EDITORS-IN-CHIEF

Benjamin Caballero is professor of International Health and of Maternal and Child Health (Bloomberg School of Public Health), and professor of pediatrics (School of Medicine) at Johns Hopkins University.

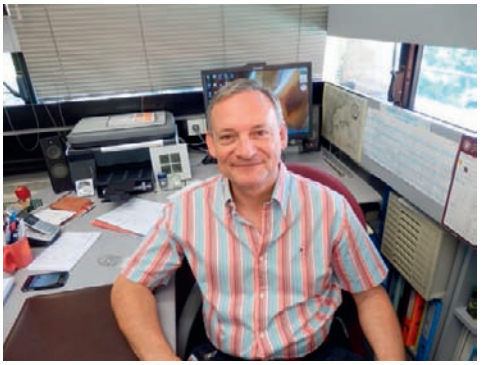
He obtained his MD from the University of Buenos Aires, his MSc in biochemistry from the University of San Carlos, and his PhD in neuroendocrine regulation from MIT, in Cambridge, MA. He started his academic career as assistant professor of pediatrics at Harvard Medical School and director of the Nutrition Unit of Boston Children's Hospital, and subsequently became the founding director of the Center for Human Nutrition at Johns Hopkins University, in Baltimore.

Prof. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries. He was a member of the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, USA, and of a number of expert panels created by the Institute, including the Dietary Reference Intakes (DRI) Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration (FDA), and of a number of advisory committees of the National Institutes of Health (USA).

He is the editor-in-chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption and biological effects. He is also editor-in-chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. His book *The Nutrition Transition: Diet and Disease in the Developing World* explored the impact of demographic and economic development on diet- and lifestyle-related diseases in developing countries. His book *Obesity in China* summarizes research conducted in rural and urban China to track the impact of socioeconomic development on health outcomes. He is also coeditor of a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

He is a member of the Spanish Academy of Nutritional Sciences, and a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK). Recent awards include the Donald Medearis Lectureship from the Massachusetts General Hospital/Harvard Medical School, the Mataix Prize for lifetime achievements in nutrition science from the Spanish Academy of Nutritional Sciences, the Ancel Keys Prize for achievements in international public health, and the Thompson–Beaudette Lectureship from Rutgers University.

Paul Finglas joined the Institute of Food Research in 1981 and is currently head of the Food Databanks National Platform and Research Leader in Food and Health at the Institute (http://www.ifr.ac.uk/science/platform/FD/default.html). He has, for most of his science career, been involved in a wide range of research in food composition and analysis, and the nutritional effects of micronutrients in food and health research. Paul has considerable experience of co-coordinating both national and international projects (e.g., EuroFIR, TDS-EXPOSURE, Bacchus and QualiFY (all EU FP7), and is currently of the spin-out EuroFIR AISBL, a non-profit international association based in Belgium, from one of these projects. Paul has a broad range of experience in science publishing and is currently editor of the journals *Food Chemistry* and *Trends in Food Science and Technology*, and was one of the coeditors for the *Encyclopedia of Food Science and Nutrition* (2nd Ed.). Paul has a degree in chemistry from Aston University in Birmingham and has published over 150 publications on a wide range of topics in food science and nutrition.



Fidel Toldrá holds a BSc in chemistry (1980), high degree on food technology (1981) and PhD in chemistry from the University of Valencia (1984). Professor Toldrá was a Fulbright postdoctoral scholar at Purdue University in West Lafayette (US, 1985–86) and visiting scientist at the University of Wisconsin-Madison (1991 and 1995), and the Institute of Food Research-Bristol (UK, 1987). Currently, he is research professor at the Instituto de Agroquímica y Tecnología de Alimentos (CSIC), in Paterna, Valencia (Spain). He is also associate professor of food technology at the Polytechnical University of Valencia.

Prof. Toldrá has focused his research on food biochemistry and its relationship with nutrition, quality and safety. He has filed 12 patents, directed 22 PhD thesis and published over 245 manuscripts in recognized scientific journals and more than 115 chapters of books. His h-index is 41. Prof. Toldrá has authored two books and edited/co-edited more than 30 books for major publishers like CRC Press, Wiley-Blackwell, Elsevier and Springer.

Prof. Toldrá is the European editor of *Trends in Food Science and Technology* (2005–) and associate editor of *Meat Science* (2014–); he was the editor-in-chief of *Current Nutrition & Food Science* (2005–2012), section editor of the *Journal of Muscle Foods* (2009–2010) and guest editor of 12 special journals issues. He is a member of the editorial boards of *Food Chemistry*, *Food Analytical Methods*, *Journal of Food Engineering*, *Journal of Food and Nutrition Research*, *The Open Nutrition Journal*, *The Open Enzyme Inhibition Journal*, *Recent Patents in Agriculture*, *Food and Nutrition*, *Food Science & Nutrition* and *Current Opinion in Food Science*.

He has been a member of the Scientific Panel on food additives, flavorings, processing aids and materials in contact with foods (periods 2003–2008) and the Scientific Panel on flavorings, enzymes, processing aids and materials in contact with foods (2008–2015) of the European Food Safety Authority (EFSA) acting as Chairman of the Working groups on Irradiation (2009–2010), Processing Aids (2011–2014) and Enzymes (2010–2015). He was a member of FAO/WHO group of experts to evaluate chlorine-based disinfectants in the processing of foods (2008–2009). He was a member of the Executive Committee of the European Federation of Food Science and Technology (EFFOST, 2002–2009). He is a Fellow of the International Academy of Food Science and Technology (IAFOST, 2008) and of the Institute of Food Technologists (IFT, 2009–). He received the Iber Award on Food and Cardiovascular Diseases (1992), the Institute Danone award in Food, Nutrition and Health (2001), the International Prize for Meat Science and Technology from the International Meat Secretariat (2002), GEA award on R+D activity from the Valencian Community (2002), and the Distinguished Research Award (2010) and Meat Processing Award (2014), both from the American Meat Science Association.

EDITORIAL ADVISORY BOARD

Siân Astley has worked extensively with individuals and organizations throughout Europe from a variety of disciplines including research, food and biotech industries, and the media. She is the author of more than 300 popular science articles for magazines and trade publications as well as 25 peer-reviewed papers, and she was awarded her Diploma in Science Communication in 2009 (Birkbeck University of London). After 14 years as a bench-scientist, Siân became communications manager for NuGO, one of the first FP6 networks of excellence, and was the European communications manager for the Institute of Food Research in Norwich (UK) until April 2012. Currently, she is the training and communications manager for the European Food Information Resource (EuroFIR AISBL) supporting training within EU-funded research projects and networks, and communication of research activities.

David J. Baer is a supervisory research physiologist with the US Department of Agriculture's Beltsville Human Nutrition Research Center located in Beltsville, Maryland. He serves as the research leader for the Center's Food Components and Health Laboratory and also serves as the director of the Center's Human Studies Facility.

Dr. Baer conducts controlled dietary intervention studies to investigate the relationship between diet and the risk for chronic degenerative diseases, especially cardiovascular disease, cancer, and diabetes in people. His research also includes studies on the health impacts of weight gain and determining the calorie content of foods. Some of the dietary interventions he has investigated include the effects of different types of protein, fats and fatty acids, fiber, margarine, butter, plant sterols, salad dressings, nuts, whole grains, berries, alcohol, and tea on overall nutrition and health. In addition to dietary intervention studies, Dr. Baer is involved in research studies to validate food survey methodologies and in developing new methods for dietary assessment.

Dr. Baer earned his bachelor's degree from the University of Illinois and his master's and doctorate in nutrition from Michigan State University.

Marina Carcea was awarded a master degree in agricultural sciences at the University of Pisa, Italy "cum laude" in 1980, and a PhD in food science also "cum laude."

She is currently a senior researcher in the Research Center on Food and Nutrition of the Council for research in agriculture and analysis of agricultural economy (CRA-NUT formerly INRAN National Research Institute on Food and Nutrition) and she was the director of the Cereals Research Programme in INRAN. CRA-NUT is a primary research institute in Italy under the egis of the Ministry of Agriculture. Dr. Carcea joined INRAN in 1989 after having worked in Italian and English universities (Queen Elizabeth College, King's College, and University of London) and after a two-year contract with the Food and Agriculture Organization (FAO) of the United Nations (UN), Rome.

She has a vast experience in the field of research on foods, cereals in particular. In recent years, her main research interests have been: chemical characterization and study of the functional properties of cereal components; study of the interactions between components and of the interrelationships between the biochemical properties of components and the technological properties of the raw material and derived products; development of new, cereal-based products; development of methods to assess technological parameters of the raw material; nutritional value of cereals; and developments of protocols for quality assurance of cereals, food authenticity.

She has taken part and/or co-ordinated several research projects within national or international programs (European Commission, FAO) involving several institutions. She is the author of more than 160 scientific publications, mostly in international journals, eight book chapters, and two scientific books. She delivered lectures on her research activity at about 150 national and international congresses and she seats in several national and international committees (Italian Ministry of Agriculture, Codex Alimentarius, and European Commission) regarding food and nutrition topics. She is also a member of the editorial board of scientific journals.

From 1994 to 2006, she has also been a lecturer of food science and technology at the University of Tor Vergata, Rome, Italy.

She is a founding member of AISTEC, the Italian Association of Cereal Science and Technology. Since 1996, she is an elected member in the Executive Committee of the same association and since 2009, president of the association.

Since 2000, she is the Italian National Delegate of the International Association for Cereal Science and Technology (ICC) and she was also the president of the same association for 2011–2012.

In 2004, she was the first woman to be awarded the International Harald Perten Prize for her excellent research achievements in the field of cereal science and technology.

She is also a member of the Georgofili Academy in Florence, Italy.

Lawrence J. Cheskin graduated from Dartmouth Medical School and completed a fellowship in gastroenterology at Yale–New Haven Hospital. He is an associate professor of health, behavior, and society at the Johns Hopkins Bloomberg School of Public Health, with a joint appointment in International Health–Human Nutrition, and in medicine (GI) at the Johns Hopkins University School of Medicine. Dr. Cheskin is also a founder and director of the Johns Hopkins Weight Management Center, a comprehensive treatment program for obesity.

In his research, Dr. Cheskin has studied the effects of medications on body weight, the gastrointestinal effects of olestra, how cigarette smoking relates to dieting and body weight, and the effectiveness of lifestyle and dietary changes in weight loss and weight maintenance.

He is also the author of four books: *Losing Weight for Good*, *New Hope for People with Weight Problems*, *Better Homes and Gardens' 3 Steps to Weight Loss*, and *Healing Heartburn*. Dr. Cheskin has appeared on television news programs and lectured to both professional and lay audiences on the topics of obesity and weight control.

Nigel Cook is a graduate of the University of Dundee. After postdoctoral research in the Universities of Aberdeen and Leicester, he moved to the Central Science Laboratory (now the Food and Environment Research Agency (FERA)) at the Food Science Laboratory, Torry, Aberdeen in September 1994, before relocating to new facilities in York. At FERA, he studies the transmission of pathogens, particularly enteric viruses, through foods and the environment. He has a visiting professorship at the Katholieke Universiteit Leuven in Belgium. He is a councilor of the International Association for Food and Environmental Virology. He is a project leader within the standardization working group ISO TC34 SC9 WG6, currently developing a standard for detection of *Cryptosporidium* and *Giardia* on berry fruits and leafy green vegetables. He was a coordinator of the European Framework 7 project "Integrated monitoring and control of foodborne viruses in European food supply chains (VITAL)," and a chair of COST Action 929 "A European Network for Environmental and Food Virology" from 2006 to 2010. Between 2009 and 2014, he was a member of various European Food Safety Authority's Working Groups preparing opinions on the risk of foodborne viruses, and represented the European Communities on the Codex Committee on Food Hygiene Working Group developing *Guidelines on the Application of General Principles of Food Hygiene to the Control of Viruses in Food*. He was a member of the UK Advisory Committee on the Microbiological Safety of Food's Viral Infections Subgroup. He was the founding editor of the journal *Food and Environmental Virology*, published by Springer.

Luca Simone Cocolin graduated in 1994 in food science with a grade of 110/110 and remark followed by food biotechnology PhD studies from 1995 to 1998. In February 1999, he defended his thesis acquiring the title of PhD in food biotechnology. From 1998 to 2001, he received a scholarship from the Friuli Venezia Giulia region (Italy). From November 1, 2001, he was an assistant professor at the University of Udine, Faculty of Agriculture, Food Science Department, Italy, and in October 1, 2006, he became an associate professor at the University of Torino, Italy. In January 2014, he had the habilitation for full professor and from June 2015, he is the full professor in food microbiology at the University of Torino.

From September 2008, he is an executive board member of the International Committee on Food Microbiology and Hygiene (ICFM) part of the International Union of Microbiological Societies (IUMS) (http://www.icfmh.org/). From January 2008, he is the editor-in-chief of the *International Journal of Food Microbiology* and he is a member of the editorial board of *Applied and Environmental Microbiology*, *Food Analytical Methods*, *Frontiers in Food Microbiology*, and *Frontiers in Nutrition and Food Science Technology*. He regularly reviews paper for *Food Microbiology*, *Meat Science*, *Journal of Applied Microbiology*, and *Letters in Applied Microbiology*. He is a co-author of more than 180 papers on national and international journals and he attended national and international congresses with oral and poster presentations. On Scopus (www.scopus.com, consulted on March 2015) he has 172 documents reviewed, which were cited 3520 times, resulting in an h index of 33.

His scientific interests comprise:

development, optimization, and application of molecular methods for the detection, quantification, and characterization of foodborne pathogens;
study of the microbial ecology of fermented foods (mainly sausage, cheese, and wine) by using culture independent and dependent methods;
bioprotection: molecular characterization of bacteriocin production and its study *in vitro* and *in situ*;
selection of new putative probiotics from artisanal fermented foods; and
study of the human microbiome and its influence on human health.

Christopher Duggan, for the past 25 years, has been performing clinical trials in the fields of pediatric nutrition, gastroenterology, and global health. His early work centered on the management of diarrheal diseases in children, including trials that demonstrated the feasibility and efficacy of oral rehydration solutions (ORS) for diarrhea management in the United States and globally. In collaboration with colleagues at Harvard TS Chan School of Public Health and Muhimbili University of Health and Allied Sciences in Dar es Salaam, Tanzania, Dr. Duggan and colleagues are evaluating the efficacy of micronutrient supplementation in infants and young children born to women with or at risk of HIV infection. Recent studies include the development of new biomarkers of environmental enteric dysfunction as well as the evaluation of nutritional status on neurodevelopment. With colleagues at St John's Research Institute in Bangalore, India, he is evaluating the efficacy of maternal vitamin B12 supplementation on biochemical and clinical parameters during pregnancy and infancy. He is a course co-director of the Bangalore, Boston Nutrition Collaborative (http://bbnc.globalhealth.harvard.edu). Past and present research support has come from the National Institutes of Health, the Gates Foundation, and the World Health Organization.

In addition to his global health research interests, he is a pediatric gastroenterologist and a nutrition physician at Boston Children's Hospital where he directs the Center for Nutrition (http://www.childrenshospital.org/nutrition). He is a medical director of the Center for Advanced Intestinal Rehabilitation, one of the largest centers in the United States for the care of children with intestinal failure/chronic diarrhea syndromes (http://www.childrenshospital.org/cair). He is also the course co-director of an inaugural Harvard College course "Nutrition and Global Health" and mentors undergraduate, graduate, and postdoctoral students at HMS and HSPH (http://www.hsph.harvard.edu/nutrition-and-global-health/).

He is a professor of pediatrics at Harvard Medical School and a professor in the Department of Nutrition at the Harvard TS Chan School of Public Health (http://www.hsph.harvard.edu/faculty/christopher-duggan/).

Jed William Fahey's current research concerns elucidating the mechanisms of how plants protect themselves against unfavorable and stressful conditions, and how this understanding can be translated to chemoprotection of eukaryotic mammalian systems. This work draws on elements of natural product chemistry, enzymology, nutritional epidemiology, and clinical research in order with isothiocyanates (e.g., sulforaphane) and glucosinolates. His work led to the discovery that broccoli sprouts are an exceptionally rich and consistent source of phytochemicals that induce the detoxification of carcinogens, and to the development of methods for their detection and for assessing their metabolism in humans. He discovered that one of the inducers, sulforaphane, has potent antibiotic activity against *Helicobacter pylori*, a causative agent of peptic ulcer and stomach cancer, and followed up with trials in animals and in *H. pylori*-infected humans. Ongoing collaborations examine the effects of broccoli, Moringa, and the other plants and their phytochemicals against a range of chronic diseases. Dr. Fahey has for years taught courses in chronic disease prevention and nutrition at both medical and public health schools.

Manuel Franco is an associate professor at University of Alcalá in Madrid (Spain) where he leads the social and cardiovascular epidemiology research group (http://www3.uah.es/cardiosocialepi/). He is also an adjunct professor at Johns Hopkins University (Baltimore).

Prof. Franco's work focuses on the social determinants of cardiovascular diseases and its major risk factors as diet. His methodological interests include the measurement of the urban environment and large social and economic changes in relation to cardiovascular health. He is the lead investigator of the Heart Healthy Hoods, study funded by the European Research Council, that will study the urban environment in relation to cardiovascular health in Madrid (http://hhhproject.eu/). This longitudinal study will be collecting neighborhood level data (via audits, Google Street view, photovoice, and qualitative methods) and linking them to clinical outcomes collected from patients enrolled at the City of Madrid primary healthcare clinics. Prof. Franco trained in Spain and Germany to obtain his MD and obtained his PhD from Johns Hopkins Bloomberg School of Public Health working with Dr. Ana Diez-Roux in the MESA study on food environment and dietary patterns. He has published over 30 international high impact articles and collaborates with universities in the United States, Europe, and Latin America.

Maria Glibetic is a research director of Centre of Research Excellence in nutrition research, Institute for Medical Research in Belgrade, University of Belgrade, Serbia, and member of executive board of directors for food data association EuroFIR AISBL. She is an experienced basic and nutritional scientist with over 250 scientific publications and presentations. Maria has considerable experience in leading national and international projects and since 2006, she participated in nine EU funded projects including EuroFIR, EURRECA, BaseFOOD, CHANCE, BACCHUS, and ODIN. Maria and her team are responsible for the creation of the first online national food database, for designing food data management system, and for the development of different nutritional tools for intake analysis. She was a principal leader of many nutrition intervention studies evaluating the plant bioactive component effects on human cardiovascular health. She leads postgraduate department for integrated nutritional sciences at University of Belgrade, where she teaches two courses.

Linda Harvey obtained her PhD from the University of East Anglia, UK. She is currently the head of the Human Nutrition Unit at the Institute of Food Research, Norwich, UK. Her research interests include micronutrient requirements, bioavailability, and metabolism.

Ronald Jackson received his bachelor's and master's degrees from Queen's University and doctorate from the University of Toronto. His time in Vineland, Ontario, and subsequent sabbatical at Cornell University, redirected his interest in *Botrytis* toward viticulture and enology. As part of his teaching duties at Brandon University, he developed the first wine technology course in Canada. For many years he was a technical advisor to the Manitoba Liquor Control Commission, developing sensory tests to assess candidates of its sensory panel, and was a member of its external tasting panel. He is the author of *Wine Science: Principles and Applications, 4th edition* (2014), *Wine Tasting: A Professional Handbook, 2nd edition* (2009), *Conserve Water, Drink Wine*, and chapters and technical reviews in other multiple books and encyclopedia. He is retired in Bronte, Ontario, but remains active writing, cycling, doing yoga, and traveling, as well as being a fellow in the Cool Climate Viticulture and Oenology Institute, Brock University, St. Catharines, Ontario, Canada.

Joe P. Kerry is a senior college lecturer and the head of the food packaging research group in the School of Food and Nutritional Sciences at University College Cork (UCC). He received his doctorate in microbiology at University College Galway in 1995. Prof. Kerry is also a qualified member of the Institute of Packaging. He is very involved in national and international research projects both at fundamental and applied levels. Primary research interests address various aspects of food packaging, shelf-life stability, food composition, and numerous aspects of food quality, particularly in relation to muscle foods. He also has very strong links with industry and his research team assists companies in relation to many aspects of new food product development. He has over 220 publications in peer-reviewed international journals, over 300 presentations at major international conferences, along with several other significant publications. His expertise includes use and manipulation of modified atmosphere packaging systems for use with foods, use of extrusion technology for the manufacture of food products/packaging materials, and applications and sensor/new technology developments within the area of food packaging, especially in the area of smart packaging.

Frédéric Leroy, after studying bio-engineering at Ghent University, obtained a PhD in applied biological sciences at the Vrije Universiteit Brussel in 2002, where he continued his academic career at the research group of Industrial Microbiology and Food Biotechnology (faculty of sciences and bio-engineering sciences). As associate professor, his lecturing activities include courses in food science and technology (i.e., "Nutrition," "Technology of animal products," "Food microbiology and ecology," and "Quantitative and predictive microbiology"). Dr. Leroy's research primarily deals with the ecology and functional roles of bacterial communities in (fermented) foods, in particular with respect to the generation of quality, safety, and/or nutritional and health advantages. Focus is mostly on meat products, but other food systems are also being studied, including fermented milks and sourdough breads. In addition, his research interests relate to elements of tradition and innovation in foods, both from a technological and societal point of view.

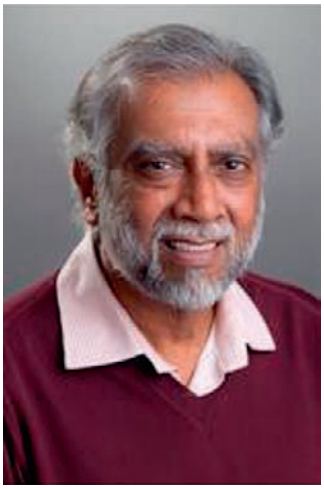
Catherine M. Logue completed her undergraduate and postgraduate degrees in Ireland and earned a PhD in meat microbiology from the University of Ulster, UK in 1996. Dr. Logue was a faculty member at North Dakota State University from 1999 to 2011 rising through the ranks of assistant to associate and full professor. In 2011, she re-located to Iowa State University's College of Veterinary Medicine and is a professor of veterinary microbiology and preventive medicine. Dr. Logue is also the director of faculty and staff advancement and equity for the college. Her research interests focus on foodborne pathogens of food animals and the contamination of meat and meat products destined for human consumption. Her research studies the detection, isolation, and characterization of a range of foodborne pathogens such as *Salmonella*, *Campylobacter*, *Listeria*, *Escherichia coli*, and methicillin-resistant *Staphylococcus aureus* (MRSA) in poultry, bovine, and swine. She also focuses her research on antimicrobial resistance in commensals and pathogens of production animals. She has been an author and a co-author on more than 90 peer-reviewed papers and book chapters as well as more than 150 abstracts and presentations at national and international meetings.

F. Xavier Malcata graduated in chemical engineering in 1986 from the University of Porto (Portugal), received a PhD in chemical engineering/food science from University of Wisconsin, Madison (USA) in 1991, and his habilitation in food science and engineering by Portuguese Catholic University in 2002. He was the dean of College of Biotechnology of Portuguese Catholic University, the chairman of Portuguese Society of Biotechnology, Portuguese representative at VI and VII European Union Framework Programs of research and development, expert for European Food Safety Agency, and a co-ordinator of Portuguese Engineering Accreditation Board in chemical engineering for Northern Region. He is currently a full professor at University of Porto.

His major research interests have focused on technological improvement of traditional Portuguese foods and upgrade of byproducts thereof, development of nutraceutical ingredients and functional foods, design and optimization of enzymatic reactors for edible oil processing, characterization of plant proteases toward cheese and whey cheese manufacture, production of starter and nonstarter cultures from adventitious microflora, and optimized application of unit operations to food processing.

With an academic career of independent research and teaching for more than two decades, Prof. Malcata published more than 450 papers in refereed journals worldwide, wrote 11 books, and prepared more than 45 chapters for edited books. Among many international distinctions, he was

recipient of Ralph H. Potts Memorial Award in 1991 by American Oil Chemists' Society (AOCS, USA), Foundation Scholar Award – Dairy Foods in 1998 by American Dairy Science Association (ADSA, USA), Young Scientist Research Award in 2001 by AOCS, Canadian/International Constituency Investigator Award in physical sciences and engineering in 2002 and 2004 by Sigma Xi (USA), Danisco International Dairy Science Award in 2007 by ADSA, Scientist of the Year Award in 2007 by European Federation of Food Science and Technology (the Netherlands), Samuel C. Prescott Award in 2008 by Institute of Food Technologists (IFT, USA), International Leadership Award in 2008 by International Association for Food Protection (IAFP, USA), Elmer Marth Educator Award in 2011 by IAFP, Distinguished Service Award in 2012 by ADSA, and William V. Cruess Award in 2014 by IFT. He has been elected for the honor societies of food science (Phi Tau Sigma, USA), scientific research (Sigma Xi, USA), and engineering (Tau Beta Pi, USA). He was also elected for fellow of IFT, ADSA, AOCS, and International Academy of Food Science and Technology.



Gopinadhan Paliyath is a professor at the Department of Plant Agriculture, University of Guelph, and the research program director for "Food for Health," under the UG/OMAFRA partnership. Dr. Paliyath is a biochemist and has an interest in various aspects of fruits and vegetables, specifically the nutraceutical components and their mechanism of action. He obtained his BSc Ed degree (botany and chemistry) from the University of Mysore, MSc degree (botany) from the University of Calicut, and PhD degree (biochemistry) from the Indian Institute of Science, Bangalore. Subsequently, he did postdoctoral work at Washington State University, University of Waterloo, and University of Guelph. Dr. Paliyath's research is focused on the biochemistry of plant senescence, specifically pertaining to postharvest biology and technology of fruits and vegetables. Investigations on the role of phospholipase D (PLD) in membrane homeostasis and signal transduction have led to advances in the understanding of the mechanism of membrane deterioration that occur during stress and senescence. Another aspect of his research is focused on understanding the mechanism of action of food components in disease prevention. The efficacy, bio-accessibility, bioavailability, and molecular mechanisms of action of nutraceuticals in fruits and processed products in relation to their cancer-preventive and anti-inflammatory actions are being investigated using mammalian cell lines, and animal model systems.

Dr. Paliyath has developed technologies and products for enhancing the shelf life and quality of fruits and vegetables based on PLD inhibition. R&D activities relevant to the industry sector include: (1) optimization of an enhanced freshness formulation for application to various fruits, vegetables, and flowers; (2) developing methods for nutraceutical carriers that would enhance the functional food quality and delivery (e.g., stabilizing lycopene in tomato juice, sauce, etc., for health beneficial effects); and (3) developing novel technologies to enhance the cancer-preventive ingredients in fruit products, etc. Patents awarded include: (1) # 6,514,914 (US) and 2,298,249 (Canada); (2) #7,198,811 (USA), 4141387-1 (Japan), 260738 (Mexico), 1469736 (Turkey), 028 284763 (China), and 223077 (India). The patents describe the use of nanoformulations based on hexanal and other generally regarded as safe (GRAS) ingredients for enhancing the shelf life and quality of fruits, vegetables, and flowers by pre or postharvest treatments. These technologies are currently being evaluated for extending shelf life and quality of mango in India and Sri Lanka with the assistance of the Canadian International Food Security Research fund. The collaboration involves researchers from Canada, India (Tamil Nadu Agricultural University), and Sri Lanka (Industrial Technology Institute).

Dr. Paliyath is also the research program director for the food and health theme-related activities under the OMAF/MRA/University of Guelph research partnership. He serves on the editorial board of several journals. He is a member of American Chemical Society and Canadian Society of Plant Biologists.

(Total-refereed publications in journals – 92; patents and intellectual properties – 2; disclosures – 4; chapters in books – 27; nonrefereed contributions – 10; research reports – 28; conference proceedings – 88; edited books – 9; book reviews – 6 (Google Scholar: h index – 31, i10 index – 68, citations – 4332; RG score – 35.63)).

Yolanda Picó is a full professor of nutrition and food science at the University of Valencia since 1998. She is currently the head of the research group on food and environmental safety of the University of Valencia. Her research interests are the development of new analytical methods to determine organic contaminants in food and the environment, identification of unknown compounds by liquid chromatography–mass spectrometry, micro-extraction separations, and environmental and food safety. To the date, she is the author of nearly 200 peer-reviewed papers, 170 scientific papers in journals of SCI, 25 book chapters, and editor of four books on food and environmental safety.

Vieno Piironen is a professor of food chemistry at the Department of Food and Environmental Sciences, University of Helsinki, Finland. She received her PhD in food chemistry at the University of Helsinki in 1987 and has approximately 35 years of experience in food research and education on bachelor, master, and PhD levels. She has participated actively in international research and education projects and networks. Her research has focused especially on chemical and nutritional properties, reactions and analysis of lipids, vitamins, and other bioactive compounds. Research on vitamins has been active from the beginning of 1980s. She has studied both lipid- and water-soluble vitamins; their chemical and nutritional properties and importance in foods and diets as well as factors influencing vitamin levels. In addition, development of analytical methods for different vitamers as well as validation and harmonization of the methods through international collaboration have been among the priorities. Recent collaboration projects have focused on enhancing vitamin contents in cereal-based foods by plant breeding, utilization of vitamin-rich grain fractions, and bioprocessing. Currently, the research focus lies on investigating microbial *in situ* synthesis of folate, vitamin B12, and other B vitamins in cereal and legume matrices as a means to improve nutritional quality of foods and to develop new food applications. In lipid research, different lipid classes and their chemical and enzymatic reactions in food matrices are studied. Diverse methods are used to study proceeding of oxidation from primary products to monomeric oxides, volatiles, and polymerization products and to study possibilities to control oxidation. Controlling enzymatic reactions leading to off-flavors in cereal and legume matrices is also among the interests. Phytosterols and their conjugates have been studied as natural food components belonging to the dietary fiber complex. On the other hand, questions related to sterol enrichment such as oxidation susceptibility and mechanisms as well as factors affecting oxidation reactions have been of interest. She has also studied nutrients and anti-nutrients in legumes and more recently started research on utilization of high value components in microalgae. She has approximately 160 papers in international journals and a number of other publications.

David Rodríguez-Lázaro is a doctor in veterinary medicine (DVM), specialized in food science (BSc and MSc) and molecular microbiology (PhD). He is a senior scientist at ITACyL and an assistant professor of microbiology at the University of Burgos. He has performed research stays in the Danish Institute for Food and Veterinary Research (Denmark), the University of Prague (Czech Republic), the Food and Environmental Research Agency (UK), and the University of Bristol (UK). He was a Leverhulme visiting professor in the Institute of Advanced Sciences in the University of Bristol during the years 2004 and 2005 and Marie Curie research fellow in the faculty of medical and veterinary sciences in the University of Bristol (UK) until 2007.

His research interest is focused on the establishment of reliable, quantitative molecular strategies for detection of important food-borne pathogens from environmental sources and various types of foodstuffs, the characterization of the prevalence of the main foodborne pathogens in food and food-related environments, and the development of emergent food preservation processes and their effects in the microbial virulence. He has participated in a number of coordinated EU-funded projects such as PROMISE, BASELINE, VITAL, FOOD-PCR, SACROHN, and MONI-QA, having established active links with the leading European research groups working in food safety.

He has published more than 100 international scientific papers and book or book chapters regarding food safety. He is currently a member of the editorial board of *Applied and Environmental Microbiology*, *International Journal of Food Microbiology*, *Food and Environmental Virology*, and *International Journal of Food Contamination* and the editor-in-chief of the journal *Food Analytical Methods*. He was awarded with the XV Jaime Ferrán Award in 2013 by the Spanish Society for Microbiology for his promising scientific career in microbiology.

Turid Rustad is a professor and the head of the food science group at the Department of Biotechnology, Norwegian University of Science and Technology. The main research focuses on the biochemistry of marine raw materials, the relationship between biochemistry and quality, and changes in raw material properties during processing. Studies of enzymatic activities in different raw materials have been linked to studies of changes in the biochemistry of these raw materials. She has worked with characterization of composition and enzymatic processes in a wide range of different raw materials, such as fish, fish by-products, and zooplankton in relation to different storage and processing methods such as chilling, heating, superchilling, and frozen storage.

Noel W. Solomons has lived and worked in Guatemala for 40 years. He was born and educated in Massachusetts in the United States. As a young child, he became an amateur naturalist and was a nature counselor at various summer camps; this would guide him to a career in science. In his young adulthood, he would participate in the civil rights and anti-war movements, only to become disillusioned by the intractable nature of the injustice elements in the fabric of American society. As a physician by graduate training, he performed his university studies at Harvard College and Harvard Medical School; it was during overseas electives in his medical training that he visited Peru and Colombia and committed to an expatriate life trajectory outside of his homeland. Clinical training included a residency in internal medicine and infectious diseases at the Hospital of the University of Pennsylvania and specialization in gastroenterology and clinical nutrition at the University of Chicago. He became a resident of Guatemala in 1974 as an affiliated investigator at the Institute of Nutrition of Central America and Panama. He would later commute for eight years to a faculty position in the Department of Nutrition and Food Science of the Massachusetts Institute of Technology. Assuming a full-time Guatemala commitment in 1985, he co-founded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) where he remains its scientific director. Over 40 local university theses have been completed by Central American students in that institution as well as an equal number of master's degree research projects from international students from Europe, and North and South America. He has supervised doctoral dissertations for 12 PhD candidates from the United States, Canada, Germany, Spain, and the Netherlands through CeSSIAM.

Dr. Solomons has 332 publications indexed on Medline. In addition, he has edited two books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection.

Among the honors bestowed upon Dr. Solomons are the International Nutrition Prize of the International Union of Nutritional Sciences and the Kellogg Prize of the Society for International Nutrition Research. He is a fellow of the American Society of Nutrition. He is an academic member of the Guatemalan Academy of Medical, Physical and Natural Sciences and the Spanish Academy of Nutrition and Food Science. He was the awardee of the 2010 National Medal for Science and Technology for Guatemala.

He has been a visiting professor in university courses in Mexico, Peru, Brazil, Indonesia, and Spain. He currently holds adjunct professorial appointments at the Boston University School of Public Health, and the Friedman School of Nutrition Science and Policy and the Department of Community Medicine and Public Health, both at Tufts University. He is a founding board of directors, member of the Hildegard Grunow Foundation in Munich and the Essential Nutrient Foundation of Singapore. Finally, Dr. Solomons is a coordinator for Central America of the Nevin Scrimshaw International Nutrition Foundation in Boston, and an associate editor for the Foundation's *Food and Nutrition Bulletin*. He serves on editorial boards for ten scientific journals.

Maria Tsimidou is a professor of food chemistry and the head of the Laboratory of Chemistry and Technology in the School of Chemistry at the Aristotle University of Thessaloniki (AUTh), Greece. Her teaching is food chemistry, analysis, quality control, and food legislation. Research interests are related to virgin olive oil chemistry, quality and authenticity, saffron chemistry, authenticity and quality, antioxidant activity of plant extracts and constituents, new sources of targeted bioactive compounds (squalene, carotenoids, and phenols), and analytical procedures for their determination. She has published many research papers, review articles, and contributions to scientific books and encyclopedias on the above-mentioned topics. Currently, she is an associate editor in the *European Journal of Lipid Science and Technology* and chairs the COST ACTION FA1101 "Saffronomics."

Jorge Welti-Chanes earned his degree in biochemical engineering (1976) and master of science in food engineering (1978) at Tecnológico de Monterrey (ITESM, Mexico), later he moved to Spain to perform his doctoral studies in chemistry, in the area of food technology, obtaining his degree at the University of Valencia. He is currently the national director of graduate studies at School of Engineering and Sciences at Tecnológico de Monterrey also is professor and researcher in the areas of biotechnology and food at the same institution. He started his academic activity in 1976 as a university professor of ITESM, has additionally been a full professor at the National Polytechnic Institute (IPN, Mexico) and the University of the Americas, Puebla, Mexico (UDLA). He has an experience of 37 years as a teacher and university researcher, 20 of which were spent in combination with the development of administration work in education, science and technology. In the UDLA, he was teaching in the Departments of Chemistry and Biology and Chemical Engineering and Food, in the latter was responsible for the leadership for a period of a year and subsequently became dean of the School of Engineering (1986–1988). From January 1989 to June 2002, he was an academic vice chancellor at UDLA. He has published 14 books and has over 200 scientific publications in refereed journals and books, has given more than 250 presentations at international conferences. He is an associate editor of the journals *Food Engineering Reviews* and *Journal of Food Science* and participates as a member of the editorial boards of *Journal of Food Engineering* and *Current Opinion in Food Science*. In May 2011, he received the Life Achievement Award by the International Association for Engineering and Food (IAEF), for his career as a researcher and academic worldwide, and in January 2014, the Romulo Garza Award from the Tecnológico de Monterrey for the impact of their research work and as recognition for being one of the most productive researchers in the life of Tecnológico de Monterrey. He has been the president of ISOPOW and IAEF and is the currently president of the International Society of Food Engineering (ISFE).

Peter J. Wilde graduated in biophysics at the University of East Anglia in 1985 and has been researching the colloidal and interfacial properties of food systems at the Institute of Food Research (IFR) for over 25 years. IFR is the only publicly funded UK research institute that focuses on the underlying science of food and health to address the global challenges of food security, diet, and health, healthy aging, and food waste. IFR is the one of eight institutes that receives strategic funding from the Biotechnology and Biological Sciences Research Council (BBSRC). It also receives funding from government agencies and departments, the EU, charities, and industry, from the UK and overseas.

Pete's research expertise is the interfacial behavior of proteins and other surface active components in food relevant systems. The aim is to determine how the molecular and interfacial processes control the functionality of foams and emulsions. Currently, the functional aspects of his research have focused on improving the dietary impact of emulsified foods. These include fundamental studies on how interfacial layers control emulsion rheology to develop novel fat reduction strategies; the design of interfacial structures to control lipid digestion to promote satiety or the delivery of fat-soluble nutrients and drugs; and to determine the physico-chemical role played by the salivary film in perceiving fat content in emulsions. The impact of this research will be to aid the rational design of foods with enhanced nutritional benefits to address the global challenges of obesity, type 2 diabetes, and other major diet-related conditions.

HOW TO USE THE ENCYCLOPEDIA

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Contents

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

The majority of articles within the encyclopedia have an extensive list of cross-references that appear at the end of each article, for example:

See also: Anemia: Causes and Prevalence; Anemia: Prevention and Dietary Strategies; Iron: Biosynthesis and Significance of Heme; Iron: Physiology of Iron.

3. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

4. Contributors

A full list of contributors appears at the end of volume 5.

INTRODUCTION

Until a few decades ago, virtually all known health effects of foods were related to their content of essential nutrients. The clinical description of most diet-related illnesses mirrored the signs of essential nutrient deficiencies, such as pellagra, beriberi, and others. Consequently, the key public health concern regarding diet was ensuring that everyone consumed enough food. It was only in the past 50 years that large-scale epidemiological observations began to associate chronic diseases like diabetes and cardiovascular disease with nonessential diet constituents such as saturated fat, fiber, and cholesterol. Taking advantage of the emergence of digital informatics, these studies were able to manipulate increasingly large sets of data and provide, for the first time, a picture of the secular changes in the health of large populations and its association with what they ate regularly. These findings progressively shifted the concern from eating enough to avoiding excessive consumption of certain foods. Eating enough was replaced by eating well.

But it turned out that defining how to eat well is far more complex than defining minimum needs of essential nutrients. First, there is no single paradigm to study those relationships, given the wide variety of biological mechanisms and the long exposures involved. Second, many of the experimental models used to define essential nutrient needs are not applicable to the study of long-term effects of diets in free-living populations. And it is now clear that experiments with isolated dietary compounds do not reflect the actual effects of the complex food matrix we consume daily. Finally, while the discovery of essential nutrients and their role in health was the domain of a few specialties speaking a common language (primarily biochemists and physiologists), the study of the long-term effects of whole diets in humans must of necessity involve epidemiologists, social and behavioral scientists, food scientists, clinicians, policy experts, etc., making far more difficult the development of consensus and foundational concepts.

It is thus not surprising that today we have still not achieved a stable consensus on how to eat 'well.' Furthermore, while few nonscientists would care about the minimum requirement of a vitamin to sustain life, there are plenty of opinions among nonscientists on how to eat 'well.'

Our goal in preparing this encyclopedia has been to contribute to the understanding of that complex diet–health relationship by providing a multidisciplinary, integrative and accurate source of information. We aim to serve the needs not only of established and in-training scientists, but also of the increasingly important group of professionals who are key to disseminate and sustain the practice of science: journalists, science writers, science administrators, fund raisers, donors, and policymakers. In preparing this work, we had the enormous advantage of working with one of the publishers with the most extensive expertise in major reference works, Elsevier. This first edition builds on the impressive breadth of knowledge of over 922 authors and on the tireless work of our editorial advisory board. We are very grateful to all of them.

Introduction

Nonnutritive sweeteners (NNSs) have been utilized since the late 1800s with a significant increase in recent decades. NNSs (also known as noncaloric sweeteners, artificial sweeteners, very low-calorie sweeteners, and intense sweeteners) are a caloric sweetener (CS) replacement, which provide minimal or no calories. NNSs have thus been an attractive option in the setting of the obesity and diabetes mellitus epidemic and are found in thousands of foods and beverages. The majority of individuals cite reduced caloric intake as a major reason for using NNS, with other common reasons including goals of weight loss and reduced glycemic load. However, there has been controversy regarding the role of NNS in weight and glycemic control, among concerns for other adverse effects. A Mintel survey accordingly indicated that 64% of individuals are concerned with the safety of NNS use, highlighting the public awareness and perception of present controversies.

To date, six NNS have been approved by the FDA: acesulfame-K (ACK) (Sunett and Sweet One), aspartame (Equal and NutraSweet), neotame, saccharin (Sweet'N Low), sucralose (Splenda), and stevia (Truvia, Pure Via, and SweetLeaf) (Table 1).

ACK, which is often used in blends with other NNSs or CSs, is one of the most commonly used NNSs. ACK was approved by the US Food and Drug Administration (FDA) in 1988 for use in specific food and beverage categories. In 1998, ACK was also approved for use in soft drinks and in 2003 as a general purpose sweetener and flavor enhancer (except for use in meat and poultry).

The goal of this article is to detail the pharmacological properties and associated controversies regarding clinical outcomes for ACK.

Table 1 Non-nutritive sweeteners with acceptable daily intake (ADI), year of FDA approval, and common serving sizes

Sweetener and chemical structure	*Common brand names*	*ADI/JECFA toxicology monograph no. (year)*	*Year FDA-approved*	*Representative amount of sweetener in 12 oz soda (mg)*	*No. of servings = to ADI for a 150 lb (68 kg) person*	*Amount of sweetener in a packet (equivalent to 2 tsp sugar) (mg)*	*No. of packets = to ADI for 150 lb (68 kg) person*
Acesulfame-K	Sweet One	15 mg kg^{-1} bw 28 (1991)	1988	40 (Blended with aspartame)	25, 12 oz servings	50	20
Aspartame	Equal NutraSweet	40 mg kg^{-1} bw 15 (1980)	1981	187	14, 12 oz servings	40	68
Neotame	Neotame	2 mg kg^{-1} bw 52 (2004)	2002	Not in carbonated beverages		No consumer product	
Saccharin	Sweet'N Low	5 mg kg^{-1} bw 32 (1993)	Before 1958	8 (Blended with aspartame)	42, 12 oz servings	40	8.5
Sucralose	Splenda	15 mg kg^{-1} bw 28 (1991)	1999	68	15, 12 oz servings	11	30
Plant-based sweeteners, Stevia	Truvia Pure Via SweetLeaf	4 mg kg^{-1} bw 60 (2009)	2008	17	16, 12 oz servings	9	30

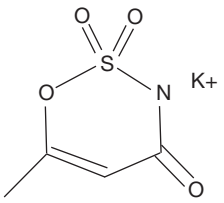

Figure 1 Chemical structure of ACK.

Sources and Production

Similar to a host of NNS previously accidentally identified, including saccharin in 1878, cyclamate in 1937, and aspartame in 1966, ACK was fortuitously discovered by Karl Claus and Harold Jensen in 1967. ACK is a potassium salt of 6-methyl-1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxide (Figure 1). Initial synthesis by Claus et al. involved a base of chlorosulfonyl or fluorosulfonyl isocyanate with propyne–acetone, which was subsequently cyclized by potassium to form ACK. Alternative methods of production later included the treatment of acetoacetamide with at least two equivalents of sulfur trioxide, which is subsequently dehydrated by sulfur trioxide to form oxathiaazinone dioxide. This results in the formation of *N*-sulfoacetoacetamide, which is then neutralized by potassium hydroxide. ACK content in processed foods can be analyzed by multiple methods, such as quantitative NMR, with high accuracy.

Availability, Absorption, and Metabolism

Radiotracer studies in animal and human models, as well as autoradiographic and quantitative studies in animals, have demonstrated that ACK is completely absorbed, distributed rapidly and evenly, and excreted renally. Human studies have shown that after the administration of a single dose of 30 mg of ACK, peak blood concentrations were achieved in 1–1.5 h. ACK was rapidly eliminated with a plasma half-life of 2–2.5 h. With up to ten repeated doses, no evidence of tissue accumulation nor increase in blood levels of ACK was seen in animals. Only the parent compound was identified in serum and urine indicating lack of significant biotransformation of ACK, suggestive of a biologically inert substance. Due to concerns about poor-quality toxicity tests, ACK was nominated twice for testing in 1996 and 2006 in the National Toxicology Program bioassay program and subsequently rejected and thus has not undergone such testing.

Patterns of Consumption

NNSs are used to enhance the flavor profile of thousands of beverages and food products and their use has increased in recent decades. ACK is touted as being approximately 200-fold sweeter than sucrose, though Antenucci et al. demonstrated that it may not surpass the perceived sweetness intensities of natural sweeteners (such as sucrose, maple syrup, and agave nectar), likely a function of increasing bitterness with concentration. Some individuals find the taste to be objectionable, and interestingly, Allen et al. identified two single-nucleotide polymorphisms felt to explain 13.4% of the variance in perceived bitterness. Accurate estimates of the exact intake of NNS are difficult as there are no requirements that the amount of NNS used in drinks and food be made available on food labels or released to federal agencies. Yang et al. estimated that 6000 new products with NNS became available between 1999 and 2004 with the most popular additives, sucralose and ACK, found in 2500 and 1103 products, respectively.

Overall, the consumption of NNS by both adults and children has increased significantly, presently utilized by 15–35% of the US population. Mattes and Popkins reported that approximately 15% of the US population consumed NNS in food or beverages from 2003 to 2004, as compared to 2.5% in 1965 based on their analysis of the data from the US Department of Agriculture Nationwide Food Consumption Survey and National Health and Nutrition Examination Survey (NHANES). The proportion of consumers ingesting NNS in beverages and foods from 1989 to 2004 increased by 6.9% and 81.2%, respectively. Overall, 10.8% of the population was estimated to consume NNS in beverages and 5.8% to consume NNS in foods. Interestingly, products with added sugars during this time period did not decrease, suggesting that NNS may not be acting as a substitute for products sweetened with sugar. Sylvetsky et al. further built upon the findings of Mattes and Popkin by using the NHANES database to evaluate trends among demographic subgroups stratified by the source of NNS. They reported that in 2007–2008, the prevalence of consumption of beverages with NNS increased from 6.1% to 12.5% among children ($P < 0.0001$) and from 18.7% to 24.1% in adults ($P < 0.001$) regardless of weight, age, socioeconomic, and race–ethnicity subgroups. They reported little change in the consumption of foods with NNS. Piernas et al. also demonstrated that from 2000 to 2010, the percent of households, particularly those with children, purchasing NNS and combined NNS and CS products increased, while those purchasing CS products alone decreased. The highest percentage of CS beverage purchases was seen among African-American and Hispanic households and households with children.

Presently, the acceptable daily intake (ADI) for ACK in the United States is 15 mg kg^{-1} body weight. Internationally, studies of estimated daily intake of ACK have generally been shown to be below the ADI in populations in Korea, Portugal, Italy, the Netherlands, Denmark, Norway, Australia, and New Zealand. A Swedish study including 1120 diabetics found that the ADI was never reached in men and women. However, worst-case calculations in young children demonstrated that ACK consumption may be as high as 169%. This study was limited in that it largely reflected soft drink use, as ACK was not used as a tabletop sweetener at that time.

Health Effects

Limited studies have examined the impact of ACK on health outcomes and the following is a focussed review.

Obesity

The relationship between NNS and weight has been controversial. While it has been hypothesized that NNSs facilitate weight

loss and/or weight maintenance as a low-calorie substitute, it has also been suggested that NNS may cause weight gain via changes in metabolic signaling and ultimately food intake. Evidence from observational studies and randomized controlled trials (RCTs) has largely been conflicting. While observational studies are limited by means of NNS assessment and confounding lifestyle factors, RCTs are generally short term in duration and may be difficult to broadly apply given increased subject awareness of NNS use and, in many instances, increased individual nutritional support from study staff.

Multiple observational studies have yielded conflicting results regarding NNS use in the setting of obesity. An early study by the American Cancer Society in 1986 demonstrated that based on survey results conducted over 1 year ($n = 78\,694$; age range 50–60 years), NNS users were significantly more likely to gain weight than nonusers. However, the difference in mean weight between treatment and control groups was approximately 0.9 kg (2 lbs), likely minimally clinically relevant. The applicability of the results was further limited due to methodological design. Subsequent short-term studies ranging from 10 days to 16 weeks did not support the initial findings from the American Cancer Society. Furthermore, an inverse association was reported in some studies. In the San Antonio Heart Study, 5158 adults were initially assessed from 1979 to 1988 and subsequently 7–8 years later. A positive dose relationship was seen between baseline intake of artificially sweetened beverages and change in body mass index (BMI). Overall, BMI changes were 47% greater among individuals who used artificial sweeteners as compared to nonusers ($+1.48\ \mathrm{kg\ m^{-2}}$ vs. $+1.01\ \mathrm{kg\ m^{-2}}$, $P < 0.0001$). Nettleton et al. performed an observational study including 5011 individuals in the Multi-Ethnic Study of Atherosclerosis cohort that demonstrated that diet soda use was associated with a 36% greater relative risk of incident metabolic syndrome as compared to individuals who did not consume diet soda (HR 1.36 (95% CI 1.11–1.66)). Specifically, an association between diet soda consumption and increased waist circumference and fasting hyperglycemia was noted. Of note, metabolic syndrome was not independent of baseline measures/changes in adiposity.

RCTs have also yielded conflicting data. De Ruyter performed a large RCT including 641 normal-weight children who were followed for 18 months and stratified to receive 8 oz $\mathrm{day^{-1}}$ of an artificially sweetened beverage or a sugar-containing beverage. The study demonstrated that the group receiving artificial sweeteners had reduced weight gain (weight 6.35 kg in the sugar-free group as compared with 7.37 kg in the sugar group (95% CI for the difference, −1.54 to −0.48) and fat accumulation. The Choose Healthy Options Consciously Everyday trial stratified adults to one of two intervention groups: water intake ($n = 106$, 94% women) or diet beverage intake ($n = 104$; 82% women). The study demonstrated both intervention groups decreased absolute intakes of total daily energy, carbohydrates, fat, protein, saturated fat, total sugar, added sugar, and other carbohydrates. However, overall, the diet beverage group decreased the intake of CS significantly more than the water group did, suggesting that the former group may have had better adherence to the diet. Furthermore, at 6 months, the diet beverage group decreased their intake of desserts significantly more than the water group. Overall, this study demonstrated that short-term consumption of diet beverages, as compared to water, did not increase preferences for sweet foods and beverages.

A recent meta-analysis by Miller and Perez including 15 RCTs and nine prospective cohort studies examined the relationship between body weight and composition and low-calorie sweeteners (LCSs) (defined as ACK, aspartame, luo han guo extract, neotame, saccharin, steviol glycosides, sucralose, cyclamate, thaumatin, neohesperidin dihydrochalcone, and alitame). Analysis of the RCTs demonstrated that the substitution of sugar for LCS resulted in modest weight reduction (0.80 kg), along with a decrease in BMI, fat mass, and waist circumference. It was hypothesized that it was unlikely that replacement of LCS for sugar was solely responsible for these changes. Rather, LCSs were felt to facilitate increased adherence to weight-loss or weight-maintenance plans. Analysis of the prospective cohort studies showed a modest significant positive association with BMI, but not with weight or fat mass. The prospective observational studies were felt to be limited due to inconsistent measurement of LCS intake and inadequate control of confounding variables such as diet and lifestyle factors.

Overall, the American Heart Association and American Diabetes Association (ADA) scientific statements concluded that there is insufficient evidence to conclude whether NNS use leads to weight loss or reduction in cardiometabolic risk factors.

Role in Diabetes Mellitus

Data regarding glycemic response to NNS have also been conflicting. Sweet taste receptors not only are expressed in the taste buds where they serve a gustatory function but also have been identified in endocrine cells in the gastrointestinal (GI) tract, pancreatic beta cells, rodent hypothalamic neurons, and adipocytes where they have roles in nutrition and fuel metabolism. Rat and mouse models have shown that CS and NNS may activate enteroendocrine sweet taste receptors by upregulation and insertion of small intestine transporters, facilitating glucose absorption. Glucose absorption at the small intestines occurs through two mechanisms predominantly: The Na^+–glucose cotransporter (SGLT) is predominantly responsible for active absorption in the setting of low glucose concentrations; however, at glucose levels of >30 mM in the lumen postprandially, SGLT2 is saturated, and thus, further glucose absorption is mediated by glucose transporter 2 (GLUT2). While SGLT1 is a known mediator of GLUT2, the activation of sweet taste receptors in the enterocyte and in the enteroendocrine cells of the gut may also be important. Zheng et al. examined the role of ACK on glucose uptake in the enterocyte by preincubating Caco-2, RIE-1, and IEC-6 cells starved from glucose for 1 h and subsequently measuring glucose uptake. The study demonstrated that ACK increased glucose uptake by 20–30% with glucose concentrations >25 mM in a GLUT2-dependent mechanism. While these effects were seen at 5 min of incubation, no additional effect was seen at 10 min suggesting that cells had maximized GLUT2 translocation by this time. Furthermore, NNS may increase GLP-1 secretion by intestinal neuroendocrine cells, but interestingly, intracellular signaling patterns were different for ACK, as compared to sucralose and saccharin.

There has accordingly been concern that the combination of NNS and glucose may worsen postprandial hyperglycemia, particularly in type 2 diabetics who may have overexpression of glucose transporters at baseline. Bryant et al. examined the role of NNS (aspartame, saccharin, and ACK) and glucose in commercially relevant doses on glycemic and appetite responses in ten individuals in a pilot study. None of the sweeteners caused a change in perceptions of hunger or fullness and neither aspartame nor saccharin had an impact on blood glucose response after administration of oral glucose. However, ACK did exert a small effect (blood glucose following oral glucose administration alone peaked at 15 min at 7.6 ± 0.3 mmol l^{-1} vs. blood glucose following combined ACK and glucose peaked at 8.3 ± 0.3 mmol l^{-1}). Post hoc analysis revealed no difference between glucose and NNS conditions.

