of the sucrose can also be used as it is relatively cheaper. Glucose syrups impart greater smoothness by contributing to a firmer and chewy body, provide better meltdown characteristics, bring out enhanced fruit flavors, and reduce heat shock potential that improves the shelf life of the finished product. Nonnutritive sweeteners, which do not provide any significant calories can also be used for diabetics. They include sucralose, aspartame, saccharin, cyclamates, acesulfame-K, and many others. As little as 0.07% aspartame can provide the sweetness equivalent to 15% sucrose.

Stabilizers

Apart from sweeteners, stabilizers are also important nondairy ingredients. The term stabilizer is used for a group of substances that help stabilize the structure of ice cream. The commonly used stabilizers in ice cream mix are a group of ingredients (polysaccharides) such as guar, locust bean gum, carboxymethylcellulose, and xanthan. Stabilizers increase the

Table 3 Approximate composition (%) of commercial frozen desserts by formulation category

Group	*Milk fat*	*Milk solids-notfat*	*Sweeteners*[a]	*Stabilizers*[b]	*Total solids*

viscosity of the mix; produce smoothness in body and texture; retard or reduce ice and lactose crystal growth during storage, especially during periods of temperature fluctuation, known as heat shock; and hold flavorings in uniform suspension. The mechanism of action of stabilizers in enhancing frozen stability is related primarily to its effect on the ice and unfrozen serum phases. Stabilized ice cream has smaller ice crystals than unstabilized ice cream after storage at fluctuating temperatures. Usually, stabilizers are used at 0.1–0.5% levels in the mix, but the actual amount depends on the type and strength of the stabilizer, total solids and fat level of the mix, duration and temperature of storage of ice cream, and the method of pasteurization. High-fat and high-total solid mixes require lower levels of stabilizers. More stabilizer is needed for ice cream that is stored for a long period of time or if the temperature fluctuation during storage is frequent.

Emulsifiers

Emulsifiers are sometimes integrated with the stabilizers in proprietary blends, but their function and action are very different from the stabilizers. They exert their action on the fat phase of ice cream. These are surface-active agents. Emulsifiers facilitate the mixing of fat and water because these molecules have two domains, one that likes water (hydrophilic) and another that likes fat (hydrophobic). When the hydrophobic part of a surfactant interacts with the fat, the water-loving part of the molecule can interact with water, thus facilitating the suspension of fat in water. Generally, mono- and diglycerides and ethoxylated esters of sorbitol (polysorbates) are the commonly used emulsifiers. Mono- and diglycerides are derived from fatty acids and glycerol. Therefore, emulsifiers are fatty substances. They also show fatlike properties such as melting point and crystallinity, and they can be composed of saturated or unsaturated fatty acids. The presence of emulsifiers in ice cream leads to smoother texture and better shape retention while improving the ability of the mix to incorporate air. The mode of action of emulsifiers is related to their activity at the air–serum and fat–serum interfaces. At the fat–serum interface, they displace proteins from the surface of the fat globules, rendering the fat globules more susceptible to partial coalescence and structure formation during the freezing and whipping process.

Figuring the Mix

Ice cream processing operations can be divided into two distinct stages: figuring the mix and freezing operations. Once a formula has been finalized, a recipe has to be created. Formulas specify composition of the desired mix in terms of percentages of fat, MSNF, sweeteners, stabilizers, and emulsifiers. A recipe calculates the weight and/or volumes of ingredients needed to meet the formula requirements. These calculations are called mix calculations. Mix calculations are essential for manufacturing consistent quality finished products. When composition of raw materials varies or the economics of ingredients changes, the recipe for making an ice cream mix has to change. Further, this change has to occur in a manner that the finished product composition is not altered. In some instances, changing regulatory definitions and health claims may necessitate manufacture of products to carefully defined specifications.

Mix calculations are important in standardizing mixes prior to freezing. Ice cream plants now use computer software programs to calculate the amounts of various ingredients to conform to required specifications of composition of ice cream mix. However, for basic understanding, the fundamentals of the mix calculations are discussed here. Mix calculations can be performed by Pearson's square, algebraic methods, and arithmetic methods. Pearson's square is of limited utility; algebraic methods are complicated and involve the use of simultaneous equations and matrices. Arithmetic calculations are simpler and require fewer computations than algebraic methods.