These findings are in contrast with a recently published meta-analysis including 11 studies with nine cohorts including nearly 280 000 participants, among whom 22 000 individuals had type 2 diabetes mellitus. The study examined the association of both sugar-sweetened and artificially sweetened soft drinks and type 2 diabetes mellitus. A positive association was seen for sugar-sweetened soft drinks (RR 1.20/330 ml day^{-1}, 95% CI 1.12, 1.19, $P < 0.001$) along with artificial sweeteners (RR 1.13/330 ml day^{-1}, 95% CI 1.02, 1.25, $P = 0.02$) and diabetes mellitus, but the association of the former was stronger and more consistent than the latter. Of note, the meta-analysis was limited to prospective observational studies, an important consideration in the setting of multiple possible confounding factors in examining this association. Four RCTs ranging in duration from 1 to 16 weeks have not found an association between NNS and glycemic response.

Interestingly, Suez et al. recently demonstrated that intake of noncaloric artificial sweeteners (saccharin, sucralose, and aspartame) resulted in gut microbiota alterations with subsequent dysbiosis and metabolic abnormalities in mice and humans. In an analysis of 381 nondiabetic individuals (44% males and 56% females; ages 43.3 ± 13.2), the authors reported increased weight and waist-to-hip ratio, higher fasting blood glucose, glucose tolerance test response, and elevated serum alanine aminotransferase levels (felt to be related to nonalcoholic fatty liver disease). Additionally, despite correction for BMI, a statistically significant difference in hemoglobin A1C levels was seen in the group reporting high consumption of NNS as compared to low consumers. Upon characterization of 16s rRNA in 172 randomly selected individuals, a statistically significant positive correlation was seen between multiple taxonomic entities and nonartificial sweetener consumption. Finally, a group of seven healthy volunteers (five men and two women; ages 28–36) who typically do not consume NNS were followed for 1 week. On days 2–7, the individuals consumed the maximal ADI of saccharin. Four of the seven individuals developed statistically significant poorer glycemic responses. The microbiome configuration of those with a poorer glycemic response was noted to be different than those who did not exhibit a response. Stool matter was subsequently transferred from two individuals who exhibit poorer glycemic response and two individuals who did not to mice. Germ-free mice that received stool from the former group replicated part of the donor-induced saccharin dysbiosis. Overall, these findings suggest that humans may have a personalized response to NNS, possibly stemming from differences in microbiota composition and function at baseline.

In 2010, the American Dietetic Association concluded that NNSs have a negligible effect on glycemic control in diabetic individuals. Similarly, the ADA recommends that if NNSs are used to replace CS without caloric compensation, then NNSs may be useful in reducing caloric and carbohydrate intake, though the need for more research in this arena is recognized.

Risk of Malignancy

The National Cancer Institute issued a statement in 2009 indicating that sweeteners such as ACK are safe for use and do not contribute to malignancy. The NTP performed a 9-month study in genetically modified p53 haploinsufficient mice fed with daily diets consisting of 0%, 0.3%, 1%, or 3% ACK. They found no increased carcinogenicity or neoplastic activity in these mice over 9 months. Follow-up *in vivo* cytogenetic studies in mice exposed to 15, 30, 60, 450, 1500, and 2250 mg of ACK did show increased toxicity via clastogenic effects. These results contradicted prior studies in animal cell lines performed prior to FDA approval. In sum, while ACK may contribute to clastogenic effects in animals exposed to high doses, there is no present evidence of carcinogenicity in humans.

Neurometabolic Effects

ACK has also been postulated to effect neurocognitive function. A series of *in vivo* and *in vitro* studies suggest that acute exposure to ACK may decrease intracellular ATP production and reduce cellular viability and protective activity of neuronal cells. Cong et al. also showed that chronic ingestion of ACK in mice (at doses within the expected exposure range for humans ingesting ACK) resulted in impairments in learning and memory in tasks localizable to the hippocampus. These studies based their dose calculations on appropriate animal to human dosage calculations and report a human equivalent dose of 18.7 -29.1 mg kg^{-1} day^{-1}, which is 1.2–1.9 times the estimated human ADI. Therefore, these results are hard to interpret since most humans may not be ingesting similar amounts of ACK on a daily basis. More studies are needed to verify and assess the applicability of these results.

Recommendations During Pregnancy

Most sweeteners are approved for use during pregnancy including ACK, sucralose, saccharin, and stevioside. Early animal studies have shown a possible association between saccharin exposure in pregnant rats and increased risk of bladder cancer; however, this has not been demonstrated in human studies. High doses of ACK were used in these studies, further limiting their applicability to humans. In 2010, a study using the National Danish Birth Cohort suggested that daily intake of carbonated beverages supplemented with ACK or aspartame was associated with preterm birth. A subsequent Norwegian study showed that high intake of artificially sweetened beverages (adjusted OR for >1 serving per day 1.11, 95% CI 1.00, 1.24) and sugar-sweetened beverages (adjusted OR 1.25, 95% CI 1.08, 1.45) was associated with preterm delivery. Given these are observational studies and limited to beverages, one cannot make a causal association between artificial sweeteners and preterm birth. However, these studies suggest caution should be used in choosing to consume artificial sweeteners.

Presently, the American Academy of Nutrition and Dietetics recommend intake that is limited to the FDA's ADI of 15 mg kg^{-1} during pregnancy.

Conclusion

The use of NNS has increased worldwide due in part to its appeal as a low-calorie and low-carbohydrate alternative. There are conflicting data regarding the health effects of the NNS as a class, most notably in terms of its implications in weight and glycemic control. Despite the prevalence of ACK use, limited research is available in terms of its specific role in health outcomes. Recent research has suggested that personalized responses to NNS may partly explain heterogeneity in terms of outcomes and may be a potential means of establishing who may be predisposed to a more adverse event profile with use of the supplement. Regardless, careful attention must be paid to the host of effects, most notably in terms of weight and glycemic control, associated with NNS use. There is no concern for nonmetabolic aspects.

Introduction

Milk is a good source of several key nutrients such as proteins (casein and whey proteins), fat, sugar (lactose), vitamins, and minerals, thus having a range of biological activities that influence digestion, growth, and metabolic response to absorbed nutrient. Digestion of milk may also result in the formation of many substances with specific biological activities, that is, bioactive peptide and fatty acid analogs. Due to its complex chemical composition, which includes a high content of water, milk is a highly perishable food; thus, preservation of its nutritional value has been an important concern in food production since ancient times. Several preservation methods are available, of which biofermentation – fermentation of milk with lactic acid bacteria (LAB) – is probably the oldest, most widely accessible, and efficient preservation method. The cumulative knowledge on LAB physiology, human health and diet needs, and processing technology has led to the development of a diversity of dairy products fermented with LAB, of which yogurts and acidophilus milk are the most known.

Sources and Production

The application of LAB to preserve milk (fermentation or biopreservation) and obtain products with specific taste and a higher shelf life is known for centuries. In fact, at the time of the Roman Empire, fermented milk was often prescribed for curing disorders of the gastrointestinal tract (GIT).

LAB have thus a long and essentially safe history of application in food processing and today are generally recognized as safe (GRAS status) for human consumption.

A number of different LAB species may be, and are indeed used and claimed to be probiotic. The European Food Safety Agency (EFSA) has proposed, however, a system for a premarket safety assessment of selected groups of microorganisms, leading to granting a 'Qualified Presumption of Safety (QPS)' status to LAB species belonging to *Lactobacillus*, *Leuconostoc*, *Bifidobacterium*, *Streptococcus*, and *Pediococcus* genera. Taxonomy and proper identification at species level is one of the main pillars of QPS.

Research anchored on previous work by Pasteur related to fermentation and Metchnikoff on the potential positive effects of fermented products in people's health has been the stimulus to the development of many fermented milk products, which are today important components or supplements in Western diet and a huge boost to the dairy industry. Specifically, a new type of milk products the so-called probiotics – also called nutraceutical, pharmafoods, or designed foods – has emerged, among which 'acidophilus milk' is one of them. Probiotic bacteria are defined as live microorganisms, which, when administered in adequate amounts, confers a health benefit on the host. Most probiotic bacteria belong to genera *Lactobacillus* and *Bifidobacterium*.

Acidophilus milk is obtained via fermentation with *Lactobacillus acidophilus*, a type of LAB commonly found in the normal digestive tract of mammals. The popularity of acidophilus milk is due to the many health effects attributed to its consumption. The name 'acidophilus milk' may be, and often is, used as a general designation for milk fermented either with *Lactobacillus acidophilus* only or with any other lactobacillus strain or even bifidobacteria. Today, food products or supplements containing strains of *Lactobacillus acidophilus*, *Lactobacillus rhamnosus* GG, or *Lactobacillus casei* Shirota, bifidobacteria, and other LAB are in the market due to a perceived positive health effect attributed to presence of these bacteria.

The processing of such food products in general requires some stringent technological processing conditions, due to specific physiological needs that these bacteria have to grow optimally and survive in the food product or supplement.

Acidophilus Milk is usually made from low-fat (partially skimmed) milk. After sterilization (120 °C 15 sec) and cooling of milk to 37 to 38 °C, *Lactobacillus acidophilus*, as a pure culture is added at the rate of 5%. The high temperature used in sterilization releases peptides from milk proteins, which helps the growth of the organism known to lack a good proteolytic system for hydrolyzing milk proteins. The inoculated milk is gently stirred to mix the inoculum, avoiding much incorporation of air, and incubated for 18 to 24 hours. When the acidity reaches 1.0%, the product is cooled to less than 7 °C, and bottled.

To effectively convey the expected health functionalities of probiotic bacteria present in acidophilus milk, it is accepted that they need to reach the lower intestinal tract in high numbers. Thus, the survival of probiotic strains during food processing and during passage in the upper and lower parts of the GIT is an important technological concern. It has been established that the minimum number of available probiotic bacteria should be in the range of 10^7–10^8 colony-forming units per ml (CFU ml^{-1}) of the product at the time of consumption. To meet these requirements, technological developments that efficiently protect probiotic bacteria from the harsh conditions present in the stomach and most parts of the upper intestinal tract have been developed, which include enteric coating and microencapsulation, directed to give higher survival rates of probiotic bacteria and increase their delivery at expected amounts in the lower GIT.

Lactobacilli and other probiotic bacteria in general grow slowly in nonsupplemented milk; therefore, technological developments targeting at creating optimal growth conditions to enhance growth and survival of the probiotic strains during processing have been developed. These include using prebiotic substances (food ingredients such as fructooligosaccharides (FOS/GOS), which stimulate the growth and activity of the desired bacteria), creating low-redox potential conditions, or

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00002-7

other technological improvements that address the sensitivity of probiotic bacteria to metabolites produced during their growth alone or in combination with other LAB starter cultures. Recall also that some of the metabolites (such as acetic acid produced by bifidobacteria) may be undesirable due to the formation of off-flavors in the product. Growing probiotic bacteria in a mixed culture with more robust species such as *Streptococcus thermophilus* is a common strategy, as it has been reported that some starter cultures may enhance the growth and survival of probiotic microorganisms either because the adjuvant starter culture produces growth-enhancing metabolites or because they reduce the oxygen content in milk. For example, a study found a strain of *Bifidobacterium animalis* that grows faster in goat's milk when in coculture with *Lactobacillus acidophilus*. Also, optimum growth for probiotic bacteria specially those of human origin may occur at slightly higher temperatures than temperatures commonly used for fermentation with traditional LAB; however, in the case of mixed cultures, increasing the fermentation temperature may also result in development of undesirable flavors. Thus, another common approach is to use traditional growth temperatures for starter cultures and then add the probiotic microorganisms at the required high numbers.

Some Lactobacillus acidophilus strains are commonly found in the human intestine, thus showing an ability to survive and grow in the presence of normal levels of surface tension-depressing bile salts found in the enteric environment. To promote wider consumption of such beneficial bacteria, modifications in the delivery of the microorganisms via milk were sought. That search gave rise to a product called *Sweet Acidophilus Milk a* forerunner of Probiotic Milks widely prevalent today. *Sweet Acidophilus Milk* is made by adding a concentrated cell suspension of the organism to cold (5 °C), pasteurized milk, mixing to obtain homogenous distribution of the culture, bottling and cold storing, thus avoiding fermentation and high acidification, which were found to inhibit Lactobacillus acidophilus.

Patterns of Consumption and Regulations

There is an overall increasing pattern of consumption of all types of fermented milks in most countries. Acidophilus milk or probiotic dairy food products represent the largest segment of the functional food market in Europe, Japan, and Australia. The fermented milks in the market today represent ~€63.2 billion with North America, Europe, and Asia accounting for 77% of the market. Sales of yogurt and fermented milks also continue to expand worldwide, most noticeably in emerging markets such as China, Brazil, and Russia and in countries in the Middle East, North Africa, and Latin America. Probiotic drinks in particular have contributed to the growth of the dairy market, and together with encapsulated supplements, they allow for a constant launching of new products, making innovation in this field a very dynamic activity.

Thus, development and consumption of functional foods, or foods that promote health beyond providing basic nutrition, are on the rise, and currently, more than a 100 probiotic fermented milk products may be found in the market (**Table 1**), of which Yakult, Actimel, and LC-1 are the most known.

The beneficial health claims associated with them are the main reasons behind such popularity, which, in many cases, has even surpassed the scientific and regulatory requirements. In fact, the market pull for functional foods has in many cases been too fast to the point where it has resulted in certain knowledge gaps in the scientific understanding of their mechanism of action on the consumer (**Figure 1**).

As the global probiotic markets are expanding rapidly, harmonization of national and international regulations and guidelines is considered very important toward evaluating the efficacy and safety of probiotic bacteria and products therefrom in fulfilling essential prerequisites before being marketed, thus avoiding false claims.

Difficulties in harmonization at the international level are due to the fact that in different countries, probiotic products may be considered either as 'drugs' or as dietary

supplements. It is easily understood in most countries that a 'drug' or a new therapeutic agent needs to follow a regulatory process until being marketed, while a dietary supplement may not need any evaluation or approval before reaching the market.

The probiotics' 'health claims,' defined as "the statements, [which] characterizes the relationship of any substance to a disease or health-related condition," must be based upon well-established scientific evidences. For reasons in general associated with the structure of the reported scientific studies, with the exception of a few cases, most therapeutic or disease-prevention claims associated with probiotic foods have not been approved yet in the EU.

In the United States, probiotic bacteria may be regulated as a biological agent and/or dietary supplement, and in the former case, there is a need of a premarket evaluation of the safety, purity, and potency, as well as efficacy.

In Canada, the amount and quality of the data to be supplied for a claimed probiotic product depend on the claim that is sought. In any case, health products are considered as a subset of drugs and require assessment and licensing before being marketed.

In Japan, functional foods, including probiotics, have been legally defined and regulated under the 'Foods for Specified Health Uses' (FOSHU) system by the Japanese Ministry of Health, Labor, and Welfare. The FOSHU system allows several health claims for probiotic bacteria such as 'colonizes the intestines alive,' 'increases the intestinal beneficial bacteria,' and 'inhibits harmful bacteria.'

Finally, the Joint FAO/WHO Expert Consultation on Evaluation of Health and Nutritional Properties of Probiotics in Food Including Powder Milk with Live Lactic Acid Bacteria has developed and proposed guidelines for evaluating probiotic bacteria in food. The recommended guidelines included (1) using a combination of phenotypic and genotypic tests to identify the genus and species of the probiotic strain, as clinical evidences suggested that the health benefits of probiotic bacteria may be strain-specific; (2) *in vitro* testing to delineate the mechanism of the probiotic effect; and (3) substantiation of the clinical health benefit of probiotic agents with human trials.

These requirements are seen as a potential base to establishing the harmonization of regulations and standards of probiotic bacteria health claims in most countries.

It seems that two important factors associated with the increase in dairy products consumption are the growing population and the increase in per capita consumption. It is generally recognized that economic factors such as higher consumer income and declining retail prices for dairy products are the main cause of the increase in per capita consumption. Secondary factors that affect per capita consumption include demographic and socioeconomic factors (such as aging population, decreasing household sizes, urbanization, and increase in the number of working women) and food preferences and consumer attitudes (including health and nutritional issues, food safety, quality (e.g., freshness, taste, and branding), and production ethics (e.g., environment and animal welfare)). In general, the demand for innovative value-added products such as probiotic fermented milk products is replacing consumption of other dairy products (Figures 2–5).

Factors such as food legislation and measures with respect to obesity, fashions, change in the age distribution of consumers, and increasing health consciousness are also expected to have large implications for overall demand and consumption patterns for individual milk and dairy products. It is known that gender, age, educational level, and socioeconomic status are important factors determining the purchasing decisions for such products.

Health Effects

The concept of probiotic or functional milk food products (such as acidophilus milk) has evolved some 100 years ago. Ellie Metchnikoff (1907), a Russian-born Nobel laureate who was working at the Pasteur Institute in Paris, attributed the longevity of Bulgarians to their regular consumption of fermented milk products such as yogurt. Minoru Shiroma in the 1930s cultivated a beneficial *Lactobacillus* strain to survive digestion and went on to incorporate it into a fermented milk beverage known as Yakult. Yakult was sold on the Japanese market from the early 1950s, but today, it is sold in over 25

countries worldwide. Since then, considerable attention has been directed on the benefits derived from consumption of milk products containing *Lactobacillus acidophilus*. The earliest work dealt with the use of fermented acidophilus milk to treat intestinal infections, while more recent studies have focused on other aspects of health or nutritional benefits that might be derived from this organism. Such studies suggest that consumption of milk products containing *Lactobacillus acidophilus* has indeed the potential for several health benefits (Table 2) such as preventing or controlling intestinal infections,

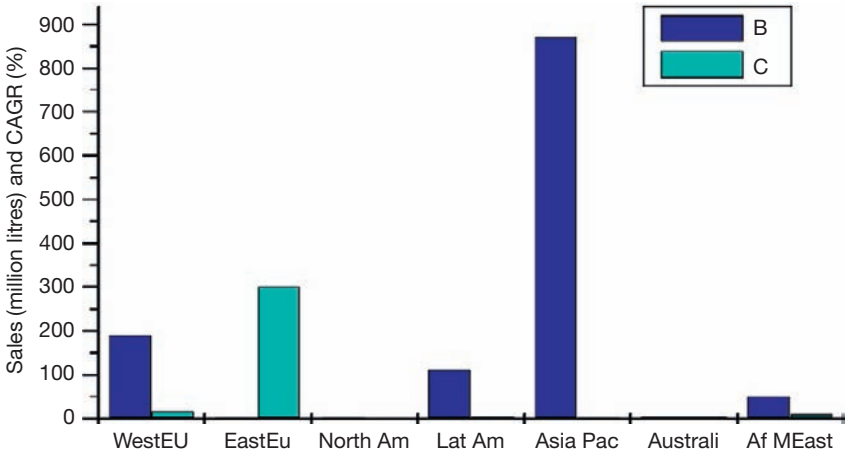

Figure 5 World fermented dairy drink sales (2003), million liters, and CAGR (%) (CAGR – compound annual growth rate 1998–2003). Adapted from Euromonitor, 2004 Agra CEAS calculations.

Table 3 Some proposed mechanisms whereby probiotic bacteria might influence the incidence of cancer, particularly colon cancer

Enhancing host's immune response
Suppression of growth and activities of intestinal microbes that produce carcinogens and promoters by competitive colonization or production of inhibitors (short-chain fatty acids or bacteriocins)
Binding and removal of carcinogens
Production of antimutagenic compounds
Production of butyrate to stimulate programmed cell death of abnormal cells
Inhibition of the conversion of bile salts to secondary bile salts

improving lactose digestion in persons classified as lactose maldigestors, helping control serum cholesterol levels, having potential to modulate the immune system, and exerting anticarcinogenic activity (Table 3).

As the importance of the colonic microbiota in human physiology and metabolism is being recognized, due to advances in molecular techniques and fermentation technology for studying the dynamics of the normal microflora, accurate information concerning the effect of probiotics is increasing.

Consistent scientific research has been undertaken in recent years regarding isolation of LAB strains to prove their health effects potentials. Functional properties of probiotics have been studied, and a few therapeutic applications seem to have been solidly demonstrated, of which the treatment of acute diarrhea and improvement in lactose digestion are probably the most known. Today, food products or supplements containing LAB strains of *Lactobacillus acidophilus*, *Lactobacillus rhamnosus* GG, or *Lactobacillus casei* Shirota are regular components of the diet of many. There is a popular perception, eventually supported by scientific data, that these bacteria exert a positive health effect in the consumer, although the mechanism by which they exert said beneficial effects is, in many cases, not very clear yet. Some of the reasons for such situation are the current (still) very limited understanding of the activities of the intestinal microbiota; the fact that health effects of probiotics are not generalized, but instead strain-specific (see Table 4); the need to definitely determine the metabolites that impact health and provide reliable biomarkers for the selection of functional diets or ingredients such as probiotics; and the fact that it is difficult to obtain optimal physiological samples from the intestine; thus, compiling large and reliable data from human trials toward established efficacy of probiotics is difficult and expensive. In a symposium sponsored by the American Nutritional Society in 2012, a designated 'panel of independent academic scientists with proved track records in probiotics research' made the final following statement: "Regulatory agencies in US and Europe must continue to protect consumers from misleading labeling and advertising; ... these agencies currently believe that the scientific evidence for probiotics does not meet the standards for approved health claims. Therefore, investigators wishing to conduct studies that will substantiate health claims for probiotics should carefully consider the study design, study populations, and select relevant experimental outcome."

Acidophilus milk is used commonly as a dietary supplement to alter the bacterial flora of the GIT in the treatment of certain digestive disorders and is one of the many dairy products considered as ideal vehicles for delivering probiotics to the human gut. In fact consumption of acidophilus milk is often prescribed by many physicians to persons suffering from either constipation or diarrhea and also for persons who experience

Table 4 Probiotic strains and some specific clinically shown health benefits

Probiotic strain	*Clinical benefits*
Lactobacillus acidophilus NCFM	Lowers fecal enzyme activity, improves lactose absorption, and produces bacteriocin
Lactobacillus rhamnosus GG	Plays a role in the prevention of antibiotic- and rotavirus-associated diarrhea
Lactobacillus casei Shirota	Helps in preventing intestinal disturbance, balancing intestinal flora, and lowering fecal enzyme activity
Lactobacillus reuteri	Colonizes the intestinal tract, shortens the duration of rotavirus diarrhea, and helps in immune enhancement
B. animalis BB-12	Plays a role in treating rotavirus-associated diarrhea and balancing intestinal flora

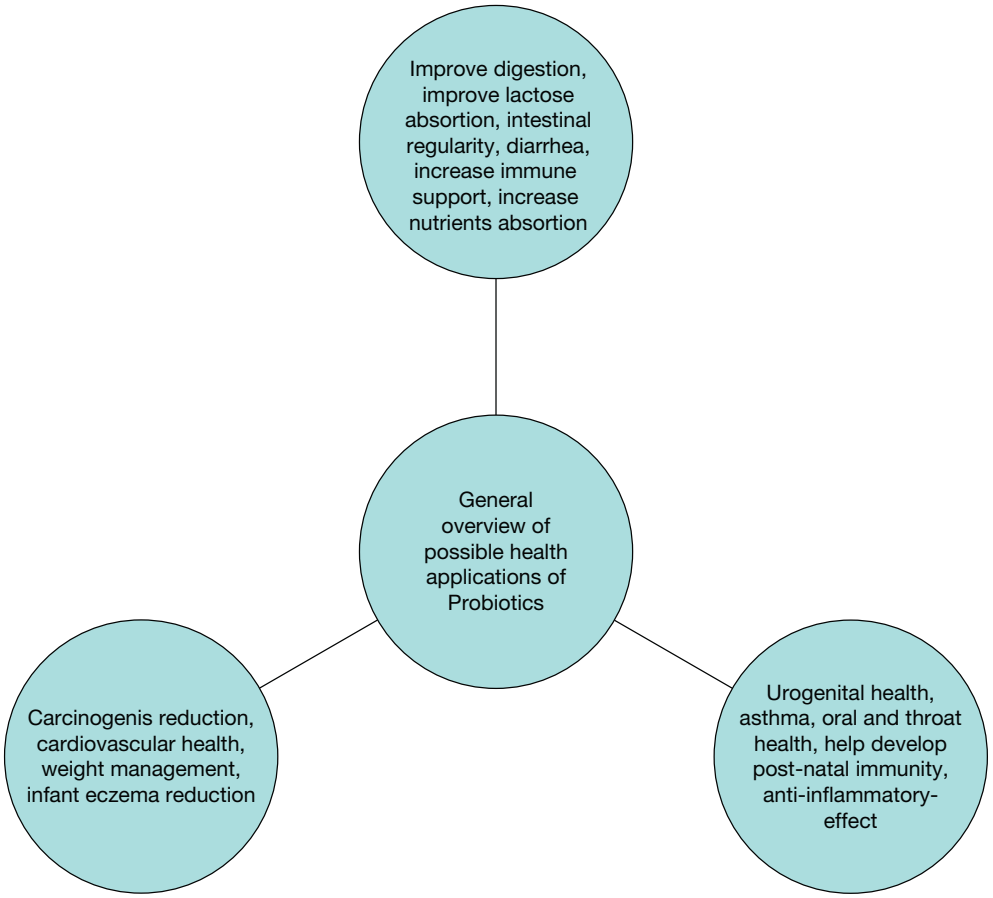

Figure 6 A broad health claims attributed to probiotic bacteria or probiotic-containing products.

intestinal distress on consuming ordinary milk, due to lactose malabsorption. Acidophilus milk is acidic in flavor as its acidity ranges from 1.5% to 2.0%.

Probiotics Use in GI Tract Conditions

The intestinal microbiota of an individual originates from the host genetics, environment factors, and microbiological influences. This culminates in a stable community of microorganisms that is unique to that individual. Although intestinal microbes are fairly stable through time, transitions occur at weaning and again in the elderly. Colonizing microbiota can be impacted by antibiotics, diet, immunosuppression, intestinal cleansing, and other factors, even though, in general, it tends to return to normal, following cessation of the disturbing factor. Probiotic research has been focused on their use in the treatment or preventative applications to solve GI health problems, due to the foreseen potential they may play in accelerating the normalization of a disturbed microbiota (see Figure 6).

The release of bacteriocins is one of positive factor associated with consumption of probiotic bacteria, as these peptides may help in protecting against proliferation of undesirable or pathogenic bacteria in GIT or even in the food product, making it safer, and many LAB bacteriocins have been so far isolated. Ingestion of *Lactobacillus acidophilus* is also expected to have a healthy effect on the consumer as it contributes to lowering the levels of undesirable bacteria in the GIT, via competition for nutrients and colonizing sites between the probiotic bacteria and the undesirable bacteria.

Lactose intolerance

The most accepted health effect of dairy products fermented with LAB is associated with their lower content in lactose as during fermentation, the bacteria feed on the lactose sugar in the milk, breaking some of it down. For lactose-intolerant people, that means that their bodies may have an easier time digesting this milk, even considering that some fermented milk may still contain milk sugar that can cause gas and bloating in more sensitive people.

Infant diarrhea

Many studies have been carried out concerning prevention or cure of infantile diarrhea, a serious problem particularly in developing countries. The best evidence of the usefulness of probiotics in the prevention of this condition comes from studies with *Lactobacillus rhamnosus* that showed that its consumption reduces the risk of infants developing diarrhea. Data from other of clinical trials also confirm a strong evidence of the role of probiotics in resolving the condition of infant diarrhea.

Crohn's disease, ulcerative colitis, pouchitis, and irritable bowel syndrome

These are inflammatory diseases associated with the GIT, whose cause in many cases is not totally understood. Research has been carried out using probiotic therapy to solve them. In general, the results regarding the efficacy of probiotics in the treatment of these conditions are regarded as either weak or essentially only promising, requiring larger-scale clinical trials.

Antibiotic-associated diarrhea and Clostridium difficile

Besides the recent worries that most antibiotics are becoming ineffective to treat many infectious diseases, oral antibiotics can and often do disturb the GI microflora, allowing for opportunistic pathogens to colonize the gut, most probably because elimination of the resident microflora by antibiotics will cause a decrease in secretion of protective antimicrobial substances, increase local pH, and allow for physical colonization by pathogens.

Clinical data seem to suggest that although there may be some benefits associated with the use of such probiotics as *Streptococcus boulardii*, *Enterococcus faecium*, and bifidobacteria, further larger-scale trials are needed to determine their efficacy in the treatment of antibiotic-associated diarrhea.

Probiotic Use in Nongastrointestinal Conditions

Urogenital infections

The majority of probiotic trials are focused on diseases related to the GI tract. However, probiotics such as *Lactobacillus*-containing supplements have been suggested for the treatment and prophylaxis of bacterial urogenital infections to restore commensal vaginal bacteria. Recent reviews found that despite enhanced cure rates reported in some studies, concerns about product stability and limited documentation of strain-specific effects prevent recommendations for the use of *Lactobacillus*-containing probiotics in the treatment of bacterial vaginosis. Also, the results of studies of lactobacilli for the prophylaxis of urinary tract infection remain inconclusive as a result of small sample sizes and the use of unvalidated dosing strategies.

Cancer prevention and treatment

There are some case-controlled studies conducted to evaluate the effects of yogurt or fermented milks on some cancer rates. An inverse relationship between frequency of fermented milk consumption and risk of breast cancer has been reported in France and the Netherlands; yogurt was found to be a protective factor in a case-controlled study of colon cancer incidence in Los Angeles County, and an intervention trial did show that the recurrence rate for superficial bladder cancer was lower for subjects receiving freeze-dried *Lactobacillus casei* Shirota than a placebo.

Several experimental animal studies demonstrated a protective effect of probiotics such as some *Lactobacillus* and *Bifidobacterium* strains or the combination of probiotics and prebiotics (oligofructose) on the establishment, growth, and metastasis of transplantable and chemically induced tumors; a 4-year study of 398 subjects found that *Lactobacillus casei* Shirota decreased the recurrence of a typical colonic polyps. The European Union (EU)-sponsored 'Symbiotic and Cancer Prevention in Humans' project tested a symbiotic (oligofructose plus *Lactobacillus rhamnosus* GG and *B. animalis* subsp. *lactis* Bb12) in patients at risk for colonic polyps. Among several intermediate end points that were used as biomarkers of colon cancer risk, the study found that the symbiotic decreased uncontrolled growth of intestinal cells.

More studies will be important in clarifying the role probiotic products play in cancer rates. For now, in a more general evaluation, a review of epidemiological studies on dairy or fermented foods in general and cancer (prostate, breast, colorectal, and others) suggests that there is no significant association (positive or inverse) between dairy food consumption and any cancer.

The positive actions of probiotics are tied to specific strains and specific doses; thus, the primary goal with any probiotic product is to deliver the right bacteria in ideal numbers to the right place in the body.

A careful selection of specific strains of *Lactobacillus acidophilus* combined with proper production and handling procedures is in general necessary to ensure that desired benefits are provided to consumers. In general, the mechanisms by which probiotics exert their effects are largely unknown but may involve modifying gut pH, antagonizing pathogens through production of antimicrobial and antibacterial compounds, competing for pathogen binding and receptor sites and for available nutrients and growth factors, stimulating immunomodulatory cells, and producing lactase, an important enzyme to digest lactose. On the other hand, in many cases, some of the beneficial effects exerted by probiotics have been so far shown to occur in animal models, thus still requiring fully human studies. Figure 6 is a schematic view of the many potential positive health effects attributed to fermented milks.

Although the physiological effects of some probiotic bacteria have been in general accepted, the health effect claims of some so-called probiotic food products are still controversial, to the point that the word 'probiotic' and descriptors such as 'live active cultures' or 'active bacteria' have been banned for

food products by some member states in the EU. Appropriately designed studies and the generation of consistent evidence for specific effects suitably to convince the regulators are required before claims can be approved. In fact, there are many confounding factors contributing to this situation, including the lack of clear direction on what research is required, exclusion of well-conducted studies because they studied patient (not healthy) populations or disease outcomes, difficulty in defining physiological benefits with healthy study subjects, and existence of studies that do not substantiate the physiological benefit (i.e., null studies). So far, the EU Nutrition and Health Claims Regulation have not granted health claims status to probiotics; that is, probiotics in general have not been accepted as having health-promoting outcomes, and while a few claims have been accepted, more than 1500 applications for claims regarding health effects of other species and strains remain unauthorized. The accepted definition of 'probiotic,' as agreed upon by the World Health Organization, is "Live microorganisms which when administered in adequate amounts confer a health benefit on the host," implying an inherent health claim. This means that if consumers are aware of this definition, they would deduce that any yogurt with 'probiotic' on the label, for example, would improve their health, even if the particular strain of bacteria in the yogurt had not been studied and proved to have benefits. One generally accepted probiotic claim is associated with lowering the lactose content of the food products, and beyond that, the term probiotic is still seen by many as describing too many and often nonproved health claims. In general, the position of the European Food Safety Authority (EFSA) is that while some specific bacterial strains have shown proved actions, those actions cannot be extended to all of the strains available in the marketplace labeled as probiotics.

In conclusion, fermented milks generally known as acidophilus milk or probiotics foods, produced via fermentation with LAB species, are now a common part of the diet in many countries. It is generally accepted that the strains used for their processing exert a variety of positive health effects, although the mechanism proposed for mediating these effects are not totally clear yet in most cases. Thus, it seems that probiotics may offer a broad range of potential health benefits, even though the extent of the effect of specific strains on the health of a generally healthy general population remains to be determined. The probiotic theory offers a complex approach to controlling negative metabolic or pathogenic activities of microbes to which we are exposed on a daily basis, representing an exciting opportunity to move toward a more preventative health-care model, expected to reduce health-care costs specially for the aged population. Scientific research and technological developments directed to the development and production of novel fermented dairy products such as acidophilus milk are on the rise. Industrial production of acidophilus milk and other probiotic products require unique processing conditions, although a wide range of fermented milks such as Yakult, Actimel, and LC-1 are already present in the market and their consumption is increasing worldwide. The key idea concerning probiotic products is that in general, more research, specially in the form of well-designed clinical trials, is needed to evaluate the efficacy and safety of probiotics. Many factors are seen as contributing to the lack of agreement on the results observed in probiotic efficacy in human health studies, that is, testing of ineffective strains, use of doses too low to be effective, and poor study design. These and the characterization of the health benefits further, the definition of the 'active principle' in probiotic preparations, and the appropriate and the posterior specific labeling concerning proved health claims are important future challenges to firmly establish acidophilus milk and other probiotic dairy products as true addition to our diets and for the consumer to make an informed consumption choice. The development of pertinent biomarkers and strain-specific genetic probes and determination of the needs of specific target groups of consumers may help meeting such challenges.

A final important remark: the GI microflora composition is unique to each individual, while regular ingestion of acidophilus milk or other probiotic supplements eventually decrease such uniqueness. Should then these supplements be consumed unless in a situation of taking advantage of their potential in accelerating the normalization of a disturbed microbiota?

Acids: Natural Acids and Acidulants

JD Dziezak, Dziezak & Associates Ltd, Hoffman Estates, IL, USA

© 2016 Elsevier Ltd. All rights reserved.

This article is reproduced from *Encyclopedia of Food Sciences and Nutrition*, volume 1, pp. 12–17, © 2003, Elsevier Science Ltd.

Background

Acids, or acidulants as they are also called, are commonly used in food processing as flavor intensifiers, preservatives, buffers, meat-curing agents, viscosity modifiers, and leavening agents. This article discusses the functions that acidulants have in food systems and reviews the more commonly used food acidulants.

Functions of Acidulants

The reasons for using acidulants in foods are numerous and depend on what the food processor hopes to accomplish. As outlined in the preceding text, the principal reasons for incorporating an acidulant into a food system are flavor modification, microbial inhibition, and chelation.

Flavor Modification

Sourness or tartness is one of the five major taste sensations: sour, salty, sweet, bitter, and umami (the most recently determined). Unlike the sensations of sweetness and bitterness, which can be developed by a variety of molecular structures, sourness is evoked only by the hydronium ion of acidic compounds.

Each acid has a particular set of taste characteristics, which include the time of perceived onset of sourness, the intensity of sourness, and any lingering of aftertaste. Some acids impart a stronger sour note than others at the same pH. As a general rule, weak acids have a stronger sour taste than strong acids at the same pH because they exist primarily in the undissociated state. As the small amount of hydronium ions is neutralized in the mouth, more undissociated acid (HA) molecules ionize to replace the hydronium ions lost from equilibrium (eqn [1]). The newly released hydronium ions are then neutralized until no acid remains. Taste characteristics of the acid are an important factor in the development of flavor systems:

$$HA + H_2O \rightarrow H_3O^+ + A^- HA + H_2O \rightarrow H_3O^{++}A^-. \qquad [1]$$

As pH decreases, the acid becomes more undissociated and imparts more of a sour taste. For example, the intense sour notes of lactic acid at pH 3.5 may be explained by the fact that 70% of the acid is undissociated at this pH, compared with 30% for citric acid. In addition to sourness, acids have nonsour characteristics such as bitterness and astringency, though these are less perceptible. At pH values between 3.5 and 4.5, lactic acid is the most astringent. Acids also have the ability to modify or intensify the taste sensations of other flavor compounds, to blend unrelated taste characteristics, and to mask undesirable aftertastes by prolonging a tartness sensation. For example, in fruit drinks formulated with low-caloric sweeteners, acids mask the aftertaste of the sweetener and impart the tartness that is characteristic of the natural juice. In another example, in substitutes for table salt, acids remove the bitterness from potassium chloride and provide the salty taste of sodium chloride. Other acids, such as glutamic and succinic acids, possess flavor-enhancement properties.

Because acids are rarely found in nature as a single acid, the combined use of acids simulates a more natural flavor. Two acids that are frequently blended together are lactic and acetic.

Microbial Inhibition

Acidulants act as preservatives by retarding the growth of microorganisms and the germination of microbial spores, which lead to food spoilage. The effect is attributed to both the pH and the concentration of the acid in its undissociated state. It is primarily the undissociated form of the acid, which carries the antimicrobial activity: as the pH is lowered, this helps shift the equilibrium in favor of the undissociated form of the acid, thereby leading to more effective antimicrobial activity. The nature of the acid is also an important factor in microbial inhibition: weak acids are more effective at the same pH in controlling microbial growth. Acids affect primarily bacteria because many of these organisms do not grow well below about pH 5; yeasts and molds, in comparison, are usually acid-tolerant.

In fruit- and vegetable-canning operations, the combined use of heat and acidity permits sterilization and spore inactivation to be achieved at lower temperatures; this minimizes the degradation of flavor and structure that generally results from processing.

Acidification also improves the effectiveness of antimicrobial agents such as benzoates, sorbates, and propionates. For example, sodium benzoate – an effective inhibitor of bacteria and yeasts – does not exert its antimicrobial activity until the pH is reduced to about 4.5. Blends of acids act synergistically to inhibit microbial growth. For example, lactic and acetic acids have been found to inhibit the outgrowth of heterofermentative lactobacilli.

Chelation

Oxidative reactions occur naturally in foods. They are responsible for many undesirable effects in the product, including discoloration, rancidity, turbidity, and degradation of flavor and nutrients. As catalysts to these reactions, metal ions such as copper, iron, manganese, nickel, tin, and zinc need to be present in only trace quantities in the product or on the processing machinery.

Many acids chelate the metal ions so as to render them unavailable; the unshared pair of electrons in the molecular structure of acids promotes the complexing action. When used in combination with antioxidants such as butylated

hydroxyanisole, butylated hydroxytoluene, or tertiary butylhydroquinone, acids have a synergistic effect on product stability. Citric acid and its salts are the most widely used chelating agents.

Other Functions

One of the most common reasons for adding acids is to control pH. This is usually done as a means to retard enzymatic reactions, to control the gelation of certain hydrocolloids and proteins, and to standardize pH in fermentation processes. In the first example, the lowering of pH inactivates many natural enzymes that promote product discoloration and development of off-flavors. Polyphenol oxidase, for example, oxidizes phenols to quinones, which subsequently polymerize, forming brown melanin pigments that discolor the cut surfaces of fruits and vegetables. The enzyme is active between pH 5 and 7 and is irreversibly inactivated at a pH of 3 or lower. In the second example, acidification to 2.5–3 is required for high-methoxyl pectins to form gels. Because pH influences the gel-setting properties and the gel strength obtained, proper pH control is critical in the production of pectin- and gelatin-based desserts, jams, jellies, preserves, and other products. In the final example, standardization of pH is done routinely in fermentation processes, such as wine making, to ensure optimum microbial activity and to discourage growth of undesirable microbes. Acids are also added postfermentation to stabilize the finished wine.

Acid salts function as buffers in various systems. For example, in confectionery products, acid salts are used to control the inversion of sucrose into its constituents, glucose and fructose, the latter being hygroscopic. The resulting lower concentration of fructose yields a less hygroscopic food system and a longer shelf life.

Acids are a major component of chemical leavening systems, where they remain nonreactive until the proper temperature and moisture conditions are attained. The gas evolved by reaction of the acid with bicarbonate produces the aerated texture that is characteristic of baked products such as cakes, biscuits, doughnuts, pancakes, and waffles. The onset and the rate of reaction of these compounds are controlled by such factors as the solubility of the acid, the mixing conditions for preparing the batter, and the temperature and moisture of the batter. Many chemical leavening systems are based on salts of phosphoric and tartaric acids. Acids have also been used for other purposes. For example, they are added to chewing gum to stabilize aspartame and to cheese to impart favorable textural properties and sensory attributes.

Commonly Used Acidulants

Among the most widely used acids are acetic, adipic, citric, fumaric, lactic, malic, phosphoric, and tartaric acids. Gluconoδ-lactone, though not itself an acid, is regarded as an acidulant because it converts to gluconic acid under high temperatures.

Acetic Acid

Acetic acid is the major characterizing component of vinegar. Its concentration determines the strength of the vinegar, a value termed 'grain strength,' which is equal to 10 times the acetic acid concentration. Vinegar containing, for example, 6% acetic acid has a grain strength of 60 and is called 60-grain. Distillation can be used to concentrate vinegar to the desired strength.)

Fermentation conducted under controlled conditions is the commercial method for vinegar production. Bacterial strains of the genera *Acetobacter* and *Acetomonas* produce acetic acid from alcohol, which has been obtained from a previous fermentation involving a variety of substrates such as grain and apples. Vinegar functions in pH reduction, control of microbial growth, and enhancement of flavor. Use in a variety of products, including condiments such as ketchup, mustard, mayonnaise, and relish; salad dressings; marinades for meat, poultry, and fish; bakery products; soups; and cheeses has been found. Pure (100%) acetic acid is called glacial acetic acid because it freezes to an icelike solid at 16.6 °C. Though not widely used in food, glacial acetic acid provides acidification and flavoring in sliced, canned fruits and vegetables, sausage, and salad dressings.

Adipic Acid

Adipic acid, a white, crystalline powder, is characterized by low hygroscopicity and a lingering, high tartness that complements grape-flavored products and those with delicate flavors. The acid is slightly more tart than citric acid at any pH. Aqueous solutions of the acid are the least acidic of all food acidulants and have a strong buffering capacity in the pH range 2.5–3.0.

Adipic acid functions primarily as an acidifier, buffer, gelling aid, and sequestrant. It is used in confectionery, cheese analogs, fats, and flavoring extracts. Because of its low rate of moisture absorption, it is especially useful in dry products such as powdered fruit-flavored beverage mixes, leavening systems of cake mixes, gelatin desserts, evaporated milk, and instant puddings.

Citric Acid

The most widely used organic acid in the food industry, citric acid, accounts for more than 60% of all acidulants consumed. It is the standard for evaluating the effects of other acidulants. Its major advantages include its high solubility in water; appealing effects on flavor, particularly its ability to deliver a 'burst' of tartness; strong metal chelation properties; and the widest buffer range of the food acids (2.5–6.5).

Citric acid is naturally present in animal and plant tissues and is most abundantly found in citrus fruits including the lemon (4–8%), grapefruit (1.2–2.1%), tangerine (0.9–1.2%), and orange (0.6–1.0%).The principal method for commercial production of the acid is fermentation of corn. Formerly, the acid had been obtained by extraction from citrus and pineapple juices. Citric acid is available in a liquid form, which solves processing problems related to incorporating the acid into a food system, such as predissolving citric acid crystals and caking or crystallate deposits on processing equipment. Also available are granulated forms that allow the particle size to be customized to meet the particular need.

Citric acid has numerous applications. It is commonly added to nonalcoholic beverages where it complements fruit flavors, contributes tartness, chelates metal ions, acts as a preservative, and controls pH so that the desired sweetness characteristics can

be achieved. Sodium citrate subdues the sharp acid notes in highly acidified carbonated beverages; in club soda, it imparts a cool, saline taste and helps retain carbonation. The acid is also used in wine production both prior to and after fermentation for adjustment of pH; in addition, because of its metal-chelating action, the acid prevents haze or turbidity caused by the binding of metals with tannin or phosphate. The calcium salt of citric acid is used as an anticaking agent in fructose-sweetened, powdered soft drinks, where it neutralizes the alkalinity of other ingredients that support browning, such as magnesium oxide and tricalcium phosphate.

Citric acid is used in confectionery and desserts. In hard confectionery, buffered citric acid imparts a pleasant tart taste; it is added to the molten mass after cooking, as this prevents sucrose inversion and browning. Citric acid is used in gelatin desserts because it imparts tartness, acts as a buffering agent, and increases the pH for optimum gel strength.

Low levels of the acid, ranging from 0.001 to 0.01%, work with antioxidants to retard oxidative rancidity in dry sausage, fresh pork sausage, and dried meats. Citric acid is also used in the production of frankfurters: 3–5% solutions are sprayed on the casings after stuffing and prior to smoking to aid in their removal from the finished product. Used at 0.2% in livestock blood, sodium citrate and citric acid act as anticoagulants, sequestering the calcium required for clot formation so that the blood may be used as a binder in pet foods.

In seafood processing, citric acid inactivates endogenous enzymes and promotes the action of antioxidants, resulting in an increased shelf life. Citric acid also chelates copper and iron ions that catalyze the oxidative formation of off-flavors and fishy odors associated with dimethylamine. In processed cheese and cheese foods, citric acid and sodium citrate function in emulsification, buffering, flavor enhancement, and texture development. Sodium citrate is also combined with sodium phosphate as a customized emulsification salt for processed cheese. Cogranulation of citric acid with malic and fumaric acids yields new tart flavor profiles.

Fumaric Acid

The extremely low rate of moisture absorption of this acid makes it an important ingredient for extending the shelf life of powdered food products such as gelatin desserts and pie fillings. Fumaric acid can be used in smaller quantities than citric, malic, and lactic acids to achieve similar taste effects.

Fermentation of glucose or molasses by certain *Rhizopus* spp. is the method used to produce fumaric acid commercially. The acid is also made by isomerization of maleic acid with heat or a catalyst and is a by-product of the production of phthalic and maleic anhydrides. Fumaric acid is also made in particulate form, where the acid makes up about 5–95% of the particulate, with the remainder being other acids such as malic, tartaric, citric, lactic, ascorbic, and related mixtures.

Applications of fumaric acid include rye bread, jellies, jams, juice drinks, candy, water-in-oil emulsifying agents, reconstituted fats, and dough conditioners. In refrigerated biscuit doughs, the acid eliminates crystal formations that may occur in all-purpose leavening systems. In wine, it functions as both an acidulant and a clarifying aid, although it does not chelate copper or iron.

Glucono-δ-Lactone (GDL)

A natural constituent of fruits and honey, GDL is an inner ester of D-gluconic acid. Unlike other acidulants, it is neutral and gives a slow rate of acidification. When added to water, it hydrolyzes to form an equilibrium mixture of gluconic acid and its δ- and γ-lactones. The acid formation takes place slowly when cold and accelerates when heated. As GDL converts to gluconic acid, its taste characteristics change from sweet to neutral with a slight acidic aftertaste.

GDL is produced commercially from glucose by a fermentation process that uses enzymes or pure cultures of microorganisms such as *Aspergillus niger* or *Acetobacter suboxydans* to oxidize glucose to gluconic acid. GDL is extracted by crystallization from the fermentation product, an aqueous solution of gluconic acid and GDL.

Because of its gradual acidification, bland taste, and metal-chelating action, GDL has found application in mild-flavored products such as chocolate products, tofu, milk puddings, and creamy salad dressings. In cottage cheese prepared by the direct-set method, GDL ensures development of a finer-textured finished product, void of localized denaturation. It also shortens production time and increases yields. In cured-meat products, GDL reduces cure time, inhibits growth of undesirable microorganisms, promotes color development, and reduces nitrate and nitrite requirements.

Lactic Acid

Lactic acid is one of the earliest acids to be used in foods. It was first commercially produced about 60 years ago, and only within the past two decades has it become an important ingredient. The mild taste characteristics of the acid do not mask weaker aromatic flavors. Lactic acid functions in pH reduction, flavor enhancement, and microbial inhibition. Two methods are used commercially to produce the acid: fermentation and chemical synthesis. Most manufacturers using fermentation are in Europe.

Confectionery, bakery products, beer, wine, beverages, dairy products, dried egg whites, and meat products are examples of the types of products in which lactic acid is used. The acid is used in packaged Spanish olives where it inhibits spoilage and further fermentation. In cheese production, it is added to adjust pH and as a flavoring agent.

Malic Acid

This general-purpose acidulant imparts a smooth, tart taste that lingers in the mouth, helping to mask the aftertastes of low-caloric or noncaloric sweeteners. It has taste-blending and flavor-fixative characteristics and a relatively low melting point with respect to other solid acidulants. The low melting point allows it be homogeneously distributed into food systems. Compared with citric acid, malic acid has a much stronger apparent acidic taste. As DL-malic acid is the most hygroscopic of the acids, resulting in lumping and browning in dry mixes, the encapsulated form of this acid is preferred for dry mixes.

Malic acid occurs naturally in many fruits and vegetables and is the second most predominant acid in citrus fruits, many

berries, and figs. Unlike the natural acid, which is levorotatory, the commercial product is a racemic mixture of D-isomers and L-isomers. It is manufactured during catalytic hydration of maleic and fumaric acids and is recovered from the equilibrium product mixture.

The acid has been used in carbonated beverages, powdered juice drinks, jams, jellies, canned fruits and vegetables, and confectionery. Its lingering profile enhances fruit flavors such as strawberry and cherry. In aspartame-sweetened beverages, malic acid acts synergistically with aspartame so that the combined use of malic and citric acids permits a 10% reduction in the level of aspartame. In frozen pizza, malic acid is used to lower the pH of the tomato paste without chelating the calcium in the cheese, as would citric and fumaric acids. This application improves the texture of the frozen pizza.

Phosphoric Acid

The second most widely used acidulant in food, phosphoric acid, is the only inorganic acid to be used extensively for food purposes. It produces the lowest pH of all food acidulants. Phosphoric acid is produced from elemental phosphorus recovered from phosphate rock.

The primary use of the acid is in cola, root beer, and other similar-flavored carbonated beverages. The acid and its salts are also used during production of natural cheese for adjustment of pH; phosphates chelate the calcium required by bacteriophages, which can destroy bacteria responsible for ripening. As chemical leavening agents, phosphates release gas upon neutralizing alkaline sodium bicarbonate; this creates a porous, cellular structure in baked products. The main reason for incorporating phosphates into cured meats such as hams and corned beef is to increase retention of natural juices; the salts are dissolved in the brine and incorporated into the meat by injection of brine, massaging, or tumbling. When used in jams and jellies, phosphoric acid acts as a buffering agent to ensure a strong gel strength; it also prevents dulling of the gel color by sequestering prooxidative metal ions.

Tartaric Acid

Tartaric acid is the most water-soluble of the solid acidulants. It contributes a strong tart taste that enhances fruit flavors, particularly grape and lime. This dibasic acid is produced from potassium acid tartrate, which has been recovered from various by-products of the wine industry, including press cakes from fermented and partially fermented grape juice, lees (the dried, slimy sediments in wine fermentation vats), and argols (the crystalline crusts formed in vats during the second fermentation step of wine making). The major European wine-producing countries, Spain, Germany, Italy, and France, use more of the acid than the United States.

Tartaric acid is often used as an acidulant in grape- and lime-flavored beverages, gelatin desserts, jams, jellies, and hard sour confectionery. The acidic monopotassium salt, more commonly known as 'cream of tartar,' is used in baking powders and leavening systems. Because it has limited solubility at lower temperatures, cream of tartar does not react with bicarbonate until the baking temperatures are reached; this ensures maximum development of volume in the finished product.

Background

In very general terms, an acid is a compound that contains or produces hydrogen ions in aqueous solutions, has a sour taste, and turns blue litmus paper red. A more comprehensive definition, given by the US chemist G.N. Lewis, states that acids are substances that can accept an electron pair or pairs, and bases are substances that can donate an electron pair or pairs. This definition, applicable to both nonaqueous and aqueous systems, requires that an acid be either a positive ion or a molecule with one or more electron-deficient sites with respect to a corresponding base.

The definition most widely used to describe acid–base reactions in dilute solution is one that was proposed independently by two scientists in 1923 – the Danish chemist J.N. Brønsted and the US chemist T.M. Lowry. The Brønsted–Lowry theory defines an acid as a proton donor, that is, any substance (charged or uncharged) that can release a hydrogen ion or proton. A base is defined as a proton acceptor or any substance that can accept a hydrogen ion or proton.

This article discusses the physicochemical properties of acids and describes several methods for their analysis.

Strong Versus Weak Acids

The strength of a Brønsted–Lowry acid depends on how easily it releases a proton or protons. In strong acids, owing to their weaker internal hydrogen bonds, the protons are loosely held. As a result, in aqueous solutions, almost all of the acid reacts with water, leaving only a few unionized acid molecules in the equilibrium mixture. The reaction takes place according to eqn [1]:

$$HA + H_2O \rightleftharpoons H_3O^+ + A^- HA + H_2O \rightleftharpoons H_3O^{++}A^- \qquad [1]$$

In this equation, HA represents the undissociated acid, H_3O^+ the hydronium ion formed when a proton combines with one molecule of water, and A^- the conjugate base of HA.

Unlike strong acids, weak acids exist largely in the undissociated state when mixed with water, since only a small percentage of their molecules interact with water and dissociate. Most acids found in foods, including acetic, adipic, citric, fumaric, malic, phosphoric, and tartaric acids and glucono-δ-lactone, are classified as weak or medium strong acids.

Physicochemical Properties

Physicochemical properties, including the ionization constant, pH, the apparent dissociation constant (pK_a), and buffering capacity, are discussed in the succeeding text and are listed in Table 1.

Ionization Constant

The tendency for an acid or acid group to dissociate is defined by its ionization constant, also denoted as pK_a. The ionization constant, given at a specified temperature, is expressed as

$$K_a = \frac{[H_3O^+][A^-]}{[HA]} \qquad [2]$$

where the brackets designate the concentration in moles per liter. The ionization constant is a measure of acid strength: the higher the K_a value, the greater the number of hydrogen ions liberated per mole of acid in solution and the stronger the acid.

Acids with more than one transferable hydrogen ion per molecule are termed 'polyprotic' acids. Monoprotic or monobasic acids are those that can liberate one hydrogen ion, such as acetic acid and lactic acid. Those containing two transferable hydrogen ions are called diprotic or dibasic acids and include adipic acid and fumaric acid. Acids such as citric acid and phosphoric acid, which have three transferable hydrogens, are called triprotic or tribasic acids. Ionization of polyprotic acids occurs in a stepwise manner with the transfer of one hydrogen ion at a time. Each step is characterized by a different ionization constant.

pH

Measurement of acidity is an important aspect of ascertaining the safety and quality of foods. Such measurements are given in terms of pH, which is defined as the negative logarithm of the hydronium ion concentration (strictly, activity):

$$pH = \log_{10} \frac{1}{[H_3O^+]} = -\log_{10}[H_3O^+] \qquad [3]$$

The lower the pH value, the higher the hydrogen ion concentration associated with it. A pH value of <7 indicates a hydrogen ion concentration $>10^{-7}$ M and an acidic solution; a pH value of more than 7 indicates a hydrogen ion concentration of $<10^{-7}$ M and a basic solution. When the hydronium and hydroxide ions are equal in concentration, the solution is described as neutral.

It is also important to note that, because the pH scale is logarithmic, a difference of one pH unit represents a tenfold difference in hydrogen ion concentration.

pK_a

The term pK_a is defined as the negative logarithm of the dissociation constant:

Table 1 Structure, ionization constant, pK_a, and key physical and chemical properties of acidulants

Acid	*Structure*	*Ionization constant(s)*	*pK_a*	*Physical form*	*Melting point (°C)*	*Solubility (g per 100 ml of water)*	*Hygroscopicity*	*Taste characteristics*
Acetic acid	$CH_3COOHCH_3COOH$	1.76×10^{-5} at 25 °C	4.76	Clear, colorless liquid	−8.5	Soluble	na	Tart and sour
Adipic acid		$K_1 = 3.71 \times 10^{-5}$	4.43	Crystalline powder	152	1.9 g at 20 °C	Low level of hygroscopicity	Smooth lingering tartness; complements grape flavors
		$K_2 = 3.87 \times 10^{-6}$ at 25 °C	5.41			83 g at 90 °C		
Citric acid		$K_1 = 7.10 \times 10^{-4}$	3.14	Crystalline powder			Moderately hygroscopic	Tart; delivers a 'burst' of flavor
		$K_2 = 1.68 \times 10^{-5}$	4.77					
		$K_3 = 6.4 \times 10^{-7}$ at 25 °C	6.39					
Anhydrous					153	181 g at 25 °C		
Hydrous					135–153	208 g at 25 °C		
Fumaric acid		$K_1 = 9.30 \times 10^{-4}$	3.03	White granules or crystalline powder	286	0.5 g at 20 °C	Nonhygroscopic	Tart; has an affinity for grape flavors
		$K_2 = 3.62 \times 10^{-5}$ at 18 °C	4.44			9.8 g at 100 °C		
Glucono-δ-lactone		1.99×10^{-4} (for gluconic acid)	3.7	White crystalline powder	153	59 g at 25 °C	Nonhygroscopic	Neutral taste with acidic aftertaste, when hydrolyzed

Lactic acid		1.37×10^{-4} at 25 °C	3.86	Liquid; also available in dry form	16.8	Very soluble	na	Acrid
Malic acid		$K_1 = 3.9 \times 10^{-4}$ $K_2 = 7.8 \times 10^{-6}$ at 25 °C	3.40 5.11	Crystalline powder	132	62 g at 25 °C	Nonhygroscopic	Smooth tartness
Phosphoric acid		$K_1 = 7.52 \times 10^{-3}$ $K_2 = 6.23 \times 10^{-8}$ $K_3 = 2.2 \times 10^{-13}$ K_1 and K_2 at 25 °C; K_3 at 18 °C	2.12 7.21 12.67	Liquid		Very soluble in hot water	na	Acrid
Tartaric acid		$K_1 = 1.04 \times 10^{-3}$ $K_2 = 4.55 \times 10^{-5}$ at 25 °C	2.98 4.34	Crystalline powder	168–170	147 g at 25 °C	Nonhygroscopic	Extremely tart; augments fruit flavors, especially grape and lime

na, not applicable.

Source: *Food Technology*, *Acidulants*: *Ingredients that do more than meet the acid test*. 44(1): 76–83. Chicago, IL: Institute of Food Technologists, with permission.

$$pK_a = \log_{10}\frac{1}{K_a} = -\log_{10}K_a \quad [4]$$

The pK_a corresponds to the pH value at the midpoint of a titration curve developed when one equivalent of weak acid is titrated with base, and the pH resulting from each incremental addition of base is plotted against the equivalents of hydroxide ions added.

The pH of a system is at the pK_a when the concentrations of acid (HA) and conjugate base (A^-) are equal. At the pK_a and, to a lesser extent, in the area extending to within one pH unit on either side of the pK_a, the system resists changes in pH resulting from addition of small increments of acid or base. In other words, at the pK_a, acids and their salts function as buffers.

The number of pK_a that an acid has depends on the number of hydrogen ions it can liberate. Monoprotic acids have a single pK_a, whereas diprotic and triprotic acids have two and three pK_a, respectively.

Strong acids have low pK_a values, and strong bases have high pK_a values.

Buffering Capacity

A solution of a weak acid (or a weak base) and its corresponding salt is called a buffer solution. In these systems, the hydronium ion content is not significantly changed when a small amount of acid or base is added to that solution. The reason that buffer solutions resist appreciable changes in pH can be best illustrated by an example. If a small amount of hydrochloric acid is added to a buffer solution composed of acetic acid and sodium acetate, the protons from the hydrochloric acid would associate with the acetate ions to form unionized molecules of acetic acid. As the newly formed acid molecules ionize, the equilibrium would shift toward forming more hydronium ions (eqn [1]). This would result in only a very slight increase in pH.

Similarly, the addition of a small amount of sodium hydroxide to the same buffer solution would have little effect on pH. Hydroxide ions from the sodium hydroxide would combine with hydronium ions in the equilibrium mixture, forming undissociated molecules of sodium hydroxide. More of the acid molecules would then dissociate to replace the hydronium ions lost; though a new equilibrium system would be created, it would produce only a minimal effect on pH.

The quantity of acid or base that a buffer solution is capable of consuming before a change in pH is realized is termed the 'buffering capacity.' The buffering capacity is defined as the number of moles of strong acid or base required to increase the pH by one unit in 1 l of buffer solution. The buffering capacity of a solution is greatest at its pK_a value where the concentrations of acid and conjugate base are equal.

Analytic Methods

Quantitative determinations of acidity play an important role in ensuring food product quality and stability. Information obtained on acid levels can help in detecting cases of food adulteration, monitoring fermentation processes, and evaluating the organoleptic properties of fermented foods. pH determination, titratable acidity, chromatographic methods, and capillary electrophoresis are procedures commonly employed by the food industry to determine food acids.

pH Determination

pH can be measured by two techniques: colorimetric and potentiometric. The colorimetric method involves adding a suitable indicator to a solution and matching the color of the solution to a standard solution containing the same indicator. This method can estimate pH to the nearest 0.1 pH unit.

A more accurate technique and the one most frequently employed, the potentiometric method, uses a pH meter to determine hydrogen ion concentration. The two electrodes of the meter – a calomel reference electrode and a glass indicator electrode – are immersed in the solution, of known temperature, whose pH is to be measured. The electrode potential of the indicator electrode is linearly related to changes in hydrogen ion concentration and therefore pH.

Titratable Acidity

The total concentration of acid in a solution can be determined by titration. The titration process is performed by placing in a flask a known volume of acid solution whose concentration is unknown. To the flask, a few drops of indicator, for example, phenolphthalein, which is colorless in acid solutions and pink in basic solutions, are introduced. A base solution of known concentration is then gradually added until the acid is completely neutralized. This point is indicated when the solution permanently changes color. The concentration of acid can then be calculated from the volume of base solution used.

The value obtained, called titratable acidity, is an estimate of the total acid in the solution. It accounts for both the free hydronium ions present in the equilibrium mixture and the hydrogen ions released from undissociated acid molecules. For weak acids, the titratable acidity is different from the actual acidity (hydrogen ion concentration), since these compounds exist largely in the undissociated state in solution. For strong acids, however, titratable acidity and actual acidity are virtually the same, since strong acids and their salts are completely ionized in solution.

Chromatographic Methods

Gas chromatography (GC) and high-performance liquid chromatography (HPLC) have almost entirely replaced paper and thin-layer chromatography as methods for identifying and quantifying food acids.

Gas chromatography

GC has been used to analyze organic acids in fruit and fruit juice. Analysis involves preparing volatile derivatives such as methyl esters of the organic acids, prior to their injection into the gas chromatograph. Derivatives are chromatographed on a nonpolar stationary phase column and detected by a flame ionization detector.

By use of GC, malic acid has been shown to be a major constituent of many fruits, including apples, pears, grapes,

peaches, and nectarines, and significant levels of citric acid have been found in citrus fruits, such as orange, lemon, and grapefruit, and in noncitrus fruits, including pears, nectarines, cherries, and strawberries.

High-performance liquid chromatography

HPLC is used more extensively than GC to determine organic acids because the technique requires little or no chemical modification to separate these nonvolatile compounds. Separation is usually done on either a reversed-phase C8 or C18 column or a cation-exchange resin column operated in the hydrogen mode. Acids are detected by either refractive index (RI) or ultraviolet (UV) detectors. RI detection requires prior removal of any sugars present that potentially can interfere with quantification; sugar removal is not required for UV detection at 220–230 nm.

Adulteration of a commercial cranberry juice drink was detected using HPLC when the test yielded different results for organic acids, sugars, and anthocyanin pigments than those obtained for a standard juice drink. Atypical citric and/or malic acid contents and presence of a natural colorant, probably grape skin extract, confirmed that the drink was adulterated.

In wine making, HPLC is used to monitor concentrations of tartaric, malic, succinic, citric, lactic, and acetic acids, which contribute tartness and stability to the finished product. A common approach involves using a column containing a strong cation-exchange resin and eluting the sample with dilute sulfuric acid; the eluant is then analyzed for acids by RI detection. This column has the additional advantage of permitting the simultaneous detection and quantification of ethanol and the monitoring of wine for adulteration with methanol. Organic acids in wine can also be separated using ion chromatography with a conductivity detector.

Capillary Electrophoresis

A relatively new technique, capillary electrophoresis, is also useful for separating and quantifying organic acids in food systems. This technique utilizes an electrical field to separate molecules on the basis of their charge and size. Small volumes of sample, usually a few nanoliters, are injected on to a fused silica capillary tube, which is usually <1 m in length and 50 μm in internal diameter. The ends of the tube are placed in electrolyte reservoirs containing electrodes. A voltage in the range of 20–30 kV is delivered to the electrodes by a power supply and causes the charged molecules to move. Because organic acids are negatively charged, they migrate away from more neutral or positively charged molecules, such as sugars and phenols, respectively. Acids are detected by a UV detector, and the signal is sent to a data collector. The resulting separation is graphically represented as an electropherogram.

Enzymatic Analysis

Enzyme assays provide another means of analyzing acids. For example, an enzymatic assay of L-malic acid uses an NAD(P)-linked malic enzyme and involves spectrophotometrically measuring the absorbance of NADPH, a reaction product, at 340 nm.

Introduction

Acrylamide (2-propenamide, CAS No. 79-06-01) is a colorless and odorless crystalline solid with a molecular weight of 71.08 and a melting point of 84.5 °C. Acrylamide is soluble in water, acetone, and ethanol but not in nonpolar solvents. Acrylamide has long been used as an intermediate in the production of polyacrylamide, which has many industrial applications, from sewage and wastewater treatment to the formulation of cosmetics. Polyacrylamide is also widely used in molecular biology as a medium for the electrophoresis separation of proteins and nucleic acids. Acrylamide is known to have acute toxicity and it is classified by the International Agency for Research on Cancer (IARC) as probably carcinogenic to humans based on genotoxic effects in animal studies. Acrylamide has become a food safety issue since, in 2002, the Swedish National Food Administration announced the detection of a substantial amount of acrylamide in several heat-treated, carbohydrate-rich foods such as potato chips and crisps, coffee, and bread. From that moment onward, acrylamide has been the object of an extensive, still ongoing, collaborative effort to clarify several aspects of its toxicity, to establish the actual risk from its dietary exposure, and to develop and implement effective mitigation strategies of its occurrence.

Mechanism of Formation

Acrylamide forms in foods upon baking, frying, microwaving, roasting, grilling, broiling, or toasting but not in pouched, boiled, or steamed products. However, the type of cooking is not an issue per se for acrylamide formation as suitable conditions for Maillard reaction development, namely, high temperature and low water activity, are present. Experimental studies with stable isotope-labeled compounds have confirmed that acrylamide mostly forms from asparagine degradation enhanced by carbonyl compounds through Maillard reaction. Although asparagine can thermally decompose to acrylamide by deamination and decarboxylation, the yield of acrylamide formation is considerably higher when a carbonyl source is present (up to 1 mol% in aqueous model systems). Reducing sugars and other carbonyl compounds (i.e., those from oxidized fats) can all contribute to asparagine conversion into acrylamide. However, in most of the cases, reducing sugars are by far the most important contributors to acrylamide formation in potato-based and cereal-based products since they are present in higher concentration. Within the Maillard reaction scheme, several pathways and intermediates can simultaneously lead to acrylamide. Acrylamide may form from (1) the β-elimination of the decarboxylated Amadori compound (from reducing sugars), (2) the Hofmann-type elimination from the Amadori compound (from reducing sugars), or (3) the deamination of 3-aminopropionamide (3-APA; from both reducing sugars and dicarbonyls). Other minor reaction routes for acrylamide formation in foods have been postulated from (1) acrolein, (2) acrylic acid, (3) preformed 3-APA (even in the absence of a carbonyl source), and (4) pyrolysis of wheat gluten, but the practical significance of those minor pathways has not been demonstrated yet. Acrylamide content of foods can be regarded as the result of concomitant reactions of formation and elimination. It starts to form at a temperature >120 °C (248 °F) and accumulates in time since a plateau is reached after which it can decrease because of the exhaustion of (one of) the reactants and/or its elimination. Indeed, acrylamide may undergo Michael-type addition reactions to the electron-deficient vinylic double bond with nucleophiles, such as amino and thiol groups of amino acids and proteins or Diels–Alder addition and radical reactions. On the other hand, the amide group can undergo hydrolysis, dehydration, alcoholysis, and condensation with aldehydes. The acrylamide elimination phase is more evident under severe heating conditions (e.g., coffee or nut roasting).

Occurrence in Foods

Acrylamide is not present in raw ingredients but it is formed during food processing or cooking. Acrylamide typically occurs in plant-derived, carbohydrate-rich heat-treated foods. The highest acrylamide levels have been indeed found in fried and baked potato products, bread and bakery products, and coffee. Significant amounts of acrylamide can also occur in hazelnuts and almonds and sometimes also in foods that have not been subjected to severe heat treatments such as olives and dried fruits. However, the contributions of those products to the overall acrylamide dietary intake have to be considered marginal. Animal-derived heat-treated foods such as meat and fish generally exhibit low or negligible levels of acrylamide because of the low concentrations of precursors (both reducing sugars and free asparagine).

Since 2003, competent authorities and food industry from each member state submit data on the occurrence of acrylamide in food commodities to the Joint Research Centre (JRC) of the European Commission. In April 2009, the European Food Safety Authority (EFSA) published for the first time the results of the monitoring of acrylamide levels in foods in response to a request of the European Commission (Commission Recommendation 2007/331/EC). Data collected in that report concerned with foods sampled in 2007 and were submitted to the commission by 21 member states and Norway. Two additional reports based on food sampled in 2008 and 2009 were published by EFSA in the following two years on a yearly basis. This monitoring has been extended for three more years till 2012. In Table 1, a summary of the results reported by EFSA in 2010 relative to samples collected in 2009 is shown. The highest median

content in acrylamide was reported for the categories 'substitute coffee,' 'instant coffee,' 'French fries,' 'potato crisps,' and 'wafers.'

Acrylamide Dietary Exposure

Dietary exposure to acrylamide has been assessed several times for many countries and many populations or segments of the population. Dietary exposure depends on the acrylamide content of the food products and the amounts consumed. Thus, a food product that exhibits a relative low concentration of acrylamide can still be a major contributor to dietary exposure if consumed frequently or in large amounts. Sources of dietary acrylamide include a broad range of foods commonly consumed daily worldwide and produced in homes, in restaurants, and by catering services or commercially available. In 2005, the World Health Organization (WHO) estimated a dietary intake of acrylamide in the range 0.3–2.0 μg kg^{-1} body weight (BW) per day for the general population and a dietary intake of up to 5.1 μg kg^{-1} BW per day for the 99th percentile. The most recent evaluation of human consumption data and acrylamide dietary exposure has been conducted by Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 2011 in eight countries and has led to very similar conclusions. The major food categories mostly contributing to the overall acrylamide intake were fried potatoes (French fries in the United States, contributing for 10–60% of the total acrylamide dietary intake), potato crisps (potato chips in the United States, 10–22%), bread and roll/toast (13–34%), and pastry/sweet biscuits (cookies in the United States, 10–15%). Other food categories (including coffee) would contribute less than 10% of the overall intake. A dietary exposure to acrylamide of 1 μg kg^{-1} BW per day has been taken as representative of the average for the general population, whereas 4 μg kg^{-1} BW per day has been considered representative of the average for consumers with the highest dietary exposure. The most recent EFSA estimation came to very similar conclusions. The mean acrylamide intake for adults (>18 years) in Europe was estimated to range between 0.31 and 1.1 μg kg^{-1} BW per day and the 95th percentile between 0.58 and 2.3 μg kg^{-1} BW per day. 'Fried potatoes' (including 'French fries'), 'soft bread,' and 'roasted coffee' were identified as the major contributors to overall adult acrylamide exposure. Higher mean and 95th percentile values were estimated for adolescent, children, and toddlers. Children have to be included in the highest percentile of the population because of their higher intake of acrylamide-rich foods (French fries and potato crisps). However, a very large variability of acrylamide concentration within the same food categories, brands of the same product, or batch of the same brand was found. This, together with the existence of profound differences in the way the foods are domestically prepared in household or by caterers and the unsuitability of the food frequency questionnaires (FFQs) for cooked foods, may further complicate the accurate estimate of acrylamide dietary intake.

Mitigation Strategies

Significant efforts at a global scale have been produced over the past years to develop strategies reducing acrylamide concentration in the main categories of concern, namely, potato products, cereal-based products (biscuits and bakery wares, breakfast cereals, bread, and crispbread), and coffee. The main problem in the mitigation of acrylamide in final products is that acrylamide form through the same reaction network, that is, Maillard reaction, which contributes to the color, flavor, and texture of the final product. Therefore, it often happens that the reduction of acrylamide concentration is paralleled by a reduction of food organoleptic quality. The mitigation efforts should therefore aim at decoupling acrylamide formation from the Maillard reaction pathways leading to the formation of desired flavor and color.

A number of mitigation strategies have been proposed, but unfortunately, some of them bring about changes in organoleptic properties of foods (excessive browning and generation of off-flavors as result of glycine addition, insufficient browning as result of the reduction in the overall heat load, etc.) that can dramatically affect the final quality and consumers' acceptance. It would be also necessary that the strategies aiming at lowering acrylamide content of foods are complemented by a risk–risk or risk–benefit analysis to reveal all the side effects and their impact on humans. For instance, prolonging yeast fermentation efficiently reduces acrylamide concentration in bread, but it brings about the increase in the levels of 3-monochloropropane-1,2-diol (3-MCPD), a harmful neoformed contaminant. Similarly, the replacement of ammonium bicarbonate with sodium bicarbonate as a raising agent for fine bakery products will reduce acrylamide levels but would concomitantly result in an increase of sodium intake, which has adverse effects on blood pressure.

The information collected by the scientific community and industry has been collated by the FoodDrinkEurope (FDE; formerly termed the CIAA (Confederation of the Food and Drink Industries of the European Union)) in a guidance document termed 'Acrylamide Toolbox.' Its last updated version was released in 2011. The FDE Acrylamide Toolbox is meant to assist manufacturers, caterers, and final consumers in implementing steps for the reduction of acrylamide levels in the final products. Many of the strategies described in the FDE Acrylamide Toolbox have been summarized by Codex Alimentarius in a 'Code of Practice for the Reduction of Acrylamide in Foods' document. Finally, the FDE and the European Commission's Directorate General for Health and Consumer Protection (DG SANCO) in collaboration with national authorities have developed the Acrylamide Pamphlets to assist small- and medium-sized enterprises in the implementation of the FDE Acrylamide Toolbox.

Cereal-Based Products

It has been widely proved that in most of the cereal products (especially those without added sugars), free asparagine rather than reducing sugar levels is the key determinant for acrylamide formation. The accurate selection of flours low in free asparagine is therefore the most obvious action to lower acrylamide levels in cereal products. Indeed, free asparagine is known to largely vary according to grain species and variety. Furthermore, asparagine content increases as the flour extraction rate (amount of bran) increases so that whole-wheat flours are richer in asparagine than more refined flours. However, the substitution of flours richer in asparagine with alternatives lower in asparagine may be not always feasible or advisable. Some products, for instance, have a particular grain as specific characteristic defining their identity, such as rye in crispbread, so that the replacement of rye with another grain species would not be possible without changing the product identity. Analogously, since whole-wheat flour contains more free asparagine, using less whole-wheat or bran compared to endosperm not only would reduce acrylamide content but also would reduce the organoleptic and nutritional properties of the resulting products (whole-wheat flour and bran are richer in dietary fiber and vitamins compared to endosperm). However, a large variation within the same grain variety is reported according to geographic and climatic conditions and, above all, agronomic practice so that it would be difficult to ensure supply of flour with consistent levels of asparagine. However, some agronomic practice has shown to have a strong impact on free asparagine content such as the level of sulfur fertilization. Asparagine level in the crop and thus the risk of acrylamide formation are inversely correlated to the level of sulfur in the soil.

Another change in the recipe that has been proposed is the replacement of ammonium bicarbonate with another leavening agent in biscuits even though the impact of the replacement on the organoleptic properties of the final product has to be assessed case by case. NH_4HCO_3 would increase acrylamide content because it would yield highly reactive dicarbonyl fragments upon baking. The addition of glycine, calcium salts, antioxidant compounds, and organic acids has been also proposed, but in most of the cases, these strategies have been only tested at lab or at pilot scale. Glycine would reduce acrylamide formation by competing with reducing sugars in the very first step of Maillard reaction. The addition of organic acids would decrease acrylamide formation because of the drop in the dough pH, which would slow down the very first step in the Maillard reaction between asparagine and sugars. However, the addition of glycine and organic acid often results in products of unacceptable quality and, in the case of organic acids, as for prolonging yeast fermentation, in products with increased 3-MCPD levels. The addition of ingredients other than flour, such as almonds and other nuts, raisins, and dried fruits, can also increase acrylamide content in cereal products.

Another obvious strategy to reduce acrylamide formation in cereal products is size dilution. Acrylamide is formed almost exclusively in the crust and the crust (area) to crumb (volume) ratio determines the quantity of acrylamide expressed on the total product. Decreasing the surface area to volume ratio by producing a larger bread loaf would therefore reduce acrylamide content in the final product. When the processing is considered, the first option would be the extension of the fermentation for bread, crackers, gingerbread, and similar products. Indeed, in fermented bakery products, acrylamide concentration is generally lower compared to nonfermented analogous products. This is because yeast rapidly assimilates asparagine, aspartic acid, and sugars and also contributes to

lower dough pH. One of the most promising technological options to reduce acrylamide in cereal products is the addition of the enzyme asparaginase (L-asparagine amidohydrolase), which is able to catalyze the hydrolysis of asparagine in aspartic acid and ammonia thus lowering the content of precursor asparagine. Gingerbread, crispbread, and short sweet biscuits and certain cereal-based snacks can be produced with the addition of asparaginase without negative impact on the final product quality. In breakfast cereals, though, the use of low moisture content matrices makes the penetration of the enzyme in the dough difficult, which results in much less efficiency in acrylamide mitigation. Finally, since acrylamide formation is related to the thermal input provided, the optimization of the time–temperature profile would be an obvious mitigation option. Since, as mentioned earlier in the text, acrylamide formation follows the same pathways leading to brown and flavor compounds, the optimization of the time–temperature profile requires the knowledge of the temperature dependence of the rate constants for acrylamide formation and for browning and flavor generation. Alternative baking technologies such as infrared heating, steam baking (during the last minutes of baking), radiofrequency, and vacuum baking (low pressure) are effective in reducing acrylamide, but the impact on sensorial properties may be quite strong.

Potato Products

In potato products, final acrylamide concentrations depend mainly on the level of reducing sugars in the raw potatoes and the intensity of the heat treatment applied. Controlling reducing sugar is therefore the primary measure implemented by the industry to reduce acrylamide levels in potato products. This can be achieved through

(1) the selection of potato varieties and lots with less reducing sugars;
(2) the growth of potato varieties best suited to the local growing conditions, selection of the appropriate fields, and adherence to good agronomic practice;
(3) processing tubers that are mature at the time of harvest because immature tubers tend to have higher reducing sugar levels;
(4) controlling tuber storage conditions, for example, storing tubers not longer than recommended for the specific variety, storing at temperature $>6\,^{\circ}C$ for long-term storage, using sprout suppressants in accordance with the law and with good agronomic practice, and reconditioning at higher temperature over a period of a few weeks.

A prolonged blanching of the potato slices or strips is another option to reduce the content of reducing sugars in the tubers even though it may result in unacceptable adverse effect of flavor and texture in potato crisps. Future opportunities are represented by breeding new potato varieties with lower reducing sugar content and/or less sensitive to cold sweetening and the optimization of agricultural practices to minimize reducing sugars and asparagine. The nitrogen fertilization regime appears to be inversely correlated to the level of reducing sugars in the raw potatoes.

On the other hand, the reducing sugar concentration of potatoes is not always directly proportional to the acrylamide concentration in the final potato product. The concentration of free asparagine and the ratio of asparagine to other free amino acids are also important. Asparagine is the most abundant free amino acid in potatoes, amounting at 0.2–4% of potato dry weight, which represents 20–60% of total free amino acids. A lower ratio of asparagine to other amino acids would lower the amount of acrylamide that forms during the heat treatment because of the competition for reactants during the Maillard reaction. From this perspective, the application of the enzyme asparaginase proved to be ineffective in potato crisps, likely because the enzyme cannot penetrate the potato matrix so as to act on asparagine and in French fries. On the other hand, it seems to be a valuable option in blanched (non-par-fried) chilled potato strips, where a longer enzyme–substrate contact time is allowed, as well as in potato-based products.

Analogous to what is observed in cereal-based products, acrylamide forms on the surface of potato-based products, and the surface area to volume ratio will have an effect on the level of acrylamide in the final product. In French fries, decreasing the surface area to volume ratio by creating thicker strips/sticks of potato could be a valuable mitigation option. However, producers have relatively little room to change the strip cut dimension, which is specified by customers. In potato crisps, which are fried to low moisture content, reducing the surface area to volume ratio can result in higher acrylamide levels as a thicker strip will require a higher thermal input to reach the optimal moisture.

However, the primary technological tool to control acrylamide formation in potato products is the optimization of the time–temperature profile during frying. Since, at low moisture contents, the activation energy for acrylamide formation is larger as compared with the activation energy for browning development, the setup of the end phase of the frying process at a lower product temperature would minimize acrylamide formation. Also, frying up to the highest moisture content, which still gives an acceptable product, is another sensible choice. For French fries, the finished frying/(oven) cooking of the prefried potato product is done by the professional end user or by the consumer at home. The par-frying step does not produce significant levels of acrylamide in the semifinished product, nor does it correlate with the acrylamide level in the final product. In the final preparation stage, it is pivotal that temperature not $>175\,^{\circ}C$ is used and that the fries are cooked to a golden yellow color rather than to a brown color. However, in some European countries, consumers prefer French fries that are cooked to a golden brown color rather than golden yellow. The use of food colorings as an ingredient in industrially produced potato products could be an option to match the consumers' expectations in terms of color in such countries. However, regulatory constraints on the use of food colorings in plain potato products can be found in many countries including the EU.

Coffee

Unlike cereal-based and potato products, few mitigation opportunities exist at the moment for reducing acrylamide content in coffee. The organoleptic properties of roasted coffee

are carefully tuned so that even limited changes in the formulation/processing may result in a product that is unacceptable to the consumers. It appears that free asparagine rather than reducing sugars is the limiting factor for acrylamide formation in such product. However, free asparagine content of green coffee beans does not vary too much so that selection of varieties having low asparagine concentration does not seem a feasible option. In coffee, acrylamide level is strongly related to the severity of the heat treatment, but the final level is inversely correlated to the total heat load being lower in dark roasted coffee. This occurs because acrylamide elimination is predominant at the end of the roasting step. However, roasting to dark color as it happens in Italy or Spain is not always an option because of consumer acceptance particularly in the Nordic countries where a light roasting is preferred.

Risk Assessment

Metabolism

Acrylamide metabolism has been thoroughly investigated by means of toxicokinetic studies in humans, rats, and mice. After ingestion, acrylamide is rapidly absorbed and distributed to many organs and tissues as well as in human placenta and breast milk. Acrylamide can be either oxidized by cytochrome P450 2E1 into the epoxide glycidamide (2,3-epoxypropionamide) or conjugated with glutathione (GSH) by glutathione S-transferases M1, T1, and P1 (GSTM1, GSTT1, and GSTP1). The extent of glycidamide formation is higher for low-dose dietary acrylamide exposure. Both acrylamide and glycidamide can bind *in vivo* hemoglobin (Hb), serum albumins, DNA, and enzymes, glycidamide being more reactive than acrylamide. Glycidamide can be further hydrolyzed by the microsomal epoxide hydrolase (EPHX1) to 2,3-dihydroxypropionamide (glyceramide) and then converted to 2,3-dihydroxypropanoic acid. GSH conjugates of acrylamide and glycidamide are further converted to mercapturic acid conjugates, *S*-(3-amino-3-oxopropyl)cysteine, *N*-acetyl-*S*-(3-amino-3-oxopropyl)-cysteine (AAMA), *N*-acetyl-*S*-(3-amino-3-oxopropyl)-cysteine and its *S*-oxide, *N*-(*R*,*S*)-acetyl-*S*-(3-amino-2-hydroxyethyl-3-oxopropyl)-cysteine (iso-GAMA), and *N*-acetyl-*S*-(1-carbamoyl-2-hydroxyethyl) cysteine, which are excreted with urines. The conversion of acrylamide to glycidamide is therefore thought as the crucial step for the toxicity of acrylamide, whereas the hydrolysis of glycidamide to glyceramide and the conjugation of acrylamide and glyceramide to GSH are regarded as detoxification pathways. Toxicokinetic studies on humans showed that approximately 60% of absorbed acrylamide is excreted in the urine mostly (86%) as GSH conjugates and to a less extent as unchanged acrylamide (4.4%), whereas only negligible amounts of unchanged glycidamide could be found in human urine. Hemoglobin adducts of acrylamide and glycidamide reflect the exposure to acrylamide over the last four months (lifetime of the erythrocytes) and can be regarded as biomarker of long-term exposure to acrylamide. On the other hand, the mercapturic acid metabolites of acrylamide and glycidamide can be regarded as biomarkers of recent acrylamide exposure (from hours up to a few days). The urinary AAMA/GAMA ratio is a measure of the extent of conversion of acrylamide to glycidamide and reflects the internal exposure to the latter. DNA adducts can be regarded as a biomarker of biologically active internal dose of acrylamide but have not been detected yet in humans so far.

Neurotoxicity

Acrylamide is neurotoxic from the high levels of exposure. Acrylamide neurotoxicity is characterized by ataxia and skeletal muscle weakness. The neurotoxicity of acrylamide is especially of concern for workers occupationally exposed to acrylamide through inhalation or dermal absorption. In rats and mice studies, the no observed adverse effect level was estimated ranging from 0.2 to 10 mg kg^{-1} BW per day and is far above dietary exposure.

Carcinogenicity

Since 1994, acrylamide is classified as probable carcinogen by the IARC (group 2A), by the US National Toxicology Program's (NTP) *Report on Carcinogens* as 'reasonably anticipated to be a human carcinogen,' and by the US Environmental Protection Agency (EPA) as 'likely to be carcinogenic to humans.' Acrylamide carcinogenicity has been tested in two early chronic oral lifetime studies in rats and one more recent two-year long study conducted on F344/N Nctr male/female rats and male/female B6C3F1 mice by the US National Center for Toxicological Research (NCTR)/National Toxicology Program (NTP). In this last study, acrylamide was administrated in drinking water ad libitum at four concentrations. The results of the study were generally in agreement with those reported in the earlier studies with a significant increase in thyroid gland adenoma and mesothelioma of the tunica vaginalis of the testes and testicular tumors in male rats and a significant increase in mammary gland fibroma or fibroadenoma, central nervous system tumors, and thyroid gland adenoma or adenocarcinoma in female rats. On the other hand, a different pattern of target organs has been observed in mice.

Currently, there is no plausible mode of action (MoA) for acrylamide-induced tumors to thyroid gland in rats and mice, but proposal on the MoA for mammary glands and testes tumors in rats has been put forward. It is widely accepted that the carcinogenicity of acrylamide would stem from its conversion in mammalians to glycidamide. Glycidamide has been shown to be mutagenic and genotoxic in bacterial and mammalian cells. The acrylamide-induced DNA adduction and consequent mutagenesis have been postulated as the key process in acrylamide carcinogenicity. In contrast, acrylamide without metabolic activation to glycidamide has not been found to be neither genotoxic nor mutagenic at biological relevant concentrations. Glycidamide is considerably more reactive toward DNA and other nucleophiles than acrylamide and may thus give numerous adducts *in vitro* and *in vivo*.

Although the results obtained *in vitro* and *in vivo* experiments support the evidence that acrylamide is genotoxic and carcinogenic, epidemiological data have not yet unambiguously proven that dietary acrylamide exposure can increase cancer risk for humans. Up to date, the epidemiological studies agree in indicating no positive association between total dietary acrylamide intake and the risk of colorectal, bladder, esophageal, prostate, oropharyngeal, laryngeal, pancreatic, gastric, and brain cancer. For renal cell cancer, ovarian cancer,

and breast cancer, the results from epidemiological studies are conflicting. One reason for the conflicting results could be that the relative risk for cancer upon acrylamide dietary exposure is so low even at high exposure levels that no epidemiological studies, albeit well designed, can detect the effect. The second reason might be the inaccurate estimation of acrylamide intake when FFQs are used to assess acrylamide dietary intake. Generally, FFQs are not specifically designed to assess the dietary exposure to acrylamide and do not take into account the way the foods are cooked or prepared at home. Moreover, the wide variability of acrylamide concentration among food categories would reduce the differences between low and high levels of exposure, thus reducing the power of the statistical tests applied.

The margin of exposure (MOE) approach has been used by EFSA and the JECFA for the risk assessment of acrylamide. The MOE is the ratio between a defined point on the dose–response curve for the adverse effect and the human intake. The BMDL (benchmark dose lower confidence limit; the lower limit of the 95% confidence interval for a dose that causes a low, but measurable response) is preferably used as a reference point on the dose–response curve. The MOE is therefore a measure of how close the intake of a specific toxic compound is to the exposure levels that are anticipated to produce adverse effects in humans. From the data provided by the recent NTP bioassay, in its latest evaluation, JECFA calculated an MOE of 310 for average consumers and of 78 for high consumers based on an acrylamide exposure of 1 $\mu g\ kg^{-1}$ BW per day (average consumers) to 4 $\mu g\ kg^{-1}$ BW per day (high consumers) and on a BMDL for the induction of mammary tumors in female rats and an MOE of 180 and 45 for average and high acrylamide exposure based on the BMDL for the Harderian gland tumor in male rats. The MOE as calculated for acrylamide is remarkably lower than the value of 10 000 that would indicate a high concern from a public health point of view and is far below those reported by JECFA for polycyclic aromatic hydrocarbons (25 000 for average consumers) and for the heterocyclic amine PhIP (260 000 for average consumers). Therefore, the dietary exposure to acrylamide for the Western population is considered a potential health risk.

Risk Management

As a genotoxic carcinogen, acrylamide is considered to have no threshold limit of exposure, that is, a single exposure to one molecule of acrylamide can trigger the biological process leading to cancer. The level of such genotoxic carcinogens in foods should conform the principle of 'as low as reasonably achievable.' Despite that, at present, no country has ever established regulatory limits to acrylamide concentration in any food category or in the diet. Risk management of acrylamide in foods has derived from the voluntary collaboration between national regulatory agencies and companies producing acrylamide-containing foods. In Germany, an acrylamide minimization strategy has been developed and implemented as of 2002. This approach is based on signal values that are established for single categories approximately as the 90th percentile within that category. If producers are found to deliver products with an acrylamide content higher than the signal value for the relevant food category, discussions are started as to which mitigation strategy to implement. The acrylamide content of foods is then reviewed annually and the signal value reduced if necessary. The European Commission has implemented a similar strategy. Since 2007, the annual monitoring of acrylamide levels in the EU has been carried out under the Commission Recommendation 2007/331/EC of 3 May 2007 subsequently extended by with a revised food categorization. Based on the occurrence data collected in these years, EC has established indicative values for ten food categories. These values do not have to be intended as safety or regulatory thresholds, but rather to indicate the need for investigating the reasons behind acrylamide levels exceeding the indicative value of the particular category.

Adipose Tissue: Structure and Function of Brown Adipose Tissue

Histology

Brown adipose tissue (BAT) is regarded as an adipose tissue because it shares the capacity of white adipose tissue to store lipids in intracellular droplets still not counted for ectopic fat. The intracellular lipid compartment may be used for storing the excess energy from the circulation, but the storage may be also released rapidly for enhanced cellular respiration. Apart from white adipose tissue, the lipid droplets in BAT are smaller and organized in multilocular shape instead of one droplet in white adipocyte. One large lipid droplet in white adipocyte squeezes the nucleus against the cell membrane (crescent-shaped nucleus), but in brown adipocyte the nucleus appears roundish.

The size of brown adipocyte is small, in average 15–60 μm in diameter, while the size of white adipocyte is 25–200 μm in diameter, owing to the capacity of increasing its size several-fold. The appearance of white adipocyte is round and spherical, but the brown adipocytes are polygonal.

Brown adipocytes include numerous mitochondria, which in part induce the darker color of this tissue compared to white adipose tissue. In fact, rodents have clearly brown-red colored adipose tissue in the interscapular region, and their white adipose tissue is clearly white, while human BAT in the supraclavicular region is colored with orange, and white adipose tissue with light yellow.

The structure of mitochondria in brown adipocytes differs from the mitochondria in white adipocytes. In addition to higher density and number of mitochondria in brown adipocytes, the size of mitochondria is larger. The inner membrane cristae in mitochondria are densely packed, which results in great surface area of the inner membrane.

In addition to cellular histology, BAT is densely vascularized and innervated. A dense capillary network with adrenergic innervation forms the basis for rapid signal transduction and response to stimuli from other parts of the body.

Biochemical Characteristics of BAT

The most typical characteristic of BAT is uncoupling protein 1 (UCP1). The gene and protein expression of UCP1 is tightly related to the function and activation of the tissue. UCP1 function is located at the mitochondrial inner membrane, where it is able to uncouple oxidative phosphorylation from ATP synthesis by affecting proton gradient and producing heat instead of ATP. This capacity denotes that BAT is primarily energy-expending tissue instead of energy-storing tissue. Relative UCP1 expression level is several 100- or 1000-fold in human BAT samples, compared to white adipose tissue samples.

Another factor highly enriched in BAT is PR domain-containing 16 (PRDM16), which has a crucial role in the fate of brown adipocytes arising from precursor cells that express Myf5. PRDM16 controls the skeletal myoblast/brown adipocyte switch from these progenitors and activates BAT phenotype. Other functional markers for brown adipocytes may be PPARγ and PGC-1α, but they are not specific to BAT.

Adrenergic β_3-receptors are abundantly found in brown adipocytes, although other adrenergic receptors exist as well. Functional activity is mainly mediated by β_3-receptors, yet β_1-receptors may also have a minor role in binding norepinephrine released from adrenergic nerve endings during activation of the sympathetic nervous system.

Beige Adipose Tissue

Classical brown adipocytes arise from myogenic lineage under controlled programming during embryogenesis. In a newborn, this kind of BAT is found back in the neck between the shoulder blades and in the thoracic cavity in the mediastinum. Classical BAT has an important role in the regulation of body temperature in infants and small children.

Previously, BAT was thought to vanish after childhood and human adults were regarded to have no functional BAT, although existence of brown-like adipose tissue around neck arteries was shown in autopsies of outdoor workers. The confirmation about functional BAT in adult humans was made less than ten years ago. This was possible due to advanced imaging technology, namely positron emission tomography (PET) combined with computed tomography (CT). PET is a non-invasive imaging tool for the measurement of physiological function in the body, while CT provides information about anatomy and tissue density.

Rapidly, it became evident that BAT in the supraclavicular region in adults is distinct from the classic BAT found in infants. In resting state these adipocytes resemble white adipocytes, but when activated by specific stimuli the adipocytes transdifferentiate to resemble brown adipocytes. These adipocytes – called beige or brite (brown-in-white) adipocytes – are UCP1 positive, but they emerge from a non-Myf5 lineage and exist also in white adipose depots. Gene expression patterns between beige and brown adipocytes are mostly different, but in the human supraclavicular depot they are partly overlapping. Plasticity of beige adipocytes provides a functionally promising target for modification; therefore, the 'renaissance' of BAT has gained interest from obesity research.

Localization of BAT in Rodents and Humans

In rodents, such as in mice and rats, the most prominent site of BAT is located in the interscapular region. This butterfly-shaped depot may be seen with the naked eye if specific activation has been carried out. Why rodents have BAT in this location is not quite clear, but it may be partly explained by the different

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00007-6

posture when compared to humans. However, rodents show a high capacity of transdifferentiation between white and brown adipose tissue, and rodents have both white and brown adipocytes mixed in several adipose depots. The fat content of the depot may be estimated with magnetic resonance imaging (MRI), and the interscapular brown adipose depot consists of a multilocular (brown) area in the deepest portion, while the surface area of the depot is mainly unilocular (white).

Human newborns have BAT in the back of the neck between the shoulder blades, and in the thoracic cavity in the mediastinum. The amount of BAT in infancy is 1–5% of the body weight, which in a full-term newborn weighing around 3500–4000 g means a mass of 35–200 g of BAT. The amount of BAT remains quite similar through the years, though the location changes.

In adult humans, the most prominent site of BAT is found in the supraclavicular region (Figure 1). This depot extends down to axillar regions and up along carotid arteries. Smaller BAT depots are found along the backbone, around big (e.g., renal) arteries, and in the adrenal area above the kidneys. Human adult BAT is regarded mostly as beige adipose tissue, at least in the supraclavicular region, which is most often the site of sampling of the tissue.

Physiological Function of BAT

Two main structural characteristics that determine the functional differences of BAT apart from white adipose tissue are (1) the multilocular organization of lipid droplets and (2) mitochondria with densely packed cristae. Organization of lipid droplets in multilocular form guarantees that the surface area for lipolysis is as high as possible. This provides a high amount of fatty acids for activated mitochondria. Similarly, densely packed cristae warrant as high a surface area as possible for uncoupling – the great surface area of the mitochondrial inner membrane is related to energy production of the mitochondria. These two characteristics interact with each other in order to rapidly optimize functional activity of the tissue.

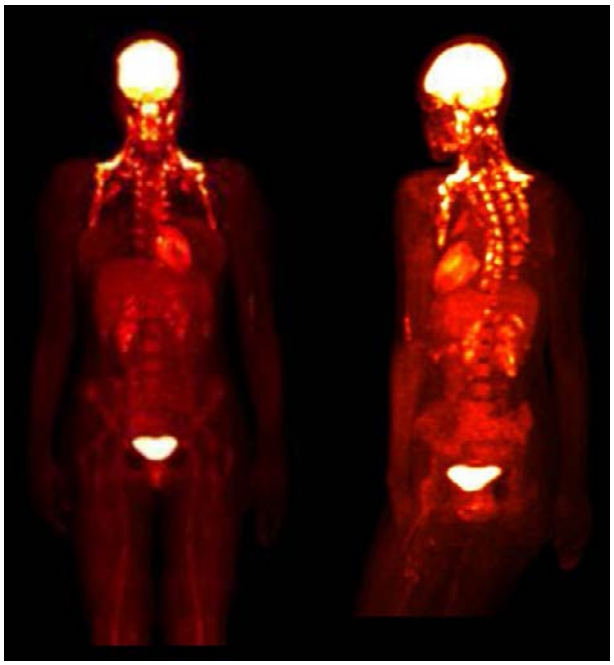

Figure 1 Human brown adipose tissue distribution illustrated with ^{18}FDG-PET/CT uptake in young female subject. Bright accumulation is found in supraclavicular and axillar regions as well as in paravertebral and slightly in adrenal regions. Metabolic activity in neck and axillar region is comparable to brain metabolic activity. The lower bright accumulation is in the urinary bladder due to excretion of the tracer through kidneys.

Thermogenesis – The Main Function of BAT

All cells in the body produce heat as a by-product in the metabolic processes. However, two tissues actively produce heat against cold, namely BAT and skeletal muscles. A cold environment increases whole-body metabolism and oxygen consumption in humans and animals, but the role of BAT is emphasized and is in optimal level during nonshivering thermogenesis, that is, when muscles are not yet producing heat by shivering.

Heat release from the activated tissue is fairly local, especially in humans, but the response may be detected rapidly after initiation of cold exposure on the skin area in the supraclavicular region. Skin temperature begins to rise within minutes, and as cold exposure continues, the skin temperature above the clavicles is not decreasing as much as on other skin areas, for example, in the legs.

The sympathetic nervous system has a crucial role in controlling and mediating the cold sensations from skin to BAT. The cold environment is sensed by skin thermoreceptors from which the signals are mediated to the lateral parabrachial nucleus and further more centrally to the thalamus and somatosensory cortex. In the hypothalamus in the preoptic area, the warm-sensitive neurons are inhibited by cold stimulus and the signal is transferred to peripheral sympathetic nerve endings, which in turn release norepinephrine. Binding of norepinephrine to β_3-adrenergic receptors in brown adipocytes initiates a signal cascade in the cell, which ends up with activation of UCP1 production and increased thermogenesis.

Thermogenic activity may be measured in animals directly from tissue samples. In adult humans, the metabolic activation of brown/beige adipose tissue reflects the activation of thermogenesis. Thus, functional in vivo imaging with PET/CT is the method of choice. With this method, it is possible to follow how much each tissue takes up glucose, oxygen, or fatty acids, and measure blood flow or oxidation rate. Imaging of the molecule of interest (e.g., glucose) requires a label with a positron-emitting radioisotope (e.g., 18-fluoro (^{18}F)), which is chemically synthesized to a glucose-like molecule and then given to the study subject by intravenous injection. The studies are most commonly performed at room temperature, but for the activation of BAT function and thermogenesis, the studies are performed during proper cold exposure.

Cold-Induced Metabolic Changes in BAT

After overnight fasting and in normal room temperature, BAT metabolism is silent and comparable to white adipose tissue

metabolic activity. Cold is one of the most potent and natural activators of BAT metabolism, and whole-body resting energy expenditure increases in line with activation of BAT. The resting metabolic rate in the whole body is increased in cold, specifically in those subjects with functionally active BAT (BAT-positive subjects).

Oxygen consumption in BAT (direct measurement with $^{15}O_2$-PET/CT) is increased during mild cold exposure and is clearly more emphasized in BAT-positive subjects. The cold-induced increment in oxygen consumption is strongly related to blood flow (measured with ^{15}O-H_2O-PET/CT) of the tissue. Therefore, measurement of blood flow may be used as an indirect measure of oxygen consumption in BAT. Blood flow increases twofold during acute cold exposure in healthy lean subjects, which supports the increased oxidative role of BAT in cold. Blood flow in BAT is closely related with glucose uptake and whole-body energy expenditure, suggesting a perfusion-dependent manner of energy expenditure in cold.

Glucose uptake by activated BAT reflects the activity of thermogenesis. This can be measured using glucose analogue ^{18}FDG and PET/CT, and the majority of the recent results by different study centers were achieved using this tracer. During cold exposure, BAT glucose uptake increases approximately tenfold in healthy lean subjects. Based on animal studies, glucose uptake by BAT is estimated to be 10% of the total energy need of the tissue during cold exposure. In animals this contribution is suggested to be significant, and in humans the contribution of glucose uptake as a part of thermogenesis is also considered remarkable – only a few tissues are able to increase their metabolic rate tenfold during short stimulation. In addition, BAT glucose uptake in cold is almost as high as cerebral glucose uptake (Figure 1).

During activated thermogenesis, such as in mild cold exposure, BAT intracellular triglycerides are rapidly hydrolyzed and utilized in activated mitochondria. Intracellular lipid content may be estimated using CT and Hounsfield units, which provide an estimate of tissue density. Cold exposure increases the radiodensity of BAT, suggesting that intracellular triglycerides are the main source of energy for increased thermogenesis. One-third of the intracellular lipid reserve in BAT may be burned in three hours of cold exposure, which corresponds to 200–250 kcal per day energy consumption.

Meal-Induced Thermogenesis

Cold is an effective activator of BAT function, but most humans do not spend a long time in a cold environment. In addition to cold, eating and feeding are related to whole-body thermogenesis, and BAT is considered important in this context. In rodents, activation of the sympathetic nervous system is integrated with feeding, and in fact, BAT thermogenesis seems to precede initiation of feeding. The term 'thermoregulatory feeding' is used to describe the role of BAT thermogenesis, not only in initiation of feeding, but also in regulation of meal size and after balancing with temperature and termination of feeding. The same phenomenon is believed to occur in newborn babies.

A single meal increases uncoupled respiration significantly in BAT during the early postprandial hours in rats. Also, the content of the meal may affect BAT thermogenesis. High-carbohydrate meals seem to increase uncoupled respiration more than equicaloric high-fat meals. However, fatty acid composition may be crucial because a diet rich in polyunsaturated fatty acids results in activation of BAT thermogenesis in mice.

In humans, whole-body energy expenditure, or meal-induced thermogenesis, increases in the postprandial state. Resting metabolic rate may be measured using calorimetry, either directly (chamber) or indirectly (canopy hood). It is questionable how much BAT could contribute to whole-body thermogenesis after a meal, and final answers remain to be seen. Two meals with high-fat and low-carbohydrate content (one in the previous evening and the other in the morning of scanning) lower ^{18}FDG uptake in BAT in humans, while a high-calorie meal rich in carbohydrates increases ^{18}FDG uptake in BAT in healthy lean men. Thus, at least ^{18}FDG (glucose) uptake as a marker of attenuated or increased thermogenesis may be affected by eating in humans. But whether fatty acid oxidation in BAT is affected by meals is not yet known in humans. One of the functional characteristics that BAT may have is clearance of triglycerides from the circulation. This has shown to occur in mice, and it could be important in the postprandial state.

Eating and feeding are related with an increase in plasma insulin concentration, along with several other neural and hormonal signals. Insulin facilitates substrate influx to skeletal muscles, adipose tissue, and the liver. The effects of insulin stimulation on the whole body may be determined using the euglycemic hyperinsulinemic clamp technique, where plasma insulin concentration is artificially elevated to postprandial levels (70–100 U l^{-1}). When ^{18}FDG PET/CT-scanning is performed during insulin stimulation, tissue-specific glucose uptake may be measured in several tissues at the same time. In health, the insulin-stimulated glucose uptake rate in BAT is fivefold when compared to the fasting glucose uptake rate. The skeletal muscle glucose uptake rate is at a similar level, suggesting that BAT is an insulin-sensitive tissue type. The effect of insulin is partly mediated via activation of the sympathetic nervous system, which subsequently activates BAT thermogenesis. Moreover, insulin may promote its effect via the central nervous system in meal-induced thermogenesis.

Regulation of BAT Function

BAT functional activity is under accurate control of the sympathetic nervous system, but the central nervous system also is involved in this regulation. Activation of the sympathetic nervous system contributes to increased lipolysis both in white and brown adipose tissue and induced uncoupling in mitochondria of brown adipocytes. Simultaneously, plasma norepinephrine and free fatty acid concentration elevate. Increased free fatty acids activate UCP1 in brown adipocytes. Activation of thermogenesis in BAT is rapid and powerful to secure warm blood flow to cold sensitive tissue such as brain.

Thyroid hormones thyroxine (T_4) and tri-iodothyronine (T_3) participate in the regulation of BAT function as brown adipocytes display thyroid hormone receptors. In animals, T_3 treatment induces hypertrophy of the tissue, while on the cellular level T_3 activates UCP1 gene expression. Thyroxine is taken up from circulation by brown adipocytes but is rapidly

converted to T_3 by the enzyme DIO2 (deiodinase type 2). However, the effect of T_3 on BAT function is dependent on the release of norepinephrine from adrenergic nerve ends in order to complete the thermogenic response. In healthy humans, plasma concentration of T_3 decreases during acute cold exposure, suggesting that activated BAT is able to utilize it. On the other hand, patients with hyperthyroidism have enhanced BAT function – glucose uptake rate as a marker of metabolic activity is threefold when compared to healthy controls.

Bone morphogenetic protein 7 (BMP7) regulates selectively brown adipogenesis and affects energy expenditure by increasing the mass of BAT in mice. In addition, BMP7 increases gene expression of PRDM16 and UCP1 in BAT. The effects of BMP7 are leptin-independent because ob/ob (obese) mice as well as diet-induced obese mice treated with BMP7 increase energy expenditure, decrease food intake and body weight, and have improvement in metabolic syndrome.

Adipokines, such as leptin, adiponectin, and resistin, affect BAT function indirectly via the central nervous system. Rodents (mice or rats) deficient either for leptin or leptin receptors have impaired BAT activity and thermogenesis, but in order to function properly, leptin requires functional β_3-receptors on brown adipocytes. In addition, the melanocortin system is involved in the effect of leptin on BAT thermogenesis. If the melanocortin system is inhibited, BAT activity decreases. Adiponectin has a suppressive effect on BAT thermogenesis, reducing protein kinase A (PKA) signaling and UCP1 expression. Resistin reduces BAT thermogenesis via hypothalamic ERK1/2 signaling pathway. In addition, the effect of estradiol on BAT thermogenesis is mediated via hypothalamic AMP-activated protein kinase.

Several brain regions are involved in the regulation of BAT function. Especially, the ventromedial hypothalamic nucleus seems essential where the peripheral signals are integrated. In humans, metabolic activity in several brain regions is increased with mild cold exposure. BAT activation coincides with brain activation in cold, but this is observed only in lean subjects.

Defective BAT Function

Dysfunctional BAT is found in obesity and type 2 diabetes. Obesity clearly decreases the probability of detecting functionally active BAT in humans. Whether obesity is a consequence of dysfunctional BAT and an inactive sympathetic nervous system or vice versa – obesity and fatty acid overflow contribute to transdifferentiation of BAT to energy-storing white adipose tissue – is not clear. Based on cross-sectional studies in humans, it is known that body mass index, body fat content, and abdominal fat mass are inversely related to BAT functional activity, which all are also related to metabolic balance in systemic glucose and lipid metabolism. However, in morbidly obese humans, the Trp4Arg mutation in β_3-receptor gene is associated with high weight gain in adulthood.

Genetically obese animals, such as fa/fa Zucker rats or ob/ob mice, have impaired BAT function. Mice lacking BAT or β-adrenergic receptors (all three subtypes 1, 2, and 3) are obese. If the mice with no β-receptors are fed a high-fat diet, they develop massive obesity.

In obesity, BAT substrate metabolism is impaired: the glucose uptake rate and blood flow in cold is half the rate found in lean subjects. In addition, the insulin-stimulated glucose uptake rate is decreased, indicating tissue-specific insulin resistance in BAT in obesity. Relation between BAT activity and cerebral activity in mild cold is lost in obesity.