Figuring the mix consists of the following unit operations: combination and blending of ingredients, batch or continuous pasteurization, homogenization, and mix aging. Ingredients are usually preblended prior to pasteurization, regardless of the type of pasteurization system used. Blending of ingredients is relatively simple if all ingredients are in the liquid form, as automated metering pumps or tanks on load cells can be used. When dry ingredients are used, powders are added either through a pumping system under high velocity or through a liquefier that chops all ingredients as they are mixed with the liquid.

Pasteurization

It is designed to destruct pathogenic bacteria, if any are present. In addition, it serves a useful role in reducing the total bacterial load and in solubilizing some of the components (proteins and stabilizers). Both batch and continuous (high-temperature short-time (HTST)) systems are in common use. In a batch pasteurization system, blending of the ingredients is done in large jacketed vats equipped with some means of heating, usually saturated steam or hot water. The product is then heated in the vat to at least 69 °C and held for 30 min to satisfy legal requirements for pasteurization. This is necessary for the destruction of pathogenic bacteria. Various time–temperature combinations can be used, depending on the legal jurisdiction. Continuous pasteurization is usually performed in an HTST heat exchanger following the blending of ingredients in a large, insulated feed tank. Regulations concerning time–temperature combinations for continuous pasteurization usually specify a minimum temperature of 80 °C for at least 25 s.

Homogenization

Following pasteurization, the mix is homogenized using high pressures. It is responsible for the formation of the fat emulsion by forcing the hot mix through a small orifice under pressures of 15.5–18.9 MPa, depending on the mix composition. The resulting eight- to tenfold increase in the surface area of the fat globules is responsible in part for the formation of the fat globule membrane, composed of adsorbing materials attempting to lower the interfacial free energy of the fat globules. With single-stage homogenizers, fat globules tend to cluster as bare

fat surfaces come together or adsorbed molecules are shared, especially in ice cream mix. Therefore, a second homogenizing valve is frequently placed immediately after the first with applied back pressures of 3.4 MPa, allowing more time for surface adsorption to occur. The net effects of homogenization are in the production of smaller, more uniform fat droplet size, resulting in a greater stability of fat droplets during aging, a better whipping ability, and a smoother, more uniform final product with a greater apparent richness.

Aging of the Mix

The time of 4 h or greater at 2–4 °C is recommended for aging following mix processing prior to freezing. Aging is performed in insulated or refrigerated storage tanks, silos, etc. or in single-walled tanks in chilled rooms, where valves and pipeline can also be kept cold. Aging allows hydration of milk proteins and stabilizers (some viscosity increase occurs during the aging period), crystallization of the fat globules, and a membrane rearrangement to produce a smoother texture and better-quality product. Nonaged mix exhibits a low viscosity, is very wet at extrusion from the dynamic freezer, and exhibits variable whipping abilities. The appropriate ratio of solid–liquid fat must be attained at this stage, a function of temperature and the triglyceride composition of the fat used, as a partially crystalline emulsion is needed for partial coalescence in the whipping and freezing step. Emulsifiers generally displace milk proteins from the fat surface during the aging period. The whipping qualities of the mix are usually improved with aging. Mix temperatures should be maintained as low as possible without freezing.

Flavorings

Flavor is an important attribute of a food. It is a sensory response that has three components, olfactory (odor/smell), gustatory (taste), and tactual (mouthfeel). Ice cream is cold, creamy, refreshing, and sweet and releases aroma upon melting in the mouth. When the word 'flavor' is used in everyday parlance, we imply taste and olfaction. Taste compounds are sweet, salty, bitter, and sour. Generally, compounds imparting these tastes can be detected at levels of 0.01–0.5. Olfactory compounds (smelly stuff) are volatile and have thresholds in the parts per million to parts per trillion range. Threshold is defined as the minimum concentration that at least 50% of the population can detect. Threshold of aroma compounds are 10–10 million times less than taste compounds.

Perception of aroma is affected by the composition, physical structure, and temperature of the food. Undesirable flavors are called off-flavors. Off-flavors affect the overall flavor qualities of the food. Deteriorative reactions are time-dependent and cumulative. Therefore, the length and conditions of storage have a profound influence on the perception of overall flavor. These deteriorative reactions occur in ingredients used in ice cream manufacture. Therefore, careful attention should be paid to the quality of ingredients used in ice cream manufacture.

Glass Transition Temperature

Temperature stability of ice cream has focused on carbohydrate glass formation as a function of temperature. A glass is characterized as a metastable solid with a high viscosity. At the glass transition temperature, polymeric materials change from a viscoelastic liquid to an amorphous solid (glass) with an associated increase in viscosity. For ice creams, this temperature is defined as the glass transition temperature of a maximally freeze-concentrated solution. The interest in glassy state in ice creams has increased steadily since the last 15 years. It is now well established that the glassy-state temperature influences the storage stability as above these temperatures, the solutions are unstable and reactive. Ice crystallization can also occur in this phase. Below the glass transient temperature, the materials become glossy and no molecular motion or chemical reaction occurs. The ice crystallization is prevented and the shelf life of the product is prolonged. Glass transition temperature for ice cream is −32 °C. Storage of ice cream at this low temperature to maintain the glassy state for enhanced stability is not practical.

Freezing Process

The process of freezing of ice cream in simple words is the creation of ice from water in the mix. Therefore, the only constituent of the mix being frozen is water. During the freezing process, the equilibrium between water and ice is altered. Freezing is facilitated by the removal of heat from a substance. In the old salt and ice machine, used prior to mechanical refrigeration, ice served as the refrigerant and addition of salt lowered the freezing point of water. The brine extracts heat from the mix. The mix temperature is lowered and the brine temperature increases. Brine is not a good refrigerant. With the advent of mechanical refrigeration, the use of ice and salt for freezing ice cream was relegated to a hobby status.

Modern ice cream freezing consists of two distinct stages: (1) passing the mix through a swept-surface heat exchanger under high-shear conditions to promote extensive ice crystal nucleation and air incorporation and (2) freezing the packaged ice cream under conditions that promote rapid freezing and formation of small ice crystals. The freezing and whipping process is one of the most important unit operations for the development of quality, palatability, and yield of finished product. Due to the incorporation of air, foam is created. It leads to the formation of the ice phase and the partial destabilization of the fat emulsion. The objective of ice cream manufacturers is to produce ice crystals that are below the threshold of sensory detection at the time of consumption. This threshold has been suggested to be between 40 and 50 μm. Therefore, the freezing steps of the manufacturing process and the temperature profile throughout the distribution system are critical factors in meeting this objective. Flavoring and colorants are added as desired to the mix prior to passing through the barrel freezer, and particulate flavoring ingredients, such as nuts, fruits, candy pieces, and ripple sauces, can be added to the semifrozen product at the exit from the barrel freezer prior to packaging and hardening.

Continuous Freezers

Continuous freezers are commonly used in larger ice cream manufacturing plants where more than 500 gal (1875 l) of ice cream per day may be manufactured. These freezers have larger capacities and can be operated continuously, ingredients can be added in-line, and packaging can be also automated. Also, continuous freezers make it possible to produce ice cream of different shapes through extrusion devices. Novelty extrusions, such as sandwiches, prefilled cones and cups, and cakes, are possible through the use of continuous freezers. The ice cream from a continuous freezer is smoother and creamier than a product from a batch freezer. This is because the ice crystals formed in a continuous freezer are smaller and the air cells may also be more uniform. The ice cream exiting a continuous freezer is also generally colder than that coming out of a batch freezer. There are a number of different types of continuous ice cream freezers; some are vertical freezers, especially for smaller-scale operations; others are horizontal ice cream freezers. Regardless of whether the freezing cylinder is horizontal or vertical, all continuous freezers have a set of blades for scrapping the walls of the freezers. In a continuous freezer, a mixture of air and the mix is introduced at one end and is progressively frozen until ice cream is discharged at the other end. The conveyance of the mixture of air and the mix and the discharge of the ice cream may be facilitated by coordinated pumps in some models. Also, the newer models of freezers are equipped with microprocessor controls that monitor and control the discharge temperature of the ice cream, the viscosity of the ice cream, and the overrun of the ice cream. Further, these microprocessors can work in tandem with other downstream equipment such as ingredient feeders and packaging lines.