Increasing age may have even more of an effect on BAT function than obesity does. The incidence of cold-activated BAT decreases with age, being only 10% in subjects ages 50–60, while in the younger population the incidence may be close to 100%.

Improvement of Dysfunctional BAT

Manipulation of BAT function is a potential target for obesity treatment. The size of the tissue is considerably low, which limits the applicability of the treatment for extensive obesity. However, the beneficial effects of functionally active BAT on glucose and lipid metabolism overcome the effect only in weight loss in kilograms per pounds.

Conventional nonsurgical weight reduction of 10% in initial body weight results in an increased metabolic activity (^{18}FDG-PET/CT) in BAT. Also, surgical gastric banding in morbidly obese subjects has a beneficial effect on BAT function one year after operation.

Cold Acclimation

Acute cold exposure is an effective tool for activation of BAT function. Prolonged cold exposure has been used to treat obese animals, and both BAT mass and activity increase. Repeated cold exposure every day for 10 days, 4 weeks, or 6 weeks in healthy lean subjects increases BAT metabolic activity and cold-induced thermogenesis. Thus, recruitment of functional BAT is possible at least in health, but whether cold acclimation improves dysfunctional BAT in obesity remains to be seen.

Browning of White Adipose Tissue

Recruitment of silent beige/brite adipocytes in white adipose tissue depots is one treatment option. Local cold exposure on the thigh increases UCP1 expression in subcutaneous white adipose tissue. Both cold and β_3-adrenergic agonists recruit beige/brite adipocytes in rodent white adipose tissue. The plasticity of beige/brite adipocytes in rodents is further emphasized by chronic treatment with PPARγ-agonists, which activate rat epididymal white adipose tissue.

The concept of browning became common when the hormone irisin was discovered. Secretion of irisin is related to exercise and cold-induced shivering by muscles, and it promotes beige/brite cell formation. The effects of irisin have been clearly shown in rodents, but human results are to date contradictory.

Expression of another interesting factor, fibroblast growth factor 21 (FGF21), is induced by cold and consequently released from BAT both in rodents and in humans. FGF21 has endocrine effects on white adipose tissue (i.e., browning) but may also have autocrine effects. It seems that FGF21 release is dependent on the presence of BAT.

Several other factors and hormones may be involved in the browning of white adipose tissue, such as BMP7, BMP8b, ANP/BNPs, and prostaglandins. The importance of these factors in human white adipose tissue browning and the role in energy balance remain to be seen.

Pharmacological Approach

Adrenergic β_3-agonists have shown to be effective in activating rodent BAT function. Most of these molecules, which were tested in the 1990s, were not, however, functional and effective in humans.

Thiazolidinediones, PPARγ-agonists induce UCP1 gene expression in brown adipocytes. Also, PPARα, which is a PPARγ-coactivator, stimulates UCP1 gene expression and lipid oxidation in brown adipocytes.

Capsinoids, including capsaicin (found in chili peppers), have shown to be effective in humans. Current evidence is from the studies in lean subjects where it was found that cold-induced thermogenesis and BAT activity are improved. Future studies will evaluate their applicability in obesity.

Adipose Tissue: White Adipose Tissue Structure and Function

Definition

The development of white adipose tissue (WAT) has evolved as a physiological adaptation to preserve energy stores during periods of food deprivation. While WAT provides a survival advantage in times of starvation, excess WAT is now linked to obesity-related health problems in the current nutritionally rich environment. At the present time, it is known that the adipose tissue not only is an energy reservoir in the form of triglycerides but also functions as an insulator preventing heat lost and providing a physical protection for the organism. In addition, in the last two decades, the adipose tissue has also been classified as an endocrine organ because it secretes enzymes, hormones, growth factors, cytokines, complement factors, and matrix and membrane proteins, collectively termed adipokines.

WAT is distributed throughout the organism and is composed of two representative anatomical depots: subcutaneous WAT (sWAT) and visceral WAT (vWAT). sWAT represents >80% of total adipose tissue in the body and is located inside the abdominal cavity and underneath the skin and interspersed among skeletal muscles. The vWAT constitutes 10–20% of total body fat in men and 5–10% in women. It is located inside the peritoneum and distributed around internal organs (the liver, stomach, kidney, and intestine). Depending on the location, vWAT is subclassified in mesenteric, retroperitoneal, perigonadal, and omental adipose tissue.

The adipose tissue is a heterogeneous tissue; although by volume, adipocytes are the most prominent cells within a given white fat depot (35–70% of adipose mass in adults), by cell number, they represent approximately 25% of the total cell population. The remaining 75% comprise diverse cell types known as the stromal-vascular fraction, which include fibroblasts, macrophages, pericytes, vascular elements, nervous elements, preadipocytes, and cells with mesenchymal and hematopoietic stem cell capacity.

The adipose tissue has been classified into two types, the WAT and the brown adipose tissue (BAT) based on their different morphologies, colors, metabolic functions, biochemical features, and gene expression patterns. WAT generally constitutes 20% of the body weight of normal adult humans and is the larger energy store in the organism, whereas BAT participates in regulating body temperature by generating heat via the consumption of stored energy, thus playing an important role in body thermogenesis.

Recently, a new type of brown-like adipocyte was discovered that shows distinct gene expression patterns from those of white or brown adipocytes. These novel brown-like cells that reside within WAT, especially inguinal WAT, were termed beige or brite ('brown in white' adipocytes or inducible brown adipocytes). The relative amount of the tissues varies with age, strain, environmental, and metabolic conditions.

Origins of WAT

The development of WAT begins *in utero* but primarily occurs after birth when specialized fat storage cells are needed to provide fuel during fasting periods.

White adipocytes derive from $MYF5^-$ (myogenic factor 5) progenitors, although recent evidence has shown that WAT adipose precursors can also derive from $MYF5^+$ lineages. Moreover, WAT and BAT share a similar transcriptional cascade that establishes and maintains the stable differentiation of the adipocyte. The cascade of transcription factors is driven by the peroxisome proliferator-activated receptor (PPAR)γ, PPARγ coactivator (PGC)-1α, the three CCAAT/enhancer-binding protein family members (C/EBPα, C/EBPβ, and C/EBPδ), and the sterol regulatory element-binding protein (SREBP)-1c. This transcriptional cascade interacts with other transcription factors, coactivators, and microRNAs during the decision to adopt a white 'nonthermogenic' cell fate or a brown or beige 'thermogenic' cell fate (Figure 1). The adipogenesis of white phenotype requires the corepressor RIP140 and the coactivator TIF2. Also, it has been described that some microRNAs including miR-27 and miR-133 drive a white phenotype. miRNAs have recently been proposed as regulators of cell differentiation in WAT and BAT. miR-27 and miR-133 are negative regulators of the brown and beige adipogenic program, and they suppress the major brown fat transcriptional regulators. PPARγ has been extensively involved in the process of adipogenesis, which is the process of adipocyte formation from preadipocytes, and mice carrying adipose-specific deletion of the PPARγ gene suffered from lipodystrophy. Thiazolidinediones, which are PPARγ agonists, are capable to induce differentiation of preadipocytes. Adipogenesis in adults can still occur, and the inability of an individual to increase cell numbers by this process contributes to the development of metabolic diseases.

Structure of White Adipocytes

WAT is composed of adipocytes held together by a loose connective tissue that is highly vascularized and innervated. The main morphological characteristic of mature white adipocytes is the presence of a large 'unilocular' lipid droplet that occupies over 90% of the cell volume and a thin cytoplasm layer that contains elongated mitochondria, Golgi complex, smooth and rough endoplasmic reticulum, nucleus, vesicles, and other organelles. The mature white adipocytes have a spherical form and a diameter from a minimum of 30–40 μm to a maximum of 150–160 μm. An average adult has 30 billion of fat cells with a weight of 14 kg.

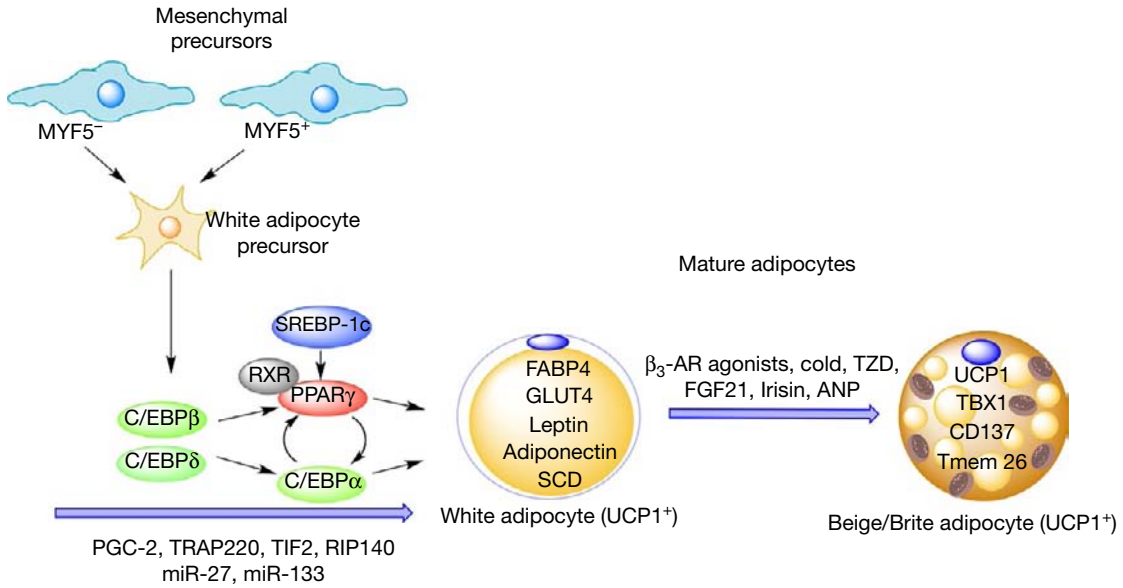

Figure 1 Origins of white adipocytes and factors regulating white adipogenesis. WAT adipocyte precursors can derive from both MYF5$^+$ and MYF5$^-$ lineages. Key transcription factors can differentiate white adipocytes and change the phenotype between white and beige adipocytes. MYF5: myogenic factor 5, C/EBPβ, C/EBPδ, C/EBPα: CCAAT/enhancer-binding protein β, δ, α, respectively. PPARγ: peroxisome proliferator-activated receptor-γ, RXR: retinoid X receptor, SREBP-1c: sterol regulatory element-binding protein 1c, FABP4: adipocyte fatty acid binding protein, GLUT4: glucose transporter type 4, SCD: stearoyl-CoA desaturase, PGC-2: PPARγ coactivator 2, TRAP220: thyroid hormone receptor-associated protein 220, TIF2: transcriptional intermediary factor 2, RIP140: receptor-interacting protein 140, miR-27: microRNA-27, miR-133: microRNA-133, β_3-AR: β_3-adrenergic receptors, TZD: thiazolidinediones, FGF21: fibroblast growth factor 21, ANP: atrial natriuretic peptide, UCP: uncoupling protein 1, Tbx1: T-box transcription factor, CD137: tumor necrosis factor receptor superfamily member 9, Tmem26: transmembrane protein 26.

Function of WAT

WAT has metabolic and endocrine functions. The metabolic functions include lipogenesis, fatty acid oxidation, and lipolysis, and the endocrine functions include the production of adipokines.

Metabolic Functions

The main functions of WAT have been described as storing and releasing highly energetic molecules, specifically fatty acids that supply fuel to the organism during fasting periods. A functional adipocyte depends on the equilibrium between lipid synthesis and fatty acid oxidation, as well as fatty acid release. These three processes are known as lipogenesis, fatty acid oxidation, and lipolysis. Lipogenesis is the synthesis of esterified fatty acids, which form triglycerides from carbohydrates or other energy sources acquired in the diet. Lipogenesis is regulated by the transcription factor sterol regulatory element-binding protein-1c (SREBP-1c). Fatty acid oxidation, also known as β-oxidation, is the process that occurs in the mitochondria to break down fatty acids into acetyl-CoA to generate energy as ATP, and it is mainly controlled by the transcription factor PPARα. Lipolysis is the release of fatty acids from triglycerides by a group of specific enzymes that hydrolyze triglycerides sequentially, which include the adipose triglyceride lipase (ATGL), the hormone-sensitive lipase (HSL), and the monoglyceride lipase (MGL). Different lipases gain access to the lipid droplet when the perilipins that are proteins that coat the vesicle are phosphorylated. Either perilipins or HSL is phosphorylated by the protein kinase A via β-adrenergic or glucagon stimulation (Figure 2).

Endocrine Functions

Adipokines. The term adipokine should refer to the proteins secreted by adipocytes; moreover, a generic concept of adipokine has been coined to include a wider range of factors, including factors released by other cell types like macrophages. WAT releases many biologically active molecules, the adipokines, that include more than 50 cytokines, hormone-like factors, and other mediators. Adipokines affect appetite and satiety, glucose and lipid metabolism, blood pressure regulation, inflammation, and immune functions (Figure 3). Precisely, they work as a network to regulate inflammation, insulin action, and glucose metabolism locally and systemically. This adipokine–cytokine networking system is altered in obesity, contributing to inflammation state and impaired adipocyte metabolism.

Within the main adipokines are adiponectin, leptin, resistin, apelin, visfatin, omentin, retinol binding protein (RBP) 4, interleukin (IL)-6, tumor necrosis factor (TNF)-α, interleukin (IL)-1, interleukin (IL)-10, monocyte chemoattractant protein (MCP)-1, angiotensinogen, and C-reactive protein (CRP), among others. A list of physiological functions of adipokines is mentioned in Figure 3. The function and physiological significance of some adipokines will be described in the succeeding text.

Adiponectin

Definition. Adiponectin is an adipokine that is specifically and abundantly expressed in WAT and BAT. Adiponectin exists in a

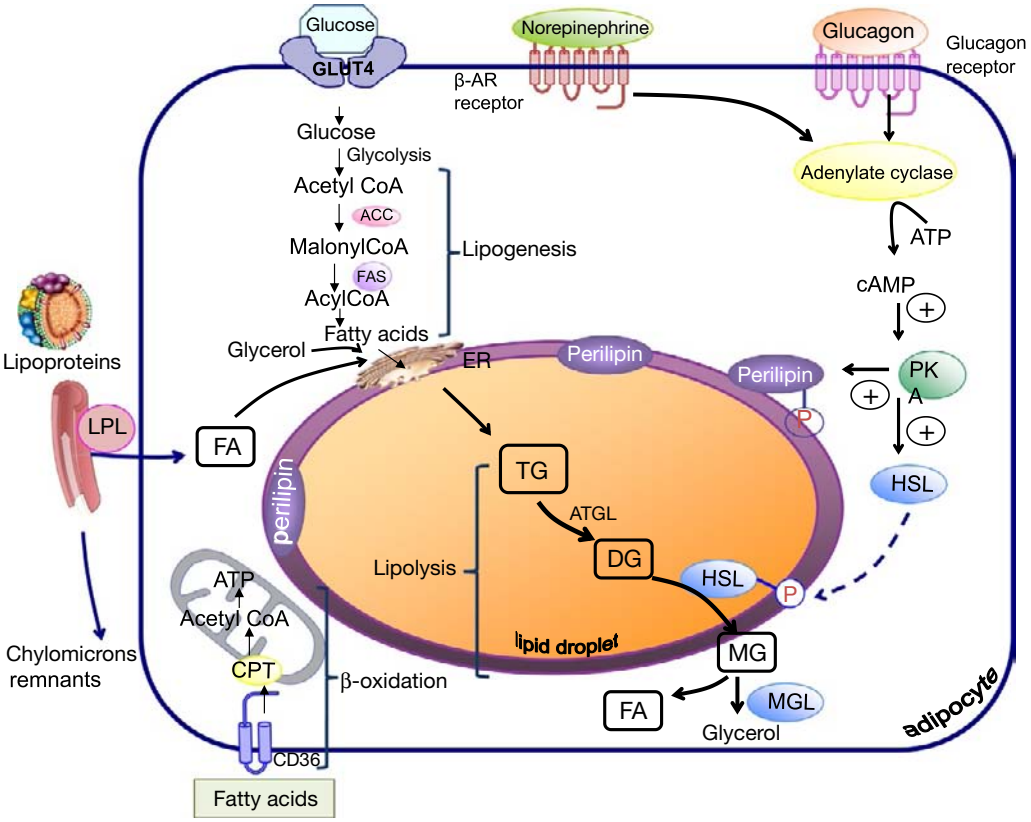

Figure 2 Metabolic functions of white adipocytes: Lipogenesis, lipolysis, and β-oxidation. LPL: lipoprotein lipase, FAs: fatty acids, ER: endoplasmic reticulum, DG: diacylglycerol, TG: triacylglycerol, MG: monoacylglycerol, ATGL: adipose triglyceride lipase, HSL: hormone-sensitive lipase, MGL: monoacylglycerol lipase, β-AR: β-adrenergic receptors, AC: adenylate cyclase, ATP: adenosine triphosphate, cAMP: cyclic adenosine monophosphate, PKA: protein kinase A, GLUT-4: glucose transporter type 4, CPT: carnitine palmitoyltransferase, ACC: acetyl-CoA carboxylase, FAS: fatty acid synthase.

wide range of multimer complexes in plasma and combines via its collagen domain to create three major oligomeric forms: a low-molecular-weight trimer, a middle-molecular-weight hexamer, and a high-molecular-weight 12- to 18-mer adiponectin.

Mechanism of action. Acute increase in the level of circulating adiponectin activates the enzyme adenosine monophosphate kinase (AMPK), triggering a transient decrease in basal glucose level by inhibiting both the expression of hepatic gluconeogenic enzymes and the rate of endogenous glucose production, indicating that adiponectin sensitizes the body to insulin. Adiponectin also increased fatty acid oxidation and energy consumption, in part via PPARα activation, which led to decreased triglyceride content in the liver and skeletal muscle and thereby a coordinated increase of *in vivo* insulin sensitivity (Figure 4).

Clinical implication. A decrease in the circulating levels of adiponectin produced by a genetic factor (adiponectin gene polymorphism) or lifestyle changes (high-fat diet and sedentary lifestyle) has been shown to contribute to the development of diabetes and the metabolic syndrome. Plasma adiponectin levels have also been reported to be reduced in obese humans, particularly those with visceral obesity, and to correlate inversely with insulin resistance (IR).

Leptin

Definition. Leptin is a circulating protein in the plasma of 167 amino acids with a molecular weight of ~16 KDa. This adipokine is secreted not only by the WAT but also by gastric epithelial cells and placenta. Leptin is involved in controlling feeding behavior and energy balance. Leptin also supports reproductive competence and immune function and contributes to the regulation of metabolic homeostasis by modulating insulin secretion, hepatic glucose production, and lipid metabolism.

Mechanism of action. Leptin acts via its cell surface receptor. There are five forms of the leptin receptor (LR) that are encoded by an alternative splicing of a single gene; however, only one has a long cytoplasmic region required for signal transduction. This receptor is located in several hypothalamic nuclei including the arcuate nucleus, ventromedial, dorsomedial, and lateral, resulting in the upregulation of the proopiomelanocortin (POMC) and downregulation of neuropeptide Y to increase energy expenditure and inhibit feeding. The actions of leptin are exerted when it binds with an LR. LR has also been located in other tissues such as the skeletal muscle, liver, kidney, intestine, immune cells, and adipose tissue, among others, and regulates the expression of genes involved in fatty acid oxidation. LR, which has a single transmembrane segment, dimerizes when leptin binds to the extracellular domains of two monomers. Both monomers are phosphorylated on a Tyr residue of their intracellular domain by a Janus kinase (JAK). The P-Tyr residues become the docking sites for three proteins that are signal transducers and activators of transcription (STATs). The docked STATs are then phosphorylated on Tyr residues by the same

JAK. After phosphorylation, the STATs dimerize and then move to the nucleus, where they bind to specific DNA sequences and stimulate the expression of target genes, including the gene for POMC from α-melanocyte-stimulating hormone (α-MSH) (Figure 5).

Clinical implication. Circulating leptin concentrations generally reflect the status of long-term adipose tissue energy stores, and obese subjects have a greater concentration than lean subjects. When fat stores are adequate after feeding, leptin is secreted to diminish the drive to feed while enabling energy expenditure, whereas during fasting or caloric restriction, leptin concentration decreases, increasing the desire to eat and decreasing energy utilization. However, in obese subjects, hyperleptinemia is frequently observed, but the elevated levels of leptin fail to return body adiposity and insulin sensitivity to the normal range. The diminished responsiveness to leptin has been designated as 'leptin resistance.'

Resistin

Definition. Human resistin is a member of a family of resistin-like molecules, also known as the FIZZ family for 'found in inflammatory zone.' Resistin is a cysteine-rich molecule composed of 108 amino acids with a molecular weight of 12.5 kDa. It was first described in obese mice and is mainly released from WAT, particularly in adipocytes. An increase in serum resistin is linked to obesity, IR, and diabetes. Although resistin is expressed in adipocytes, in humans, it appears that macrophages are the most important source of this protein. Low levels of resistin are also detected in tissues such as the skeletal muscle, placenta, small intestine, stomach, thyroid gland, uterus, and thymus.

Mechanism of action. Human resistin is a cytokine that induces low-grade inflammation by stimulating monocytes. Resistin-mediated chronic inflammation can lead to obesity, atherosclerosis, and other cardiometabolic diseases. Recently, the receptor for resistin was identified as adenylyl cyclase-associated protein 1 (CAP1). Resistin directly binds to CAP1 in monocytes and upregulates cyclic AMP concentration, protein kinase A activity, and NF-κB-related transcription of inflammatory cytokines. Stimulation of CAP1 by resistin aggravates adipose tissue inflammation. In addition, reduction in resistin levels is associated with an increase in AMPK activity in the liver, leading to a decrease in the expression of gluconeogenic enzymes and a consequent reduction in hepatic glucose production. Conversely, elevation in resistin levels is associated with an increase in hepatic glucose production and glucose intolerance.

Resistin also is involved in various inflammatory processes, such as in the recruitment of immune cells and in the secretion of proinflammatory factors. Resistin stimulates monocytes inducing vascular inflammation and aggravating atherosclerosis. The

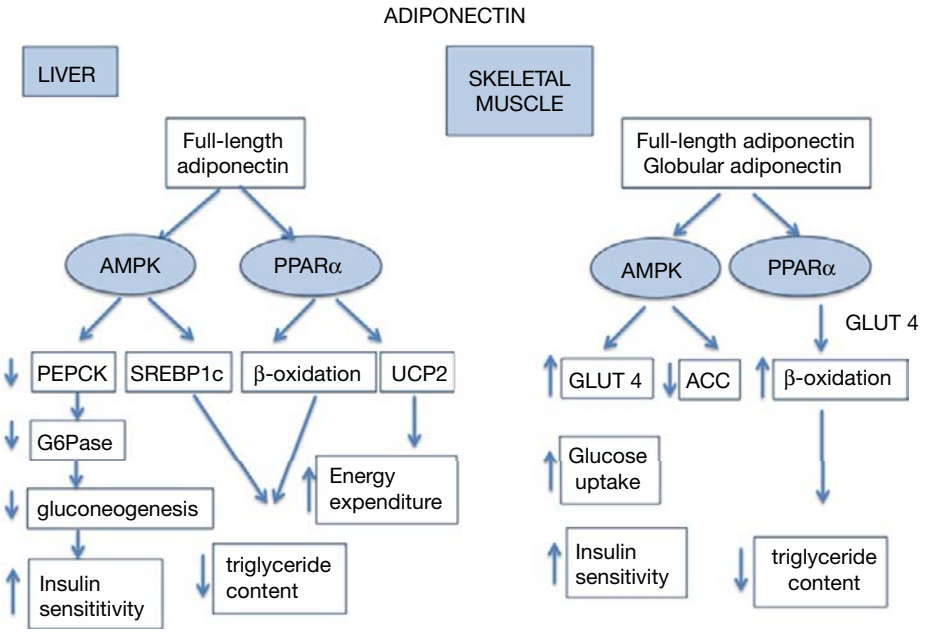

Figure 4 Adiponectin activates AMPK and PPARα on the liver and skeletal muscle, increasing insulin sensitivity and decreasing TG content. AMPK: AMP-activated protein kinase, PPARα: peroxisome proliferator-activated receptor-α, PEPCK: phosphoenolpyruvate carboxykinase, SREBP-1c: sterol regulatory element-binding protein 1c, G6PAse: glucose 6-phosphatase, UCP2: uncoupling protein-2, GLUT4: glucose transporter type 4, ACC: acetyl-CoA carboxylase.

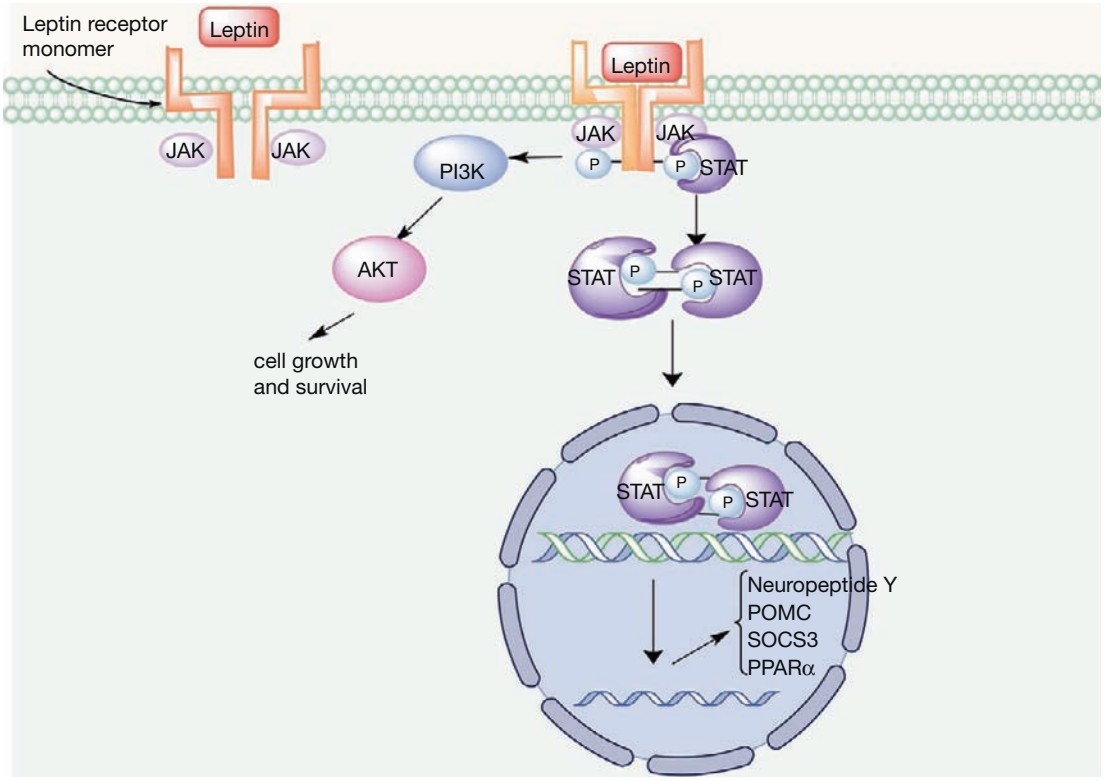

Figure 5 Leptin signaling pathway induces activation of JAK/STAT3 (Janus kinase/signal transducer and activator of transcription 3). This results in the production of NPY: neuropeptide Y, POMC: proopiomelanocortin, SOCS3: suppressor of cytokine signaling 3, and PPARα: peroxisome proliferator-activated receptor-α. Leptin signaling also activates PI3K: phosphoinositide 3-kinase for cell growth and survival.

release of resistin is often stimulated by an inflammatory process and by IL-6, hyperglycemia, and hormones such as growth hormone and gonadal hormones.

Clinical implication. Some studies in rodents have implicated that resistin is involved in the pathogenesis of obesity-mediated IR and type 2 diabetes; thus, resistin is proposed to antagonize insulin action. However, in humans, these effects remain inconclusive, partly because there are no differences in resistin expression among normal, insulin-resistant, and type 2 diabetic subjects.

Visfatin

Definition. Visfatin, also named NAMPT (nicotinamide phosphoribosyltransferase), is a protein with a molecular weight of 52 kDa coded by a gene of 34.7 kb located on chromosome 7q22.2 that is transcribed in a 2.4 kb long mRNA. Visfatin is secreted predominantly by the adipose tissue, but it is also synthesized in other tissues such as the skeletal muscle, liver, immune cells, cardiomyocytes, and brain. It is involved in the synthesis of nicotinamide adenine dinucleotide (NAD), and it has been associated with obesity development, insulin secretion, lipid profile, and inflammation, among others.

Mechanism of action. Visfatin is an enzyme involved in the synthesis of NAD, and it converts nicotinamide to nicotinamide mononucleotide (NMN), an NAD precursor. The synthesis of NMN is essential for the maintenance of NAD levels. NAD synthesis modulates insulin secretion. On the other hand, it has been suggested that visfatin can bind to the insulin receptor and is capable of stimulating the insulin signaling pathway modifying the IR. A suggested mechanism involves TNF-α, a master disruptor of insulin signaling. The mechanism suggests that TNF-α downregulates the expression of visfatin, leading to a decrease in intracellular NAD^+ concentrations. Thus, Sirt1 activity decreases because this enzyme is highly dependent of NAD^+. Inhibition of Sirt1 in adipocytes leads to a reduction in tyrosine phosphorylation of insulin receptor substrate (IRS)-1, Akt and ERK phosphorylation, and an increase of serine phosphorylation of IRS-1. Hence, the lack of Sirt1 inhibits downstream insulin signaling and decreases insulin sensitivity.

Clinical implication. A correlation of the levels of circulating visfatin with the appearance of type 2 diabetes has been shown. On the other hand, other studies have demonstrated a negative correlation between visfatin levels with the body mass index (BMI). Furthermore, it has been observed in several studies that visfatin concentration is positively associated with an increase in HDL-cholesterol concentration.

Retinol binding protein 4

Definition. RBP4 is a protein of 201 amino acids with a molecular weight of ~21 kDa. It belongs to the lipocalin family of proteins that transport small hydrophobic molecules and is the only retinol (vitamin A) transporter in the circulation. The main site of synthesis is the liver followed by the adipose tissue. In serum, 90% of circulating RBP4 is bound to retinol (holo-RBP4) and 10% is present in the unbound form (apo-RBP4). RBP4 transports retinol from the liver to the peripheral tissues.

Mechanism of action. RBP4 has an important role in regulating vitamin A metabolism and maintaining a constant and continuous supply of vitamin A to peripheral tissues for a variety of physiological processes. Circulating RBP4 coordinates cellular retinoid homeostasis through the membrane receptor stimulated by retinoic acid 6 (STRA6) and RPB4 receptor-2 (RBPR2). STRA6 mediates cellular retinol uptake from holo-RBP4. Within cells, retinoids bind to cellular retinol binding proteins or cellular retinoid-acid binding proteins and produce effects via activating retinoic acid receptors and retinoic X receptors that are involved in the regulation of adipogenesis.

Clinical implication. Epidemiological studies have demonstrated that RBP4 is a biomarker for IR, metabolic syndrome, and myocardial infarction. In these pathologies, RBP4 increases and may contribute to the development of metabolic dysfunction by impairing adipocyte differentiation and increasing secretion of proinflammatory cytokines by macrophages through Toll-like receptor 4 (TLR4) and c-Jun N-terminal protein kinase pathways. Also, the holo-RBP4 stimulates JAK2/STAT5 signaling in hepatocytes, thus contributing to the development of IR by inducing the suppressor of cytokine signaling 3 (SOCS3).

Tumor necrosis factor-α

Definition. TNF-α is a proinflammatory cytokine consisting of 157 amino acids with a molecular weight of 17 kDa. Its bioactivity is mainly regulated by soluble TNF-α–binding receptors. TNF-α is expressed and secreted by WAT, macrophages, T lymphocytes, and natural killer cells, Fibroblasts, smooth muscle cells, and tumor cells express low levels of TNF-α.

Mechanism of action. Biological functions of TNF-α are mediated by two receptors, TNF receptor-1 (TNFR-1), which is ubiquitously expressed, and TNF receptor-2 (TNFR-2), which is found in cells of the immune system. Although the affinity for TNFR-2 is five times higher than that for TNFR-1, the latter initiates the majority of the biological activities of TNF-α. TNF-α has several effects in adipocytes, for instance, inhibits adipogenesis via TNFR-1, inhibits insulin-stimulated glucose, lipogenesis, and fatty acid oxidation in differentiated human adipocytes. Other functions of TNF-α are involved in host defense and in various types of systemic toxicity. One main action of TNF-α consists in inducing apoptosis by TNFR-1 activation and by cross talk with TNFR-2 to strongly enhance TNFR-1-induced apoptosis. An early proposal was that TNF-α plays a role in immune surveillance against tumors, but in some cases, it seemed to promote tumor cell survival. Hence, TNF-α can elicit dual but opposing reactions from many different cell types.

Clinical implication. TNF-α acts as a link between adiposity and development of IR. Obese humans and mice present high levels of TNF-α in both serum and WAT. TNF-α reduces the expression of mRNA encoding the insulin-sensitive glucose transporter (GLUT-4), which is responsible for glucose uptake in the peripheral tissues. Also, TNF-α decreases the expression of insulin receptor and insulin receptor substrate-1 (IRS-1). Moreover, elevated serum free fatty acids during obesity have also been involved as potential mediators of IR, and TNF-α stimulates lipolysis and release of free fatty acids from fat cells.

WAT and Branched-Chain Amino Acids

In addition to its classical metabolic and endocrine functions, WAT plays a key role in the metabolism of branched-chain

amino acids (BCAAs). Altered regulation of BCAA has been associated with metabolic abnormalities observed during obesity.

BCAAs, leucine, isoleucine, and valine are substrates for protein synthesis via the insulin signaling pathway and precursors for the synthesis of alanine and glutamine when the minimum need for protein synthesis is met. In contrast to the other 17 amino acids, which are predominantly metabolized in the liver, BCAAs are metabolized in extra hepatic tissues by the mitochondrial branched-chain aminotransferase (BCAT2), the first enzyme in the catabolism of BCAAs in most peripheral tissues. It transfers the amino group of a BCAA to α-ketoglutarate to form glutamate and the corresponding branched-chain α-keto acid. The transamination reaction is rapid and of high capacity in muscle and WAT. The second step is regulated by the branched-chain α-keto acid dehydrogenase (BCKD) complex. The complex catalyzes the oxidative decarboxylation of the branched-chain α-keto acids, forming the branched-chain acyl-CoA derivatives, CO_2, and NADH. Because BCAT2 is not expressed in the liver, BCAAs from dietary protein bypass first the metabolism in the liver. This may contribute to the sharp rise of plasma leucine in response to a meal, thereby promoting leucine signaling in the peripheral tissues that respond to leucine.

BCAA and Obesity

WAT is second only after the skeletal muscle in its capacity to catabolize BCAAs and is capable of metabolizing significant quantities of BCAAs in rodents and humans. During the obesity, the BCAAs rise due to an alteration in BCAA catabolism. The rises in the BCAAs are of particular interest because they appear to have unique obesity-related effects. Our findings and previous work indicate that omental WAT plays an important role in BCAA homeostasis because this organ has a large capacity to catabolize BCAAs, and the presence of IR or metabolic syndrome downregulates adipose tissue BCAA pathway enzyme expression. The higher the BMI and IR, the higher the serum BCAA concentrations due to a decrease in the expression of the two key BCAA enzymes, *BCAT2* and *BCKDH E1α*, in the adipose tissue. BCAA catabolic pathway in the adipose tissue is sensitive to changes in insulin action, and IR impairs efficient BCAA catabolism in the adipose tissue. During obesity, hypertrophic adipocytes develop metabolic inflexibility, which may prevent the utilization of BCAA. It has been proposed that high tissue and blood concentrations of BCAAs in human obesity cause or exacerbate IR through mechanisms involving leucine; this amino acid promotes the activation of the mechanistic target of rapamycin (*mTOR*) in the muscle and the phosphatidylinositol 3-kinase signaling pathways. In addition, high serum BCAA (especially leucine) concentrations are associated with obesity and hyperinsulinemia, a finding that is consistent with earlier studies suggesting that BCAAs may augment the pancreatic secretion of insulin in the IR state. Studies in transgenic mice with disruption of BCATm or BCKD kinase support the evidence that dysregulation of BCAA metabolism results in sustained changes in plasma BCAA concentrations. Microarray studies have suggested that mRNA for enzymes involved in BCAA metabolism in the adipose tissue is depressed in mutant or transgenic animals with an obese phenotype.

WAT and Renin–Angiotensin System

Renin–angiotensin system (RAS) exerts a central role in blood pressure regulation and also participates in adipocytes homeostasis, specifically in growth regulation, differentiation, and metabolism. The systemic RAS starts with the release of angiotensinogen mainly from the liver. Recent findings demonstrate that human and rodent adipose tissues also contain all of the RAS components. The adipose tissue is a major contributor of extrahepatic angiotensinogen (AGT), particularly in obesity. Nutritional status, nutrient distribution, and nutrients per se modulate the RAS expression and activity in various tissues including the adipose tissue. Fasting and feeding affect AGT production. Nutrients or food components, such as fructose, lipids, and soy protein, among others, influence tissue and systemic RAS activity. Dietary fructose treatment results in hypertension, glucose intolerance, and hypertriglyceridemia in animals. This is in part because fructose feeding exacerbates the presence and activity of the RAS. On the other hand, soy protein has beneficial effects on RAS mediated by soy protein gastrointestinal digestion-derived amino acids, peptides, and isoflavones that ameliorate metabolic syndrome. Conversely, the consumption of a high-fat diet increases the components of RAS, leading to an increase in blood pressure.

WAT and Diet

The amount of dietary fat plays a central role in the development of obesity. Recent evidence demonstrated that chronic consumption of a high-fat diet regardless of the type of fat, either polyunsaturated fatty acids (PUFAs) or saturated fatty acids (SFAs), represses the expression of lipogenic, fatty acid oxidation, and thermogenic genes in the adipose tissue, leading to the accumulation of lipids in the adipose tissue and liver. However, adequate consumption of PUFAs decreases the expression of lipogenic genes in WAT and increases the expression of genes involved in fatty acid oxidation.

Not only the type of fat but also the type of protein regulates the expression of genes in the adipose tissue. This effect is mediated in part by the capacity of each type of protein to stimulate insulin secretion to a different extent. Vegetable proteins such as soy protein stimulate insulin secretion to a lesser extent than animal proteins such as casein. It has been shown that rats fed with a soy protein–high-fat diet show lower body weight gain and adipocyte size compared with rats fed with a casein–high-fat diet. In addition, dietary soy protein activates PPARγ in the adipose tissue, preventing metabolic abnormalities during obesity by stimulating adipogenesis.

Interestingly, there is evidence that shows an interaction between the type of protein and the type and amount of dietary fats that play an important role in the functionality of WAT.

Adolescent Nutrition

K Schroeder, Boston Children's Hospital, Boston, MA, USA
K Sonneville, University of Michigan, Ann Arbor, MI, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Adolescence is a time of major physical change. Girls gain an average of 12.5 pounds per year and boys gain an average of 20 pounds per year during puberty. Although both gain weight during adolescence, males have a decrease in body fat percentage to an average of 12% during this time, while females experience an increase to 16–27% body fat. Weight gain is only one of the countless changes a young person will experience during adolescence. The adolescent period is characterized by profound biological, psychosocial, and cognitive changes. Teens are also gaining increasing independence as they grow into young adulthood. Where previously, their parents were making the decisions about where, when, and what they would eat, a teenager starts to make some of these decisions on their own. Adolescence is a critical period in the development of lifelong health behaviors, and ideally, they have been given the skills to make healthy choices when confronted with this new-found freedom. Unfortunately, teens that develop unhealthy habits may be at risk for serious health consequences. Some problems, like obesity, might have started developing at a younger age. Others, like an eating disorder, might only come to light once puberty occurs and changes start to happen to a person's body. The choices that a teenager makes with regard to his or her diet can have lasting effects; healthy eating can reduce risk of diseases such as heart disease, cancer, stroke, and diabetes. Unhealthy eating can have the opposite effect.

In addition, being a teenager today means being exposed to media constantly. From magazines emphasizing the 'right' size for your waistline and social media sites like Facebook and Tumblr allowing teens to view 'thinspiration' posts to TV commercials and website pop-up advertisements encouraging teens to drink more soda and eat more fast food, no one can avoid being influenced by the media.

What Are Teenagers Eating?

Many teenagers are not meeting the suggested requirements for major food groups, especially fruit and vegetables. According to the Continuing Survey of Food Intakes by Individuals and the National Health and Nutrition Examination Survey, major contributors to the adolescent diet in the United States include sugar-sweetened beverages, pizza, full-fat milk, grain-based desserts, breads, pasta dishes, and savory snacks. Recent data from the Youth Risk Behavior Surveillance System (YRBSS) show that 6.6% of high school students surveyed had not eaten a single vegetable 7 days preceding the survey and 5% had not eaten fruit or had 100% fruit juice to drink. A recent study on dietary adequacy in teenage girls specifically found that they were lacking in fruits, vegetables, and diary, giving them lower than adequate intakes (AIs) of calcium, magnesium, potassium, and vitamins D and E.

The setting where adolescents eat can have an impact on the quality of their food intake. A recent review article of family meals found that adolescents who have more frequent family meals also have healthier diets. Higher frequency of family meals is also associated with reduced prevalence of overweight and obesity. Unfortunately for many families, evening meals together are not feasible given busy schedules or the lack of interest in these gatherings on the part of the adolescent.

American adolescents who eat the lunch provided at their school will be eating a meal that is nutritionally balanced and meets the nutrition standards set forth by the National School Lunch Program. The meal will have no more than 30% calories from fat and less than 10% calories from saturated fat. Each meal must provide one-third the recommended dietary allowance (RDA) of protein, vitamin A, vitamin C, iron, calcium, and calories. Additionally, recent changes to school lunch guidelines involve increasing fruits and vegetables and whole grains in school meals.

Skipping meals is prevalent among adolescents, with breakfast being the meal skipped the most often. According to the YRBSS, 13.7% of teens surveyed had not eaten breakfast 7 days preceding the survey and only 38.1% had eaten breakfast on all 7 days. Meal skipping has been associated in numerous studies with risk of overweight and obesity. Nutrition counseling can help a teenager identify quick and easy breakfast items for those who cite lack of time in the morning as the main reason that they are missing this important meal. Counseling would also be warranted for a teen who might mistakenly think that skipping a meal is an effective strategy for weight loss.

Snacking is also common among adolescents and has only increased over time. The types of snacks showing the biggest increase within this age group are nutrient-poor, energy-dense foods including desserts, candy, salty snacks, and sugar-sweetened beverages (SSBs). One study showed that more than 27% of a child's calories each day came from snacks, often three or more per day. While snacking is not necessarily unhealthy, calories should ideally come primarily from balanced meals in addition to small, nutrient-dense snacks throughout the day. See articles by Popkin and others, based on NHANES and Nielsen datasets.

Factors Influencing Food Choice

There are many factors that can influence an adolescent's food choice; some are external such as peer pressure, and others are internal such as cravings. Some are affected by cultural or religious beliefs (such as not eating meat during Lent), and others are based purely on availability. A teenager who does not have access to a car, has no nearby grocery store, and mainly shops at a neighborhood convenience store is not likely to develop a strong affinity towards fresh fruits and vegetables. Current food trends, home environment, body image, and health status are other factors that can readily contribute to the decisions that adolescents make daily regarding food choices.

What adolescents themselves identify as factors that influence their intake do differ from internal/cultural factors that a teen might not personally think are relevant factors. One focus group study showed that adolescents identify hunger/food cravings, appeal of food, time, and convenience as the most important factors influencing food choices. This same group of teenagers identified making healthy food look and taste better as the primary suggestion to increase adolescent healthy eating.

Dietary Assessment

When assessing an adolescent's diet, it is important to ask specific questions. There are several dietary assessment strategies, among which the 24 h recall is the commonly used clinically. The 24 h recall involves asking the teenager very specifically about what they ate and drank over the past day including portion sizes. Depending on the population, it might be worthwhile to provide a food frequency questionnaire where the teen can check off how many times per week they eat vegetables and how often they drink soda, for example. Some adolescents might have an easier time remembering what they ate if they are asked to take a photo of each meal or log the meal into an online tracker. The best dietary assessment strategy to use will depend on the adolescent's nutritional goals. For example, you would not necessarily want a teenager struggling with an eating disorder to track their intake using a website that listed calories.

Energy Requirements

Energy requirements for teenagers can vary greatly depending on their physical activity level (PAL) and current stage of growth. The Institute of Medicine (IOM) published estimated energy requirements (EERs) based on a global doubly labeled water database. The EER for adolescents 9–18 years of age includes the total energy expenditure, in addition to calories needed for energy deposition.

For boys, EER is calculated as follows:

$$\text{EER} = 88.5 - (61.9 \times \text{age [y]}) + \text{PA} \times (26.7 \times \text{weight [kg]} + 903 \times \text{height [m]}) + 25 \text{ kcal}$$

where PA is the physical activity coefficient:

PA = 1.00 if PAL is estimated to be ≥ 1.0 < 1.4 (sedentary).
PA = 1.13 if PAL is estimated to be ≥ 1.4 < 1.6 (low active).
PA = 1.26 if PAL is estimated to be ≥ 1.6 < 1.9 (active).
PA = 1.42 if PAL is estimated to be ≥ 1.9 < 2.5 (very active).

For girls aged 9–18 years, EER is calculated as follows:

$$\text{EER} = 135.3 - (30.8 \times \text{age [y]}) + \text{PA} \times (10.0 \times \text{weight [kg]} + 934 \times \text{height [m]}) + 25 \text{ kcal}$$

where PA is the physical activity coefficient:

PA = 1.00 if PAL is estimated to be ≥ 1.0 < 1.4 (sedentary).
PA = 1.16 if PAL is estimated to be ≥ 1.4 < 1.6 (low active).
PA = 1.31 if PAL is estimated to be ≥ 1.6 < 1.9 (active).
PA = 1.56 if PAL is estimated to be ≥ 1.9 < 2.5 (very active).

Dietary Guidelines

Various agencies and organizations around the world have published standards and guidelines for what constitutes an optimal diet. In the United States, the USDA has published the MyPlate icon, recommending that everyone eat balanced meals with half of their plates composed of fruits and vegetables and the other half divided between protein and grains with a serving of dairy at each meal (Figure 1). The Harvard School of Public Health has countered MyPlate with their own Healthy Eating Plate (Figure 2), a similar guide that provides additional guidance such as encouraging the protein to be healthy (i.e., limiting red meat and high-fat or processed protein) and grains to be whole grain (i.e., whole-wheat bread, brown rice, and whole-wheat pasta).

The USDA provides suggested servings per day of various food groups as well. See Table 1. For vegetables, the cups given are intended as cooked vegetables; if eaten raw, the amounts should be doubled. For reference, a large banana, orange, or peach counts as one cup of a fruit.

Carbohydrates

The recommended dietary allowance (RDA) of carbohydrates for adolescents of both genders is 130 g per day. Carbohydrates provide essential energy to the body, especially for the brain. Foods that contain carbohydrate include grains (cereal, bread, pasta, rice, oats, tortillas, and pita), starchy vegetables (potatoes, sweet potatoes, corn, and peas), fruit, dairy, and legumes. The body stores carbohydrate as glycogen in the muscles and liver.

Fiber

AI of fiber for males aged 9–13 is 31 g per day, for males aged 14–18 is 38 g per day, and for females aged 9–18 is 26 g per day. Fiber is found naturally in foods such as fruits, vegetables, beans, legumes, and whole grains. Fiber is essential for maintaining bowel health and for preventing constipation throughout the life span. Despite the health benefits of fiber and its availability in multiple food sources, low fiber intake is extremely common among adolescents.

Protein

Protein is essential for building and repairing muscles, in addition to other important functions in the body. The RDA for

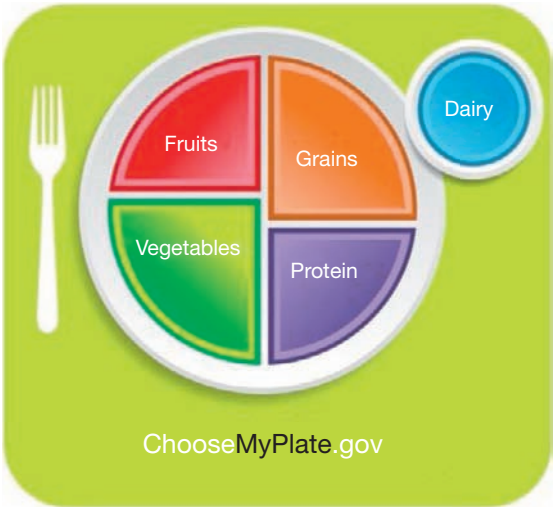

Figure 1 Choose MyPlate.gov.

Table 1 Select micronutrients suggested intake

	Males		*Females*	
Nutrient	Aged 9–13	Aged 14–18	Aged 9–13	Aged 14–18
Vitamin A (IU per day)	600	900	600	700
Vitamin C (mg per day)	45	75	45	65
Vitamin D (IU per day)	15	15	15	15
Vitamin E (mg per day)	11	15	11	15
Vitamin K (IU per day)	60	75	60	75
Thiamin (mg per day)	0.9	1.2	0.9	1.0
Riboflavin (mg per day)	0.9	1.3	0.9	1.0
Niacin (mg per day)	12	16	12	14
Vitamin B6 (mg per day)	1.0	1.3	1.0	1.2
Folate (IU per day)	300	400	300	400
Vitamin B12 (IU per day)	1.8	2.4	1.8	2.4
Calcium (mg per day)	1300	1300	1300	1300
Iron (mg per day)	8	11	8	15
Potassium (mg per day)	4.5	4.7	4.5	4.7
Sodium (g per day)	1.5	1.5	1.5	1.5

Source: National Research Council. (2006). *Dietary Reference Intakes*: *the essential guide to nutrient requirements*. Washington, DC: The National Academies Press

adolescent boys aged 9–13 is 34 g per day and for adolescent boys aged 14–18 is 52 g per day. The RDA is 34 g per day for girls aged 9–13 and 46 g per day for girls aged 14–18. Protein is found in animal products such as meat, poultry, fish, dairy, and eggs and in beans, legumes, and nuts.

Fat

It is necessary for the diet to contain fat in order to help absorb fat-soluble vitamins (vitamins A, D, E, and K) and to provide linoleic acid and linolenic acid, essential for neurological

Table 2 Recommended fruit and vegetable intake

Gender and age	*Fruit servings*	*Vegetable servings*
Girls 9–13	1 ½ Cups	2 Cups
Girls 13–18	1 ½ Cups	2 ½ Cups
Boys 9–13	1 ½ Cups	2 ½ Cups
Boys 13–18	2 Cups	3 Cups

Source: www.choosemyplate.gov.

development and growth. The acceptable macronutrient distribution range for fat for teenagers of both genders is 25–35 g per day. Adolescents should attempt to eat as little trans fat as possible and limit the amount of saturated fat in their diet. Sources of fat in the diet include dairy, cheese, butter, oil, avocado, certain fish, certain cuts of meat, and nuts.

Vitamins and Minerals

Certain vitamins and minerals have a recommended dietary allowance (RDA), while others have only an established AI because no RDA has been established. See Table 2 for a list of select vitamins and minerals and the suggested intake levels for adolescents. Most of these nutrients can be consumed in these suggested amounts by eating a balanced, varied diet that includes fruit and vegetables. In the absence of adequate portions of these healthy foods, however, a multivitamin or other supplement may be warranted.

One particular nutrient of special importance during adolescence is calcium, which is aided in absorption by vitamin D. Adequate calcium intake during adolescence is key for preventing osteoporosis because childhood and adolescence are the time when bones are gaining strength and density that cannot be made up for later in life. Calcium can be found in the diet in beverages such as milk and soy milk and in foods such as tofu, beans, yogurt, cheese, almonds, canned seafood, leafy green vegetables, and fortified foods such as cereal and snack bars.

Hydration

The Holliday–Segar method of figuring hydration needs is used in hospitals but can also be applied to healthy adolescence. The equation is as follows:

Patient weight	*Fluid needs*
11–20 kg	1000 ml + 50 ml kg^{-1} for each kg >10 kg
>20 kg	1500 ml + 20 ml kg^{-1} for each kg >20 kg

The daily recommended intake (DRI) can also be used to determine the recommended fluid intake for teenagers. For males aged 9–13 years, the DRI is 2.4 l per day; for males aged 14–18, it is 3.3 l per day. For females aged 9–13, the DRI is 2.1 l per day; for females aged 14–18, it is 2.3 l per day. This includes all liquids consumed such as water and other beverages, in addition to liquids and moisture in foods such as soup, watermelon, and cucumber.

Supplements and Alcohol

Energy Drinks

Energy drinks such as Red Bull, 5-Hour ENERGY, and Monster Energy drink are a growing product category that seems to appeal to adolescents. Studies have shown not only that there are potential negative health effects to the energy drinks themselves but also that those adolescents who consume energy drinks are at higher risk of substance use such as smoking, drinking alcohol, and using illicit drugs. The American Academy of Pediatrics recommends that children and adolescents avoid consuming energy drinks, suggesting that they use water as their primary source of hydration.

Alcohol

According to a recent YRBSS report, 66.2% of high school students reported having had at least one alcoholic drink in their life. During the 30 days prior to the survey, 34.9% of teenagers had consumed alcohol at least once and 20.8% had had five or more drinks in one sitting, the definition of binge drinking. Teen consumption of alcohol remains a problem for many reasons. According to the American Academy of Pediatrics, alcohol can interfere with adolescent brain development, which continues into young adulthood. In addition, using alcohol during adolescence can promote the risk of alcoholism later in life, can lead to motor vehicle-related fatalities (the leading cause of death among US teens), and can lead to other mental and physical disorders. From a nutritional perspective, alcohol provides excess calories, which when consumed in large quantities can lead to overweight and obesity. Alcohol consumption is also often associated with poor dietary choices, and long-term use can affect the absorption of certain vitamins and minerals.

Obesity

The criterion for children aged 2–20 for overweight is a BMI between the 85th and 95th percentile according to Centers for Disease Control and Prevention growth charts. For obesity, the criterion is a BMI over the 95th percentile. Obesity rates among adolescents have increased significantly over the past fourteen years. An article looking at the prevalence and trends in obesity and severe obesity showed that from 2011 to 2012, 17.4% of children aged 2–19 were obese and prevalence among adolescents exceeded 20%. Prevalence of severe obesity is also growing among youth aged 2–19 with 5.9% meeting criteria for class 2 obesity (with a BMI greater than or equal to 120% of the 95th percentile or a BMI of greater than or equal to 35) and 2.1% meeting criteria for class 3 obesity (with a BMI of greater than or equal to 140% of the 95th percentile or a BMI of greater than or equal to 40).

Sugar-Sweetened Beverages

According to YRBSS data, 27% of teenagers had consumed one nondiet soda per day 30 days leading up to the survey, and even more worrisome, 19.4% had consumed nondiet soda two

or more times per day. SSBs include juice, lemonade, punch, soda, and other drinks that adolescents consume on a regular basis. These beverages (with the possible exception of juice) provide no nutritional value, but contain a large amount of calories. This is often referred to as 'empty' calories because they are providing nothing besides energy. Soda is often vilified when discussing causes of increased obesity in society. Indeed, the serving sizes have grown larger over the years, and the marketing does directly target young people. One recent study of SSBs on adolescents linked increased intake with greater waist circumference, a risk factor for metabolic syndrome. However, it is important to remember that while SSBs can contribute to excess calories, it is often only one piece of the obesity puzzle.

Screen Time

There is strong relationship between screen time and excess weight gain/obesity in children and adolescents. Whether this is due to the effects of commercials advertising to teens on television, the fact that one often mindlessly consumes calories when in front of a screen, the lack of physical activity due to screen time, or the effect that screen time has on sleep, experts agree that less screen time is beneficial to all children and teens, especially those at risk of overweight or obesity.

Extreme Dieting

According to the recent YRBSS data, 47.7% of teenagers reported that they were trying to lose weight with females being more likely to report this than males. Of concern, 13% of students reported that they had not eaten for twenty-four or more hours in an attempt to lose weight and 5% reported having taken diet pills. Additionally, 4.4% reported vomiting or taking laxatives to lose weight or keep from gaining weight. Extreme dieting does not work and often leads to a heavier weight in the long run. In addition, it can cause numerous health issues and nutritional deficiencies. For more information, see the section on '**Eating Disorders**.'

Type 2 Diabetes

Type 2 diabetes, also referred to as non-insulin-dependent diabetes as a way of differentiating it from type 1 diabetes (previously called juvenile diabetes), is an increasing problem among children and adolescents commonly caused by obesity. In the past, this type of diabetes was called adult-onset diabetes, but that name is no longer accurate due to the rising number of diagnoses in younger populations. In addition to obesity, several comorbidities such as proteinuria (protein in the urine), hypertension, dyslipidemia, nonalcoholic fatty liver disease, polycystic ovary syndrome (PCOS), and obstructive sleep apnea are seen among adolescent with type 2 diabetes. There are currently few treatments for type 2 diabetes in adolescents that include lifestyle changes (eating a healthy, balanced diet plus exercising regularly), pharmacology, and gastric bypass surgery.

Polycystic Ovary Syndrome

PCOS is a disease that affects 7–14% of adult women (depending on the diagnostic criteria used), with the onset happening mainly during adolescence. While no specific causes of PCOS have been definitively identified, childhood obesity is thought to be a contributing factor. PCOS is often associated with obesity, metabolic syndrome, and type 2 diabetes; it is characterized by irregular periods, hirsutism, acne, weight gain, and acanthosis nigricans. Weight loss can reduce some symptoms, but elevated insulin levels may make weight loss more difficult for adolescent girls who have PCOS compared with their healthy counterparts. Adolescent girls with PCOS can manage their insulin levels by decreasing the amount of refined carbohydrates they eat or drink, increasing the amount of protein and fiber in their diet, and getting plenty of physical activity.

Eating Disorders

Adolescence is a particularly hard time for a person to deal with body image issues since there are so many changes happening to the body during puberty. This can set the stage for an eating disorder that may not have been an issue previously. While any disordered relationship with food can be considered an eating disorder of concern, there are differing levels of clinical severity. The Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V), published in 2013, revised several of the previous definitions for specific eating disorders. It is important to keep in mind that just because an adolescent might not fit one of these diagnoses entirely, they may still have a disordered relationship with food that would warrant treatment.

Anorexia Nervosa

The DSM-V includes the following diagnostic criteria for anorexia nervosa (AN):

1. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health
2. Intense fear of gaining weight or of becoming fat or persistent behavior that interferes with weight gain
3. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight

The DSM-V removed the requirement for AN that a patient have amenorrhea (not applicable to males or to females who have not yet reached menarche) and took out the specific percent ideal body weight, changing the terminology to 'significantly low' that does include some indicators in the manual. According to the DSM, prevalence for AN among young women is 0.4% in the course of 12 months. Increasing numbers of males are being diagnosed with AN, but females tend to seek treatment more often.

Bulimia Nervosa

The DSM-V includes the following diagnostic criteria for bulimia nervosa (BN):

1. Recurrent episodes of binge eating characterized by eating an amount of food that is definitely larger than what most individuals would eat in a similar period of time associated with a lack of control over eating during the episode.
2. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.
3. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
4. Self-evaluation is unduly influenced by body shape and weight.
5. The disturbance does not occur exclusively during episodes of AN.

While AN has a prevalence of 0.4%, BN is much higher among young females at 1–1.5% according to the DSM.

Binge Eating Disorder

Binge eating disorder (BED) was not an official diagnosis until the DSM-V was released. Previously, patients who binged without purging were grouped into a category called Eating Disorder Not Otherwise Specified. The diagnostic criteria for BED are the following:

1. Recurrent episodes of binge eating characterized by eating an amount of food that is definitely larger than what most individuals would eat in a similar period of time associated with a lack of control over eating during the episode.
2. The binge eating episodes are associated with three (or more) of the following: eating much more rapidly than normal, eating until feeling uncomfortably full, eating large amounts of food when not feeling physically hungry, eating alone because of feeling embarrassed by how much one is eating, feeling disgusted with oneself, depressed, or very guilty afterward.
3. Marked distress regarding binge eating is present.
4. The binge eating occurs, on average, at least once a week for 3 months.
5. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in BN and does not occur exclusively during the course of BN or AN.

Avoidant/Restrictive Food Intake Disorder

While many children will grow out of being picky eaters, some will continue to restrict their intake without having concerns about their weight (differentiating it from one of the other eating disorders). Clinically, this is referred to as avoidant/restrictive food intake disorder (ARFID) and is diagnosed as follows:

1. An eating or feeding disturbance as manifested by persistent failure to meet appropriate nutritional and/or energy needs associated with one or more of the following: significant weight loss, significant nutritional deficiency, dependences on enteral feeding or oral nutritional supplements, and marked interference with psychosocial functioning.
2. The disturbance is not better explained by lack of available food or by an associated culturally sanctioned practice.
3. The eating disturbance does not occur exclusively during the course of anorexia or bulimia or better explained by another medical or mental disorder.

Sometimes, adolescents with ARFID have sensory issues or it can be comorbid with the autism spectrum. Presentations differ, but a few case examples are a teenager who will eat only foods that are soft in texture such as macaroni and cheese and mashed potatoes or one who refuses to eat any fruit or vegetables and rarely eats protein-containing foods, preferring mainly white carbohydrates such as crackers, chips, bread, and rice.

Other Specified Feeding or Eating Disorder

There are some eating disorders that do not fit within the criteria for AN, BN, BED, or ARFID. These eating disorders fall into the category called Other Specified Feeding or Eating Disorder (OSFED) and include atypical AN, subthreshold BN, subthreshold BED, purging disorder, and night-eating syndrome. One example of a patient with OSFED is a teenager whose BMI goes from the 95th percentile down to the 50th percentile in a short period of time. Being at the 50th percentile would preclude them from being 'significantly low weighted,' but they might be restricting intake, hyperexercising, or using other unhealthy behaviors that will have an effect on their health.

'Orthorexia'

According to Mayo Clinic, 'orthorexia' comes from the Greek words 'orthos,' meaning straight or proper, and 'orexia,' meaning appetite. While not an official eating disorder diagnosis, people who become obsessive about eating healthy can have disordered eating patterns and thoughts that can get in the way of living a happy life. Steven Bratman is the doctor who first described and named this disorder. He differentiates healthy eating from orthorexia by the level of obsession that a person has (i.e., whether or not they allow themselves to eat foods they might think of as unhealthy in appropriate situations such as birthday cake at a party).

Other Nutritional Issues in Adolescents

Female Athlete Triad

Female teenage athletes are especially at risk for the female athlete triad. In the past, this triad was considered to be eating disorder, amenorrhea, and osteoporosis. Now, however, it is considered to be more of a continuum, with low energy availability taking the place of eating disorder, implying that the athlete does not necessarily have an eating disorder but is for whatever reason not taking in enough calories that is causing the functional amenorrhea that then causes the low bone mineral density. Female athletes should be screened for the female athlete triad on a regular basis to prevent any interference with bone growth and development. If a female athlete has amenorrhea, nutrition counseling is warranted to identify ways that she can consume adequate calories in order to resume menses.

Iron-Deficiency Anemia

During adolescence, teens have increased iron needs due to normal growth and development. Girls in particular have increased iron needs due to the blood loss during menstruation. Because of this, adolescents are more susceptible than adults to iron-deficiency anemia, which is characterized by not enough or especially small red blood cells. To prevent iron-deficiency anemia, adolescents should make sure to include iron-rich food sources in their diet including red meat, eggs, poultry, fish, legumes, and fortified breads and cereals. Girls and boys aged 9–13 need 8 mg per day, boys aged 13–18 need 11 mg per day, and girls aged 13–18 need 15 mg per day. Consuming foods rich in vitamin C (such as fruits and vegetables) in conjunction with iron-containing foods can help with the absorption of iron.

Vegetarianism/Veganism

As with any population including growing children, adolescents can eat a healthy, varied, and balanced vegetarian or vegan diet that will provide all of the necessary nutrients that they need for growth. With adolescents who might already have suboptimal nutritional intake, however, extra precautions are necessary to ensure that they are actually consuming enough of each nutrient on an animal-free diet, specifically protein, calcium, B12, vitamin D, and iron. Many products that are available to vegetarians and vegans are fortified with some of these important nutrients, but assessment and monitoring by a dietitian may be warranted. It is also important to assess why a teenager has chosen to become a vegetarian. In some cases, eliminating meat and/or dairy could be the beginning of a restrictive eating disorder. In general though, a vegetarian diet can be a healthy option for an adolescent. One study showed that vegetarian teenagers had better fruit and vegetable consumption and less total and saturated fat consumption than their meat-eating peers.

Celiac and Food Allergies

Food allergies are not specific to adolescence, and in fact, some childhood food allergies may no longer be an issue by the time the child reaches puberty. However, others will persist through childhood into adulthood and may be particularly tricky to deal with during adolescence when a teenager might not want to bring attention to himself or herself by asking about ingredients when out at a restaurant, for example, or carrying an EpiPen.

The general public has recently become much more aware of celiac disease and gluten sensitivity. For some, this awareness leads to a diagnosis of celiac disease where the only treatment is to avoid gluten. For others, the hype in the media causes them to needlessly avoid gluten altogether. While a gluten-free diet is an absolutely necessary treatment for someone with celiac disease, gluten (the protein found in wheat, barley, triticale, and rye) should not be removed from the diet without reason. Grain products provide an important source of carbohydrate in addition to being fortified with iron and often good sources of fiber.

Future Trends in Adolescent Nutrition

As teenagers across the world continue to be influenced by popular media and increasingly by various forms of social media, diet trends will likely continue to affect their foods choices, body image concerns, and health habits. Practices like juice cleansing, fasting, eating clean, consuming only organic foods, and cutting out items like sugar, gluten, and dairy without being medically advised to do so are just a few of the trends that adolescents are starting to follow. Whatever popular media decides as the next big weight loss secret or key to having clear, glowing skin will be seen before too long in the adolescent population. With any luck, these same teens will also have a caring, educated community supporting him or her to provide education on healthy, balanced, adequate nutrition.

Aerated Foods

GM Campbell, University of Huddersfield, Huddersfield, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Aerated foods and drinks such as bread and other baked products, beer, sparkling wines, fizzy drinks, ice cream, whipped cream, meringues, chocolate, Swiss cheese, puffed rice, and popcorn offer novel and luxurious textures and represent the height of culinary and technological skill. A diverse range of air contents and aerated structures are achievable from aeration processes that include low-viscosity whipping and high-viscosity mixing, gas injection, and slow or rapid generation and expansion of gases within foods. Aerated foods can be characterized in terms of the gas content, bubble or gas cell distribution, texture, and stability, which together deliver novelty, luxury, and appeal.

The benefits of aerating foods include

(i) reduced density and increased volume;
(ii) improved palatability and sensory appeal (smoothness, lightness, crispness, crunch, and fizz);
(iii) creation of novel textures and structures;
(iv) reduction in the intensity of flavors;
(v) entrapment of aroma compounds and subsequent delivery for retronasal olfaction, enhancing flavor perception;
(vi) increased digestibility;
(vii) altered perceptions of satiety;
(viii) aesthetic appeal;
(ix) enhanced ability to take up sauces, due to increased surface area and capillary action;
(x) connotations of luxury;
(xi) the advertising and market appeal of bubbles.

These benefits have been exploited across a diverse array of aerated foods, which can be broadly categorized in several ways as illustrated in Table 1: food type, historical appearance, aeration processes, stability, stabilization mechanism, and the principal gases contributing to aeration. Such categorization helps to identify common themes and challenges and opportunities for cross-fertilization. Table 2 presents the primary aeration methods used across the different food types.

Tables 1–2 illustrate the wide range of aerated foods and hint at the challenges of their manufacture in industry or in the domestic kitchen. Most food processing, either domestic or commercial, is concerned with creating desirable, distinctive, or novel textures, along with pleasant flavors and an attractive appearance. Many of the most appealing foods deliver their characteristic texture and appearance by exploiting the presence of bubbles. Examples include bread, cakes, ice cream, breakfast cereals, meringues, whipped cream, waffles, soufflés, aerated chocolate bars, beer, champagne, popcorn, and many others. Bubbles in foods offer no nutritional benefit; they represent pure luxury and proclaim the skill of the chef or his or her industrial counterparts. Aeration transforms food from merely flavorsome fuel into textural novelty. The textures achieved vary from the soft but strong crumb of bread to the crispness of breakfast cereals, to the crunch of honeycomb, to the smoothness of whipped cream, to the 'melting bubbles' of aerated chocolate bars, to the tingle of carbonated beverages.

Aerated foods offer product differentiation and marketing advantage in the highly competitive, innovative, and dynamic food market. They also inspire delight and praise in the dining room. Their creation requires detailed understanding, empirical and fundamental, of the complex interactions between food chemistry and physics in the kitchen or in the manufacturing environment.

Aeration Processes and Equipment

Aerated foods are produced using one or more of the three general methods: (1) Liquid is forced around air to form bubbles, (2) gas is sparged into liquid to form bubbles, and (3) gas is generated within the food to create bubbles. The first of these can be divided into low- and high-viscosity systems, while the third method can be divided into slow and rapid generation and expansion of gas, giving a total of five categories of aeration method. Within these five broad categories, a wide range of specific processes and operations are used, including whipping cream, beating eggs, dough and paste mixing, widgets in beer, fermentation, gas injection, frying, vacuum puffing, and extrusion. Thus, the major food aeration methods are as follows:

Type 1(a)

- *Whipping*, *beating*, or *shaking* of low–medium-viscosity liquids to entrap air
- *Pressure beating* (dissolution of air or gas under pressure), for example, in a syrup, fat mixture, or chocolate, for confectionery manufacture

Type 1(b)

- *Mixing* of doughs or high-viscosity pastes, in which air bubbles are entrapped as surfaces come together. The high viscosity of the dough or paste prevents rising and disengagement of bubbles. In raised bread, the bubbles incorporated by the mixing act as nucleation sites for the CO_2 produced during fermentation. During creaming of butter and sugar, sugar crystals aid aeration; fat crystals in cake batters and ice cream act similarly, with the particle size of the crystals affecting the size and number of bubbles entrained.
- *Entrapment* of air between sheeted layers, as in pastries and croissants, or between pulled strands, as in pulled taffy and candies.

Table 1 Bases for categorizing aerated foods, with examples

Food type	*Historical appearance*	*Aeration processes (in rough order of historical appearance)*	*Stability*	*Stabilization mechanisms*	*Principal aeration gases*
Bread and baked products Chocolate and confectionery Dairy foams Egg-based foams Breakfast cereals Snack products Beverages Miscellaneous	Ancient (4000–1000 BC): bread, beer, wine Classical period and Dark Ages (1000 BC–AD 1000): few new aerated foods Medieval (1000–1492): Swiss cheese, wafers, biscuits, koumiss, popcorn (Aztecs) Age of discovery (1492–1800): cakes, waffles, pastries, crumpets, bagels, whipped cream, ice cream, egg foams, bubbly beer, sparkling wines, soda water Industrial Revolution (1800–1900): baking powders, croissants, doughnuts, ice cream, angel cake, sponge cake, sabayon, modern marshmallow, carbonated soft drinks Early modern (1900–50): ice cream cone, instant whipped cream, crema on espresso and cappuccino, pavlova, bubblegum, aerated chocolate, breakfast cereals, potato crisps, extruded cereals and snacks, extruded marshmallows, mechanically developed doughs Recent (1950–the present): Chorleywood bread process, whipped margarine, widgets, Nescafé Foam Booster	Fermentation Whipping (low viscosity) Mixing (high viscosity) Steam generation and thermal expansion during slow cooking Entrapment between layers Frying Chemical raising agents Rapid dry heating Gas injection (including steam injection) Expansion extrusion Pressure beating Puffing Vacuum expansion Sudden pressure release Gas dissolved in a glassy matrix	Seconds: champagne foams Minutes: beer foams, crema on espresso and cappuccino Hours: batters, whipped cream, milk shakes Days: bread, mousse Weeks: cakes Months: chocolate, cereals, Swiss cheese, biscuits, ice cream Years: meringues, crackers, confectionery, rice cakes	Proteins: egg foams, beer and wine foam, bakery products, crema on espresso and cappuccino Fat crystals: whipped cream Ice crystals: ice cream, frozen desserts Emulsifiers: milk shakes High-viscosity, semisolid: batters, fruit fools, dairy desserts, mousses Solid matrix ● starch/protein: bread, bakery products, ice cream cone ● sugar: meringue ● fat: aerated chocolate	Carbon dioxide ● Yeast or bacteria: bread, yeast-leavened cakes, Swiss cheese, beer, wine, ginger beer ● Chemically leavened: cakes, biscuits, batters, soda bread, wafers, waffles ● Direct injection: carbonated soft drinks, sparkling wines, pressure beating of chocolate Steam: crema on espresso and cappuccino, unleavened breads, popcorn, puff pastry, puffed rice, cornflakes Air: whipped cream, egg foams, angel food cake, bread dough, chocolate Nitrogen: widget-induced beer foam, chocolate Nitrous oxide: instant whipped cream

Table 2 Primary aeration methods used with different food types

Food type *Aeration process*	*Baked products*	*Dairy products*	*Egg products*	*Chocolate and confectionery products*	*Breakfast cereals and snacks*	*Beverages*	*Others*
Fermentation	• Breads • Crackers • Crumpets • Pikelets • Stollen • Pretzels • Bagels	• Swiss cheese			• Fermented extruded products	• Beer • Wine • Ginger beer	
Whipping or shaking	• Batters • Yorkshire puddings	• Cream • Ice cream • Mousses • Sherbet • Frozen desserts • Milk shakes • Butter • Koumiss • Whipped margarine	• Meringue • Soufflé • Omelet • Sponge cake • Angel cake • Chiffon cake • Zabaglione • Sabayon	• Frappé • Marshmallow • Foamed chocolate beverage (Aztecs)			• Fruit fool • Sorbet • Meat foams • Fish foams
Dough and paste mixing	• Bread dough • Biscuit dough	• Soft butter • Cream cheese • Creaming of butter and sugar for cakes	• Choux pastry	• Fondant • Nougat • Chocolate			• Crèmes • Icings • Peanut butter • Snack preparations • Meat doughs
Slow dry heating/ baking (steam generation and thermal expansion)	• Unleavened bread • Pancakes • Doughnuts • Pizza base • Wafers • Yorkshire puddings • Bagels		• Soufflé • Omelet • Sponge cake • Angel cake • Chiffon cake				• Micronized wheat, lentils
Rapid dry heating (steam generation and thermal expansion)					• Cornflakes • Micronized wheat • Popcorn (Aztecs) • Popped sorghum		• Crisps
Frying	• Poppadoms				• Snacks • Potato crisps		• Bubble and squeak

Type 2

- *Gas injection*, for example, air or nitrogen injection in ice cream and sugar confectionery, carbon dioxide injection in soft drinks, steam frothing of espresso and cappuccino, or children blowing bubbles into milk to make it more interesting

Type 3(a)

- *Fermentation*, in which aeration is achieved through carbon dioxide production by yeast in bread, beer, and wine or by *Propionibacterium* in Swiss cheeses.
- *Steam generation* during slow to moderate cooking, baking, or frying. Steam generation is often accompanied by *thermal expansion* of the gases already in the bubbles and by evaporation of other dissolved components (e.g., CO_2 and ethanol).
- The use of *chemical raising agents* such as baking powders in cakes or sodium bicarbonate in soda bread, honeycomb, or dulce de leche.
- *Vacuum expansion*, followed by rapid cooling to set the expanded product, for example, chocolate bars.

Type 3(b)

- *Rapid dry heating* or *toasting* of small or thin products to induce blistering or slight puffing
- *Frying* in very hot oil, such that internal steam is formed rapidly, causing the product to puff
- *Expansion extrusion*, in which superheated product under pressure emerges suddenly from an extruder, such that internal moisture immediately vaporizes into steam bubbles, to produce crisp snacks, cereals, and sugar confectionery
- *Puffing*, in which products such as breakfast cereals containing superheated moisture are subjected to a sudden release of pressure
- *Popping*, in which the material (e.g., popcorn) is naturally able to retain pressure for explosive release and structure formation

Despite the wide variety of processes, aeration equipment comprises primarily mixers of various designs, extruders, or specialized puffing or expansion equipment. Most other aeration processes are achieved by heating or by chemical raising agents.

Several aeration operations may contribute together or consecutively during the process; for example, in breadmaking, bubbles are incorporated into the high-viscosity dough during mixing (a type 1b process); these bubbles are inflated slowly by carbon dioxide gas generated by yeast fermentation (type 3a) and are further inflated by steam generation and thermal expansion during baking (also type 3a) while also undergoing coalescence and rupture along with setting of the matrix structure.

Mixers for food aeration include high-speed whisks and beaters with stainless steel wire assemblies for egg foams, whipped cream and cake batters, and high- and low-speed heavy-duty mixers for doughs and pastes. Pressure beating delivers greatly accelerated aeration and produces fine foams, with air consumption of up to $1000\,l\,h^{-1}$. Blades can be mounted horizontally within the mixer bowl or, more usually, vertically from the top or through the base of the bowl. Industrial-scale high-speed whisks operate at speeds of around 200 rpm with a specific power input of around $50\,W\,kg^{-1}$. Low-viscosity mixers must use high speeds to entrain air and break up the bubbles, while in dough mixing, bubbles are entrained unavoidably simply through the action of surface renewal during mixing. In both high- and low-viscosity mixing operations, the air content and bubble-size distribution depend on the balance between entrainment and disentrainment of air, along with bubble breakup and coalescence, with viscosity, surface tension, and the presence of particles influencing these processes.

In modern breadmaking processes, the bubble structure created in the dough directly affects the baked loaf structure. Some dough mixers use pressure-vacuum mixing, in which the dough is mixed initially under high pressure to provide additional oxygen (which contributes to the development of the gluten network), followed by mixing under a partial vacuum to reduce the air content in the dough. Some batch dough mixers, for example, the BiPlex, operate initially at slow speed to blend and hydrate the ingredients and then at high speed to develop the dough.

Continuous dough mixers lack the versatility of batch mixers to modify the bubble structure in the dough and in the resulting bread. Continuous, tubular, pressurized scraped-surface aerator freezers with a residence time of about 30 s are used in ice cream manufacture to give air contents of up to 50% by volume.

Aeration Gases

The three gases of greatest importance in food aeration are carbon dioxide, steam, and air. Nitrogen may also find application in specific instances, for example, in pressure beating to produce microaerated chocolate in which the bubbles are too small to be visible or to produce a foamy head on beer. Oxygen can be bubbled through cheap wine to approximate aging, while nitrous oxide is the gas that propels instant whipped cream from a can, chosen for its similar solubility to carbon dioxide but not imparting a sour taste. However, most aerated foods employ carbon dioxide, steam, and air, separately or together, to achieve aeration.

Table 3 presents a two-dimensional categorization of aerated foods according to processing methods and the major gases used in their manufacture. Carbon dioxide can be produced biologically from bacterial or yeast fermentation, as in bread, beer, wine, and Swiss cheese. Carbon dioxide can also be produced from chemical reactions involving sodium bicarbonate and a suitable acid, as in baking powders used in cakes and honeycomb/cinder toffee, or can be directly introduced to the food or beverage as gaseous CO_2, as for carbonated soft drinks and cheap sparkling wines or in certain pressure-beating applications. Steam can be injected into, for example, milk to produce the attractive *crema* on espresso and cappuccino coffees. Slow generation of steam occurs in all baking processes, along with dissolution of gases when the temperature rises and

Table 3 Processing methods for aerated foods and the major gases involved in their creation

Processing method	*CO_2 – yeast or bacterial fermentation*	*CO_2 – chemically leavened*	*CO_2 – direct injection*	*Steam*	*Air*	*Other*
1(a). Low–intermediate-viscosity whipping			Pressure beating of chocolate		Batters Whipped cream Egg foams Mousses Frappe Angel cake, sponge cake Foamed chocolate beverage	Nitrogen – pressure beating of chocolate to produce microaerated chocolate
1(b). High-viscosity mixing or layering					Bread dough (during mixing) Pastry dough (puff pastry, Choux pastry, croissants)	
2. Gas injection			Carbonated soft drinks Sparkling wines	Cappuccino, espresso	Bubble gum	Nitrogen – widgets to produce a creamy foam on beer Oxygen – bubbled through wine to approximate aging
3(a). Slow *in situ* generation or expansion of gases	Bread dough (during proving), yeast-leavened cakes, crumpets Swiss cheese Beer, wine, ginger beer	Cakes, soda bread, biscuits, pancakes, doughnuts, wafers, waffles		Bread (during baking); baking of all baked products	Vacuum-expanded chocolate Thermal expansion during baking	
3(b). Rapid *in situ* generation or expansion of gases				Unleavened breads Popcorn Fried snacks Potato crisps Extruded snacks	Extruded marshmallow	Nitrous oxide – instant whipped cream

accompanied by expansion of the steam, air, and released gases. Meanwhile, rapid creation of steam and expansion of air and steam occur in rapid heating or rapid pressure reduction processes, giving the explosive power to create extruded snacks, rice crispies, and popcorn. Whipping is perhaps the archetypal aeration process, in which air is the relevant gas, entrained via the rapid deformation of the surface of a liquid, as in whipped cream and beaten egg whites. Air can also be entrapped more slowly via layering of pastry or slow mixing of high-viscosity materials such as bread doughs. In processes that involve heating, this air, and any other gases, undergoes thermal expansion, accompanied by the creation and expansion of steam. Alternatively, the air may be expanded without heat by reducing the pressure, either by aerating under positive pressure and releasing to atmospheric pressure or by applying a vacuum to the foamed liquid and allowing it to set.

As ever, tidy classifications are impossible, as the creation of a given food may involve several operations and different gases at each stage. Air is frequently the initial and the final aerating gas – steam and carbon dioxide may contribute intermediate roles, but frequently, the initial aeration (as the word implies) is with air, while for porous products, the final aerated structure is also filled with air. Breadmaking has, for example, been described as 'a series of aeration stages': Air bubbles are created during mixing; these bubbles are inflated with carbon dioxide gas produced by yeast during proving; there is further expansion during baking due to ongoing CO_2 production until the yeast is killed by the increasing temperature, the evaporation of water into steam, the dissolution of CO_2 from the liquid phase due to the higher temperature, and the thermal expansion of the steam, CO_2, and air; and on setting of the porous crumb structure, the steam and CO_2 are released and replaced once again by air.

Characterization of Aerated Foods

Aerated foods can be characterized in terms of their rate of aeration, air content, bubble size distribution, the resulting

texture, and the stability of the aerated structure. Foamability (the ease with which a foam is formed, in terms of rate and air content) and foam stability are usually applied to transient food foams such as beer and wine foams and beaten egg whites. Foamability may be measured by sparging gas or by rapid whipping to determine the time required to form a prescribed volume of foam, while foam stability is characterized by the half-life of the foam, the rate of foam drainage, or the change of conductivity of the foam. Foamability and foam stability are often inversely related – a greater foam volume is achieved at the expense of a less stable foam. Stability is conferred through a range of stabilization mechanisms, discussed later in the text.

For more solid aerated foods, texture is of greater importance, and rheometers and textural measurements, including sensory evaluation, are applied. Rheometers may be empirical, imitative, or fundamental. Crisp aerated foods can be characterized by calculating the apparent fractal dimension of the jagged stress–strain curve resulting from crushing. Mechanical properties of solid aerated foods depend on the mechanical properties of the matrix, the amount and distribution of the air, and whether the foam is of open or closed gas cells. Closed gas cells occur in aerated chocolate bars, for example, in which each bubble is discrete, while bread has an open-cell or sponge structure, in which the gas cells are interconnected to form a porous network. Mechanical properties of foams, such as Young's modulus, collapse stresses, crushing strength, and fracture toughness, can be related to the density of the foam by a power law model:

$$\frac{\sigma}{\sigma_m} \propto \left[\frac{\rho}{\rho_m}\right]^n$$

where σ is a general mechanical property, σ_m is the mechanical property of the matrix material in the foam, and ρ and ρ_m are the density of the foam and of the matrix material, respectively. The exponent n is usually in the range 2–3. For constant matrix properties, mechanical properties vary with foam density raised to the power of n, such that as air content increases, the foam becomes less strong.

Air contents of aerated foods range from 2% for some confectionery products to >95% for popcorn, rice cakes, and beer foam, with every air content in between. The air content of highly aerated fluids such as ice cream and whipped cream is characterized in terms of the overrun, OR, calculated as

$$\mathrm{OR} = \frac{\text{Weight of unwhipped product} - \text{weight of whipped product}}{\text{Weight of whipped product}} \times 100\%$$

where weights are measured in a container of constant volume. The overrun represents the additional air added. In aerated foods with lower air contents, the void fraction of air as a fraction of the total volume is more usually calculated as

$$\phi = \left(1 - \frac{\rho}{\rho_{gf}}\right) \times 100\% = \left(\frac{\mathrm{OR}}{\mathrm{OR} + 100}\right) \times 100\%$$

where ρ is the density of the product and ρ_{gf} is the gas-free density. Table 4 gives typical values of the density and air content of a range of aerated foods, from which the other parameters describing aeration can be calculated. Figure 1 shows typical air contents and specific volumes of a selection of aerated food products.

Table 4 Typical values of density and gas content of aerated foods (dependent in all cases on temperature, composition, and processing factors)

Food	*Density (g cm^{-3})*	*Void fraction of gas (%)*
Popcorn	<0.07	>95
Rice cakes	0.11–0.13	90–92
Puffed rice	0.13–0.17	88–90
Extruded products	0.10–0.33	75–90
Meringue	0.17–0.18	88–90
Beaten egg whites	0.15–0.20	80–85
Baked loaf	0.20–0.35	72–85
Sponge cake	0.25–0.35	70–80
Risen dough	0.25–0.40	68–80
Marshmallow	0.35–0.45	68–75
Cake	0.35–0.40	68–72
Whipped cream	0.40–0.60	40–60
Ice cream – hard	0.54–0.55	50
Cake batter	0.55–0.80	30–50
Aerated chocolate bar	0.70–0.80	40–45
Nougat	0.80–0.90	30–40
Fruit fool	0.75–0.8	25–30
Ice cream – soft	0.78–0.8	28
Milk shake	0.90–0.95	9–13
Micronized wheat	1.15–1.25	7–11
Bread dough (unrisen)	1.15–1.20	4–8
Wheat grains	1.25–1.35	2–3

Source: Campbell, G. M. and Mougeot, E. (1999). Creation and characterisation of aerated food products. *Trends in Food Science and Technology* **10**, 283–296.

Density measurements indicate the gross air content of a food, but not how that air is distributed. The size distribution of bubbles or gas cells determines the texture, appearance, and mass transfer behavior of an aerated food. The size distribution can be determined by image analysis of an aerated surface or of thin slices of the product. When thin slices of a food material are taken, the holes appearing on the slice are, on average, smaller than the bubbles from which they came. The hole size distribution measured is therefore different from the true bubble size distribution, which must be reconstructed using stereological techniques. The advent in recent years of accessible x-ray microtomography has begun to empower studies of aerated foods, in terms of more precise characterization of aerated structures and insights into the dynamic processes by which those structures are created. Figure 2 illustrates x-ray tomographic images of bread dough during proving.

Stabilization of Aerated Foods

The lifetimes of aerated food products range from a few seconds for wine foams, to minutes for beer foams and soufflés, to hours for whipped cream, to days for bread, to weeks for cakes, to several months for Swiss cheeses, cereals, chocolate bars, and ice cream. Liquid aerated systems are inherently unstable, and the bubble structure must be stabilized against collapse. In solid aerated foods such as crackers and snack and chocolate bars, stability is achieved through the solid matrix. These products are however delicate due to their fine aerated structure, and their high surface area makes them prone to oxidative deterioration or picking up atmospheric moisture, these factors ultimately

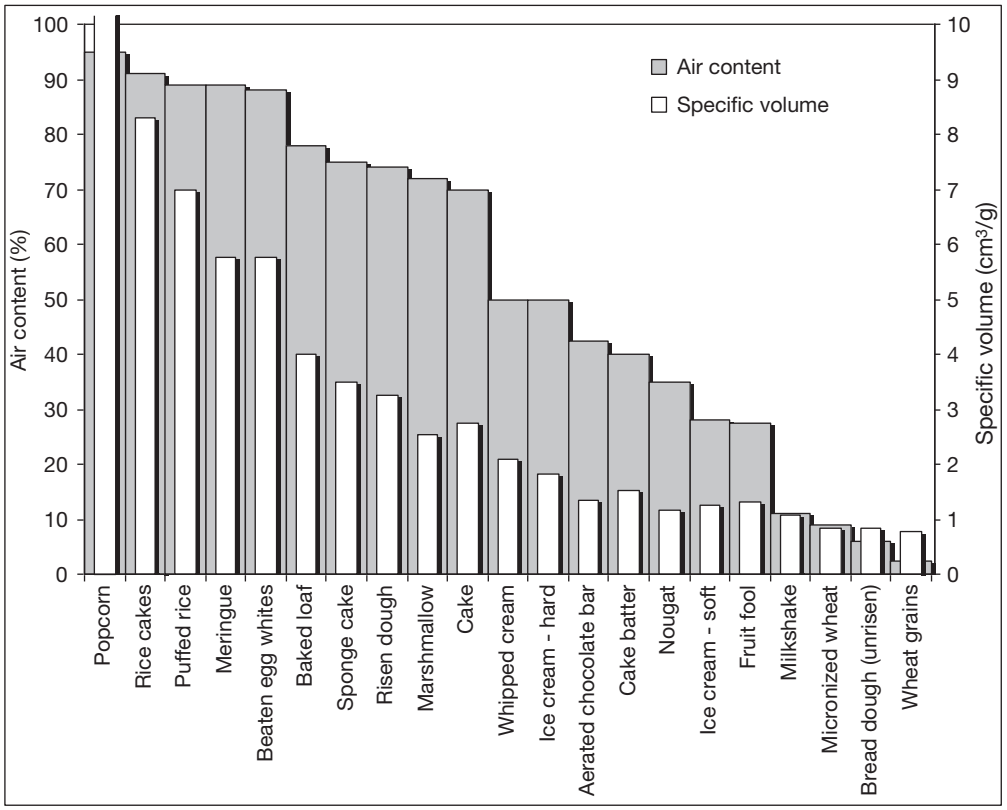

Figure 1 Typical air contents and specific volumes of a selection of aerated foods. Adapted from Campbell, G. M. and Mougeot, E. (1999). Creation and characterisation of aerated food products. *Trends in Food Science and Technology* **10**, 283–296.

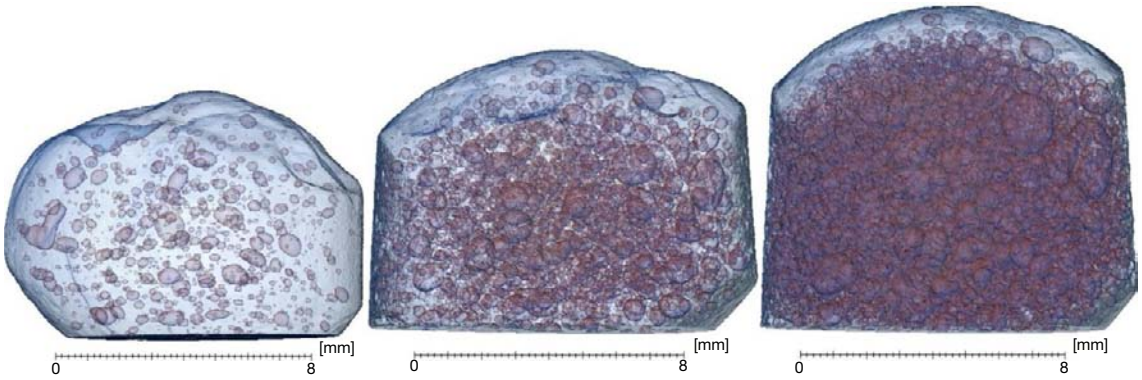

Figure 2 x-Ray tomographic images of bread dough showing the volume of dough (blue) and the bubbles within it (red) during proving of bread dough. (With acknowledgements to Linda Trinh and Peter Martin.)

limiting their shelf-life. During the formation of these products, however, and in other more liquid food foams, the bubbles must be stabilized against their thermodynamic tendency to coalesce. Stability is conferred to aerated foods through the action of indigenous or added emulsifiers, proteins (as in beer foams, egg foams, proving bread doughs, and cakes), fat or ice crystals, or other particles (whipped cream, ice cream, and puff pastry) or through a high-viscosity or solid continuous matrix (chocolate bars, meringues, breakfast cereals, Swiss cheese, and mousse).

In low-viscosity foams, three distinct mechanisms of destabilization occur: drainage, coalescence, and disproportionation. Drainage occurs when liquid flows from the thin lamellae between bubbles into the Plateau borders that form at the meeting point of three bubbles. Plateau borders form a continuous pathway through the foam, allowing liquid to drain until the bubble lamellae thin sufficiently to allow coalescence. If the foam is stable against coalescence, drainage will continue until a relatively dry polyhedral foam skeleton remains. Higher viscosity in the liquid slows both drainage and coalescence.

Coalescence between bubbles is thermodynamically favorable because of the resulting reduction in surface area. The presence of surface-active materials (e.g., emulsifiers and proteins) stabilizes against coalescence; pure liquids, free of surfactants, are unable to produce stable foams. The presence of hydrophilic particles may stabilize a foam, while hydrophobic particles destabilize foams by thinning the film between bubbles, as illustrated in Figure 3. Pickering particles, which have both hydrophobic and hydrophilic regions and so accumulate at interfaces, are the subject of much current research in food foam stabilization as they are able to confer remarkable stability.

Disproportionation in foams is the growth of large bubbles at the expense of smaller ones, equivalent to Ostwald ripening in emulsions. The gas pressure in smaller bubbles is greater than that in larger bubbles, due to the contribution of surface tension, γ, as described by the Laplace equation:

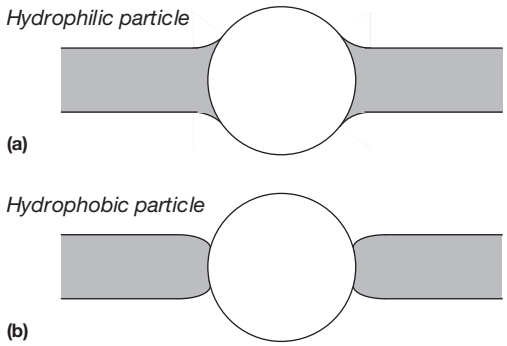

Figure 3 Effect of particles on foam stability: (a) stabilization of bubble lamellae by hydrophilic particles that draw liquid to the particle and oppose film thinning; (b) destabilization by hydrophobic particles.

$$P_b = P_\infty + \frac{2\gamma}{r}$$

where r is the bubble radius. The higher Laplace pressure in smaller bubbles causes a higher gas solubility in the neighboring region. This results in a mass transfer driving force between small and large bubbles that causes the diffusion of gas to the latter. The process is self-accelerating, as the loss of gas makes small bubbles even smaller, the Laplace pressure higher, and the gas solubility greater. Ultimately, small bubbles implode and the foam coarsens. However, the increasing concentration of surface-active components at the surface of the shrinking bubble slows down and can even arrest the process. Disproportionation is a major factor in foam stability of carbonated beverages such as beer, due to the high solubility of carbon dioxide in water. The presence of a small proportion of nitrogen in the gas phase stabilizes against disproportionation, as the loss of carbon dioxide by disproportionation from a small bubble lowers the partial pressure of carbon dioxide remaining in the bubble, lowering its concentration in the surrounding liquid, and thus ultimately removing the driving force for diffusive mass transfer.

Most aerated foods are not low-viscosity foams, and in most aerated foods, bubble coalescence is the most significant destabilization mechanism. Stability against bubble coalescence in both low- and high-viscosity systems is conferred by the presence of surface-active materials such as low-molecular-weight lipids and high-molecular-weight proteins. These two types of surfactant stabilize against coalescence via different mechanisms, as illustrated in Figure 4. Two adjacent bubbles will coalesce when the lamella between them thins and breaks as a result of drainage or mechanical disturbance (Figure 4 (a)). When the lamella thins, it experiences greater stress, which rapidly causes further thinning and breakage of the film. If a low-molecular-weight surfactant is present at the

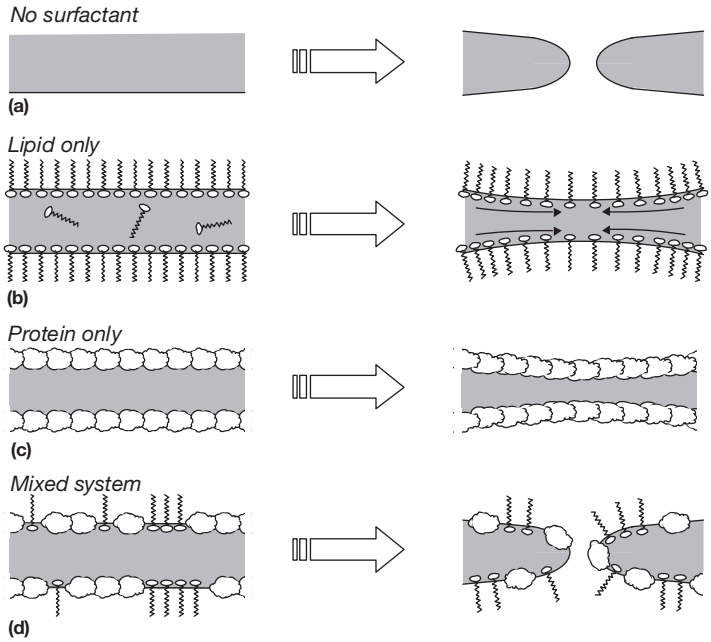

Figure 4 Illustration of film stability between bubbles with (a) no surfactant present; (b) low-molecular-weight surfactants such as lipids; (c) protein-stabilized bubbles; and (d) mixed protein–lipid systems.

surface, its concentration decreases at the point of film thinning. This creates a surface tension gradient that causes surfactant molecules from the adjacent area to diffuse rapidly to the depleted region, sweeping liquid into it and restoring the thickness of the region (the Marangoni effect) and thus safeguarding against coalescence (**Figure 4(b)**). The effectiveness of low-molecular-weight surfactants thus depends on their rates of surface lateral diffusion. Large-molecular-weight surface-active molecules such as proteins have low lateral diffusivities; they stabilize against coalescence via a different mechanism, in which they interlink to form a rigid layer at the surface (**Figure 4(c)**). If both proteins and low-molecular-weight surfactants such as lipids are present, competing for space at the bubble interface, these two stabilization mechanisms can interfere; the presence of protein prevents rapid surface diffusion of lipid molecules, while the presence of lipids prevents the formation of a rigid interlinked protein network (**Figure 4(d)**). Such mixed systems are responsible for the reduction in egg foam volume when a small amount of egg yolk is allowed in with the whites, the reduction in loaf volume when small amounts of polar lipids are added to bread dough formulations, and the disastrous effects of lipids on beer foam stability. In other cases, low-molecular-weight lipids may act cooperatively with proteins to improve foam stability.

Introduction

The genus *Aeromonas* belongs to the Aeromonadaceae family and comprises gram-negative, non-spore-forming, rod-shaped, facultative anaerobic bacteria that can be isolated from a very wide spectrum of environmental niches. The history and the perception of *Aeromonas* by the scientific community have evolved over 100 years, from its discovery in the late nineteenth and early twentieth centuries until nowadays. Aeromonads were first described as pathogens of poikilothermic animals. Today, they are recognized as causing severe illnesses in aquatic organisms (fish and other cold-blooded species) and also as emerging pathogens associated with several human infections and, in particular, as food-borne pathogens. In 2010, Janda and Abbott published an excellent review about *Aeromonas* spp., providing a wide and comprehensive view of the genus. However, many open questions regarding the ecology, pathogenicity, and taxonomy of aeromonads were present, and after 4 years, *Aeromonas* still represents a very complex genus.

A distinctive characteristic of *Aeromonas* has always been its controversial taxonomy. The complexity in identifying and discriminating *Aeromonas* species relies on the extremely high intra- and interspecies genetic variability. The genus was first discovered in 1891 and included in the family of Vibrionaceae together with *Vibrio* spp., *Plesiomonas* spp., and *Photobacterium* spp. This was due to the prevalence of these genera in the aquatic environments and the common phenotypic characteristics. The genus was officially created in 1943 and aeromonads were roughly divided into two major groups, based upon growth characteristics and other biochemical features. The mesophilic group, named *A. hydrophila*, consisted of motile isolates that grew well at 35–37 °C and were associated with a variety of human infections. The psychrophilic group, referred to as *A. salmonicida*, included nonmotile strains that had optimal growth temperatures of 22–25 °C and caused diseases in fish. From the mid-1970s until nowadays, an enormous explosion in the number of proposed species has been seen, and the list of species assigned to the genus is constantly changing. This is mainly due to two reasons: (1) the general and recent tendency to propose new species based upon single strains, especially in the last 5 years, and (2) the invalidity of some species names or the use of heterotypic synonyms of previously published species.

To date, there are 27 valid published species names among *Aeromonas* spp. included in the List of Prokaryotic names with Standing in Nomenclature (Table 1), but the second edition of *Bergey's Manual of Systematic Bacteriology* (*Bergey's*) recognizes far fewer. The genome sequences of 46 *Aeromonas* strains, including both draft and complete genomes, are now available in GenBank.

Aeromonas and Laboratory Identification

Aeromonas spp. can be easily isolated from clinical and environmental samples. Several media are routinely used for *Aeromonas* isolation, but their performances can vary according to the nature of samples (food, clinical, or water) and some selective agents that can reduce the recovery of some species. *Aeromonas* grow well on routine enteric isolation media (MacConkey, XLD, HE, SS, and DC media); however, the lactose-negative isolates must be differentiated from commonly isolated pathogens such as *Salmonella* and *Shigella*. The media that are frequently used for both qualitative and quantitative evaluations of *Aeromonas* spp. are listed in Table 2.

Microbiological methods are clearly needed for bacterial isolation, but their use as species identification tools can be very challenging, especially for aeromonads. For instance, it can be difficult to separate *A. veronii* bv. sobria or *A. caviae* from *A. hydrophila* or they may be confused with other genera, such as *Vibrio* and *Plesiomonas*.

In the last decade, DNA-based molecular methods have become more popular and widely acceptable for bacteria species identification due to their reproducibility, simplicity, and high discriminatory power. Several molecular methods have been applied for discriminating *Aeromonas* species. 16S rRNA gene sequencing represents the most commonly utilized molecular technique for this purpose. However, it is now recognized to be problematic for bacterial characterization mainly because of its intragenomic heterogeneity. This suggested that a single-gene-based identification approach may not be appropriate for characterizing *Aeromonas* spp. As a consequence, the multilocus sequence typing (MLST) approach became the new trend in the last 10 years. From 2011, three MLST schemes were published for *Aeromonas* spp. demonstrating the validity of this technique in discriminating aeromonads at species level. Moreover, the first *Aeromonas* MLST online database was opened (www.pubmlst.org/aeromonas) and is now available for collecting and sharing information about *Aeromonas* strains from different laboratories all over the world.

Aeromonas in the Environment

Aeromonas are described as ubiquitous bacteria. They can be isolated not only from a variety of aquatic environments and from different terrestrial ecosystems, such as food, invertebrates, plants, and slurry and fecal contents of farm animals, but also as a digestive tract symbiont of fish, leeches, and bats.

Initially, three *Aeromonas* genomospecies (*A. hydrophila*, *A. caviae*, *and A. veronii*) were considered to be related to the vast majority to human infections, while *A. salmonicida* has been

Table 1 List of the valid and proposed species in the genus *Aeromonas*

Species	*Year of proposal*	*Synonym (year of proposal)*
A. hydrophila	1943

[a]Not yet included in the species with standing in nomenclature.

included as the predominant species in fish and water samples. However, *A. hydrophila* and *A. veronii* have been also recognized as involved in fish diseases, resulting in enormous economic losses. Some studies have also identified the presence of less frequently encountered species in environmental samples, such as *A. schubertii* in organic vegetables. However, although *Aeromonas* are still described as ubiquitous, the preferential association and adaptation between particular species and defined habitats have been recently highlighted. Two main different habitats were identified for *Aeromonas* species: aquatic (fish and water) and terrestrial (mainly food and human cases of disease). *Aeromonas* were first described as water bacteria, and the use of water on foods and irrigation and in human consumption could have easily contributed to their wide dispersal. The differentiation of species to a particular habitat might be the result of their adaptation over time. Species such *A. hydrophila*, *A. salmonicida*, *A. veronii*, *A. bestiarum*, *A. sobria*, and *A. allosaccharophila* are commonly isolated from the aquatic environment, while species such *A. caviae*, *A. media*, *A. enteropelogenes*, *A. jandaei*, and *A. schubertii* are described as 'terrestrial' (mainly associated with ready-to-eat food and human diseases). Unfortunately, limited data exist on the distributions of newly described species (such as *A. rivuli*, *A. taiwanensis*, *A. sanarellii*, *A. australiensis*, and *A. cavernicola*) in the environment outside their initial taxonomic description.

Aeromonas in Water

The main reservoir of the genus *Aeromonas* has always been the aquatic environment, with isolates from rivers, lakes, ponds, seawater (estuaries), drinking water, groundwater, wastewater, and sewage in various stages of treatments.

Many studies have demonstrated the ability of *Aeromonas* to survive and grow in drinking water supplies. The bacterium can resist to water treatment strategies such as rapid/slow sand filtration, hyperchlorination/direct filtration, and the use of granular activated carbon. Studies indicated that after disinfection with 1 mg l^{-1} of chlorine, 10% of the pipes had aeromonads and that *A. hydrophila* in biofilms could survive up to 0.6 mg l^{-1} of monochloramine, which could remove *E. coli* biofilms. Some studies reported that the presence of *Aeromonas* in drinking water could lead to septicemia in immunocompromised persons, although no link has been demonstrated so far. Due to the prevalence of *Aeromonas* in drinking water, the onset of new resistance mechanisms, and the presence of several virulence factors, aeromonads are included in the 'Contaminant Candidate List' by the Environmental Protection Agency. The World Health Organization lists *Aeromonas* in the third edition of Guidelines for Drinking-water Quality. On the basis of the Consumer Confidence Report Rule, public water systems are required to report unregulated contaminants, such as *Aeromonas*, when detected. Moreover, the presence of aeromonads in water supplies poses risk factors for the transmission of these bacteria to food products such as ready-to-eat vegetables. Decontamination with a lactic acid solution and not chlorine seems to show the highest potential to reduce *Aeromonas* spp. and to guarantee prolonged shelf lives of fresh-cut vegetables.

Aeromonas in Animals

Animals represent a very frequent reservoir for the transmission of *Aeromonas* species in the environment. Aeromonads are implicated in infections of both aquatic and terrestrial organisms. *A. salmonicida* causes fish furunculosis, especially in salmonids, and the disease has several presentations, from an acute form characterized by septicemia with hemorrhages at the bases of fins, inappetence, and melanosis to a chronic variety in older fish, consisting of lethargy, slight exophthalmia, and hemorrhaging in muscle and internal organs. *A. hydrophila* and *A. veronii* cause similar diseases, including hemorrhagic septicemia in carp, perch, catfish, and salmon; red sore disease in bass and carp; and ulcerative infections in catfish, cod, carp, and goby. *Aeromonas* have been implicated in several infectious processes; in seals, they can also cause 'red leg' disease in frogs, ulcerative stomatitis in snakes and lizards, septicemia in dogs and septic arthritis in calves, and seminal vesiculitis in bulls.

Aeromonas in Food

In the last 15 years, many studies were conducted to determine both the frequency and the concentration of *Aeromonas* spp. in food products (Table 2) from supermarkets and retail stores, and it has been observed that aeromonads are inhabitants of

Table 2 Isolation and characterization of *Aeromonas* spp. in food

Approach	*Medium*	*Matrix*	*N° samples*	*Species identification*[a]

most types of food, from seafood to vegetables, meats (lamb, veal, pork, chicken, and ground beef), and dairy products.

Their presence in foods often leads to spoilage reactions, but in some products, such as milk, they can reach high concentrations (up to 10^8 CFU ml^{-1}) without any detectable organoleptic changes. Since their main reservoir is the aquatic environment, they have been isolated from several seafood species and the most common *Aeromonas* species found were *A. salmonicida*, *A. bestiarum*, *A. veronii*, and *A. encheleia*. Their frequent presence in these food matrices represents again a potential risk seen in the actual trend of eating raw seafood. Stratev and colleagues recently published a detailed review about the prevalence of *Aeromonas* spp. in food, but the final species description was clearly affected by the methods of isolation and identification (biochemical vs. biomolecular) (Table 2). *Aeromonas* is frequently found in vegetables, especially in ready-to-eat salads that are usually consumed without washing. The type of vegetables seems to influence the *Aeromonas* growth rate (more than the type of the atmosphere present), with more rapid growth occurring on shredded endive and lettuce than on sprouts or grated carrots. A work conducted on RTE at the University 'Federico II' of Naples on 320 food products revealed the presence of *Aeromonas* in 46% of samples, mostly vegetables (45% lettuce, 40% endive, and 15% rocket), but also on dairy products (45% ricotta cheese) and meat (25% salami and raw ham) (Table 2). *A. hydrophila* was the most common species isolated from food of animal origin, while *A. caviae* was mostly found in vegetables. Initial counts in food ranged from $<10^2$ to $>10^5$ CFU g^{-1} at 5 °C, and after 7 days at refrigeration temperature, *Aeromonas*

concentration increased one to three log as most aeromonads are psychrotolerant. In the majority of the studies, the isolates were recovered after enrichments techniques, indicating that *Aeromonas* concentrations were relatively low. However, enrichment is suggested for processed food, since food-preserving methods affect the recovery of *Aeromonas*, while for raw foods, the quantitative methods could provide a view of contamination.

Aeromonas importance in food bacteriology is due to their strong adaptive capacity, their high lipolytic and proteolytic action, and their surviving ability at wide ranges of temperatures and pH that make this genus able to grow on any food matrix. Moreover, some strains produce thermostable toxins and can survive in some processed food. *Aeromonas* strains can be recovered from foods stored at −20 °C for considerable periods (years) and it has been demonstrated that *A. hydrophila* resists to 5% NaCl at specific temperatures. Their capacity to grow at low pH values or high NaCl concentrations may represent a risk in ready-to-eat products where acidifications techniques are used for food conservation. Acetic, lactic, tartaric, citric, sulfuric, and hydrochloric acids are effective at restricting growth, and polyphosphates can also control their growth in certain foods. Overall, *Aeromonas* grow anaerobically as they do aerobically, their growth under modified atmospheres depends on the nature and number of competing microbiota, and the use of modified atmospheres to extend shelf lives of packaged meats and fresh vegetables may enable aeromonads to grow to high populations. However, *Aeromonas* spp. are readily killed by heat treatment or irradiation, but they are resistant to chlorination processes and to multiple antibiotics.