These freezers dominate the commercial ice cream industry. In this type of process, ice cream mix is drawn from the flavoring tank into a scraped-surface heat exchanger, which is jacketed with a liquid, boiling refrigerant (usually ammonia; a chlorinated, fluorinated hydrocarbon (CFC) such as R-12, R-22, or R-502; or one of the newly developed CFC substitutes).

A continuous freezer is usually operated under pressure, to minimize the volume of air in the ice cream and thus maximize heat transfer. Air bubbles expand rapidly when the ice cream is drawn through the outlet valve to atmospheric pressure. The introduction of low-temperature extrusion equipment has been a recent development in ice cream freezing technology. This is a continuous-flow heat exchanger in the form of a screw extruder that reduces the temperature of ice cream from the draw temperature of the barrel freezer, typically $-5\,^{\circ}C$, to a range of -10 to $-14\,^{\circ}C$. The ice cream passes at low shear through a twin-screw or single-screw design with a residence time of 1–2 min. Ice cream that results from such processing shows much smaller ice cream and air bubble sizes, and the fat is agglomerated into a structure that provides a creamy texture.

When the product emerges from the low-temperature extruder, it is still pliable, so some particulates can be added to it, and it can be cut and packaged, but it sets up very quickly thereafter to a very firm consistency. Hence, the claim is made that low-temperature extrusion can replace the need for conventional hardening of ice cream.

Batch Freezers

Batch freezers are commonly used by small ice cream units that make ice cream on the premises. In batch freezers, a predetermined amount of mix is charged into the freezing chamber; refrigeration is turned on as is the agitation. Generally, the mix will occupy half of the barrel. The mix is agitated and whipped while being cooled. After some time, the mix begins to freeze, and when it achieves a certain consistency, it begins to incorporate air. Incorporation of air in conjunction with the freezing stiffens the ice cream. At this point, the refrigeration should be turned off and agitation continued for some additional period of time. When the desired overrun is achieved, the ice cream is discharged from the barrel with the agitator mechanism still on.

Just prior to discharge of the ice cream, fruits and nuts can be added to the barrel, but the preferred method of addition of particulate inclusions is to fold them into the ice cream as they are being discharged from the barrel. Once this process is complete, the next batch of mix can be charged into the freezer barrel and the process repeated.

The batch freezer differs considerably from the continuous systems described in the preceding text. The barrel of a batch swept-surface heat exchanger is jacketed with refrigerant and contains a set of dashers and scraper blades inside the barrel. It is filled to about one-half volume with the liquid mix. Barrel volumes usually range from 2 to 12 l. The freezing unit and agitators are then activated, and the product remains in the barrel for sufficient time to achieve the desired degree of overrun and stiffness. Whipping increases with time and cannot exceed the amount that will fill the barrel with the product (i.e., 100% overrun when starting half full). Batch freezers are used in smaller operations where it is desirable to run individual flavored mixes on a small scale or to retain an element of the 'homemade'-style manufacturing process.

The formation of the ice phase during the continuous freezing stage is responsible in part for the structure and texture of the final product. The crystallization of water to ice involves two major steps: nucleation and crystal growth. Nucleation occurs at the wall of the heat exchanger during start-up. After start-up, the continual scraping action of the blades acts as a seeding mechanism, by providing a source of tiny crystals into the bulk where they grow.

Overrun in Ice Cream

Incorporation of air into ice cream, termed the overrun, occurs at this stage. Some overrun is necessary to produce desirable body and texture. Two main types of air incorporation systems are used in continuous freezers. In older systems, the pump configuration resulted in a vacuum either at the pump itself or on the mix line entering the pump. Air was then incorporated through a spring-loaded, controllable needle valve. Newer types of freezers use compressed air, which is injected into the mix. This type of air handling system allows for air filtration (0.65 μm micropore filter) prior to admission into the mix.

Following aeration, the water in the mix is partially frozen as the mix and air combination passes through the barrel of the heat exchanger. Ice forms on the inside wall of the heat exchanger from the water in the mix, resulting in a freeze

concentration of the dissolved solutes. Rotating knife blades are responsible for continually scraping this frozen mix off the surface of the heat exchanger wall and mixing it into the bulk flow of freeze-concentrated liquid mix, where these tiny ice crystals grow. The dasher keeps the product agitated inside the barrel and provides a more homogeneous mixture of ice and freeze-concentrated liquid. Residence time for mix through the annulus of the freezer varies from 0.4 to 2 min, although some products may remain for much longer times; especially with open cage dashers, freezing rates can vary from 5 to 27 °C min^{-1}, and a draw temperature of −6 °C can easily be achieved.