Aeromonas in Human Health

From 1954, when *Aeromonas* was first associated with the death of a 40-year-old-woman in Jamaica, to the present date, the role of this bacterium in human colonization and infection is still much debated. Although *Aeromonas* does not belong to the human enteric microbiota, it has been demonstrated that it is present in 1% of the adult people and this value increases to 3% in warm periods and up to 30% in developing nations.

Since *Aeromonas* spp. are ubiquitous bacteria, the association with humans is easily established. They are mainly acquired via contact with contaminated drinking water or through the ingestion of foods that are naturally exposed to aeromonads through irrigation processes or other 'farm-to-table' operations. Also, raw seafood represents a common way of contamination. Bivalves such as oysters and mussels are naturally bathed in estuary waters containing these bacteria, and through their filter-feeding process, they actually concentrate these bacteria within their meats. It has been also reported that recreational activities such as boating, fishing, and diving can lead to infection, although no reliable data are available.

Janda and Abbott listed a detailed survey of the incidence of *Aeromonas* infections all over the world, based on available data. In 1988, California reported that the incidence of *Aeromonas* infections was 10.6 per million. In 2006, 99 *Aeromonas* infections were reported in 70 hospitals in France; this represents a prevalence of 1.62 infections per million, a value much lower than that reported in the Californian study. In England and Wales, *Aeromonas* bacteremia is a voluntarily reportable condition and 82 cases of *Aeromonas* bacteremia were recorded in 2004. Based upon these data, it has been calculated that the incidence of *Aeromonas* septicemia in England/Wales and the United States is 1.5 per million. To date, the exact incidence of *Aeromonas* infections on a global basis is unknown as many cases may be asymptomatic or not reported.

It has been observed that *Aeromonas* species implicated as causes of human colonizations and infections are not restricted to a single genomospecies, and it seems that an association between some *Aeromonas* species and their effects on humans exists. Among the 27 species identified to date, *A. hydrophila*, *A. caviae*, *A. veronii*, and *A. jandaei* are most commonly associated with humans and account for more than 85% of all clinical isolates.

While *Aeromonas* was originally thought to be an opportunistic pathogen in immune-compromised humans, an increasing number of cases of *Aeromonas*-associated intestinal and extraintestinal disease documented worldwide seem to suggest it is an emerging human pathogen irrespective of the host's immune status. A recent study reports 91 cases of bacteremia caused by *Aeromonas* spp. recorded in a computerized database of a regional hospital in southern Taiwan and confirms this bacterium as a nosocomial pathogen. To date, it is described as bona fide enteropathogen, but it is not universally accepted as a pathogen bacterium. The proof that establishes *Aeromonas* as a true pathogen is lacking, and this is mainly due to the failure to identify a single clonally related outbreak of disease and to detect an immune-specific response in human serum. However, *Aeromonas* spp. have been isolated from several cases of human infections and are described as responsible of several intestinal and extraintestinal diseases and syndromes. *Aeromonas* are mainly the cause of gastrointestinal syndromes, but they have been also described as causing other types of infections.

Aeromonas in gastroenteritis

The gastrointestinal tract is the most common site from which aeromonads are recovered. The colonization of the human gastrointestinal tract by aeromonads is most likely a result of the consumption of food and drinking water containing *Aeromonas* spp. In recent years, the incidence of gastroenteritis due to *Aeromonas* spp. has increased significantly, affecting all age groups in both industrialized and developing nations. In industrialized countries, the frequency of *Aeromonas* in stool samples has been reported to be between 2.2% and 10%. The results recently obtained by Global Enteric Multicenter Study to identify the etiology and population-based burden of pediatric diarrheal disease in developing countries report *Aeromonas* as a common cause of diarrhea in children younger than 5 years in Pakistan and in Bangladesh.

Aeromonas infections of the gastrointestinal tract can lead to five different settings, from nondescript enteritis to more severe forms accompanied by bloody stools or chronic intestinal syndrome, traveler's diarrhea, or even cholera-like disease. The most common setting is the secretory enteritis, which has been reported to account for up to 89% of all cases of *Aeromonas* gastroenteritis. It includes fever and abdominal pain and in some cases also vomiting. The dysenteric form is more rare,

accounting for up to 22% of *Aeromonas* gastroenteritis. Moreover, there are several complications associated to *Aeromonas* gastroenteritis; they mainly include segmental colitis or the hemolytic uremic syndrome.

Despite all these data, *Aeromonas* is not officially considered a gastrointestinal pathogen, as a real proof of pathogenicity still lacks. To date, there is no animal model that can faithfully reproduce the *Aeromonas*-associated diarrheal syndrome, although many attempts have been made. However, several studies reported *Aeromonas* as the sole pathogen present in patients affected by gastroenteritis, but it was also found in the stools of 1–4% of asymptomatic individuals. Thus, their role in gastroenteritis is still problematic.

A hypothesis that seems to be the most reliable so far suggests the possibility that the pathogenicity of *Aeromonas* spp. relies on the presence of specific virulence factors in the genome and of particular conditions in hosts that favor the onset of the disease (i.e., immunocompromised patients and persons with hematologic cancers, tumors of the gastrointestinal tractor, and other underlying pathological anomalies of the alimentary canal).

Other infections

Aeromonas spp. are also associated with a variety of skin and soft tissue infections, mainly as a consequence of direct contact with contaminated water and traumatic injuries. In terms of incidence, wound infections are much less frequent than gastroenteritis and, while the overall incidence of *Aeromonas* infections in United States was ~10 per million (when reported), wound infections were estimated to be 0.7 per million. The manifestations range from mild infections of the subcutaneous tissues (cellulitis), which represent the most common symptom, to serious conditions affecting deeper tissues (necrotizing fasciitis and myonecrosis). *Aeromonas* infection was also associated with the use of medicinal leech therapy that mainly causes cellulitis. *Aeromonas* species were recognized as important pathogens in natural disaster situations; they were isolated in high concentrations (10^6–10^7 CFU ml^{-1}) after both the hurricane Katrina in New Orleans and the tsunami in Thailand in 2004.

Another disease form associated with *Aeromonas* infections is septicemia. The vast majority of cases are seen in persons who are severely immunocompromised or have underlying complications such as diabetes mellitus, renal problems, cardiac anomalies, and other hematologic conditions. However, some cases of septicemia caused by *Aeromonas* in healthy persons have been described. The most common symptoms include fever, jaundice, abdominal pain, septic shock and dyspnea. *Aeromonas* septicemia is mostly caused by traumas and direct contact with microorganisms through wounds, and, in some instances, it was associated with leech therapy. As a matter of fact, leeches harbor aeromonads symbiotically and their use in therapeutic procedures may cause infections. Currently, it is not possible to clinically distinguish *Aeromonas* bacteremia from those caused by other gram-negative bacteria such as *Escherichia coli* or *Klebsiella pneumonia*. However, a peculiar indicator of *Aeromonas* infection is the presence of ecthyma gangrenosum-like lesions in the form of petechiae or bullae.

Aeromonads are also recognized as causing intra-abdominal diseases such as peritonitis and infections of the hepatobiliary and pancreatic systems. In Southeast Asia, *Aeromonas* is the third most common gram-negative cause of peritonitis. The peritonitis caused by *Aeromonas* results mainly from extensions of infections from the biliary or gastrointestinal tract. However, the source of infections is unclear in most cases, with few medical histories suggesting an environmental origin.

Aeromonas have been associated with respiratory tract infections, not only mainly pneumonia but also with cases of empyema. The main cause was the presence of near-drowning events involving seawater and other massive aquatic exposures. Again, the presence of underlying syndromes has often been reported

Finally, *Aeromonas* species have been occasionally implicated in eye and urogenital tract infections.

Pathogenicity

As already discussed, it is presently unclear whether aeromonads can be considered proper pathogens. An animal model of infection is lacking and the attempts made to reproduce the illnesses were unsuccessful. In addition, the microbial factors responsible for the onset of the diseases are still unknown and their identification is even more clouded by the widespread presence of genes potentially implicated in microbial infections throughout the genomes of most *Aeromonas* species.

To shed light onto the role of *Aeromonas* in gastroenteritis, the use of putative gene markers for pathogenicity has been widely applied to characterize strains from different food origins (Table 2), but their presence is still only indicative of potential virulence.

The species involved in the vast majority of systemic infections in humans are *A. hydrophila*, *A. caviae*, and *A. veronii*; however, recent environmental studies extended the knowledge of 'human-related' *Aeromonas* to other taxa, including *A. jandaei* and *A. enteropelogenes*. Moreover, an ecological and genetic link has been found between species isolated from food matrices and human cases of diseases. Thus, if initially the main cause of *Aeromonas* infection was considered to be just the aquatic environment, now, the connection between human infections and the ingestion of contaminated food seems to become a more common scenario. The adaptation to specific habitats may suggest that the infectious process involves, at least in part, selection of species (or strains) with certain characteristics that favor infections. However, this has not been demonstrated so far. One of the problematic issues in understanding the pathogenicity of *Aeromonas* concerns the fact that this genus produces an impressive array of virulence factors and also the lack of consensus on standardization of terminology regarding these factors between different research groups. *Aeromonas* spp. produce several extracellular products that fall into several broad categories, including cytolytic toxins with hemolytic activity, cytotonic enterotoxins, hemolysins, lipases, proteases, leukocidins, phospholipases, fimbriae or adhesins, and the capacity to form capsules.

Several classes of genes have been identified that play important roles in the colonization of the leech digestive tract, including bacterial cell surface modifications, regulatory factors, nutritional elements, and genes involved in the secretion system

(SS) (such as T2SS and T3SS). *Aeromonas* spp. produce a wide range of proteases, which cause tissue damage and aid in establishing an infection by overcoming host defenses and by providing nutrients for cell proliferation. Lipases secreted by *Aeromonas* may also constitute virulence factors by interacting with human leukocytes or by affecting several immune functions through fatty acids generated by lipolytic activity. Two factors thought to play intimate roles especially in the colonization of gastrointestinal tract are flagella and pili. *Aeromonas* produces two types of flagella, a constitutively expressed polar flagellum (Pof) and multiple inducible lateral flagella (Laf), which are, respectively, involved in the initial attachment of bacteria to the gastrointestinal epithelium and in cell adherence, long-term colonization, and biofilm formation. Biofilm development may also be regulated by quorum sensing that appears to act in concert with T3SS to regulate the expression of the *Aeromonas* enterotoxins, as its production increases when bacterial cell density increases. The cytotonic enterotoxin Act/Asa is a pore-forming toxin, also known as aerolysin AerA: it was originally recovered from a diarrheal isolate of *A. hydrophila* and was subsequently determined to possess a variety of biological activities, including hemolysis, cytotoxicity, and enterotoxicity, and to cause lethality in mice. While it is clear that Act induces extensive host cell signaling (it stimulates proinflammatory responses by increased cytokine production through elevated tumor necrosis factor, IL-1β and IL-6 levels), it is unknown how the toxin exerts the effects. Another well-characterized toxin (AHH1) belongs to the family of β-hemolysins and has a high sequence homology to the HlyA hemolysin of *Vibrio cholerae*. These toxins are also named Act- and aerolysin-like molecules and are enterotoxigenic cytolysins. Many *Aeromonas* strains possess a surface layer (S-layer), which resists complement-mediated killing of the organism by impeding complement activation. It seems that the set of bacterial virulence factors and host responses that eventually lead to *Aeromonas*-associated diseases are ill-defined. Regarding gastrointestinal diseases, aeromonads can apparently produce diarrhea by elaboration of enterotoxigenic molecules and/or by invasion of the gastrointestinal epithelium. At least two cytotonic toxins have been identified: a heat-labile cytotonic enterotoxin (Alt) and a heat-stable cytotonic enterotoxin (Ast). Invasins have also been reported, but they are difficult to detect *in vitro*; some studies suggested that only a fraction of *Aeromonas* strains are invasive and the degree of invasion is considerably less than the observed for classic enteropathogens, such as *E. coli* and *Yersinia enterocolitica*. The gene encoding enolase was also found in *A. hydrophila* strains recovered from stools. Enolase is a glycolytic enzyme whose surface expression was shown to be important in the pathogenesis of *Streptococcus pyogenes*-associated rheumatic fever. It has been suggested that the surface expression of enolase occurs only in gram-positive bacteria, while other researchers have demonstrated the ability of this protein to bind human plasminogen, potentially indicating an important role during *Aeromonas* infections. The T3SS includes several factors with multiple biological functions, and the gene AexT, a homologue of *Pseudomonas aeruginosa* T3SS-secreted ExoT/S, was detected in some *Aeromonas* isolates, but no information is available on its role in bacterial virulence using *in vivo* models. Another well-known T3SS gene is *ascV* that codes for an inner-membrane component of the T3SS channel.

TagA has been described as a new virulence factor found in an *A. hydrophila* isolate from diarrhea and only present in pathogens as *E. coli* O157:H7 and *V. cholerae*; its role seems to be related to the inhibition of the classical complement-mediated lysis of the erythrocytes but, even in *V. cholera*, its function in pathogenesis is speculative.

There are a large number of unresolved questions regarding the role of the potential virulence factors in *Aeromonas* infections. Some genes, such as *act*, are also found in species that are infrequently associated with human diseases (*A. bestiarum*). Moreover, research on *Aeromonas* pathogenicity demonstrated the enormous complexity of the situation involving polygenic expression in both the pathogen and the host. Thus, there is still much to be learned about *Aeromonas* virulence determinants and how they combine to result in the virulent subsets within each *Aeromonas* species that causes disease. At present, it is not possible to identify the disease-causing strains because of the incomplete understanding of *Aeromonas* virulence mechanisms.

Aeromonas and Antimicrobial Susceptibility

A particularly interesting area that is receiving more attention in the last years is the susceptibility of *Aeromonas* to antimicrobial agents. The studies regarding this topic reported data on the three major species associated with human disease, *A. hydrophila*, *A. caviae*, and *A. veronii*, so we do not know yet if the available information is also valid for the other species.

The first studies recording the antibiotic susceptibility of *Aeromonas* were conducted between the mid-1980s and mid-1990s. Inducible chromosomal β-lactamases are still the major resistance mechanism for most aeromonads, although their resistance to other antibiotics is dramatically increasing. Upon characterization of the antimicrobial resistance of 94 *Aeromonas* isolates from warm- and cold-water ornamental fish species using microarray analysis and conventional PCR, a surprisingly high level of antimicrobial tolerance was identified in the strains tested. Half of the *Aeromonas* spp. isolates were tolerant to more than 15 antibiotics, representing seven or more different classes of antimicrobials. The quinolone and fluoroquinolone resistance gene was detected at high frequency, although it has been reported that *Aeromonas* strains are almost universally susceptible to fluoroquinolones. Resistance has been also observed to carbapenems, imipenem, chloramphenicol, and florfenicol. Moreover, tetracyclines were particularly widespread across all screened isolates.

The discovery of multidrug resistance in strains isolated from wild shellfish in the Adriatic Sea suggests an involvement of *Aeromonas* in the dissemination of antibiotic resistance in the environment and in seafood. The susceptibility status of *Aeromonas* isolates for therapeutically active drugs appears to be independent of species designation. While some species-specific susceptibility differences have been found, these results should be considered preliminary at present. Moreover, no connection between a specific resistance pattern and the origin of isolation has been identified so far. Certainly, more studies need to be performed in this area.

Conclusions

After more than a century from its discovery, the *Aeromonas* genus is still intricate. Indeed, great improvements have been made in the last years, as molecular genetics have led to considerable advantages in the taxonomic determination of these bacteria, which was one of the most controversial issue of the genus. Moreover, the ecology and the mechanisms of environmental adaptation have been tackled, identifying a genetic adaptation process of *Aeromonas* species toward specific habitats. However, the image of *Aeromonas* as a human pathogen is still blurred, as no evidences of a clear association exist. There is still much to be learnt about *Aeromonas* pathogenicity and virulence determinants and how they combine to result in disease, but the advent of next-generation techniques and the possibility to analyze and combine massive amounts of data make us believe it is likely to happen.

Discovery and Exposure to Aflatoxin

The aflatoxins were discovered in the early 1960s, when they were identified as causative agents of 'turkey X' disease, an epidemic involving deaths of thousands of young turkeys, ducklings, and chicks fed with diets containing certain lots of peanut meal originating in South America. Careful investigations revealed that toxicity was associated with the presence of the common spoilage mold *Aspergillus flavus* and further that extracts of cultures of the fungus isolated from toxic meal were capable of inducing the toxicity syndrome. The name 'aflatoxin' was accordingly assigned to the toxic agents. Subsequent studies on extracts of *A. flavus*-contaminated groundnut meal confirmed that these agents were capable of inducing acute liver disease in ducklings and liver cancer in rats. Detection of aflatoxins in extracts of contaminated peanut meal was facilitated by their intense fluorescence in ultraviolet light, and soon thereafter, purified metabolites with identical physical and chemical properties were isolated from *A. flavus* cultures. Structural elucidation of aflatoxin B_1 was accomplished and confirmed by its total synthesis in 1963. Development and application of fermentation technology for production of substantial quantities of aflatoxins led to the availability of purified compounds, which in turn enabled extensive investigations into their toxicology and relationships to human diseases ranging from acute liver damage to liver cancer. As a result, to date, the aflatoxins represent a limited group of ubiquitous and structurally identified environmental carcinogens for which quantitative estimates of human exposures have been systematically sought and risk assessments carried out. These efforts have produced well over 10 000 scientific publications to date, dealing with all aspects of the problem. Collectively, available data led the International Agency for Research on Cancer (IARC) to classify aflatoxins as a category I known human carcinogen. Recently, IARC published an updated monograph outlining public health-based methods that could be applied in different societies to control aflatoxin contamination and reduce human exposures.

Chemically, the aflatoxins are highly substituted coumarins containing a fused dihydrofurofuran moiety (Figure 1). Aflatoxins B_1 and B_2 (AFB_1 and AFB_2) were so named because of their strong blue fluorescence in ultraviolet light, whereas aflatoxins G_1 and G_2 (AFG_1 and AFG_2) fluoresced greenish yellow. These properties facilitated the very rapid development in the early 1960s of methods for monitoring grains and other food commodities for the presence of the toxins. AFB_1 and AFG_1 possess an unsaturated bond at the 8,9 position on the terminal furan ring, and future studies demonstrated that epoxidation at this position was critical for their carcinogenic potency. AFB_2 and AFG_2 are essentially biologically inactive unless they are first metabolically oxidized to AFB_1 and AFG_1 *in vivo*.

Human populations are exposed to aflatoxins by consumption of foods on which strains of *A. flavus* or *A. parasiticus* have grown during harvest or storage. In general, diets may contain AFB_1 and AFB_2 in concentration ratios of 1.0:0.1, and when all four aflatoxins occur, AFB_1, AFB_2, AFG_1, and AFG_2 proportions of 1.0:0.1:0.3:0.03 exist. Grains and foodstuffs found to be contaminated with aflatoxins include corn, peanuts, milo, sorghum, copra, and rice. While contamination by the molds may be universal within a given geographic area, levels of aflatoxins in the grain product can vary from less than 1 $\mu g\ kg^{-1}$ (1 ppb) to greater than 12 000 $\mu g\ kg^{-1}$ (12 ppm). Indeed, in a recent outbreak of aflatoxin-induced death of people in Kenya, the daily ingestion of AFB_1 was estimated to be 50 mg per individual.

The present action-level guideline for seizure of aflatoxin-contaminated agricultural commodities in the United States is 20 µg total aflatoxins/kg (20 ppb). However, in Europe and Japan, aflatoxin limits in foods and feeds are lower, ranging from detection limit to 10 ppb. The US Food and Drug Administration (FDA) has also set a practical action guideline of 0.5 µg aflatoxin M_1 (AFM_1) per liter (0.5 ppb) for fluid milk based in part on the demonstration that AFM_1 was about tenfold less carcinogenic than AFB_1 in rats. In recent years, based on epidemiological data, much lower tolerances for aflatoxin exposures have been advocated for people who are hepatitis B virus carriers.

Aflatoxin Carcinogenesis and Metabolism

The carcinogenic potency of AFB_1 has been well established in many species of animals, including rodents, nonhuman primates, and fish. The liver is consistently the primary target organ affected and the toxin induces a high incidence of hepatocellular carcinoma (HCC). Additionally, under certain circumstances, depending on animal species and strain, dose, route of administration, and dietary factors, significant numbers of tumors have been found at other sites, such as the kidney and colon. Indeed, no animal species has been shown to be completely resistant to aflatoxin-induced carcinogenesis. Wide cross species potency, including sensitivity of nonhuman primates, provided the initial experimental basis for proposing that this agent would contribute to human cancer.

The high experimental potency of AFB_1 provided an impetus for research to characterize the metabolism of AFB_1 and to elucidate underlying molecular mechanisms of tumor initiation by this compound. Metabolic products that have been identified are summarized in Figure 2. Aflatoxin–DNA and aflatoxin–protein addition products (adducts) have been of particular interest because they are direct products of (or

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00015-5

surrogate markers for) damage to critical cellular macromolecular genetic targets. Metabolic pathways for the formation and chemical structures of the major aflatoxin macromolecular DNA and protein adducts have been elucidated and are shown in Figure 2. The finding that the major aflatoxin–nucleic acid adduct AFB_1–N^7-guanine was excreted in the urine of exposed rats spurred interest in exploiting this metabolite as a biomarker of exposure and risk. The serum aflatoxin–albumin adduct was also employed as a biomarker of exposure. The longer half-life *in vivo* of the albumin adduct as compared with the urinary DNA adduct reflects exposures over longer time periods, and subsequent studies in experimental models have shown that levels of aflatoxin–DNA adducts in liver, excretion of the urinary aflatoxin–guanine adduct, and levels of serum albumin adduct are highly correlated. Collectively, these data led to the application of these aflatoxin metabolites as biomarkers of human exposure and risk (Figure 3).

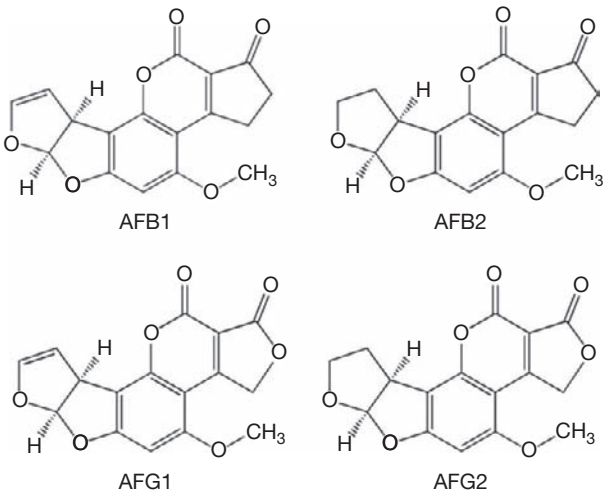

Figure 1 Structures of the four major aflatoxins.

Human Liver Cancer and Aflatoxin

Collectively, liver cancer, including HCC, accounts for 5.7% of all reported cancer cases and is the sixth most common cancer diagnosed worldwide. Globally, the incidence of liver cancer varies enormously, and the incidence of this fatal disease is much higher in economically less-developed countries of Asia and sub-Saharan Africa. Nearly 700 000 new cases and over 300 000 deaths occur annually in the People's Republic of China (PRC) alone. In contrast to most common cancers in the economically developed world, where over 90% of cases are diagnosed after the age of 45, in high-risk regions for liver cancer, onset begins in both men and women by 20 years of age, peaking between 40 and 49 years of age in men and 50 and 59 years in women. The earlier onset of HCC might be attributable to exposures that are both substantial and persistent across the life span. Gender differences in liver cancer

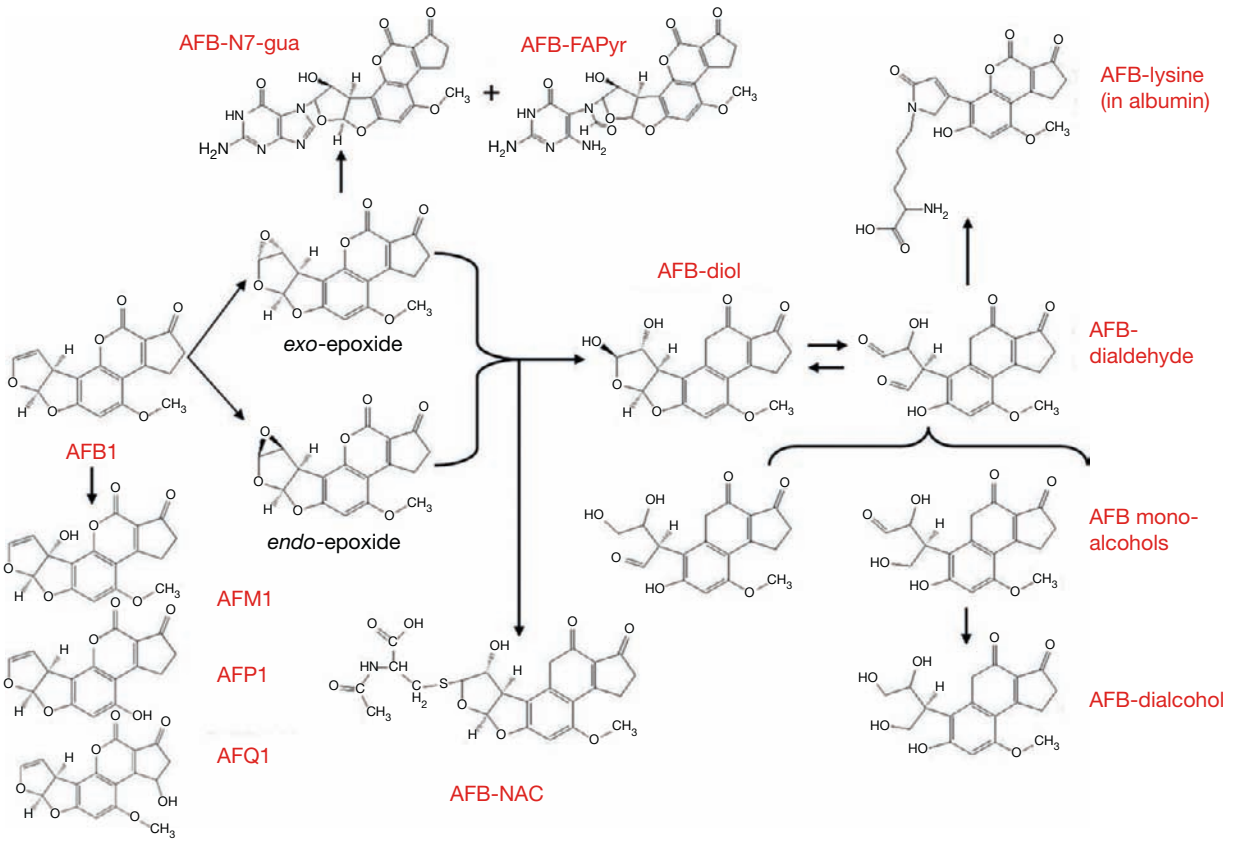

Figure 2 Major metabolites of aflatoxin B_1.

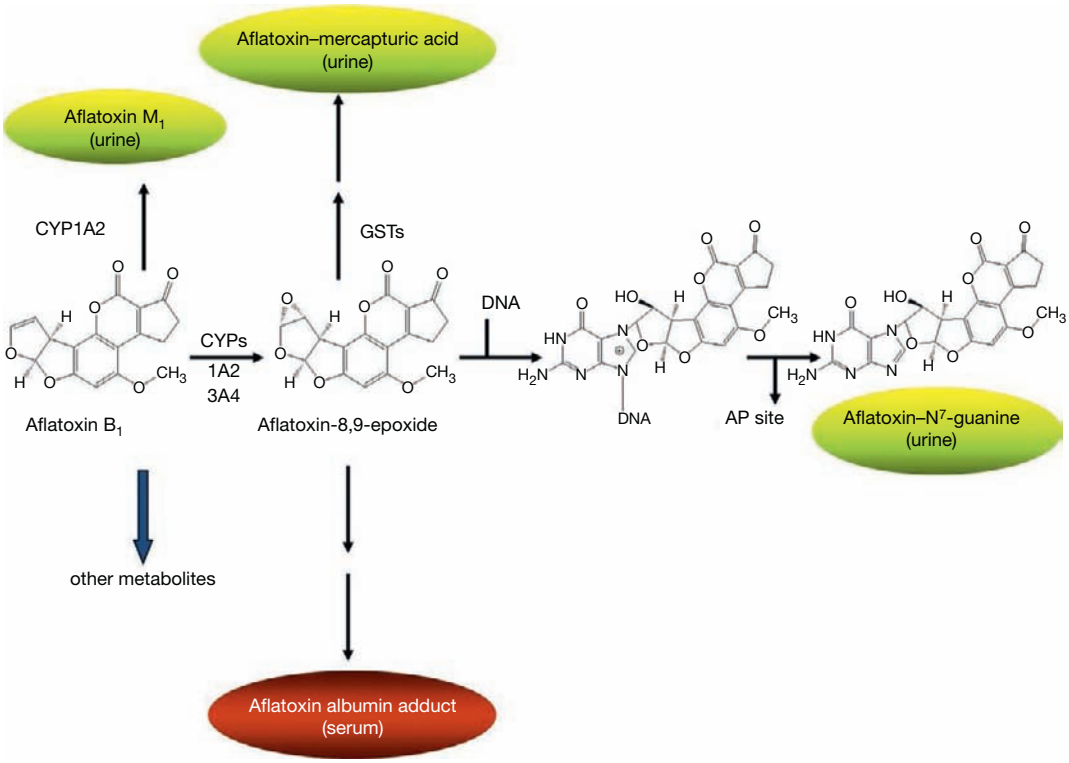

Figure 3 Aflatoxin metabolites used as biomarkers of exposure and risk.

incidence have also been described; the worldwide annual age-standardized incidence rate among men is 15.8 per 100 000 and 5.8 per 100 000 among women. These epidemiological findings are also consistent with experimental animal data, in which male rats have been found to have an earlier onset and higher tumor incidence than female animals of aflatoxin-induced liver tumors.

To date, two major cohort studies incorporating aflatoxin biomarkers have clearly demonstrated the etiologic role of this carcinogen in HCC. The first study, comprising over 18 000 men residing in Shanghai, examined the interaction of HBV and aflatoxin biomarkers as independent and interactive risk factors for HCC. The nested case-control data revealed a statistically significant increase in the relative risk (RR) of 3.4 for those HCC cases in whom a urinary aflatoxin biomarker (AFB_1–N^7-guanine) was detected. In men whose serum was HBsAg-positive but whose urine did not indicate aflatoxin exposure, the RR was 7, but in individuals exhibiting both urinary aflatoxin marker and positive HBsAg status, the RR was 59. These results strongly support a causal relationship of both biomarkers and the risk of HCC, as well as strong synergy between the presence of aflatoxin and viral-specific biomarkers and HCC risk.

Subsequent cohort studies in Taiwan have substantially confirmed the results from the Shanghai investigation. Wang et al. examined HCC cases and controls nested within a cohort and found that in HBV-infected people, there was an adjusted odds ratio of 2.8 for detectable compared with nondetectable aflatoxin–albumin adducts and 5.5 for high compared with low levels of aflatoxin metabolites in urine. In a follow-up study, there was a dose–response relationship between urinary AFM_1 levels and risk of HCC in chronic HBV carriers. As in the Shanghai cohort, HCC risk associated with AFB_1 exposure was most striking among HBV carriers with detectable AFB_1–N^7-guanine in urine.

Thus, these cohort data from two different populations demonstrate the power of validated aflatoxin biomarkers to define a previously unrecognized chemical–viral interaction in the induction of human HCC. These findings have significant public health implications. First, vaccination to prevent HBV infection will substantially ameliorate a major risk factor for HCC. Unfortunately, in most parts of the world, HBV infection is acquired before 3 years of age; consequently, worldwide elimination of HBV infection by vaccination will require much of the next century to accomplish. Second, minimizing aflatoxin exposure would also significantly reduce HCC risk. This goal could be attained through available technologies, and dose–response data from epidemiological studies indicate that, in a manner similar to reduction of lung cancer risk through smoking cessation, minimization of aflatoxin exposure during an individual's lifetime should reduce risk of HCC.

A recent report demonstrates that in China, the impact of agricultural reforms in the 1980s led to diminished maize consumption and that this change has had a major impact on PLC primary prevention. In Qidong, China, a population-based cancer registry was used to track PLC mortality, which was compared with the timeline of HBV immunization. More than 50% reductions in PLC mortality rates occurred across birth cohorts from the 1960s to the 1980s for Qidongese younger than 35 years, although all were born before universal vaccination of newborns began. Levels of aflatoxin biomarkers were determined in randomly selected archived serum samples

collected from subject cohorts from the 1980s to 2013. Median levels of the aflatoxin–albumin adduct biomarker decreased from 19.3 pg mg^{-1} albumin in 1989 to undetectable (<0.5 pg mg^{-1}) by 2009. A population-attributable benefit of 65% for reduced PLC mortality was estimated to result from a government-facilitated change of dietary staple from maize to rice; 83% of this benefit occurred in those infected with HBV. Thus, food policy reforms in China resulted in a dramatic decrease in aflatoxin exposure, which, independent of HBV vaccination, substantially reduced liver cancer risk.

Aflatoxin and *p53* Mutations

The relationship between aflatoxin exposure and development of HCC has been further highlighted by molecular biological studies on the *p53* tumor suppressor gene, the gene most commonly mutated in many human cancers. Many studies of *p53* mutations in HCC occurring in populations exposed to high levels of dietary aflatoxin have found high frequencies of G:C to T:A transversions, with clustering in the third base of codon 249.

Results from previous mechanistic studies showed that AFB_1-induced almost exclusively guanine to thymine transversions in bacteria and that aflatoxin-8,9-epoxide could bind to codon 249 of *p53* in a plasmid *in vitro*. Further, mutagenesis of the *p53* gene in human HepG2 cells and hepatocytes exposed to AFB_1 and found preferential induction of the guanine to thymine transversion in the third position of codon 249. A further study has mapped AFB_1 adduct formation to codon 249.

Additional experimental data support the role of aflatoxin as a generator of the codon 249 mutation. The primary DNA adduct of AFB_1 is AFB_1–N^7-guanine, which in double-stranded DNA is readily converted into two secondary lesions, an apurinic site and an AFB_1–formamidopyrimidine (AFB_1–FAPY) adduct. AFB_1–FAPY is detected at near maximal levels in rat liver DNA days to weeks after AFB_1 exposure, underscoring its persistence *in vivo*. Experimental mutagenesis studies revealed two striking properties of this DNA adduct: (i) $AFB(_1)$–FAPY was found to cause a G to T mutation frequency in *Escherichia coli* approximately six times higher than that of AFB_1–N^7-guanine, and (ii) one proposed rotamer of AFB_1–FAPY was a block to replication, even when the efficient bypass polymerase MucAB was used by the cell. Taken together, these characteristics make the FAPY adduct a prominent candidate for inducing both the genotoxicity of aflatoxin, since mammalian cells have similar bypass mechanisms for combating DNA damage, and mutagenicity that ultimately may lead to liver cancer.

In summary, studies of the prevalence of codon 249 mutations in HCC cases from patients in areas of high or low exposure to aflatoxin suggest that a G:C to T:A transversion at the third base is associated with aflatoxin exposure and *in vitro* data support this hypothesis. A majority of codon 249 mutations are found in liver tumors of patients infected with HBV, implicating an association. In comparisons of codon 249 mutations in regions of high HBV infection but varying levels of AFB_1 exposure, the mutation only occurs in areas of high AFB_1 exposure. HBV evidently plays an important role in mutagenesis, perhaps by causing preferential selection of cells harboring the mutation. Interpretation of the codon 249 mutation as a marker of aflatoxin exposure to aflatoxin must be done with caution until evidence has been obtained from studies measuring both AFB_1 adducts and mutations in the same individual. However, in general, available experimental data strongly support the findings of cross-sectional epidemiological studies indicating that AFB_1 is an important etiologic factor for HCC.

As illustrated earlier, detection of specific *p*53 mutations in HCC tumors has provided valuable insight into the etiology of primary liver cancer. Application of these specific mutations as biomarkers for early detection also offers great promise for HCC prevention. In a seminal study, Kirk et al. reported for the first time detection of *p*53 codon 249 mutations in plasma of liver tumor patients residing in the Gambia; however, the mutational status of their tumors was not determined. These authors also reported the presence of this mutation in the plasma of a small number of cirrhosis patients. Given the strong relationship between cirrhosis and future development of HCC, the possibility of this mutation serving as an early detection marker merits further exploration. Jackson et al. compared results obtained with short oligonucleotide mass analysis of plasma DNA with results of sequencing of DNA from 25 HCC tumors for specific *p*53 mutations. Mutations detected in plasma samples were in agreement with those found in HCC DNA by DNA sequencing. Jackson et al. further explored the temporality of detection of this mutation in plasma before and after clinical diagnosis of HCC in the same patient. This study was facilitated by availability of longitudinally collected plasma samples from a cohort of 1638 high-risk individuals in Qidong, PRC, who have been followed since 1992. Sixteen patients diagnosed with liver cancer between 1997 and 2001 from which plasma samples had been collected before and after HCC diagnosis were selected for study. Results showed that in samples collected prior to liver cancer diagnosis, 21.7% of the plasma samples had detectable levels of the codon 249 mutation, with a 95% confidence interval of 9.7–41.9%. The persistence of this prediagnosis marker was borderline statistically significant ($P = 0.066$, two-tailed). The codon 249 mutation in *p*53 was detected in 44.6% of all plasma samples following the diagnosis of liver cancer with 95% confidence intervals from 21.6% to 70.2%. This level of positive samples following liver cancer diagnosis compares with about 50% of all liver tumors in Qidong, suggesting a nearly 90% concordance between plasma and tumor *p*53 codon 249 mutation outcome. Further, persistence of this mutation in plasma once it became measurable was statistically significant ($P = 0.024$, two-tailed) in repetitive samples following diagnosis. Collectively, these data suggest that in nearly 50% of persons at high risk of HCC, this marker can be detected at least 1 year, and in one case 5 years, prior to diagnosis of clinical disease.

Children's Health

While much of the international focus on aflatoxin contamination has been framed within its carcinogenic properties, many of its other toxic effects can have both short- and long-term health consequences. In South Asia, where both maternal health status and child health status are seriously compromised, the potential effects of aflatoxin exposure are most

likely manifested in these noncarcinogenic end points. However, in the future, as early-life health status improves across this region, these potential cancer end points could become much more consequential for these populations. Nonetheless, when aflatoxin exposure is determined to be substantial, these data should be viewed as being a sentinel for overall poor quality of staple food commodities and nutritional status.

A number of studies, primarily in West Africa, have raised the potential etiologic contribution of aflatoxin to diminished child growth and development. Stunting has been calculated to affect nearly 200 000 000 children worldwide, primarily in sub-Saharan Africa and South Asia. Stunting has profound associations with a variety of growth and development deficiencies in these children; to date, the overall etiology of this problem remains obscure. Since aflatoxin has profound impacts on growth and development in a number of animal species, as has been well characterized in the veterinary literature, it is reasonable to hypothesize that similar growth and developmental effects can occur in humans. The first step in the exploration of this hypothesis will be to characterize exposures in specific high-risk communities. Aflatoxin albumin adducts, a biologically effective dose biomarker, provide an objective metric for characterizing these exposures for subsequent follow-up and potential intervention.

Summary and Perspectives for the Future

HCC is a slowly developing disease involving progressive genetic insults and their resulting genomic changes. HCC may not become evident before more than 30 years of chronic infection with HBV, HCV, and/or aflatoxin exposure. Chronic hepatitis and cirrhosis may develop only 5 years before HCC is evident; globally, 70–75% of all HCC is accompanied by cirrhosis. This genomic heterogeneity may be a reflection of different etiologies of HCC and their effect upon the molecular regulation of hepatocytes.

Over the past 25 years, the development and application of molecular biomarkers reflecting events from exposure to development of clinically recognizable disease have rapidly expanded our knowledge of the mechanisms of disease pathogenesis. These biomarkers will have increasing potential for early detection, treatment, interventions, and prevention. Biomarkers derived from toxicant/carcinogen metabolism include a variety of chemicals and their metabolites in body fluids and excreta, which serve as biomarkers of internal dose. Carcinogen macromolecular adducts such as DNA and protein adducts formed in blood and tissues or excreted in urine can be employed as specific biomarkers for various purposes: as biomarkers for exposure to assess human exposure to the complex mixture and occupational carcinogens, as biomarkers for biologically effective dose or early biological effect to measure the actual dose to the carcinogen target site, and as biomarkers for assessment of relationships between carcinogen exposure and eventual cancer formation.

The molecular epidemiology of aflatoxins and liver cancer produced one of the most extensive data sets in the field and should constitute a useful template for future investigations. Molecular biomarkers played a crucial role in this endeavor. Development of aflatoxin biomarkers required fundamental knowledge of their biochemistry and toxicology, gleaned from both experimental and human studies. These biomarkers were successfully utilized in experimental models to provide data on their modulation and in epidemiological investigations in humans under different situations of disease risk. This systematic approach demonstrates the potential power provides encouragement for preventive interventions and should serve as a template for the development, validation, and application of other biomarkers to cancer or other chronic diseases.

Agglomeration

A Bück and E Tsotsas, Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Agglomeration is a size enlargement process in solid process engineering and describes the formation of relatively large assemblies made out of smaller primary particles. The size of primary particles varies in typical application from a few nanometers to several millimeters; the size of the formed agglomerates ranges typically from several micrometers to several centimeters. Instead of agglomeration, the terms aggregation for the process and aggregate for the formed assemblies are used synonymously. In polymer technology, also the term coagulation is used to describe this size enlargement process. Although the physical mechanisms leading to the formation may be different, in all agglomeration processes, the total number of primary particles decreases gradually, whereas fewer but larger agglomerates are formed. This situation is depicted in Figure 1 for binary agglomeration where the agglomerates are built up by pairwise assembly of particles. It can be seen that the primary particles need not to be of the same size; they can also vary in other properties, for example, shape and material.

Agglomeration processes find widespread application in many industries, for instance, in food, mining, fertilizers, and detergents, and many unit operations, for instance, in mixing, pelletization, polymerization, sintering, and granulation. The main reasons for agglomeration of fine solid materials are the following:

- Improvement of flow behavior: Very fine particles tend to caking due to interparticle forces, which reduce their ability to flow. By agglomeration, these interparticle forces are overcome and the flow behavior is improved. In practical application, this results in easier dosing and conveying, for example, dosing of food powders like instant coffee or soup mixes in vending machines.
- Improvement of rewettability: By agglomeration, particles sink easier in liquid, which penetrates by capillary suction and can disintegrate the agglomerates to the original primary particles. In this way, the rewettability is increased and the so-called instant properties are created, which are essential for the use of food and beverage powders.
- Safety and health improvement: In many applications, hazardous dust, for instance, a toxic material, is formed. Depending on their size, particles may be airborne, becoming a danger to human or animal health if inhaled. Agglomerated dust is, however, no longer airborne and the danger of inhalation is reduced significantly. Also, the handling of the dust-free product is much easier due to the improved flow behavior. By agglomeration also, the danger of dust explosion, for example, in the handling of flour, is significantly reduced, reducing the necessary amount of safety installations at an operating plant.

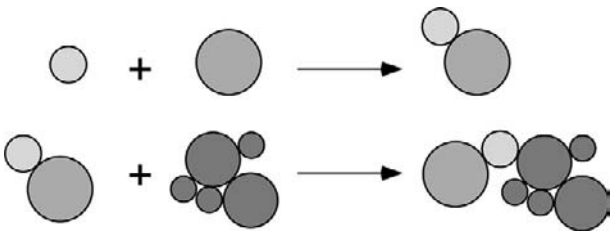

Figure 1 Scheme of binary agglomeration.

In many applications, the improved particle properties increase the economic value of the product, but agglomeration can also be an unwanted effect, for instance, in milling, screening, sifting, drying, transportation, or storage of solid materials.

Agglomeration is often accompanied by other processes, for instance, drying, depending on the formation process. Formation processes can be classified in different ways, for instance, in processes using a binding agent and processes without a binding agent.

Formation Processes

In all agglomeration processes, the particles have to come very close or in contact with each other (collision) for the individual formation mechanics to become active. The motion of the particles in an apparatus has therefore significant influence on the probability of an agglomeration event, that is, the successful formation of an assembly of particles.

Agglomeration with Binding Agent

In these processes, agglomeration is initiated by the formation of bridges between the primary particles made up of the binding agent, which is often sprayed onto the primary particles. The sprayed liquid spreads on the particle surface building up a film of a certain height and viscosity. The film needs not to cover the total surface area of the particle; discrete spots may also be sufficient. If on collision with another primary particle, the wetted area is hit and the kinetic impact energy can be absorbed by the liquid film and then a new agglomerate is formed, as none of the collision partners are able to rebound. The connection between the primary particles is established by a liquid bridge. The strength of the liquid bridges and the formed agglomerate depends on the viscosity of the liquid. The higher the viscosity, the higher the strength of the bridge and the higher the forces the agglomerate can withstand.

With increasing amount of liquid, the initially discrete liquid bridges will fully fill the interior voids between the primary particles until saturation. Capillary forces will then also contribute to the binding of the primary particles. If sufficient liquid is supplied, then the agglomerate can also be formed directly by immersion of primary particles in a liquid droplet, for example, dust in a rain droplet. The strength of the

agglomerate depends in this case on the surface tension of the liquid.

If the liquid contains also a solid material, either dissolved (solution) or dispersed (suspension), or is a melt (solid with a temperature larger than the melting temperature), then a solid bridge can be formed between the primary particles. The process is initially similar to the formation of liquid bridges: The binding agent is sprayed onto the particles and partially wets the surface area. If upon collision the kinetic energy can be absorbed, then a liquid bridge will form between the collision partners. In an additional step, the liquid from either the solution or suspension is removed, for instance, by evaporation, or the liquid melt is cooled below the melting temperature. In both cases, solidification of the bridge, possibly after a crystallization or precipitation process, will take place. In Figure 2, a scanning electron microscope picture of an agglomerate produced from glass beads by using a binding agent (hydroxypropyl methylcellulose (HPMC)) in a fluidized bed is shown, in which the solidified bridges are clearly visible. In the food industry, often, sugars, for example, glucose and maltodextrins, are used as binding agent to form solid bridges between the primary particles, for example, in the production of chocolate powder, instant coffee, or soup ingredients. The structure and morphology of the formed bridges depend significantly on the process conditions, for instance, the drying conditions under which the liquid is removed or the temperature profile for the cooling of the melt. In Figure 3, for the same material combination as in Figure 2 but different drying conditions, the formed solid bridges between the primary particles are shown. Whereas bridges solidified at low drying temperatures appear smooth and compact, bridges solidified at higher drying temperatures are visibly porous and fragmented, influencing their strength and the strength of the agglomerate as a whole.

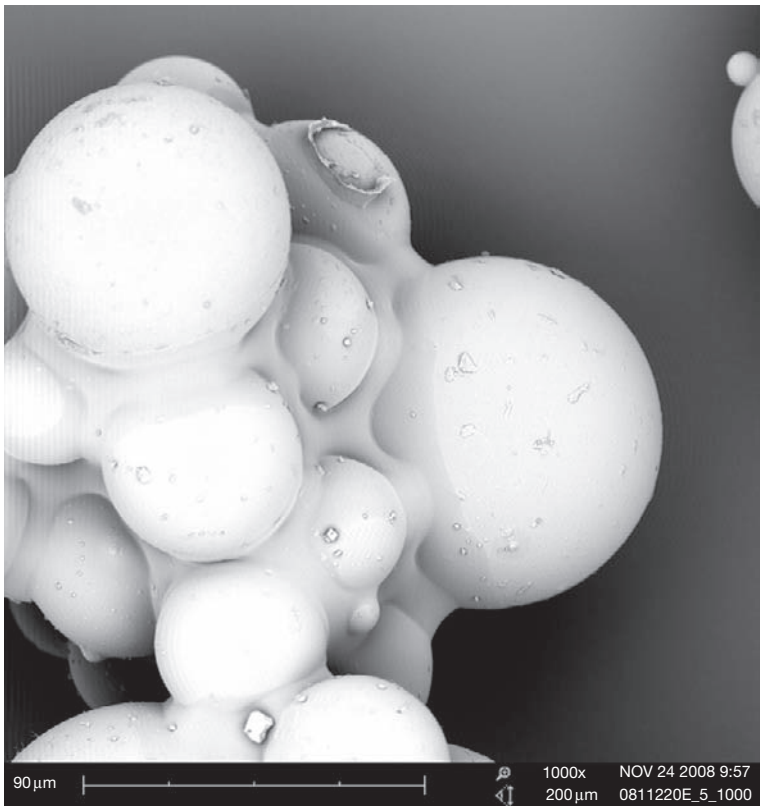

Figure 2 Agglomerate bound by solid bridges of a binding agent (glass, HPMC).

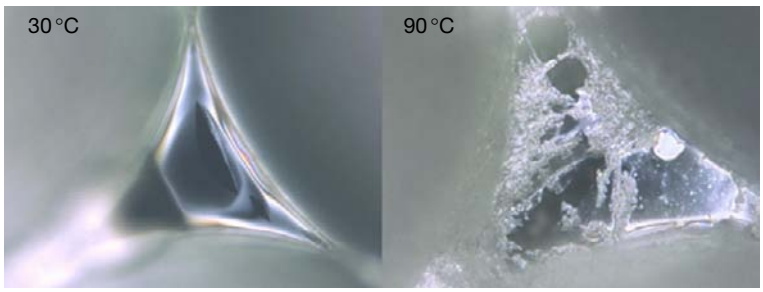

Figure 3 Differences in the structure of formed bridges due to different drying conditions.

Agglomeration Without Binding Agent

Agglomerates can be formed without a binding agent by molecular, electrostatic, or magnetic interparticle forces, by thermal effects and chemical reactions, or if the primary particles possess special surface structures that create the binding of the primary particles.

The main force acting on agglomerates from the millimeter scale upward is weight. For agglomerates and particles significantly below this size, molecular forces are dominating, as the influence of gravity decreases cubically with decreasing size. The most important among the molecular interparticle forces are the van der Waals forces, which are, for instance, for sizes of 1 μm, one million times stronger than gravity. Hence, such forces are significant in the formation of small agglomerates out of nanosized primary particles. The van der Waals forces are, however, only short-range forces, decreasing quadratically in intensity with increasing distance between two primary particles or agglomerates. A similar behavior is shown by adhesion forces, ionic or hydrogen bonds that also become only dominant for very small particles and are only active over very short ranges. Agglomerates bound by the van der Waals forces and other molecular forces can usually be broken by increasing the distance between the primary particles above a critical, material-dependent threshold, for instance, by mechanical stress.

Similarly, electrostatic forces and magnetic forces can lead to the formation of agglomerates. These too are short-range forces only effective on very small particles that are in close contact. Agglomeration due to these forces is considered unwanted in almost every application.

The group of formation processes by thermal effects consists mainly of

- sintering,
- partial melting,
- glass transition.

Sintering is a thermal agglomeration process that finds widespread application in ceramics and metallurgy for the production of solids with a predefined shape out of a powdery mixture of different ceramic or metallic components. The powder mixture is put into the desired shape and is heated, but the temperature of the mixture stays below the lowest melting temperature of the components. During heating, contacts between primary particles are transformed into solid bridges, the so-called sinter bridges, due to surface diffusion from both primary particles. The diffusion process aims at the minimization of surface energy during the formation of the bridges and the growth of the agglomerate. During this process, which can also be conducted under increased operating pressures, the volume of the mixture decreases significantly, that is, a compaction is achieved. The strength of the sintered agglomerate and many other properties can be influenced by the temperature profile used to control the sintering process. However, the compaction is generally not uniform, resulting in different agglomerate sizes and internal morphologies, which are two of the major drawbacks of sintering processes.

If a particulate material is heated to a solid temperature above the melting temperature of at least one of the components, a partial melting of the particles starting at the surface can be achieved. Upon collision of the particles with each other, liquid bridges are formed and kept in place by capillary forces if the collision energy can be absorbed. Cooling leads to solidification of the bridges and the formation of agglomerates. The necessary heat can either be supplied thermally or be released by friction or plastic deformation of the material. One particular application of this effect in food is in the production of whipped cream. Here, initially, solid fat particles begin to stabilize the air bubbles created by whipping. With increasing temperature, the solid fat particles melt partially at the surface, forming a cohesive and stable shell around the air bubble.

Glass transition of amorphous materials is an important thermal binding mechanism, especially in the food industry. In comparison with crystalline materials where the molecules, atoms, or ions are structured regularly on a grid, amorphous materials possess only a short-range order, that is, the molecules have the possibility to move inside the formed structure. This structure develops during the solidification of melts by cooling or in the case of solutions by evaporation of the solvent. The main reason is the increasing viscosity of the melt or solution and the decrease in agility of the molecules, which is further decreased by the movement of the neighboring molecules. The inner structure of the solidifying melt or liquid tends to the amorphous state, which is not thermodynamically stable but a kinetic-controlled equilibrium, that is, it depends on the process history.

Typical examples of amorphous substances in food are, for instance, maltodextrins, glucose, starch, milk powder, hydrolyzed fish protein, and vegetable pulp and powders. In the polymer industry, the important amorphous materials are, for instance, PVC, PET, PMA, and PE.

The main characteristic of amorphous substances is the glass transition. This effect takes place at a characteristic temperature, the glass transition temperature (T_g), at which the amorphous material transforms from its solid and brittle glassy state to a rubbery and viscoelastic state. This regime is bounded by the glass transition temperature from below and the melting temperature (T_m) of the solid from above. By increasing the temperature from the glass transition temperature to the melting temperature, the viscosity of the solid decreases, and it behaves increasingly like a fluid. As the diffusion coefficient depends inversely on the viscosity, the mobility of the molecules in the solid increases significantly above the glass transition temperature, amplifying chemical and enzymatic reactions. In the food industry, in order to extend the shelf life, products must therefore be stored below the glass transition temperature to avoid premature spoilage.

The glass transition temperature of a pure substance can be roughly estimated based on the knowledge of its melting temperature. For many practically important amorphous substances, the glass transition temperatures (in °C) typically range between

$$\frac{1}{2}T_m \leq T_g \leq \frac{2}{3}T_m$$

The glass transition temperature of a one-component system can be significantly changed by adding a plasticizer, which has a lower glass transition temperature than the component and thereby decreases the glass transition temperature of the mixture, or by adding a vitrifier, which has a higher glass transition

temperature and thereby increases the glass transition temperature of the mixture. Based on the mass fraction of the plasticizer in the mixture, the glass transition temperature typically behaves as shown in Figure 4. With increasing amount of plasticizer, the glass transition temperature of the mixture tends toward the glass transition temperature of the plasticizer.

If instead a vitrifier is added, then the initial component acts as a plasticizer, and the roles in the diagram have to be interchanged.

The glass transition temperature of a two-component mixture (amorphous solid and plasticizer) can be estimated based on the known glass transition temperatures of the two components, for instance, by the Gordon–Taylor equation:

$$T_g = \frac{wT_{g,p} + k(1-w)T_{g,s}}{w + k(1-w)}$$

In this equation, the subscript p denotes the plasticizer, s denotes the amorphous solid, and w denotes the mass fraction of the plasticizer in the blend; the parameter k is a mixture-dependent constant that has to be determined from measurements. In Table 1, the glass transition temperatures of various important amorphous materials in the food and polymer industries are presented. The given values correspond to the pure amorphous substance, that is, without any plasticizer. The values for the parameter k then correspond to one specific plasticizer, which is given in square brackets.

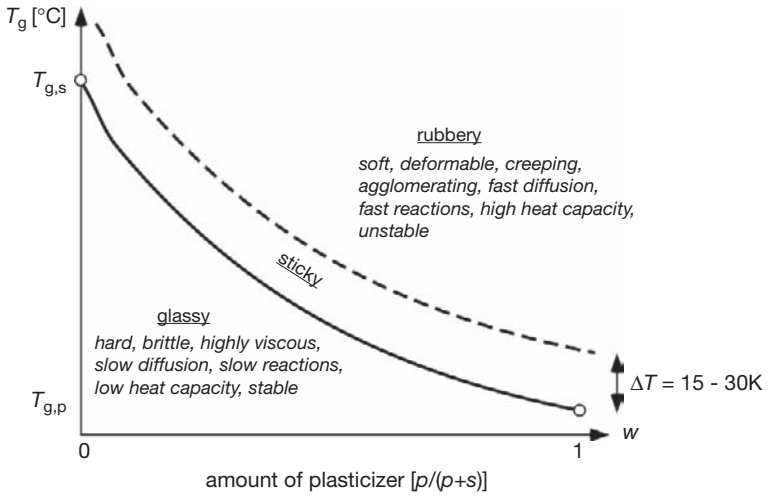

Figure 4 Diagram illustrating the glass transition phenomenon and the accompanying changes in material properties.

Table 1 Glass transition temperatures and Gordon–Taylor constants for selected food materials and polymers

Component	T_g (°C)	k	*Component*	T_g (°C)	k
Fructose [water]	5	3.8	Glucose [water]	31	4.5
Lactose [water]	101	6.7	Glucose [sorbitol]	32	0.464
Maltose [water]	87	6.2	Trehalose [sucrose]	114	0.56
Sucrose [water]	57	5.4	Polyethylene (PE)	−23	–
Maltodextrin DE 20 [water]	141	6.8	Polyvinyl chloride (PVC)	74	–
Maltodextrin DE 10 [water]	160	7	Polytetrafluoroethylene (PTFE)	127	–
Maltodextrin DE 5 [water]	188	7.7	Polyethylene terephthalate (PET)	69	–
Starch [water]	250	5.2	Poly methyl acrylate (PMA)	7	–
Water	−135	–	Poly methyl methacrylate (PMMA) [PMA]	105	0.65
Wheat flour [water]	128	–	Polyvinyl alcohol (PVA) [PE]	71	4.38
Whole milk powder [water]	101	8.6	Butyl methacrylate (BMA) [PMMA]	32	1.36
Tomato powder [water]	55	5.5	Styrene [MA]	107	0.9
Glycerol	−95	–	Polypropylene	−14	–

The Gordon–Taylor constant k refers to binary blends with the plasticizer given in square brackets, for example, [water].

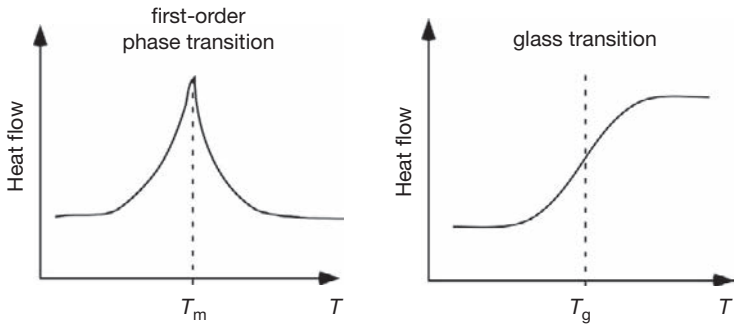

Figure 5 Detection of glass transition by differential scanning calorimetry (DSC). On the left-hand side, the change in measurement signal at the occurrence of a first-order phase transition, for example, melting, is illustrated. On the right-hand side, the change at the occurrence of glass transition is shown.

The glass transition temperature can be measured due to the fact that by glass transition, the values of many material properties change significantly, for instance, the specific heat capacity. This can be exploited, for instance, in differential scanning calorimetry where, given a specific cooling or heating rate (constant heat flow), the sample temperature is recorded. If glass transition occurs, then a stepwise change in the measured curves can be observed (Figure 5). The temperature at which this step is observed is the glass transition temperature. Its location may slightly depend on the cooling and evaporation rates, as glass transition is kinetically controlled.

The importance of glass transition in the food industry for the formation of agglomerates stems from the fact that liquid water is a powerful plasticizer with a glass transition temperature of $-135\,^{\circ}C$. Additionally, many amorphous food substances are water-soluble. If liquid water is sprayed onto a food powder, then the water integrates into the solid matrix of the amorphous material. It does not dissolve the structure as in crystalline solids but reduces the viscosity of the amorphous material, initially only at the surface of the particle. Important for application is the region where the solid temperature is $\sim 15–30\,K$ higher than the glass transition temperature as shown in Figure 4. On this curve, the viscosity is high enough that the material becomes sticky, that is, upon contact with another particle, a viscous bridge is established and an agglomerate is formed. In Figure 6, an example of agglomeration of a food powder by glass transition is shown. Water was sprayed onto maltodextrin (MD12) particles in a fluidized bed, and an agglomerate is formed without any binder. The sprayed water that initiates the formation is evaporated so that over process time, the glass transition temperature of the mixture increases again and the formation process stops. Agglomeration of water-soluble amorphous substances by glass transition is an important example of the simultaneous occurrence of particle formation and drying.

Knowledge of the glass transition temperatures can also be used to prevent the formation of agglomerates in solid processing, for example, in drying, for instance, by adding a vitrifier, such as corn starch, or by conducting the process at temperatures well below the glass transition temperature.

Chemical reactions can also lead to the creation of solid bridges between primary particles. The formation can be initiated by different components, for example, other liquids or gases in the apparatus, or by thermal conditions. Bonds created

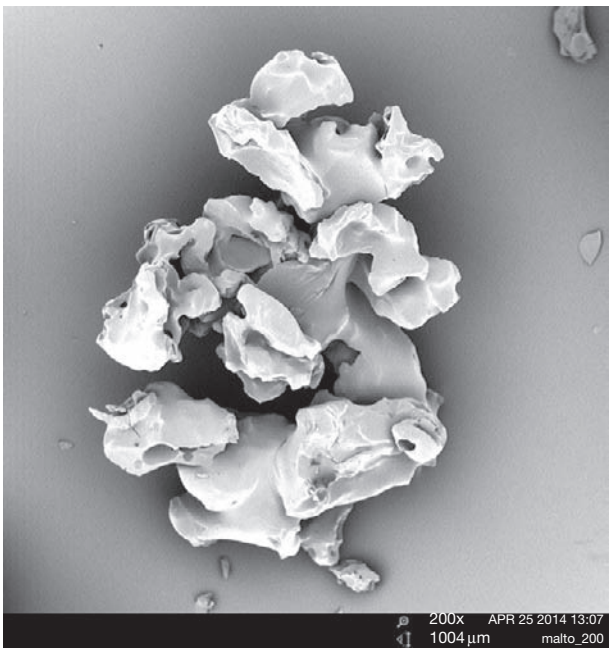

Figure 6 Agglomerate of maltodextrin (MD12), produced in a fluidized bed by glass transition using water as plasticizer.

by chemical reactions are usually very strong so that the formed agglomerates can withstand large external forces and do not break easily.

Agglomeration of particles can, moreover, be achieved by the interlocking of particle surfaces with a fibrous surface structure, for example, in felting. The strength of the agglomerate then depends primarily on the fiber length, the degree of interlocking, that is, the length of the fiber accessible for locking, and material properties, for example, the elasticity of the fibers.

Product Quality Aspects in Food Applications

By agglomeration of primary food particles by one of the described mechanisms, several application-related product properties can be modified: The optical and color appearance can be changed by varying the porosity of the formed agglomerates due to a change in light reflectance and scattering at the porous surface. This can be easily observed in cocoa powder,

which after agglomeration attains a dark brown color. The porosity of the agglomerates can also influence the shelf life of a product, for instance, in the encapsulation of antioxidants or flavors. The agglomerates build a layer around the antioxidant and can limit the oxidation. Additionally, it can also regulate the release of flavors and thus the taste intensity. Furthermore, porosity influences the rewettability of the agglomerated material, thus creating the instant behavior. However, it may occur that oils or fats migrate from the interior of an agglomerate to the surface, thereby reducing the wettability. A good wettability also poses the danger of stickiness, for example, by glass transition, forming insoluble lumps of the food powder. For the use in vending machines, a good flowability of food powders is required. This implies high agglomerate density and low porosity, which reduce the instant capabilities. The mouthfeel, which is, for instance, expressed by crunchiness, creaminess, or melting behavior, depends on various particle properties. The crunchiness can be related to the shape of the particles and to the required stress to break up the agglomerate in the mouth. The stress is applied to the agglomerate by the tongue (against the roof of the mouth) or the teeth. Similarly, the creaminess of a product, for example, thick soup, cream cheese, or ice cream, can be related to the agglomerate structure. The melting behavior, for instance, of dark chocolate, is reported to depend on particle size, with smaller size particles having a higher melting temperature. In order to produce a chocolate with a high melting point, fine particles may be preferred; however, simultaneously, the flow behavior and instant properties are reduced. In general, the product quality aspects in food are competing, and an importance ranking is necessary for each application.

Characterization of Agglomerates

Agglomerates can be characterized in many different ways, depending on the application requirements. Often, at least one of the following agglomerate properties is of interest:

- Size distribution
- Bulk density
- Porosity and pore size distribution
- Shape
- Flow behavior
- Strength, breakage, and attrition behavior
- Specific surface area
- Drying behavior
- Instant/rewettability behavior

These characteristics are not necessarily independent of each other, for instance, the specific surface area influences the instant behavior, but in many applications, only a few agglomerate properties dominate the product quality, very often the size distribution, bulk density, and agglomerate shape.

The size distribution of the produced agglomerates can be determined in various ways. The classical, standardized way is by using mechanical screens with defined gap widths. The screening process is often realized in a cascade of screens with decreasing mesh size, starting with the largest mesh size at the top of the screening tower. The size distribution is then determined from the mass fractions not being able to pass a screen with a certain mesh. Mechanical screening applies a considerable amount of mechanical stress on the agglomerates, for instance, due to the load of the screen, that is, the weight of other agglomerates, or movement of the screen, so that very brittle agglomerates may break during screening and introduce errors in the measurement of the size distribution.

The size distribution can also be determined by other measurement principles, for instance, by image-based techniques. Here, a thin free-falling curtain of agglomerates is created in front of a high-speed camera that records the fall and provides a sequence of two-dimensional projections of the three-dimensional agglomerates. By image processing, equivalent diameters, for instance, Sauter and Feret diameters, can be assigned to each projection and are used as representatives for size distribution.

Further measurement techniques, which are often used for the monitoring of an agglomeration process, are laser diffraction where the scattering of electromagnetic waves at the boundaries of an agglomerate is used to determine its size, focussed beam reflectance where the backscattering of the emitted light after having hit a particle and traveled on its surface is recorded and translated into a chord length, and spatial filter velocimetry where the size of an agglomerate is determined in the following way: Inside a measurement volume, a sequence of optical fibers with a known distance to each other is installed. These fibers are illuminated by laser light; agglomerates entering the measurement volume will subsequently pass and disrupt these rays. The total information of passing the whole set of optical fibers, which create pulse signals proportional to the velocity of the agglomerate, is used to determine a chord length of the agglomerate.

Bulk density is in many applications, especially if the handling or storage of agglomerates is involved, the second most important product characteristic. Bulk density is defined as the ratio of the mass of a randomly packed agglomerate sample to the occupied volume, incorporating the packing porosity. The porosity is closely linked to particle shape and size distribution, for example, for monosized spherical particles, the porosity of a random packing ranges between 0.38 and 0.42, but a polydisperse packing can have a significantly lower porosity. The porosity of a random packing of cylindrical objects depends heavily on the aspect ratio of the rods, allowing for a wide variety of bulk densities. Although the bulk density can be measured easily, it is quite difficult to influence directly in an agglomeration process due to the connection to other particle properties. The bulk density may be adjusted after the agglomeration process by screening the product and mixing with other agglomerate sizes.

Agglomerate shape has a large influence on the flow behavior of an agglomerate bulk. Whereas spherical agglomerates are mostly free-flowing, nonspherical agglomerates possess a reduced flowability due to the possible surface interaction. The particle shape can be measured using image-based probes where projection images of the agglomerate are taken. By image processing, the outer contour of the agglomerate is determined, and the sphericity, a measure of deviation from a sphere with, for instance, the same mean diameter, can be calculated.

The drying, rewettability, and instant behavior are closely connected to the inner morphology of the agglomerates. This morphology, characterized by the macroscopic porosity of the

agglomerates, that is, how much volume is occupied by the arrangement of primary particles, and the pore size distribution can be modified in the course of the agglomerate production process to achieve easy rewetting and a good instant behavior. The same is true for the drying of agglomerates by evaporation of liquid from their interior.

One way to investigate the inner morphology is by means of tomography, for instance, x-ray microcomputed tomography. Here, the agglomerate is subjected under different angles to a beam of x-rays, which are, after passing the agglomerate, detected. Based on the different x-ray absorption capacities of the constituents, for example, primary particles, binder, liquid, and air, two-dimensional projections of the inner morphology are obtained. These projections can be transformed into a three-dimensional representation of the agglomerate, and quantities of interest, for example, porosity, pore size, and fractal dimension, can be extracted via image processing and evaluation algorithms. The outer surface structure can be investigated by various methods, for instance, light microscopy, scanning electron microscopy, and confocal laser scanning microscopy. The latter can also be used to investigate the inner morphology of semitransparent materials of biological origin, such as food materials.

Agglomeration Equipment

To perform agglomeration on an industrial scale, many different apparatuses are available. Common in each design is that the particle bed is kept in movement to increase the probability of collision of primary particles. The means by which this particle movement is achieved differ, depending on the solid material, the formation process, that is, the active binding mechanism, and the product specifications. The throughput of the apparatuses can also vary significantly, from some kilograms per day to several hundred tons per hour.

In fluidized and spouted beds, which find widespread application in pharmaceutical, food, and, to some extent, fertilizer production, the initial powdery particle bed is subjected to a flow of heated gas, for instance, air, which yields a fluid-like, well-mixed behavior of the particles, the fluidized state. A binding agent or plasticizer, for instance, water, is sprayed from the top, from the bottom, or tangentially, and the particles are partially wetted. Due to the mixing, the particles collide and agglomerates are formed, for instance, by first establishing liquid bridges, which are then solidified by evaporation of the solvent by the heated gas flow. The intensity with which the agglomerate formation takes place depends not only on the amount of binding agent or plasticizer sprayed but also on the drying conditions, that is, the temperature and the mass flow rate of the fluidization gas. The mixing of the bed may improve at higher mass flow rate of fluidization gas, but simultaneously, the number of collisions and the mechanical stress on the agglomerates increase. The agglomerate size distribution of the product depends on the residence time and is a result of the apparatus design or implementation of the fluidized bed process. It can be performed in a single, cylindrical vessel, very similar to a continuously operated stirred tank reactor, with a very broad residence time distribution and final agglomerate size distribution, or in a cascade of single, rectangular vessels, called horizontal fluidized bed, which is similar to a plug flow reactor, yielding a narrow residence time distribution and more uniform agglomerate sizes. The latter configuration, implemented in one apparatus with weirs or baffles separating the individual vessels, can also be used for posttreatment, for instance, cooling or drying, in the same apparatus. The high flexibility of fluidized bed technology is however balanced by higher investment and operating costs as compared, for instance, with agglomeration in rotating drums. Fluidized and spouted beds are commonly used for the encapsulation of ingredients and instantizing of food powders, for example, tomato and cocoa powders, flour products, or baby foods.

Rotating drums are often used for agglomeration processes in fertilizer production, curing of ores, or concrete production. The dimensions of these cylindrical apparatuses can range up to several meters in diameter and hundreds of meters in length. The particle bed is mixed, inducing collisions, by a steady rotation of the drum. Depending on the process, a binding agent or substances initiating chemical reactions are sprayed or injected into the drum. Also, a pure thermal treatment of the solid is possible. By direct and indirect heating, temperatures well above 1000 °C can be achieved in rotating drums, realizing agglomerate formation by partial melting or sintering. Rotating drums are simple and robust apparatuses, which enable their use even under harsh environmental conditions. Due to differences in the residence time of the agglomerates in the drum, the resulting agglomerate size distribution is quite broad, necessitating a subsequent screening of the outlet of the drum and a partial recycle of the solid stream. The mechanical stress on the formed agglomerates in the drum depends, for instance, on the loading of the drum, the rotational speed, and the use of internal flights, which not only facilitate a better mixing of the bed but also exert a significant amount of stress on the agglomerates.

In high- and low-shear mixers, the primary particles and later agglomerates are moved by installed impellers, the speed of which can be manipulated externally, thus exerting high- or low-shear forces on the agglomerates. A binding agent is sprayed onto the particles and is distributed by the rotation of the impeller among them. The main formation process is the establishment of liquid bridges, which then solidify. Depending on the speed of the impeller and its geometric design, either quite compact and strong or rather porous and brittle agglomerates can be produced. A strengthening of the agglomerates can be achieved either by heating the particle bed directly or in a subsequent drying process. Low- and high-shear mixers find much application in the further processing of food powders, for example, created by spray drying, to improve the flow behavior and instant properties, for example, in dairy, the production of condiments, and flours. By the adjustment of the shear rate, the strength of the agglomerate can be influenced, which can be used to create a desired mouthfeel, as discussed in a previous section. Low- and high-shear mixers are also often used in the production of pharmaceutical intermediates before tableting.

Agglomeration in pans is similar to agglomeration in rotating drums, with the main difference that the particle bed is placed in a rotating, inclined disc, instead of a drum. The binding agent is again sprayed, usually from the top or

tangentially to the particle movement. The movement of the tray yields a segregation of agglomerates with respect to size, with smaller particles situated below the larger agglomerates. This results in a relatively uniform agglomerate size of the product so that a subsequent classification or screening of the solid stream at the outlet is not necessary.

Pressure agglomeration is an alternative if no liquid component is to be used in forming agglomerates. By increasing the pressure on the individual particles in a powdery bed, the interparticle space is reduced, and the number of contact points is increased. The van der Waals forces and sintering become dominant due to the plastic deformation of the contact points into attractive contact areas. A further improvement can be obtained by inserting a limited amount of binding agent, for instance, as a solid component. Agglomerates of high strength can be produced by pressure agglomeration; if the material behaves plastically, it becomes less efficient if the material is elastic. Pressure agglomeration is used in the food and feed industries, for instance, in the production of confectionery, flakes, pellets, or cereal bars.

In extruders, pressure agglomeration with additional heating is used to form agglomerates from a powdery plastic material, often some kind of plastic. Due to pressure and heating, a partial melting of at least one compound is achieved. This solid–liquid mixture is then pressed through a matrix, often made from steel or copper, producing strains of the agglomerated material, which are cut at the required length. The strength of the agglomerates can be improved by adding an additional binding agent; also, the viscosity of the mixtures directly at the matrix influences the strength of the agglomerate, so that by manipulation of the temperature, different product properties can be realized. Extruders are heavily used in food and feed, for example, for the production of pellets or various types of pasta. The strength of the formed extrudates, for instance, determines the cooking behavior of the pasta by controlling the water uptake and heat conduction in the material.

Equipment in which agglomeration is in most cases unwanted are

- screens,
- mills,
- spray dryers.

Agglomerate formation in screens and mills, which can result in a breakdown of the unit operation, is initiated by the load of the screen or the mill, the particle shape – which may lead to the interlocking and blocking of the transport – and the moisture content of the agglomerates. The latter is important in the milling operation: If agglomerates are surface-dry but contain a significant amount of moisture in the interior, this may be released upon breakage due to the stressing by the mill and initiate the formation of liquid bridges. The interlocking and blocking can often be reduced by adding a small amount of dispersant.

Spray drying is used to produce particles with a size from a few to about 200 μm from a solution, which is sprayed into a cocurrent or countercurrent heated gas flow, for instance, spray drying of milk in air. The evaporation of the solvent depends heavily on the drying conditions; if these are not sufficient to produce particles with a dry crust from the droplets, then agglomeration will occur in the vessel where the dried particles are collected. Furthermore, care has to be taken to keep the amount of liquid, usually water, and the temperature within bounds such that glass transition does not set in, which is another significant formation process, as many spray-dried food products are amorphous materials. However, agglomeration can also be desired in spray dryers to, for instance, obtain better flow behavior of the bulk product. Such agglomeration can be achieved by, for example, recycling fines to appropriate positions of the spray tower.

Summary

Agglomeration is a size enlargement process that can be used to tailor the properties of particulate products. The effects leading to agglomeration are manifold, also depending on the material properties and the used production equipment. Agglomeration processes find widespread application in the production of food powders to influence, for example, optical appearance, mouthfeel, instant behavior, melting properties, mechanical stability, or shelf life. The quality aspects can be competing due to the complex interplay of particle properties, for example, size and porosity, and material properties, for example, the occurrence of glass transition, making product formulation by agglomeration a challenging task in food engineering.

Alcohol: Metabolism and Health Effects

CH Halsted, University of California Davis, Davis, CA, USA
V Medici, University of California Davis Medical Center, Sacramento, CA, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Although alcohol is a nutrient containing 7.1 kcal g^{-1}, it is also one of the most abused and addictive drugs in the world and is consumed by about two-thirds of adult Americans. Most consumers of alcoholic beverages are moderate drinkers, while about 13% are alcohol abusers whose habit has resulted in risks of harm, including drunk driving, disrupted family relationships, alcohol withdrawal states, and a variety of chronic illnesses. Adult male drinkers consume about three times more alcohol than adult women drinkers. Moderate drinking can be defined as no more than two drinks per day for men or one drink per day for women, where one drink contains 12–15 g of alcohol. Heavy drinking is defined as consuming more than 15 drinks per week or 5 drinks on one or more occasions per week in men or 8 drinks per week or 4 drinks on any given day per week for women and people over 65 years of age. Chronic alcoholics, about 9% of the US population, are addicts who typically consume excessive amounts of alcohol on a daily basis and have alcohol-related health and/or social problems. Binge drinkers are chronic alcoholics who escalate their alcohol intake over weeks or months, typically to the exclusion of the essential components of their regular diets. Alcoholic beverages differ in their alcohol content, such that spirits contain about 40 g/100 ml, wine about 12 g/100 ml, and beer about 4.5 g/100 ml. Thus, the amount of alcohol in 12 oz of beer is roughly equivalent to the amount found in 5 oz wine or 1.5 oz spirits, and each is equally potentially damaging to health.

Chronic alcoholism is an underlying factor in at least one-quarter of general hospital admissions in the United States. Alcohol consumption has the potential to damage many organ systems including the liver, brain, pancreas, and heart and also increases the risk of cancers of the throat and esophagus, breast, and colon. In addition, acute alcoholism contributes to significant trauma deaths including suicide, homicide, and household and motor vehicle accidents. When consumed in moderation, alcoholic beverages protect against cardiovascular disease, but when alcohol is consumed in excess, it can become an addictive drug with potential for displacement of beneficial components of the diet. Also, the consumption of excessive amounts of alcohol contributes to generalized malnutrition, with particular effects on the availability and metabolism of both water- and fat-soluble vitamins including folate, thiamine, pyridoxine, niacin, and vitamins A and D. This article will address the risks and benefits of alcohol consumption on health including human nutritional status.

Acute Effects and Metabolism of Alcohol

The level of alcohol in the blood is dependent upon the amount and rate of alcohol consumption as well as the efficiency of its metabolism. Blood levels of alcohol determine its effects on mood and mental function. Thus, blood alcohol levels of 0.05–0.07 g dl^{-1} as typically occurs after one drink associate with euphoria, while levels of 0.08–0.10 g dl^{-1} associate with impaired judgment, reaction time, and motor skills and constitute legal intoxication in the definition of drunk driving in different locations. Blood alcohol levels of 0.10–0.20 g dl^{-1} associate with impaired judgment, balance, and memory; levels of 0.20–0.30 g dl^{-1} associate with confusion and disorientation; and levels greater than 0.35 g dl^{-1} cause stupor, disordered breathing, and ultimately coma and death. Most alcohol-related trauma occurs at legal intoxication levels or higher, while coma and death have been described in young men or women who drink excessive amounts of alcohol over a short period of time.

Although alcohol is a nutrient, it is rapidly metabolized to acetaldehyde in the human liver and negligible amounts are stored as energy in the body. There are three principal routes for alcohol metabolism, two in the liver and one in the stomach. Alcohol dehydrogenase (ADH) is present in the cytosol of hepatocytes and metabolizes the relatively low levels of alcohol that would be expected after moderate drinking. The metabolism of alcohol by ADH causes a redox change that contributes to lipid synthesis in the liver, reduces gluconeogenesis, and increases lactate production. Thus, even moderate drinking can cause fatty liver with elevated serum triglyceride levels and, in the absence of dietary carbohydrate, may result in low blood glucose levels that impair brain concentration and even consciousness. The second liver enzyme, cytochrome P4502E1 (CYP2E1), is a microsomal oxidizing enzyme that metabolizes alcohol at levels to be expected during heavy drinking. During the metabolism of high levels of alcohol, CYP2E1 utilizes adenosine triphosphate energy units and thus 'wastes' alcohol calories, with resultant potential for weight loss in heavy drinkers. At the same time, the activation of CYP2E1 contributes to the cascade of oxidative liver injury that results in alcoholic liver disease. Another form of this enzyme, gastric CYP2E1, exists in the stomach and, as the first of the three alcohol-metabolizing enzymes to encounter alcohol, accounts for about 30% of all alcohol metabolism in men, but only 10% in women. This gender difference may explain why women's tolerance to alcohol is much less than men's, hence the recognized lower 'safe' level for moderate drinking in women. The fact that CYP2E1 is induced by its substrate alcohol may account in part for increased tolerance of chronic alcoholics for alcoholic beverages, with subsequent requirement for increasing amounts of ethanol to produce its intoxicating effects.

The Potential Benefits of Moderate Alcohol Consumption

In 1992, French scientists published a report indicating that cardiovascular mortality was much less among wine-drinking residents of the Mediterranean southern provinces of France than in northern provinces where wine is less frequently

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00018-0

preferred, in spite of similar overall dietary components and rates of consumption of alcoholic beverages. The initial report on the 'French paradox' attributed specific cardioprotective benefit to wine but was soon tempered by *in vitro* studies that showed that the protective effect of wine on the oxidation of low-density lipoprotein could be mimicked by constitutive antioxidant flavonoids present not only in grapes but also in many other fruits and vegetables. A comprehensive study from Copenhagen, Denmark, demonstrated decreased mortality among men and women consuming up to three drinks daily of wine, whereas equivalent amounts of beer or spirits resulted in greater mortality than abstainers. Another epidemiological study concluded that the lower mortality risk among wine drinkers compared to non-wine drinkers could be attributed in large part to a better lifestyle, including less smoking, more exercise, and better diet. The medical benefits of moderate drinking include reductions in incidences of coronary vessel occlusions and ischemic strokes, but not of hemorrhagic strokes. Whereas red wine and white wine each contain protective antioxidant flavonoids, moderate amounts of alcohol also improve the circulating lipid profile by increasing levels of high-density lipoprotein and tissue plasminogen activator while reducing platelet adhesiveness (Table 1).

The Medical Risks of Excessive Alcohol Consumption

Unlike other abused drugs, chronic alcohol in excess affects many different organ systems, which include the liver, pancreas, heart, and brain, and increases the risk of cancers of the esophagus, breast, colon, and liver. While these risks are apparent among alcohol abusers in the United States, their prevalence is generally no less in countries such as France, Italy, and Spain where drinking wine with meals is considered part of the culture. The organ damage from chronic alcoholism may impact on processes of nutrient assimilation and metabolism, as is the case with chronic liver and pancreatic disease, or may be modulated in large part by nutrient deficiencies, for example, that of thiamine with resultant effects on brain function. This section will consider specific effects of alcohol abuse on certain organs as a background for consideration of specific effects on nutritional status.

Alcoholic Liver Disease

Alcoholic liver disease is the 12th leading cause of death in the United States with similar or higher mortality rates in Western European countries where wine is considered a dietary staple. The three stages of alcoholic liver disease include, first, alcoholic fatty liver, which can occur after short-term drinking and is completely reversible with abstinence; second, alcoholic hepatitis, which is associated with inflammation and destruction of functional liver cells in about 40% of heavy alcohol abusers; and, third, subsequent alcoholic cirrhosis with advanced fibrosis of the liver in about 10–20% of chronic alcoholics . A classical study of well-nourished German male executives who agreed to undergo liver biopsies found that the incidence of alcoholic cirrhosis was directly related to the

Table 1 Benefits and risks of alcohol consumption

	Minimal amount of drinks	*Mechanism*
Benefits		
Coronary disease protection	1–2 (women), 2–4 (men)	Antioxidants
Cerebrovascular disease (nonhemorrhagic) protection		Elevated HDL lipoprotein
Risks		
Cancer		
Oropharynx and esophagus	>2 (women), >4 (men)	Unknown; higher risk in smoking alcoholics
Breast (women)	>2	Increases estrogen production
Colon	>2 (women), >4 (men)	Initiation risk increases with low folate; proliferation risk increases with excessive folate
Alcoholic liver disease		
Fatty liver	>2	Increased liver fat synthesis, decreased oxidation and export
Alcoholic hepatitis	>3 (women) × 10 years >6 (men) × 15 years	Toxicity of alcohol metabolism
Alcoholic cirrhosis	>3 (women) × 15 years >6 (men) × 20 years	Increased collagen synthesis
Pancreas		
Pancreatitis	~10 years	Acute inflammation of pancreas
Pancreatic insufficiency	~10–15 years	Loss of exocrine and endocrine pancreatic cells
Cardiomyopathy	Binge drinking	Mitochondrial damage of muscle cells or thiamine deficiency
Neurological		
Acute trauma, for example, motor vehicle accidents	1–2 in social setting	Legal intoxication
Coma and death	10–20 in rapid succession	Severe toxicity
Withdrawal syndrome	Follows binge	Neuronal hyperexcitability
Wernicke–Korsakoff syndrome	Unknown	Thiamine deficiency
Blood		
Anemia	Unknown	Folate, iron, pyridoxine deficiencies

amount and duration of alcohol consumption. Specifically, the data showed that the daily ingestion of 160 g alcohol, equivalent to that found in somewhat less than a pint of whisky, predicted a 50% risk of cirrhosis over a 15-year period. Other worldwide demographic data indicate that mortality rates from cirrhosis of the liver can be related to national per capita alcohol intake. Since a minority of chronic alcohol drinkers develop clinically significant alcoholic liver disease with hepatitis and subsequent cirrhosis, it is likely that genetic factors play a significant role in the risk of developing this disease.

Several mechanisms are implicated in the pathogenesis of alcoholic liver disease. Alcohol-induced translocation of bacterial lipopolysaccharide from the intestinal lumen initiates an inflammatory process in the liver by activating tumor necrosis factor alpha. This cytokine promotes oxidative liver injury and also has systemic effects including fever, anorexia, and weight loss. Steatosis (increased lipid deposition in the liver) is initiated by several factors. These include the effects of alcohol on methionine and adipokine metabolism that promote lipid synthesis in liver cells, while other mechanisms reduce fatty acid oxidation and the export of lipid from the liver. Altered methionine metabolism in the liver also contributes to apoptosis (programmed cell death) and reduction of antioxidant glutathione. Fibrosis results from collagen synthesis by hepatic stellate cells and is in part initiated by their incorporation of apoptotic liver cells as well as a functional switch in vitamin A storage to the production of collagen.

Among the three stages of alcoholic liver disease, fatty liver is related to the acute effects of alcohol on hepatic lipid metabolism and is completely reversible with sobriety. By contrast, alcoholic hepatitis usually occurs after a decade or more of chronic alcoholism, is associated with steatosis and inflammation of the liver with death of liver cells, and carries about a 40% mortality risk within 6 months. Alcoholic cirrhosis represents irreversible scarring of the liver as a sequel of alcoholic hepatitis. The scarring process greatly alters the circulation of blood through the liver and is associated with increased blood pressure in the portal venous circulation and shunting of blood flow away from the liver and through other organs such as varices in the esophagus. The potentially lethal complications of portal hypertension include rupture of esophageal varices, ascites or accumulation of fluid in the abdominal cavity, and hepatic encephalopathy caused by inadequate hepatic detoxification of ammonia.

Pancreatitis and Pancreatic Insufficiency

Acute pancreatitis occurs in about 10–15% of chronic alcoholics after at least 10 years of heavy alcohol abuse and is characterized by severe attacks of abdominal pain due to pancreatic inflammation, the etiology of which is unclear. Chronic recurrent pancreatitis can result from repeated acute attacks, most likely due to progressive damage to pancreatic duct outflow. This destructive process is associated with progressive scarring of the pancreas together with distortion and partial blockage of the pancreatic ducts, which limits secretion of pancreatic enzymes. Pancreatic insufficiency is a consequence of chronic pancreatitis and is associated with the destruction of exocrine pancreatic cells that secrete digestive enzymes and of endocrine cells that secrete insulin. Since the pancreas is the site of production of proteases and lipases for protein and lipid digestion and of insulin, destruction of more than 90% of the pancreas results in significant malabsorption of dietary fat with consequent steatorrhea (fat in the stool), weight loss, and adult insulin-dependent diabetes. Since the absorption of fat-soluble vitamins is dependent upon pancreatic lipase for solubilization of dietary fat, these patients are also at risk for deficiencies of vitamins A, D, and E. These patients can usually be managed by commercially available oral compounds of pancreatic enzymes, daily insulin injections, and strict abstinence from alcohol.

Heart

Although the risk of coronary heart disease may be decreased by moderate alcohol consumption, excessive alcohol use also impairs cardiac muscle function. Episodic heavy drinking bouts can lead to arrhythmias with potential for sudden death in the 'holiday heart' syndrome. Chronic alcoholics are prone to left-sided heart failure, secondary to decreased mitochondrial function of cardiac muscle cells, possibly mediated by abnormal fatty acid metabolism. A specific form of high-output heart failure, or 'wet beriberi,' occurs in association with thiamine deficiency as described in more detail in the succeeding text.

Neurological Effects

Chronic alcoholics in the Unites States are affected by neuropsychological difficulties that occur earlier than in the general population. The many neurological effects of acute and chronic alcohol abuse can be categorized as those related directly to alcohol, those secondary to chronic liver diseases, and those mediated by thiamine deficiency. The variable effects of alcohol on the brain are related to several factors including the duration and amount of drinking, the age when drinking was started, malnutrition, genetic background, and family history of alcoholism. As described earlier, the stages of acute alcohol toxicity progress upward from legal intoxication with blood levels of alcohol greater than 0.08 g dl^{-1} to coma and death with blood levels of alcohol greater than 0.35 g dl^{-1}. Automobile accidents, which account for a large portion of alcohol-related deaths, are equally, if not more, common in intoxicated pedestrians than in drunk drivers. Intoxication also leads to frequent falls and head trauma, and subdural hematoma can be present with a loss of cognition, headaches, and eventual death. Chronic alcoholics are prone to episodes of alcohol withdrawal, which can be characterized by stages of tremulousness, seizures, and delirium tremens, with hyperexcitability and hallucinations at any time up to 5 days after the last drink. This state of altered consciousness is distinct from hepatic encephalopathy in chronic alcoholic liver disease, which is associated with progressive slowing of cerebral functions with stages of confusion, loss of cognition, and eventual coma and death. Progressive altered cognition and judgment can also result from cerebral atrophy following years of heavy drinking and may also be mediated by thiamine deficiency as described in greater detail in the succeeding text.

Cancers

Chronic alcoholics are at increased risk for cancers of the oropharynx and esophagus, colon, breast, and liver as a sequel to cirrhosis. The risk of oropharyngeal cancer is greatest when heavy smoking is combined with excessive daily alcohol. Increased risk of squamous cell cancer of the esophagus is also compounded by smoking and may be associated with deficiencies of vitamin A and zinc. Breast cancer in women alcoholics is mediated in part through increased estrogen production during heavy alcohol intake. Colon cancer risk is increased among chronic alcoholics with marginal folate deficiency.

Anemia

Chronic alcoholics who substitute large amounts of alcohol for other dietary constituents are at risk for developing anemia. The causes of anemia in chronic alcoholics are multifactorial, including iron deficiency secondary to occult bleeding from episodic gastritis or other gastrointestinal sites; folate deficiency from inadequate diet, malabsorption, and increased renal excretion of folic acid; and deficiency of pyridoxine (vitamin B6) due to abnormal effects of the metabolite acetaldehyde on its metabolism. Consequently, the bone marrow may demonstrate absent iron and mixtures of megaloblastosis from folate deficiency and sideroblastosis from pyridoxine deficiency.

The Effects of Chronic Alcohol Consumption on Nutritional Status

Body Weight and Energy Balance

The effects of alcoholism on body weight are dependent upon the timing and amount of alcohol consumption in relation to meals and on the presence or absence of organ damage, in particular alcoholic liver disease. Whereas body weight is usually unaffected by moderate alcohol consumption, chronic alcoholics who substitute alcohol for other dietary constituents lose weight since alcohol is predominantly metabolized without body storage of its caloric value. Conversely, since alcohol consumption reduces dietary restraint, obese moderate drinkers on weight loss regimens are less likely to lose weight than obese dieting teetotalers.

The presence of alcoholic liver disease results in significant changes in body composition and energy balance. According to large multicenter studies, alcoholic hepatitis patients demonstrate universal evidence for protein calorie malnutrition, which plays a role in its overall mortality risk. Anorexia is universal and a major cause of weight loss in patients with alcoholic hepatitis. Furthermore, active alcoholic hepatitis contributes to increased resting energy expenditure. On the other hand, resting energy expenditure is normal in stable alcoholics with cirrhosis of the liver who are also typically underweight or malnourished in part due to preferential metabolism of endogenous fat stores. At the same time, the digestion of dietary fat and the absorptions of fat-soluble vitamins A, D, and E are decreased in cirrhotic patients due to diminished secretion of bile salts from the liver and digestive enzymes from the pancreas.

Micronutrient Deficiencies in Chronic Alcoholism

Chronic exposure to excessive amounts of alcohol is associated with deficiencies of many micronutrients, in particular thiamine, folate, pyridoxine, vitamin A, vitamin D, zinc, and iron. The frequency of these deficiencies is increased in the presence of alcoholic liver disease, which results in decreased numbers of hepatocytes for vitamin storage and metabolism. Many of the clinical signs of alcoholic liver disease are related to vitamin deficiencies (Table 2).

Table 2 Common micronutrient deficiencies in chronic alcoholic patients

Deficiency	*Cause*	*Effect*
Thiamine	Poor diet Intestinal malabsorption	Peripheral neuropathy Wernicke–Korsakoff syndrome High-output heart failure
Folate	Poor diet Intestinal malabsorption Decreased liver storage Increase urine excretion	Megaloblastic anemia Hyperhomocysteinemia and liver disease Neural tube defect Altered cognition
Vitamin B6	Poor diet Displacement from circulating albumin Promotes urine excretion	Peripheral neuropathy Sideroblastic anemia
Niacin	Poor diet	Pellagra with dermatitis, diarrhea, dementia
Pantothenic acid	Poor diet	Paresthesias 'burning feet' syndrome
Vitamin A	Malabsorption Increased biliary secretion	Night blindness May promote development of fibrosis in alcoholic liver disease
Vitamin D	Malabsorption Decreased sun exposure	Calcium deficiency Metabolic bone disease
Zinc	Poor diet Increased urine excretion	Night blindness Decreased taste Decreased immune function
Iron	Gastrointestinal bleeding	Anemia

Thiamine deficiency

Low circulating levels of thiamine, or vitamin B1, have been described in up to 80% of patients with alcoholic cirrhosis. Thiamine pyrophosphate is a coenzyme in the intermediary metabolism of carbohydrates, in particular as a coenzyme for transketolases that play a role in cardiac and neurological functions. Alcoholic beverages are essentially devoid of thiamine, and acute exposure to alcohol also decreases the activity of intestinal transporters required for thiamine absorption. The major neurological signs and symptoms of thiamine deficiency in alcoholics include peripheral neuropathy, partial paresis of ocular muscles with double vision, and wide-based gait secondary to cerebellar lesions. The presence of peripheral neuropathy is sometimes referred to as 'dry beriberi,' while the other symptoms constitute the Wernicke–Korsakoff syndrome, which is associated with severe impairment of judgment and memory loss in aging alcoholics. Whereas abnormal eye movements are an early sign of deficiency and can be treated acutely by thiamine injections, the other signs are often permanent and contribute to the dementia that often afflicts alcoholics after years of drinking. 'Wet beriberi' refers to high-output cardiac failure that can also occur in thiamine-deficient alcoholics and is responsive to thiamine therapy in addition to conventional treatment. Since endogenous thiamine is consumed during carbohydrate metabolism, acute and generalized paralysis can be precipitated by the administration of intravenous glucose to malnourished and marginally thiamine-deficient patients by depletion of remaining thiamine stores. This process can be prevented by the addition of soluble vitamins including thiamine to malnourished chronic alcoholic patients who are undergoing treatment for medical emergencies.

Folate deficiency

Folates, a family of vitamins with folic acid at its core, function in DNA synthesis and cell turnover and play a central role in methionine metabolism in the liver. While originally recognized as a cause of megaloblastic anemia, the expanding known consequences of folate deficiency are related to elevated circulating homocysteine and include increased risk for neural tube defects and other congenital abnormalities in newborns as well as altered cognition in the elderly. Prior to folate fortification of grains in the United States in 1998, the incidence of low serum folate levels in chronic alcoholics was at about 80%, but there are no data in alcoholics on the incidence of postfortification folate deficiency. Megaloblastic anemia, due to the negative effects of folate deficiency on DNA synthesis, has been described in about one-third of chronic alcoholics. Furthermore, folate deficiency may play a role in the pathogenesis of alcoholic liver disease by reducing hepatic levels of *S*-adenosyl methionine (SAM) with consequent reduction in antioxidant glutathione. Furthermore, since SAM is the principal methyl donor, its deficiency can result in decreased DNA and histone methylation with increased potential for activation of genes relevant to alcoholic liver injury. Whereas supplemental SAM prevented the ethanol-induced production of alcoholic liver disease in a small pig model, its use as a therapeutic agent in treatment of clinical alcoholic liver disease has not been successful.

The causes of folate deficiency in chronic alcoholism are multiple. With the exception of beer, all alcoholic beverages are devoid of folate, and the typical diet of the binge drinking chronic alcoholic does not include fresh vegetable sources and fortified grains. Owing to its effects on various membrane transporters, chronic alcoholism causes intestinal folate malabsorption, decreased liver folate uptake, and accelerated folate excretion in the urine. In addition, alcoholic liver disease results in decreased liver stores of folate, so the duration of time for development of folate deficiency with marginal diet is shortened.

Pyridoxine deficiency

Pyridoxine (vitamin B6) is required for transamination reactions, including the elimination of homocysteine. Pyridoxine deficiency in chronic alcoholism is caused by poor diet, whereas displacement of pyridoxal phosphate from plasma albumin by the alcohol metabolite acetaldehyde increases its urinary excretion. Low serum levels of pyridoxal phosphate are common in chronic alcoholics, and pyridoxine deficiency is manifest by peripheral neuropathy and sideroblastic anemia. In alcoholic hepatitis, the serum level of alanine transaminase (ALT) is disproportionately low compared with aspartate transaminase, due to the requirement of ALT synthesis for pyridoxine.

Vitamin B12 deficiency

The incidence of vitamin B12 deficiency in chronic alcoholism is undefined, since serum levels are often normal or increased due to the increased presence of B12 analogs in the presence of alcoholic liver disease. Nevertheless, the intestinal absorption of vitamin B12 is decreased in chronic alcoholics due to defective uptake at the ileum, and low liver levels of vitamin B12 have been described, which may contribute to abnormal hepatic methionine metabolism with elevated serum homocysteine, since this vitamin is a cofactor for methionine synthase.

Other less common water-soluble vitamin deficiencies in chronic alcoholism

Niacin deficiency is typically found in less-developed countries in association with decreased intake of the animal protein, in particular the amino acid tryptophan, which is a precursor of nicotinic acid and nicotinamide. Clinical symptoms of niacin deficiency constitute the syndrome known as pellagra, which can occasionally be found in chronic alcoholics as a component of severe malnutrition due to inadequate diet. These signs include the 'three D's' of chronic diarrhea, dermatitis including a scaly rash over sun-exposed areas such as the neck and forearms and hands, and dementia with features of disorientation, confusion, memory loss, and psychosis. In addition to this typical triad, laboratory features include low urinary *N*-methylnicotinamide excretion. Recovery from pellagra in chronic alcoholism follows treatment for protein malnutrition with supplemental niacin and abstinence from alcohol.

Pantothenic acid is a component of coenzyme A, which is involved in many reactions related to lipid and carbohydrate metabolism, and is found in animal proteins, dairy products, and whole grains. Pantothenic acid deficiency is rare and may sometimes be found in malnourished chronic alcoholics with symptoms of paresthesias that include the 'burning feet' syndrome. Its causation in chronic alcoholism is most likely related to inadequate diet and generalized malnutrition. There is no specific diagnostic test, and the deficiency

symptoms usually respond to restoration of nutrition and supplemental pantothenic acid.

Vitamin A deficiency

Although serum levels of vitamin A are usually normal in chronic alcoholics, liver retinoids are progressively lowered through the stages of alcoholic liver disease during the conversion of hepatic stellate cells from vitamin A storage to collagen synthesis.

The causes of vitamin A deficiency in alcoholic liver disease include intestinal malabsorption, which is due to decreased secretion of bile and pancreatic enzymes necessary for the digestion of dietary retinyl esters and their incorporation into water-soluble micelles prior to intestinal transport. In addition, the transport of retinol is impaired due to decreased hepatic production of retinol-binding protein. Thirdly, the metabolism of alcohol induces microsomal enzymes that promote the production of polar retinol metabolites that are more easily excreted in the bile. The signs of vitamin A deficiency include night blindness with increased risk of automobile accidents and increased risk of esophageal cancer due to abnormal squamous cell cycling. Conversely, patients with alcoholic liver disease are more susceptible to vitamin A hepatotoxicity so that supplemental doses of vitamin A should be used with caution.

Vitamin D and calcium deficiencies

Chronic alcoholic patients are at increased risk for metabolic bone disease due to low vitamin D levels and hence decreased intestinal absorption of calcium. Alcoholic liver disease increases the likelihood of vitamin D deficiency because of decreased excretion of bile required for absorption of this fat-soluble vitamin, poor diet, and often decreased sun exposure. Calcium deficiency results from low levels of vitamin D that is required to regulate its absorption and also from fat malabsorption that often accompanies alcoholic liver disease, which results in increased binding of calcium to unabsorbed intestinal fatty acids.

Zinc deficiency

Zinc is a cofactor for many enzymatic reactions including retinol dehydrogenase, is stored in the pancreas, and circulates in the blood bound mainly to albumin. Chronic alcoholic patients are frequently zinc-deficient due to poor diet, pancreatic deficiency, and increased urine excretion because of low zinc-binding albumin in the circulation. The consequences of zinc deficiency include night blindness due to decreased activity of retinol dehydrogenase, decreased taste, and hypogonadism that may result in lowered testosterone levels and increases the risk of osteoporosis in men. Since zinc is required for cellular immunity, its deficiency may contribute to increased infection risk in alcoholic patients.

Iron

Chronic alcoholic patients are often iron-deficient because of increased frequency of gastrointestinal bleeding, typically due to alcoholic gastritis or esophageal tears from frequent retching and vomiting or from rupture of esophageal varices in patients with cirrhosis and portal hypertension. The major consequence of iron deficiency is anemia, which may be compounded by the concurrent effects of folate and pyridoxine deficiencies. Conversely, increased exposure to iron, for example, from cooking in iron pots, increases the likelihood and severity of alcoholic liver disease, since increased iron promotes oxidative liver damage during the metabolism of alcohol.

Alcohol Sources and Production

Alcoholic Fermentation

The most important method for alcohol production is fermentation, which is a natural process, during which microorganisms consume organic compounds under anaerobic conditions to produce gas (CO_2) and ethanol, a substance with intoxicating properties. The process of alcoholic fermentation has been known to humanity for more than 10 000 years, and it has been speculated, based on archaeological findings, that it played a significant role in driving humans to abandon nomad life, settle in permanent fertile locations in order to grow crops, and develop organized communities, thus creating civilizations. During history, various cultures have developed prejudices regarding alcohol, either due to the adverse effects of alcohol consumption (Islamic nations, prohibition era and neoprohibitionist movements in the United States, etc.) or even due to occasional poisoning effects as a result of spoilage or contamination (e.g., medieval beer witch hunting). However, the applications and benefits of alcoholic fermentation to humanity are enormous including the production of alcoholic beverages, bread, ethanol for fuel, pharmaceutical and medical uses, and acetic acid. Fermentation leads to better preservation and microbial safety of the product, as well as improved nutritional value due to degradation of complex components to more biologically available ones, enrichment in bioactive compounds, etc.

Alcoholic fermentation takes place, through the Embden–Meyerhof–Parnas (glycolytic) pathway, that is, the metabolism of hexose sugars into pyruvate. Under anaerobic conditions and high initial substrate concentration, pyruvate is decarboxylated by the enzyme pyruvate decarboxylase with thiamine pyrophosphate as cofactor, into acetaldehyde and CO_2. Acetaldehyde acts as an electron acceptor oxidizing NADH with the formation of ethanol in order to regenerate NAD^+ and allow ATP synthesis to proceed under these conditions (Figure 1). Theoretically, 1 g of sugar should yield 0.51 g of ethanol and 0.49 g of CO_2. However, the usual yield of alcoholic fermentation is about 0.46 g of ethanol and 0.44 g of CO_2, due to heat losses and other yeast metabolic activities.

The yeast *Saccharomyces cerevisiae* is the most widely used species for alcohol production because it is remarkably tolerant to high concentrations of sugar, alcohol, and SO_2 (a common preservative and antioxidant used in alcoholic beverages), low pH, low temperatures, and high pressures. It can completely utilize the sugars during beer or wine fermentations, producing low amounts of undesirable compounds such as hydrogen sulfide (H_2S), acetic acid, and urea. Because it has a low respiratory potential, it converts sugars mainly to alcohol and flavor-active compounds rather than microbial biomass in the absence of oxygen. Different strains differ regarding the production of flavor by-products and can be selected accordingly depending on the desired characteristics of the final products. Numerous pure yeast species are commercially available to cover the needs of the alcoholic fermentation industries, including brewer's, wine, and distiller's yeasts. Spontaneous fermentations, such as in traditional wine making, involve various yeast species, each of which may dominate at different stages of the process. The basic nutritional requirements for yeast growth are water, nitrogen and carbon sources, oxygen, phosphorus, magnesium, trace minerals, and vitamins. Water, free and bound, comprises about 85% of the cellular mass.

Factors That Affect Alcoholic Fermentation

The factors that affect yeast growth and alcoholic fermentation as well their regulation influence the quality of the final product. These have been extensively studied, and various theoretical models have been developed to describe the process. The principal factors are mainly the carbon and nitrogen sources, temperature and pH, oxygen and alcohol levels, and minor substances that affect yeast metabolism such as minerals and vitamins. Carbohydrates other than glucose and fructose, such as sucrose, maltose, maltotriose, raffinose, and lactose, can be fermented by yeast after hydrolysis to their monosugar constituents. The sugar concentration is directly related to ethanol production; however, above 20% sugar, fermentation is significantly retarded and yeast viability and alcohol tolerance decrease due to osmotic stress. At high sugar concentrations, the formation of flavor-important compounds is affected, for example, the production of glycerol, acetic acid, and acetate esters increases.

Fermentation is also highly affected by temperature, which is one of the easier controlled parameters during industrial processes. Below or above extreme temperature limits, yeast cells may die. At high temperatures, this effect is increased by other inhibitory factors such as ethanol concentration. At low temperatures, growth is suppressed but the cells are more tolerant to ethanol due to alterations in their membranes composition. At low temperatures, the fruit esters' synthesis and the retention of aroma volatiles are also favored.

The rate of fermentation is also highly affected by pH and ceases at values below 3. However, at low pH, the antimicrobial activity of SO_2, inhibition of spoilage microorganisms, uptake of nutrients, and ester hydrolysis are enhanced. Yeasts ferment sugar in the absence of oxygen. Nonetheless, low levels ($0.3–1.0\ mg\ l^{-1}$) may be desirable to accelerate the start-up of fermentation. Oxygen is essential for the synthesis of membrane components such as sterols and fatty acids. On the other hand, hyperoxidation may cause oxidative browning and increased synthesis of fusel alcohols, acetaldehyde, acetic acid, H_2S, urea, and ethyl carbamate (a suspected carcinogen).

Assimilable nitrogen is necessary for yeast to initiate and complete fermentation as it is required for protein and nucleic acid synthesis. High concentrations (e.g., above $400–500\ mg\ l^{-1}$ in wine fermentations) may promote cell growth and reduce ethanol yield. Low nitrogen leads to

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00017-9

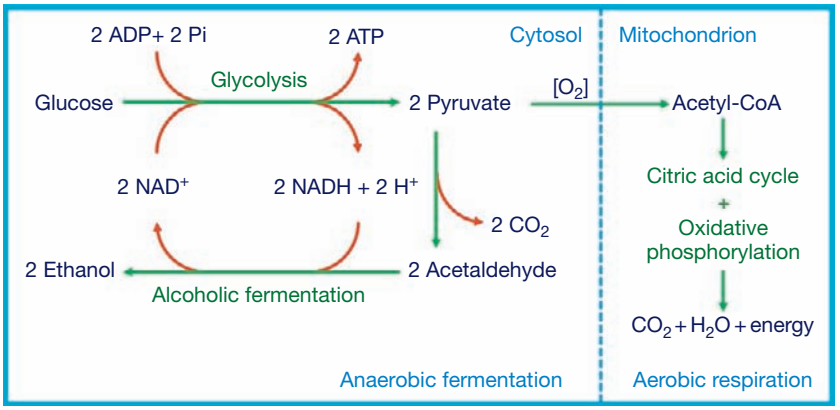

Figure 1 Overview of alcoholic fermentation.

increased production of glycerol and trehalose and enhances the release of fusel alcohols and H_2S as a consequence of restricted amino acid synthesis.

Finally, vitamins play a crucial role in yeast performance as coenzymes and enzyme precursors. A noticeable example is the reduced fusel alcohol production during fermentation by thiamine, while deficiencies in pyridoxine and pantothenic acid may result in increased H_2S synthesis.