Hardening of Ice Cream

After freezing, the flavors, nuts, chocolates, etc. are added, and the product is packed and immediately transferred to a hardening chamber (−30 °C or colder, either forced convection or plate-type conduction freezers) where the majority of the remaining water freezes. Rapid initial freezing is essential to set up as many crystal nuclei as possible so that during the maturation or growth stage, their size stays small. In the same context, rapid hardening is also necessary to keep ice crystal sizes small.

Further temperature reduction during hardening accounts for continued growth of the preformed crystals. As water freezes out of solution in a relatively pure form, the formation of ice acts to concentrate the dissolved sugars, lactose, milk proteins, salts, and hydrocolloids in an ever-decreasing amount of water. Water and its dissolved components are referred to as the serum or matrix of the mix. Because the freezing point of the serum is a function of the concentration of dissolved solids, formation of more ice concentrates the serum and results in an ever-decreasing freezing temperature for the remaining serum. Therefore, at temperatures several degrees below the initial freezing temperature, there is always an unfrozen phase present. Ice cream hardness is a function of temperature due to its effect on this conversion from unfrozen water to ice and further concentration of the serum phase surrounding the ice crystals, which helps to give ice cream its ability to be scooped and chewed at freezer temperatures.

Structure Formation During Manufacture

The texture of ice cream is perhaps one of its most important quality attributes. It is the sensory manifestation of structure. Hence, establishment of optimal ice cream structure is critical to maximal textural quality. The structure of ice cream begins with the mix as a simple emulsion, with a discrete phase of partially crystalline fat globules surrounded by an interfacial layer composed of proteins and surfactants. Ice cream is a complex food colloid in that the mix emulsion is subsequently foamed, creating a dispersed phase of air bubbles, and is frozen, forming another dispersed phase of ice crystals. Air bubbles and ice crystals are usually in the range of 20–50 μm. The serum phase is freeze-concentrated. In addition, the partially crystalline fat phase at refrigerated temperatures undergoes partial coalescence during the concomitant whipping and freezing process, resulting in a network of agglomerated fat, which partially surrounds the air bubbles and gives rise to a solid-like structure.

Packaging of Ice Cream

A good package must contain the product, protect it, provide convenience, and provide information on the product to the consumer. Food packages provide protection against physical, chemical, and biological damages. It also provides information useful to the consumer, for example, ingredient label, nutritional label, net contents, serving suggestion, and methods of preparing the product. Besides these attributes, a good food package keeps the food at nearly the same quality as when it was manufactured. During distribution, packages are subjected to physical abuses such as shocks, vibrations, compression, and, in the case of ice cream and frozen desserts, heat shock.

For frozen dessert packaging, three main factors have to be considered. First, the package has to protect the product against temperature fluctuations, photooxidation, dehydration, and odor transmittance. Second, it has to take into consideration distribution-related factors such as package integrity, thermal shock, and cube efficiency. Third, municipal solid waste management factors have also to be considered.

Storage and Distribution

Frozen and hardened product is stored and often distributed prior to the enjoyment by the end consumer. The intermediate steps involved in storage vary depending upon the scale of manufacture, market share, point of sale, and consumer preferences. In the simplest case of a retail ice cream manufacturer, the product is made fresh in the store and sold very soon after manufacture, and this requires relatively few controls. Ice cream is unique in that it is the only product that is consumed in the frozen state. Therefore, once it is manufactured, it has to be stored, transported, distributed, and sold in the frozen state. In the United States, frozen foods are distributed in a separate chain than ice cream is because the cold chain for frozen foods is −18 °C (0 °F) and is inadequate for ice cream. Ice cream cold chain maintains −23 °C (−10 °F). The distribution chain is called the cold chain and varies from manufacturer to manufacturer. Regardless of variations, the cold chain is imperfect. This imperfection affects the quality of the product at the point of purchase and impacts consumer satisfaction. Factors affecting the shelf life of ice cream are manufacturing procedures, warehouse equipment, warehouse handling practices, transportation, storage at retail premises, retail display equipment, and retail handling practices.

Uses of Ice Cream

Ice cream is such a frozen dessert that is liked by all age groups. It is an energy-rich product and may be a part of countless recipes and gastronomic specialties. It can be used as a most promising carrier medium for probiotic organisms.

Introduction

Immunoassays encompass a wide range of antibody-based testing platforms that have successfully been applied by food manufacturers and regulatory agencies to ensure the safety of the food supply. Because of the diversity in the platforms, suitable antibody detection assays are available for use at any stage during pathogen testing including enrichment screening, presumptive isolate confirmation, and subspecies characterization. Additionally, immunocapture assays may in some cases replace or minimize enrichment times or be used as an additional means to increase the overall sensitivity of a bacterial isolation procedure. Immunoassays exploit the high binding affinity and the stringent binding selectivity of antibodies to identify target foodborne pathogens or other targets of interest (e.g., bacterial toxins, fungal toxins, and allergenic proteins). The popularity of immunoassays for food safety testing is due in large part to the availability of a wide variety of diagnostic platforms that allows them to be applied at any step of the sample analysis, which is both time- and labor-intensive. Their popularity is also due in part to the commercial availability of highly specific antibodies for the majority of the recognized foodborne pathogens and many of their toxic metabolites. There are many benefits to including immunoassay detection in a food testing program. One of the biggest hurdles in foodborne pathogen surveillance programs is the number of samples that can be effectively processed within a given time period. The use of immunoassays decreases the time required for detection and the time needed to confirm the identity of foodborne pathogens. By speeding up analysis time, more samples can then be tested within the same time frame. Immunoassays can also provide subspecies-level information about the target pathogen that cannot be obtained from biochemical testing alone. This is an important initial step taken by regulatory agencies for linking foodborne and clinical strains during a food-associated illness outbreak.

Antibody Modifications

Antibodies

Immunoassays rely on antibodies to capture and/or detect the target of interest. The antibodies used in immunoassays are broadly classified as either polyclonal or monoclonal. Polyclonal antibodies are a population of antibody molecules that target the same antigen (e.g., bacterial cell wall) but at different locations on the antigen (i.e., epitopes). Polyclonal antibodies are purified from the serums of animals that have been inoculated with the target antigen; commercially available antibodies are frequently obtained from goats, rabbits, or mice. In contrast, monoclonal antibodies recognize the same epitope on the target antigen. The production of monoclonal antibodies is more complicated than the production of polyclonal antibodies. The host animal is inoculated with the target antigen, and after an appropriate incubation period, B cells (antibody-producing cells) are isolated from the host's spleen. Individual B cells are fused with myeloma cells (cancerous B cells), forming a hybridoma and allowing the antibody-producing B cell to be propagated *in vitro* without the need for an animal host and, with proper maintenance, allowing for the production of the antibody for an indefinite period of time. There are several excellent references at the end of this article that provide a more in-depth description of antibody production.

Both polyclonal- and monoclonal-based immunoassays are frequently used for food safety applications, and each type has its own benefits. Polyclonal antibodies are usually far less expensive to produce than monoclonal antibodies, and so, immunoassays using the former tend to be more popular and more widely available. Recognizing multiple epitopes can be an added benefit for polyclonal antibody-based assays when the entire genus or species is pathogenic. A good example of this situation is the genus *Salmonella*. There are two recognized species of *Salmonella*, *S. bongori* and *S. enterica*, and both are considered pathogenic. There is considerable variation associated with the cell wall of *S. enterica*. This variation can limit which strains of the organism can be captured and/or detected by the assay depending on the presence or absence of the specific epitope recognized by the antibody. The use of a monoclonal antibody-based assay for the capture and/or detection of *Salmonella* may limit its sensitivity (i.e., inclusivity) by only being able to recognize a fraction of the strains associated with foods. In order to ensure that the assay recognizes as many strains as possible, a polyclonal antibody assay would be more appropriate; sometimes, antibodies are used in combination with other ligands such as recombinant phage proteins to further increase assay sensitivity. For other foodborne pathogens, it is more desirable to use a monoclonal antibody-based immunoassay for capture or detection. A good example is *Escherichia coli*, which has both pathogenic and nonpathogenic strains within the same species and can frequently be found in food environments; the most widely recognized pathogenic subtype is *E. coli* O157:H7, which gets its designation based upon its reaction with specific monoclonal antibodies or antiserums. When only a fraction of the species is pathogenic, it is desirable to use a monoclonal

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00386-X

antibody-based assay that targets the pathogenic strains with little to no cross-reactivity with the nonpathogenic strains.

Another beneficial utility of monoclonal antibody-based immunoassays is the ability to exploit their narrow epitope recognition sensitivity for classifying bacteria at the subspecies level. Subspecies classification is commonly used to establish relatedness between strains, to distinguish between pathogenic and nonpathogenic strains within the same species, and to provide an initial link between clinical and foodborne isolates during a foodborne outbreak of disease. At the subspecies level, there are numerous subtypes of *S. enterica* based upon monoclonal antibody typing; these are referred to as serotypes or serovars and are based on the original classification by Kauffman and White. Although there are only two species of *Salmonella*, there are over 2400 serotypes of *S. enterica*.

Several advancements have been made that enhance the performance or extend the utility of antibodies in terms of assay design and function. One such advancement is the use of antibody fragments as opposed to the entire antibody. The use of antigen-recognizing fragments of the antibody for either capture-based or detection-based assays can result in increased sensitivity. For capture-based assays, this is due primarily because more antibody fragments can occupy the same surface area compared with intact antibodies. For detection-based assays, steric hindrance will limit the number of intact antibodies that can bind to a target (e.g., bacterial cell). Antibody fragments, because of their smaller size, may be able to occupy more of those available binding sites on the target.

Attachment Chemistries

Although antibodies are the 'backbone' of immunoassays, the ability to modify antibodies in order to maximize their utility is almost as equally important. Modification of antibodies allows them to be tethered to solid supports such as columns, beads, or plates, giving rise to several different types of antigen capture platforms. Immobilized antibodies are useful in recovering low levels of target pathogens directly from foods, aiding in removing potential matrix-specific interferences, which hinder subsequent detection steps, and isolating pathogenic species/subtypes from enrichment broths containing other closely related species/subtypes. Additionally, antibody attachment chemistries allow for the addition of specific signal-generating chemistries such as fluorescent molecules or enzymes that yield colored signals upon the addition of substrate.

Perhaps, the most widely recognized and utilized attachment chemistry for modifying antibodies is based on the avidin–biotin interaction. Avidin is a commercially available biotin-binding protein typically isolated from the egg whites of hens. Biotin is also known as vitamin B_7 and is a water-soluble B vitamin that is an important cofactor for many carboxylase enzymes. The biotin molecule has a reactive carboxylic acid group to which a spacer molecule can be attached. The spacer molecule separates the biotin from the antibody, thus minimizing steric hindrance during avidin binding. Spacer groups are typically simple alkyl groups (6-aminohexanoic acid) or polyethylene glycol groups linked together. At the end of the spacer, there is another reactive group that allows the biotin to be covalently attached to the antibody. A succinimidyl ester is the most commonly used reactive group, and it reacts with primary amine groups (i.e., ε-amino group of lysine) on the surface of the folded protein. In addition to amine-reactive chemistries, there are reactive chemistries that target sulfhydryl groups of proteins (e.g., maleimide and iodoacetyl) and reactive chemistries that target carboxyl groups of proteins (i.e., amine).

Signal/Detection Chemistries

Another important antibody modification that has greatly expanded the number of immunoassay platform types is the ability to label with a reporter group (e.g., fluorescent molecule or enzyme). The antibody recognizing the target antigen (i.e., the primary antibody) can be directly labeled with a reporter group. However, more frequently, a secondary antibody is labeled with the reporter group; a secondary antibody does not directly recognize the target antigen but binds to the primary antibody, which recognizes the target. The purpose of using a labeled secondary antibody is to amplify the signal since the target antigen may be present in low quantities and because multiple-labeled secondary antibodies can bind to a single primary antibody. An added benefit to using labeled secondary antibodies is that they are commercially available with a wide variety of reporter groups. Because secondary antibodies are species-specific in their epitope recognition and are produced from just a few animal species (e.g., anti-goat and anti-rabbit), they can be used in a wide range of applications, making it economical for manufacturers to supply them.