Chemical Synthesis of Alcohol

Alcohol intended for human consumption is produced exclusively by fermentation. On the other hand, most ethanol for industrial purposes is produced by chemical synthesis from petrochemical feedstocks, mainly the acid-catalyzed hydration of ethylene (50% water/sulfuric acid; 250 °C): $CH_2{=}CH_2 + H_2O \rightarrow CH_3CH_2OH$. This reaction yields alcohol directly without need for a separate alkyl hydrogen sulfate hydrolysis step. Ethanol can also be produced from carbonyl compounds by reduction of carboxylic acids, esters, ketones, and aldehydes with specified reducing agents.

Properties of Alcohol

Physicochemical Properties

Ethyl alcohol (or ethanol) is a 2-carbon aliphatic alcohol with the structural formula CH_3CH_2OH. It is a colorless liquid with a characteristic odor and taste (sweet and burning sensation; 100 mg l^{-1} sensory threshold level in water at 20 °C). The main physical properties of ethanol are presented in Table 1.

Ethanol is a versatile solvent, miscible with water and with many organic solvents, light aliphatic hydrocarbons (up to undecane), aliphatic chlorides, and other nonpolar substances such as essential oils. The polar nature of the hydroxyl group allows ethanol to dissolve many ionic compounds, such as Na and K hydroxides and Mg, Ca, and NH_4 chlorides. Ethanol is also able to participate in hydrogen bonding (H-bonding), which renders it more viscous and less volatile than other organic compounds of similar molecular weight, such as propane. H-bonding in ethanol occurs between the oxygen of a molecule and the hydroxyl group proton of another. This type of bonding is much stronger than other types of dipole–dipole attractive forces, such as those between amine (=NH) groups. H-bonding makes ethanol highly hygroscopic to the extent that it can readily absorb water from the air. Distillation of ethanol/water solutions will not yield more than 95% concentrated ethanol because it produces an 'azeotrope' mixture (95% ethanol and 5% water) that boils at lower temperature (78.15 °C) than either its pure ingredients.

Table 1 Physical properties of alcohol

Molecular weight	46.069
Melting point	−117.3 °C
Boiling point	78.5 °C
Density	0.789 g ml^{-1}
Refractive index	1.3568 (at $\lambda = 830$ nm and 20 °C)
Triple point	150 K (−123.15 °C) at 4.3×10^{-7} kPa
Flash point	16.6 °C for pure alcohol 26 °C for spirits with 40% alcohol 52 °C for wine with 12.5% alcohol
pK_a	15.9
Dipole moment	1.69 D
Dielectric constant	24.55
Water solubility	Completely miscible
Reaction with sodium	Displaces hydrogen

Spectroscopic Properties

Ethanol, like all alcohols, has characteristic IR absorptions, associated with hydrogen-bonded O—H and C—O stretching vibrations, in the regions 3200–3650 cm^{-1} (broad absorption of moderate intensity) and 1025–1200 cm^{-1} (moderate to strong absorbance), respectively.

The ^1H NMR spectrum of ordinary ethanol, containing acidic and basic impurities, appears as a singlet for the proton of the hydroxyl group and as a quartet for the methylene (—CH_2—) group protons. No signal splitting from coupling of the hydroxyl and the methylene group protons appears, although they are on adjacent atoms. However, in the ^1H NMR spectrum of very pure ethanol, the signal of the hydroxyl group protons and that of the methylene group protons are split into a triplet and a multiple of eight peaks, respectively. The chemical shift in ^{13}C NMR spectra for the carbon of the

C—O group of alcohols (60–75 ppm) is higher than the corresponding alkanes, because of the electronegative oxygen that decreases the shield of the carbon to which it is attached. The chemical shift for the $—CH_2OH$ in ethanol is 56–58 ppm.

Regarding ultraviolet–visible spectra (UV–vis), alcohols are transparent above 200 nm, unless there are other chromophores in the molecule (double bonds, aromatic rings, etc.). The minimum absorption wavelength for the use of ethanol as a solvent in UV–vis determinations is 205 nm.

In mass spectra, the molecular ion peak of alcohols is usually small. Alcohols fragment in a way that the molecular ion loses an alkyl group from the hydroxyl-bearing carbon, forming a stable cation ($CH_2{=}OH^+$) with a prominent peak at m/z 31.

Chemical Reactions

Like all alcohols, ethanol is involved in many chemical reactions including the conversion to ethers, esters, carbonyl compounds, and carboxylic acids. In summary, the main reactions of ethanol are the following:

(1) Diethyl ether synthesis by heating in the presence of acid catalyst:

$$2CH_3CH_2OH \rightarrow (CH_3CH_2)_2O + H_2O$$

(2) Ethyl ester synthesis by reaction with (a) a carboxylic acid with acid catalyst (Fischer esterification), (b) an acyl chloride in the presence of pyridine, and (c) a carboxylic acid anhydride:
   (a) $CH_3CH_2OH + \text{R-COOH} \rightarrow RCOOCH_2CH_3 + H_2O$
   (b) $CH_3CH_2OH + \text{R-COCl} \rightarrow RCOOCH_2CH_3 + HCl$
   (c) $CH_3CH_2OH + \text{RCO-O-OCR} \rightarrow RCOOCH_2CH_3 + \text{RCOOH}$

(3) Conversion to an inorganic acid ethyl ester (ethyl nitrate, ethyl sulfate, or triethyl phosphate) by direct reaction with the acid:

$$CH_3CH_2OH + HNO_3 \rightarrow CH_3CH_2ONO_2 + H_2O$$

(4) Oxidation to acetaldehyde using pyridinium chlorochromate or dichromate in dichloromethane as oxidizing agents:

$$CH_3CH_2OH \rightarrow CH_3CHO$$

(5) Oxidation to acetic acid using acidified dichromates, chromic acid, or potassium permanganate as oxidizing agents:

$$CH_3CH_2OH \rightarrow CH_3COOH$$

Biological Oxidation and Health Effects

In humans, the main enzymes involved in ethanol oxidation are alcohol dehydrogenases (ADHs). These are mostly dependent on the coenzyme nicotinamide adenine dinucleotide (NAD^+) and convert ethanol to acetaldehyde:

$$CH_3CH_2OH + NAD^+ \rightarrow CH_3CHO + NADH + H^+$$

ADHs are abundant in the liver and present in other tissues, being possibly indirectly responsible for the toxicity or carcinogenicity of ethanol in these tissues. Ethanol oxidation may also occur via the action of cytochrome P450 enzymes and peroxisomal catalase, or it can be nonoxidatively metabolized to form cytotoxic fatty acid ethyl esters. The latter appear in human serum soon after ingestion. Several minor pathways for ethanol conversion to acetaldehyde have also been proposed, involving nitric oxide synthases, cytosolic xanthine oxidoreductase, threonine aldolase, and enzymes that have not yet been identified.

Acetaldehyde is subsequently metabolized, predominantly by NAD^+-dependent ALDHs. These are expressed in a many tissues and have broad substrate specificity for a variety of aldehydes. Chronic ethanol consumption reduces the liver's ALDH activity and increases blood acetaldehyde levels. Acetaldehyde is toxic and there is sufficient evidence of malignant human carcinogenicity, especially those deficient in ALDH.

The quality of alcoholic beverages may impact human health and mortality as a result of heavy drinking and addiction. Also, occasional poisoning may occur due to adulteration or contamination with methanol, as in the case of illegally produced and sold alcoholic beverages (unrecorded alcohol), or with other toxic substances. According to the WHO *Global status report on alcohol and health*, world consumption in 2010 was 6.2 l of pure alcohol per person, aged 15 or older. Of this, 24.8% was estimated to be unrecorded and 50.1% consumed in the form of spirits (Figure 2). More than 200 alcohol-related disease and injury conditions have been recorded, including dependence (alcoholism), neuropsychiatric disorders, gastrointestinal diseases, cancer, violence, traffic- and work-related injuries, cardiovascular diseases, pregnancy implications, and increase of sexually transmitted diseases. However, various beneficial effects of low alcohol consumption (mainly of wine and beer) have been noted, such as reduction of undesirable stress and depression effects, enhanced sociability, and cardioprotective effects. These positive effects may be attributed to a variety of compounds found in these drinks, notably antioxidant polyphenols and ethanol.

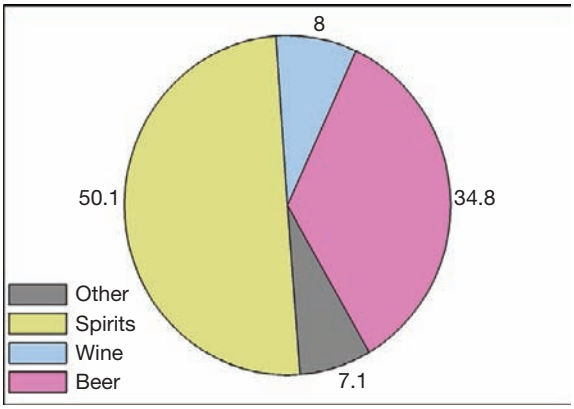

Figure 2 Proportion (%) of recorded alcohol per capita (15+) consumption consumed in the form of beer, wine, spirits, and other types of beverages in the world in 2010. World Health Organization. (2014). *Global status report on alcohol and health – 2014 ed*. Geneva: WHO Press.

Types of Alcohol

Alcoholic Beverages

According to the United Nations Statistics Division, the activity of manufacture of alcoholic products based on fermentation can be divided into three categories:

- Distilling, rectifying, and blending of spirits: distilled, potable, alcoholic beverages (whisky, brandy, gin, liqueurs, and mixed drinks), blended distilled spirits, ethyl alcohol from fermented materials, and neutral spirits
- Manufacture of wine (including sake, cider, perry, mead, other fruit wines, mixed fermented beverages, vermouth, fortified, and low-alcohol and nonalcoholic wine)
- Manufacture of malt and malt liquors (low-alcohol and nonalcoholic beer)

A general scheme for alcoholic beverages' production from various raw materials is illustrated in Figure 3.

Wine is the product of fermentation of grape juice (must), traditionally carried out spontaneously with the indigenous grape skin and/or winery yeast microflora. Cider is the product of controlled yeast fermentation of apple juice and perry is derived from pears. Beer is the alcoholic beverage made by fermentation of the wort extracted from malted cereal grains, mainly barley, and flavored with hops. Rice wines are naturally brewed alcoholic beverages made from rice, which undergo simultaneous starch hydrolysis and alcoholic fermentation by koji fungi (*Aspergillus oryzae*) and yeasts, respectively. Distilled spirits are alcoholic beverages produced by distillation of fermented broths. The distillation process carries over most of the volatile compounds to the distillate, and due to the high alcohol content, microbial spoilage is unlikely to occur. Based on the distillation process, two kinds of spirits may be defined: (a) those produced by rectification (repeated distilling) and sometimes filtration, thus removing most of the flavor characters of the raw material (e.g., vodka and gin), and (b) those produced according to specific fermentation and distillation techniques that allow retention of the unique raw material flavors (e.g., whisky, rum, brandy, and tequila). Neutral alcohol, or rectified spirit, or ethyl alcohol of agricultural origin is a highly rectified alcohol without the organoleptic properties of the raw materials. It is used for the production of spirits such as vodka, gin, aniseed-flavored drinks, and most liqueurs.

Denatured Alcohol

The term 'denatured alcohol' refers to alcohol products adulterated with toxic and/or bad tasting additives (e.g., methanol, benzene, pyridine, castor oil, gasoline, isopropyl alcohol, and acetone), making it unsuitable for human consumption. The most common additive used is methanol (5–10%), giving rise to the term 'methylated spirits.' Denatured alcohol is used as a lower-cost solvent or fuel for home-scale or industrial use, compared with the heavily taxed pure alcohol and alcohol used in beverages.

Absolute Alcohol

To produce pure alcohol, which is called absolute alcohol, various dehydration processes exist, such as azeotropic distillation, extractive distillation, adsorption with molecular sieves, and pervaporation membrane techniques. Azeotropic distillation is the most common process, involving solvents such as benzene and cyclohexane, which form a different azeotrope mixture with ethanol and water. Distillation of this mixture eventually yields absolute alcohol, which contains $<1\%$ water and trace amounts of the separation agent. Absolute alcohol is not intended for human consumption. It is mainly used as solvent for laboratory and industrial applications and as a fuel.

Composition of Alcohol Products

Ethanol

The ethanol percentage in alcoholic beverages is mostly indicated as percentage by volume (% vol) (French or Gay-Lussac

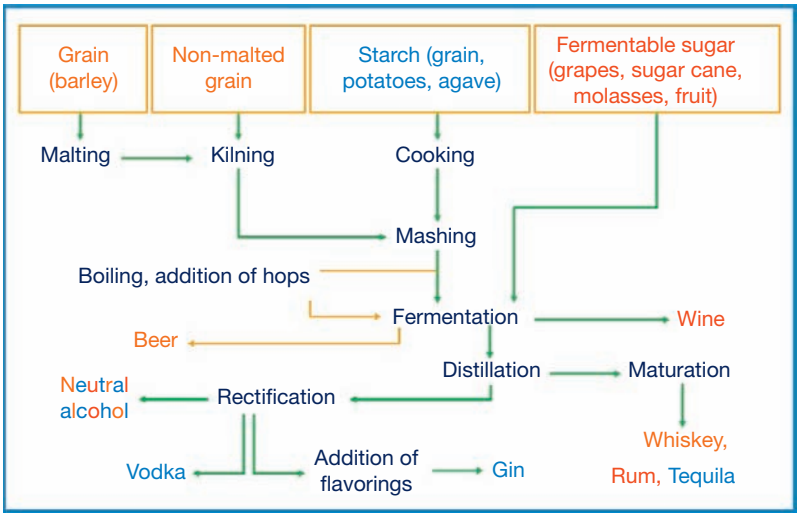

Figure 3 Raw materials and processes for alcoholic beverages production.

Table 2 Properties of neutral alcohol and some distilled spirits

	Neutral alcohol	*Scotch whiskey*	*Brandy*	*Rum*	*Gin/vodka*
Minimum actual alcoholic strength (% vol.)	96.0[a]	40.0[b]	36.0 (wine)/37.5 (fruit)[b]	37.5[b]	37.5[b]
Maximum methanol content (g hl^{-1} pure alcohol)	50[a]	–	200 (wine)–1000 (fruit)[b]	–	–
Total acidity as acetic acid (g hl^{-1} pure alcohol)	<1.5[a]	3–70[b]	5–160[b]	80–240[b]	–
Volatile acidity as acetic acid (g hl^{-1} pure alcohol)	–	9–40[b]	–	50–140[b]	–
Esters as ethyl acetate (g hl^{-1} pure alcohol)	<1.3[a]	10–85[b]	70–580[b]	40–280[b]	–
Aldehydes as acetaldehyde (g hl^{-1} pure alcohol)	<0.5[a]	2–270[b]	2–80[b]	0–40[b]	–
Higher alcohols (g hl^{-1} pure alcohol)	<0.5 (as 2-methyl-1-propanol)[a]	–	140–780[b]	100–200[b]	–

[a]WHO/IARC (2010).
[b]Kirk and Sawyer (1991).

system). In America, the proof system is usually used, which is double the % vol. The ethanol content in wines varies from 8% to 15%; concentrations above 14–15% are usually the result of fortification. Beer usually contains 4–6% alcohol although a variety of products exist with 0.5% (alcohol-free beer), 2.3% (low-alcohol beer), or even 20–40% alcohol. Spirits contain about 35–40% (or up to 74% in some cases). Neutral alcohol contains at least 96% ethanol (Table 2). Ethanol is crucial to the stability, aging, and sensory properties of alcoholic beverages, suppressing the growth of pathogenic or spoilage microorganisms, acting as solvent in extracting constituents from the raw material, participating in essential reactions leading to important volatile compounds such as esters, and affecting the overall aroma perception in fermented products.

Water

Water has a critical effect on the quality of fermented beverages. In wines, these include the solubility of flavor compounds and pigments, control of the basic flow characteristics, and chemical reactions involved in fermentation, aging, etc. In beer, the chemical composition of water exerts a strong effect on flavor, color, head retention, and clarity. In whisky, water affects the efficiency of the mashing process as well as the chemistry of the fermentation and distillation processes. The quality of mixed spirits, such as vodka or gin, is also affected by the quality of the dilution water. The addition of water in the preparation of spirits is authorized, if its quality is in conformity with legislated specifications relating to the exploitation of natural waters, quality relative to human consumption, and that it does not change the nature of the product.

Methanol

Methanol is not a fermentation by-product. It is generated from the enzymatic breakdown of pectins (galacturonic acid polymers with carboxyl groups partly esterified with methanol) by the action of pectinesterases. Therefore, methanol content is directly related to the pectin content of the raw material. The addition of pectolytic enzymes to facilitate clarification or blending with distilled spirits may increase the methanol content of alcoholic beverages. Because distillation potentially concentrates the methanol content in the distillate, it is of major concern for the quality of distilled spirits, notably in unreported and adulterated alcohol products, where quality control is largely nonexistent. The principal detrimental by-products of methanol metabolism (formaldehyde and formic acid) can cause optic nerve destruction and blindness.

Volatile By-Products (Congeners)

The formation of fermentation by-products is mainly yeast-dependent. Secondary factors include the raw materials, temperature, and pH. The main by-products of alcoholic fermentation are esters, carbonyl compounds, fusel alcohols, volatile organic acids, sulfur compounds, glycerol, and methanol. Their effect on product flavor depends mainly on their concentrations and odor detection threshold, as well as the levels of other volatile compounds, ethanol, O_2, and CO_2. Due to concentration during distillation, spirits contain higher amounts of volatile compounds unless they have been removed by rectification and filtration processes.

Esters are considered important aroma components of fermented drinks, because they impart fruity/flowery odors and have low odor threshold values. They are produced during fermentation as by-products of yeast lipid metabolism (alcoholysis of acyl CoA compounds) or by slow reactions between alcohols and fatty acids during aging (Figure 4). Important esters in fermented beverages are ethyl acetate (fruity below 150 mg l^{-1}), isoamyl acetate (banana), benzyl acetate (apple), ethyl hexanoate (apple and aniseed), ethyl octanoate (fruity, fat), and ethyl decanoate (brandy-like).

Fusel alcohols (more than two carbon atoms) are mainly produced by yeast during fermentation (Figure 4). The few exceptions, such as hexanols, benzyl alcohol, and 2-phenylethanol, are usually derived from the raw material. The most abundant alcohols are 1-propanol, 2-methyl-1-propanol, 2-methyl-1-butanol, and 3-methyl-1-butanol. They contribute more positively to aroma complexity at low concentrations

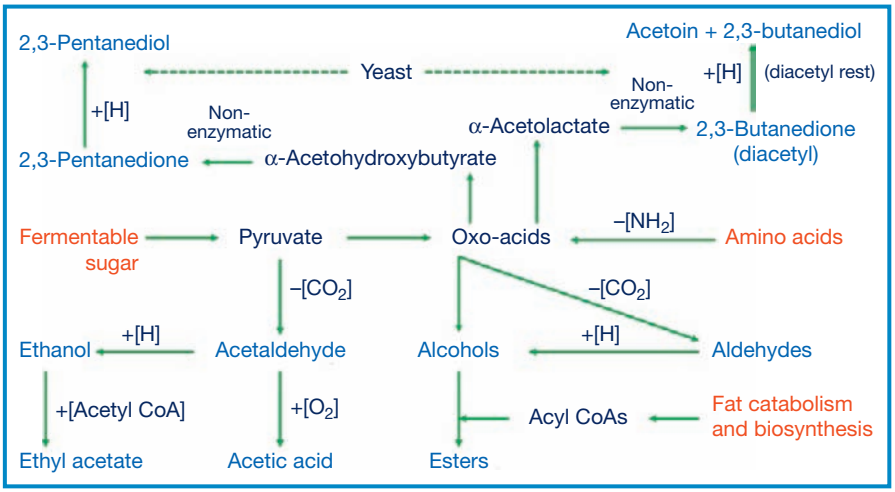

Figure 4 Formation of volatile by-products during alcoholic fermentation.

(<300 mg l^{-1}). At higher concentrations, they may musk the product aroma with their strong pungent smells.

Most aldehydes found in alcoholic beverages are produced during fermentation (e.g., acetaldehyde), processing (e.g., furfural), or extraction from oak cooperage (e.g., cinnamaldehyde and vanillin). Acetaldehyde is usually considered an off-odor above threshold values (herbaceous). Examples of ketones derived from the raw material are the norisoprenoid ketones, β-damascenone (exotic flower or rose), and α-ionone. Various ketones are also produced during fermentation. They usually have no sensory significance, with the major exception being diacetyl (2,3-butanedione). It imparts buttery, nutty, or toasty flavors at low levels (<5 mg l^{-1}). Diacetyl is a key aroma compound in beer, where it is slowly converted by yeast to derivatives of lower sensory significance during maturation at very low temperatures (~0 °C). This process, known as 'diacetyl rest,' is a time-consuming and energy-demanding process for breweries (Figure 4).

Acidity is commonly classified into two categories – volatile and fixed. Volatile acidity refers to acids that can be removed by steam distillation, whereas fixed acidity refers to poorly volatile acids. Acetic acid is the major volatile acid found in wines, but other carboxylic acids such as formic, butyric, and propionic, and longer chain fatty acids also may be involved. All volatile acids have specific odors but typically occur at detectable levels only as a result of microbial spoilage.

Finally, the main sulfur compounds in wine are inorganic sulfites due to deliberate addition of SO_2. The major, organic sulfur-containing compounds are the amino acids cysteine and methionine, the peptide glutathione, the vitamins thiamine and biotin, thiols, and a wide diversity of volatile compounds. The latter are derived from yeast metabolism and nonenzymatic reactions during fermentation, maturation, and aging postbottling. Although they are found in trace amounts, their low sensory thresholds can give them great significance.

Toxic Contaminants

Toxic substances that can be found in alcoholic beverages are ethyl carbamate, chloropropanols (CPs) (mainly 3-monochloropropane-1,2-diol), acrylamide, furan, phthalate esters (PAEs), mycotoxins, pesticides, and heavy metals. Ethyl carbamate is a by-product of fermentation. Levels up to 45 μg kg^{-1} have been reported in wine. Many chemical and biological techniques have been proposed to reduce or avoid these levels. CPs, acrylamide, and furan are formed during heat-involving processing (e.g., kilning or boiling in brewing). They are all suspected carcinogens for humans (Table 3).

PAEs are the most commonly used plasticizers for polymers such as polyvinyl chloride, polyethylene, polyethylene terephthalate, and polyvinyl acetates. High alcohol contents may cause migration of lipophilic PAEs during their contact with plastic materials. PAEs and some metabolites and degradation products can cause toxic effects in multiple human organ systems.

Other toxic contaminants that have been detected in alcoholic beverages are benzene (from contaminated industrial CO_2 or formation in the presence of sodium benzoate), monostyrene (contact with polyester tanks), halogenated acetic acids (equipment disinfectants), polydimethylsiloxanes, and polycyclic aromatic hydrocarbons.

Metals find their way into alcoholic products during all stages of production including raw materials, process type, equipment, bottling, aging, storage, and adulteration. The soil composition, environmental pollution, and agrochemical treatments all affect the mineral content and presence of toxic metals in the raw materials. Wine and beer contain much higher amounts of metals than distilled beverages.

Finally, two important classes of toxic organic compounds that may be present in alcoholic products are mycotoxins (secondary fungal metabolites) and pesticides. Mycotoxins are frequent contaminants in grain and, therefore, potential contaminants in beers. Established maximum limits for their presence in foodstuffs have been set for ochratoxin A and aflatoxins B1, B2, G1, and G2. The distillation process effectively reduces the contamination risk in distilled spirits. Regarding pesticides, various studies have shown that residues in alcoholic beverages are smaller than those in the raw material. Pesticides may pass into the distillates only if present at very high concentrations.

Table 3 List of potential carcinogens in alcoholic beverages

Substance	*Type of alcohol*	*Evaluation of carcinogenicity in humans*
Ethanol	All	Sufficient
Acetaldehyde	All	Sufficient
Formaldehyde	Wine, spirits, unrecorded	Sufficient
Aflatoxins	Beer	Sufficient
Ochratoxin A	Beer, wine	Inadequate
Patulin	Apple cider	Inadequate
Ethyl carbamate	Beer	Inadequate
Acrylamide	Beer	Inadequate
Furan	Beer	Inadequate
Benzene	Beer	Sufficient
Safrole	Liqueurs	Inadequate
4-Methylimidazole	Caramel-colored beer and whisky	Inadequate
N-Nirosodimethylamine	Beer	Inadequate
Arsenic	Beer	Sufficient
Cadmium	Beer	Sufficient
Lead	All	Limited

Analysis of Alcohol Products

Analytic procedures and quality assurance standards for alcohol products are delivered by various international, intergovernmental, national, and private organizations in the form of comprehensive and reliable collections of methods such as the European Community Reference Methods, the Compendium of International Methods of the International Organisation of Vine and Wine (OIV), the Official Methods of Analysis of the Association of Analytical Chemists (AOAC International), and the Analytica-EBC of the European Brewery Convention. Numerous analytic techniques have also been proposed at research level for the analysis of ethanol, congeners, minerals, and toxic compounds.

Determination of Ethanol

Various methods are available for the analysis of ethanol in alcoholic products, including determination by specific gravity (SG), chemical, chromatographic, and spectroscopic methods.

Determination by specific gravity

For determination of the alcohol strength of a product based on SG, distillation or steam distillation is usually required. Some samples such as straight bourbon whiskey and alcohol–water mixtures containing low amounts of volatile ingredients may not require distillation prior to analysis. Determination of alcohol in the distillate may be carried out after neutralization by an alkaline solution to avoid volatile acids to pass into the distillate or by sulfuric acid in the case of abnormal concentrations of ammonium anions. The measurement of the alcoholic strength of the distillate may be done by pycnometry, densitometry (frequency oscillation or hydrostatic balance), hydrometry, and refractometry techniques.

- For determination of alcohol by the pycnometer method, the sample is distilled using an apparatus consisting of a flask connected to a vertically assembled Liebig condenser. For samples containing 60% or less alcohol, the pycnometer is filled at the calibration temperature and the content is then quantitatively transferred into the distillation flask. The distillate is collected into the same pycnometer and the volume is completed with water at the calibration temperature. The SG of the sample and that of the distillate are determined by the ratio of weight of sample (or distillate) per weight of water, and the corresponding % vol alcohol content of the distillate at 15.56 °C (AD) is obtained using conversion tables. Samples containing more than 60% alcohol are distilled into higher volume pycnometers than the ones used for sample preparation under the same process conditions.
- The hydrometer (or alcoholmeter) method is applicable to spirits containing <600 mg extract/100 ml. Clean and dry graduated (0.1–0.2° proof) hydrometers are used. Calibration corrections are applied to both hydrometer and thermometer readings.
- In densitometric methods, a density meter is used, which determines the SG at 20 °C by measuring the frequency of oscillating U-tube filled with sample compared with that of two standards: in air (apparent SG = 0.00000) and with freshly double-distilled or deionized water (apparent SG = 1.00000).
- In refractometer methods, a specific volume of sample is measured and distilled. The distillate is diluted to an indicated volume at calibrated temperature, and the refractometer reading is obtained by immersion.

In the methods mentioned earlier, the % by volume alcohol content at 15.56 °C is obtained, after temperature corrections, using suitable conversion tables. The alcohol content by weight can also be determined following similar procedures after accurately weighing specific amounts of sample.

Chemical methods

Simple, rapid, and sensitive colorimetric/fluorometric methods for quantitative determination of alcohol have been

developed, applicable to alcoholic beverages, biofuels, basic research, and clinical studies. A common method is the use potassium dichromate to oxidize ethanol to acetic acid and then determine the unreacted oxidant by titration with ammonium iron(II) sulfate. The reaction of ethanol with ceric ammonium nitrate in acidic medium to produce an intensely red-colored complex has also been proposed. Finally, the enzyme alcohol oxidase (AOX) is a valuable tool for ethanol analysis in complex samples. Various AOX sensors have been developed based on monitoring O_2 consumption or H_2O_2 formation using amperometric electrodes. Bienzymatic systems have also been assembled using AOX coupled to another enzyme such as horseradish peroxidase.

Chromatographic methods

Gas chromatography (GC) methods usually involve the use of flame ionization detectors (FID); columns made with chemically inert and thermally stable porous polymers, such as polyethylene glycol and polyaromatic-type cross-linked resins; ethanol/water solutions as standards; and N_2 as carrier gas with pressure control. These GC systems are also suitable for the analysis of other volatile compounds such as alcohols and fatty acid esters. These methods may require headspace sampling or organic extraction of small sample volumes or even no extraction at all, followed by direct injection in the GC-FID system. Finally, ethanol can be determined by high-performance liquid chromatography (HPLC) techniques, usually involving columns packed with ion-moderated partition polymers, dilute acid or distilled water as mobile phase, and refractive index detectors.

Spectroscopic methods

Ethanol can be determined by infrared spectroscopy (IR) techniques, based on the measurement of the absorption of different wavelengths that pass though the sample. Although the equipment involved is cheaper and the methods are simpler and faster, IR techniques do not have the high resolutions of GC or HPLC and are mainly used for qualitative analysis. However, near-infrared spectroscopy has become an important quantitative tool for solvent characterization. Raman spectroscopy techniques have also been proposed for the quantification of ethanol and methanol in distilled alcoholic beverages.

Determination of Dry Extract and Inorganic Elements

The total dry extract (TDE) includes all matter that is nonvolatile under specified conditions. Gravimetric methods for TDE involve weighing of the residue left after evaporation and drying. The TDE can also be calculated indirectly based on the density of the sample from which alcohol has been removed and has been returned to the original volume by adding water. The inorganic content is represented by ash, which is defined as the amount of substances remaining after igniting (500–550 °C) the solid residue left after sample evaporation (dry ashing), in a way that all cations (except ammonium) are converted into carbonates or other anhydrous inorganic salts. Specific metals in alcohol products are often determined by atomic absorption or emission techniques as well as by colorimetric and electrochemical methods.

Determination of Volatile Congeners

Determination of other volatile substances (congeners) in alcoholic beverages, such as acetaldehyde, ethyl acetate, acetal, and methanol, can be directly analyzed or after distillation by GC-FID using suitable internal standards. Methanol can also be determined colorimetrically after oxidation to formaldehyde by potassium permanganate followed by reaction with chromotropic acid to form a violet product. Minor volatile constituents can be identified and analyzed by a variety of gas chromatography–mass spectrometry techniques (GC-MS).

Determination of Organic Contaminants

For the analysis of pesticides, several analytic methodologies have been proposed. GC coupled to tandem mass spectrometry (GC-MS/MS) is increasingly becoming the analytic tool of choice regarding pesticides in complex matrices, because it is a highly selective technique not affected by the sample matrix or coeluting interferences. LC-MS(/MS) techniques have also been recently introduced for pesticide analysis. Analytic methods for mycotoxins, such as LC with fluorescence detection and LC-MS/MS, have been developed mainly for ochratoxin A (OTA) determination in wines. Multiresidue methods for the simultaneous determination of pesticides and mycotoxins have also been proposed. Finally, the determination of phthalates in alcoholic beverages can also be done by GC-MS after extraction with a nonpolar solvent, while ethyl carbamate can be determined by GC-MS/MS.

Alkaloids: Properties and Determination

M Wink, Heidelberg University, Heidelberg, Germany

© 2016 Elsevier Ltd. All rights reserved.

Definition

The definition of alkaloids has changed throughout the years. Formerly, this class of secondary compounds was restricted to plant bases with a heterocyclic nitrogen atom. Exocyclic nitrogen bases were termed 'pseudoalkaloids.' Other definitions demanded that the skeleton of alkaloids should derive from amino acids or that these bases have explicit pharmacological activities. At present, alkaloids are defined in a more pragmatic way; they include all nitrogen-containing natural products that are not otherwise classified as peptides, nonprotein amino acids, amines, cyanogenic glycosides, glucosinolates, cofactors, phytohormones, or primary metabolites (such as purine and pyrimidine bases). Even a number of antibiotics produced by bacteria or fungi are therefore included in the group of alkaloids.

Occurrence

Alkaloids have been detected in about 15% of plants, bacteria, fungi, and even in animals. Within the plant kingdom, they occur in primitive groups such as *Lycopodium* or *Equisetum*, in gymnosperms and angiosperms. In higher plants (angiosperms), some families contain more alkaloid-containing taxa than others. Such alkaloid-rich taxa include Papaveraceae, Berberidaceae, Fabaceae, Boraginaceae, Apocynaceae, Asteraceae, Liliaceae, Gnetaceae, Ranunculaceae, Rubiaceae, Solanaceae, and Rutaceae. Also, several food plants and food items may contain alkaloids (Table 1).

It has been speculated that alkaloids evolved early in evolution and were already present at the time (*c*.200 Ma) when the angiosperms began to radiate. In general, specific alkaloid types are restricted to particular systematic units and are therefore of some importance for the systematics, taxonomy, and phylogeny of plants. For example, benzylisoquinoline alkaloids are typical for Papaveraceae, Berberidaceae, and Ranunculaceae, which seem to be phylogenetically related. Other alkaloids occur in phylogenetically unrelated plant families. Ergot alkaloids occur not only in fungi (*Claviceps*) but also in members of the Convolvulaceae; quinolizidine alkaloids (QAs) are typical for some Fabaceae but have also been detected in Berberidaceae (*Caulophyllum* and *Leontice*). It has been speculated that the genes encoding enzymes leading to the main QA skeleton are distributed much more widely in the plant kingdom but are normally switched off. Alternatively, convergent evolution, horizontal gene transfer, and the production of alkaloids by endophytic fungi (e.g., ergot alkaloids) have been shown or suggested.

Isolation and Detection

Alkaloids form free bases in alkaline solutions. The free base is usually lipophilic and mostly insoluble in water but soluble in organic solvents (ethanol, methanol, diethyl ether, and methylene chloride). At higher hydrogen ion concentrations (i.e., $pH < 7$), alkaloids occur in a protonated state and are usually soluble in water but insoluble in apolar organic solvents. The different solubilities are useful to isolate and purify alkaloids. In the laboratory, alkaloids are often solubilized from plant material by dissolving them in acidic solutions (e.g., 0.5 M HCl). Treatment of this solution with organic solvents will remove nonalkaloidal substances. The solutions are then brought to $pH > 12$ in the next step and extracted with CH_2Cl_2, ethyl acetate, or diethyl ether to yield free alkaloids.

Plant extracts are often analyzed by thin-layer chromatography (TLC) as a first screening to find out whether alkaloids are present or not. A number of reagents give typical color reactions, such as Dragendorff's or Mayer's reagent. Because alkaloids are typically present in complex mixtures consisting of two to five main and up to 20–50 minor alkaloids, TLC does not have sufficient separation capacities for a complete analysis. Better methods are high-performance liquid chromatography (HPLC) and capillary gas–liquid chromatography (GLC). The latter method is extremely useful because it has a strong separation power and is very sensitive and selective if a nitrogen-specific detector is used. Furthermore, GLC can be directly coupled with a mass spectrometer, allowing mass spectra to be obtained, even from very minor components. Since many alkaloids have been analyzed by mass spectrometry, already a large collection of mass spectra is available, making it possible to identify many of the known alkaloids unambiguously. Usually, mass spectra are recorded in the electron impact (EI) mode, which promotes fragmentation. If information on the molecular ions is needed (which can be elusive in EI-MS), other MS techniques, such as chemical ionization, field desorption, and fast-atom bombardment, are the methods of choice.

HPLC tends to be less sensitive and of lower separation capacity than capillary GLC. However, modern photodiode array detectors are very helpful to identify known metabolites by UV–VIS spectroscopy. Today, also, HPLC and capillary electrophoresis can be coupled to a mass spectrometer, thus widening the use of MS for the analysis of natural products. LC–MS has become a major technique in many analytic applications.

In addition, HPLC has a major advantage in that it is possible to isolate a compound in milligram quantities that allow structural elucidation by nuclear magnetic resonance (^1H, ^{13}C). Nuclear magnetic resonance is the method of choice if unknown structures are to be elucidated, whereas mass spectrometry is extremely useful for identifying previously described substances or substances that are slightly different to known compounds.

If small quantities (femtogram or nanogram amounts) of known alkaloids need to be detected routinely, immunologic procedures such as radioimmunoassays (RIA) and enzyme immunoassays (EIA, ELISA) should be appropriate. In order

Table 1 Alkaloids present in food plants and beverages and in addition as stimulants or hallucinogens

Substance	*Occurrence*	*Biological activity*
Alkaloids in food		
Solanine and other steroid alkaloids	*Solanum* (potato and tomato)	Membrane disruption, acetylcholine esterase inhibition, mutagenicity
Pyrrolizidine alkaloids	*Symphytum* (comfrey); honey (if bees have visited PA plants)	DNA and protein alkylation; mutagenicity, cancer
Cycasin	Cycas, other cycads	Mutagenicity
Ergot alkaloids	*Claviceps purpurea*; on rye, wheat, barley	Neuroreceptor interaction; vasoconstriction; uterus contraction
Saxitoxin	Algae; ends up in food chain (mollusks and fish)	Neurotoxin (Na^+ channel)
Lupanine and other quinolizidine alkaloids	*Lupinus*; other genistoids	Interaction with AChR[a], Na^+, K^+ channels
Pelletierine	*Punica granatum*	Interaction with AChR
Alkaloids in beverages		
Caffeine, theophylline, theobromine	*Coffea*, *Thea*, *Paullinia*, *Ilex paraguariensis*	Stimulants
Quinine	*Cinchona succirubra*	Bitter tonic; neuroreceptor and ion channel interaction
Alkaloids as stimulants and hallucinogens		
Ephedrine and related compounds	*Ephedra*; *Catha edulis*	Central stimulant
Morphine	*Papaver somniferum*, opium	Hallucinogen; analgesic
N-Methyltryptamine	Fungi, plants	Central stimulant
N, *N*-Dimethyltryptamine, 5-methoxy-*N*, *N*-dimethyltryptamine	Mimosaceae: *Anadenanthera* (syn. *Piptadenia*), *Mimosa hostilis*; Myristicaceae: *Virola*; Malpighiaceae: *Banisteriopsis*; Poaceae: *Phalaris*	Central stimulants, hallucinogen
Serotonin	Fungi (*Amanita*); stinging hairs of *Urtica*, *Laportea*, *Jatropha urens*, *Mucuna pruriens*; seeds and fruits	Local inflammation
Bufotenine	Fungi (*Amanita*); animal poisons (Cnidaria, spider, scorpions, wasps, and toads)	Central stimulant, hallucinogen
Psilocybin, psilocin	Fungi (*Psilocybe*, *Stropharia*, *Conocybe*, *Panaeolus*, *Gymnopilus*, *Psathyrella*, etc.)	Central stimulant, hallucinogen
Mescaline	*Lophophora williamsii*; other cacti	Hallucinogen
Harmaline and other β-carboline alkaloids	*Peganum harmala*, *Banisteriopsis caapi*	Hallucinogens
Cocaine	*Erythroxylon coca*	Stimulant, analgesic
Arecoline	Nuts of areca palm	Stimulant

[a]AChR, acetylcholine receptor.

to obtain specific antibodies, the alkaloid in question has to be coupled chemically to a large protein, such as albumin, usually by some sort of spacers (e.g., succinic acid). Such constructs induce the generation of specific antibodies.

recombinant DNA technology allows the production of such enzymes in microbial systems. In the future, it is likely that several of the medicinally important alkaloids could thus be produced in recombinant microorganisms.

Biosynthesis

The skeleton of most alkaloids is derived from amino acids (Figure 1 and Table 2), although moieties from other pathways, such as terpenoids, are often combined. In addition, in a number of alkaloids (e.g., steroid alkaloids), the nitrogen (deriving from glutamine or other NH_2 sources) is added near the end of a biosynthetic pathway, that is, the alkaloid skeleton does not stem from amino acids. Biosynthetic pathways have been worked out in detail for several alkaloids. For isoquinoline and monoterpene indole alkaloids, not only the enzymes but also the corresponding genes are known that catalyze individual steps in the biosynthesis. Employing

Accumulation and Storage

Although the exact site of alkaloid formation in a plant cell has been elucidated for a few species only, it is certainly correct to assume that most compounds are synthesized in the cytoplasm. Membrane-enclosed vesicles have been implied in the biosynthesis of berberine. Not only is the chloroplast the site of photosynthesis and related processes, but also it harbors a number of biosynthetic pathways, such as those for fatty acids and amino acids. In addition, QAs are synthesized in the chloroplast stroma; thus, both the alkaloid and its amino acid precursor, L-lysine, share the same compartment. QA formation is regulated by light and displays a diurnal rhythm.

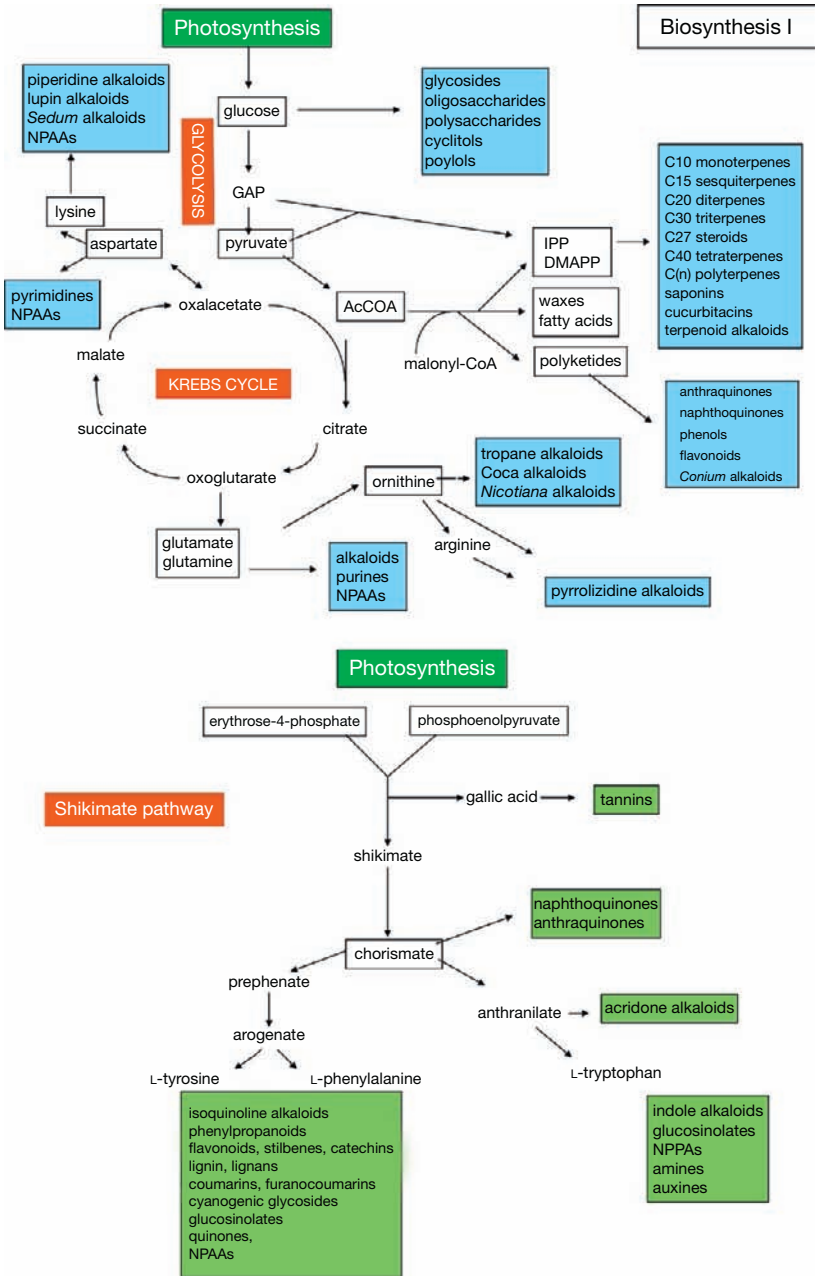

Figure 1 Schematic overview of biosynthetic pathways leading to different groups of alkaloids.

continued

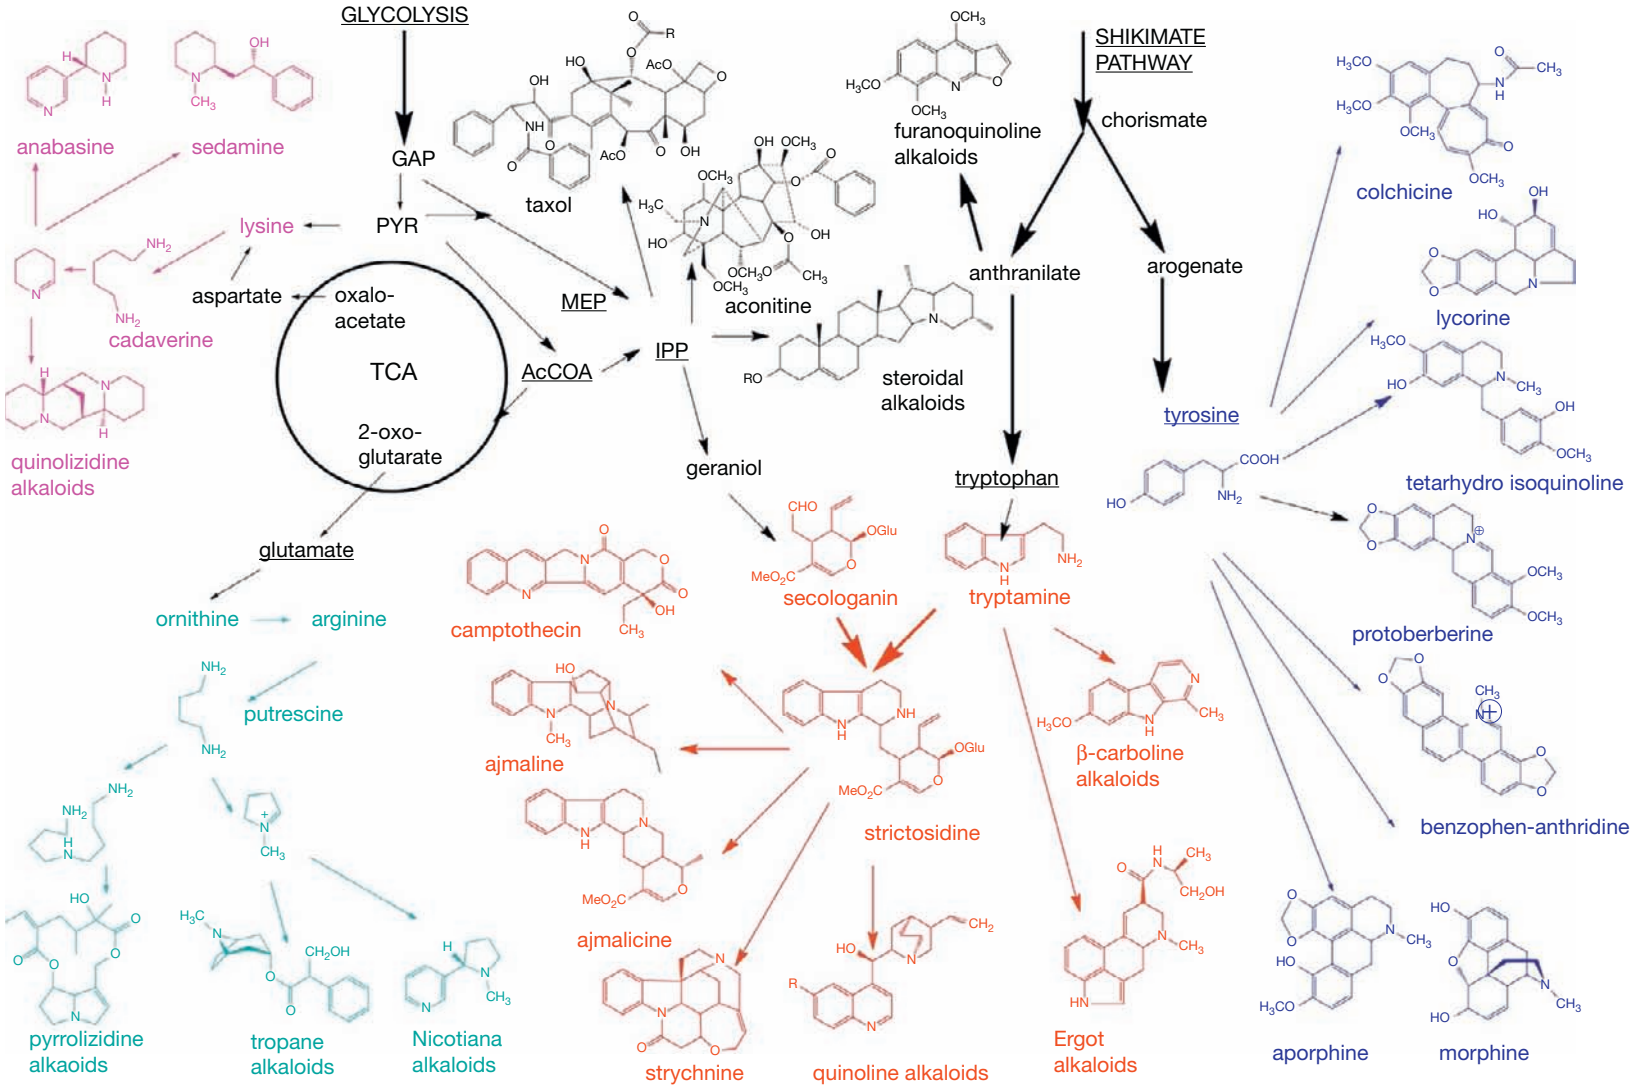

Figure 1—Cont'd

Table 2 Examples for important alkaloids and their biosynthetic precursors

Amino acid	*Alkaloid*	*Main occurrences*	*Example structure*
Lysine	Quinolizidine alkaloids	Fabaceae	Lupanine, sparteine, cytosine
	Lycopodium alkaloids	Lycopodiaceae	Lycopodine
	Piperidine alkaloids	Punicaceae, Crassulaceae	Pelletierine, sedamine
Ornithine	Tropane alkaloids	Solanaceae, Erythroxylaceae	Hyoscyamine, cocaine
	Pyrrolizidine alkaloids	Asteraceae, Boraginaceae, Fabaceae	Senecionine, heliotrine
	Nicotiana alkaloids	Solanaceae	Nicotine, anabasine
Tryptophan	Monoterpene indole alkaloids	Apocynaceae	Strychnine, vincamine, yohimbine, ajmalicine, etc.
	Simple indole alkaloids	Fabaceae	Physostigmine
	Quinoline alkaloids	Rubiaceae, Cornaceae	Quinine, cinchonine, camptothecin
	Ergot alkaloids	*Claviceps*, Convolvulaceae	Ergotamine, lysergic acid
	β-Carboline alkaloids	Loganiaceae, Zygophyllaceae	Harman, harmaline
Phenylalanine/ tyrosine	*Ephedra* alkaloids	Ephedraceae	Ephedrine
	Tetrahydroisoquinoline alkaloids	Rubiaceae	Emetine
	Benzylisoquinoline alkaloids	Papaveraceae, Berberidaceae	Papaverine
	Benzophenanthridine alkaloids	Papaveraceae	Sanguinarine
	Protoberberine alkaloids	Berberidaceae, Papaveraceae	Berberine
	Morphinan alkaloids	Papaveraceae	Morphine, codeine
	Aporphine alkaloids	Monimiaceae	Boldine
	Phenylethylisoquinoline alkaloids	Colchicaceae	Colchicine
	Aristolochia alkaloids	Aristolochiaceae	Aristolochic acid
Anthranilic acid	*Ruta* alkaloids	Rutaceae	Skimmianine, dictamine

Light regulation seems to be triggered by (1) lysine availability (it is also made during the day), (2) the change in stromal hydrogen ion concentration to pH 8 (enzymes of QA formation have a pH optimum at pH 8), and (3) the reduction of QA enzymes by thioredoxin (reduced thioredoxin is generated under illumination).

Alkaloids are not formed in the extracellular space or in the vacuole. The storage of high concentrations of alkaloids is a prerequisite for their allelochemical roles as defense compounds. Since these concentrations would interfere with the normal metabolisms, the allelochemicals are safely stored in the vacuole (**Table 3**) of often specialized cells or tissues (such as epidermis). The vacuole of these alkaloid-accumulating cells has been termed the 'toxic' or 'defense' compartment. A number of plants produce latex, which, in addition to its gluing properties (think of insect mandibles!), often contains defense chemicals, such as alkaloids (morphine and related benzylisoquinoline alkaloids in Papaveraceae, protoberberine and benzophenanthridine alkaloids in *Chelidonium*, and lobeline and other piperidine alkaloids in *Lobelia*) and terpenoids (e.g., phorbol esters). The alkaloids are selectively sequestered in small (diameter < 1 μm) latex vesicles and reach local concentrations of up to 1 M.

Storage in the vacuole or in vesicles demands that alkaloids pass the tonoplast and accumulate within the vacuole against a concentration gradient. For the passage across the tonoplast, three mechanisms are plausible:

- Simple diffusion (takes place in the case of lipophilic alkaloids, e.g., nicotine, ajmalicine, vinblastine, and colchicine)
- Carrier-mediated transport (in the case of polar and charged alkaloids, which is the rule for most alkaloids under physiological conditions, e.g., hyoscyamine, lupanine, reticuline, scoulerine, and senecionine)
- Membrane fusion (in the case of alkaloids that are formed in vesicle-enclosed compartments, e.g., berberine)

Table 3 Storage of alkaloids in the vacuole

Alkaloid	*Genus*
Leaf vacuoles	
Lupanine	*Lupinus*
Sparteine	*Cytisus*, *Lupinus*
Hyoscyamine	*Atropa*
Nicotine	*Nicotiana*
S-Coulerine	*Fumaria*
S-Reticuline	*Fumaria*
Ajmalicine	*Catharanthus*
Serpentine	*Catharanthus*
Catharanthine	*Catharanthus*
Betalains	*Beta*, *Chenopodium*
Senecionine-*N*-oxide	*Senecio*
Capsaicin	*Capsicum*
Latex vesicles	
Sanguinarine	*Chelidonium*
p-Berberine	*Chelidonium*
Morphine and other morphinane alkaloids	*Papaver*

Because alkaloids are sequestered against a concentration gradient in the vacuole or in latex vesicles, the driving force of uphill accumulation needs to be determined. In some instances, vesicles or vacuoles contain alkaloid binding or complexing compounds. For example, latex vesicles of *Chelidonium majus* contain between 500 and 1200 mM chelidonic acid, which binds or

complexes berberine and benzophenanthridine alkaloids. It has been shown experimentally that chelidonic acid acts as a trapping agent that causes the apparent uphill transport, resulting in alkaloid concentrations in vesicles of 500–1200 mM. Protonation, organic acids, and specific peptides may constitute other trapping mechanisms. There is some evidence that amino acids and some ions are transported into the vacuole with aid transporters that are fueled by proton–substrate antiport mechanisms. Protons are enriched in the vacuole, which generally has hydrogen ion concentrations of 0.001–1 mM (=pH 6–3), by proton-translocating ATPases and pyrophosphatases. In analogy, it has been assumed (supported by experimental evidence) that carrier transport of alkaloids is achieved by a proton–alkaloid antiport mechanism or with the aid of ABC transporters. There is good evidence that plants have a large number of ATP-binding cassette (ABC) transporter genes and that these pumps play a role in the distribution of alkaloids within plants and within cells.

Whereas a few alkaloids are formed ubiquitously in all plant organs, organ- or even tissue-specific formation seems to be more common (Table 4). Since most eukaryotic genes are regulated in a cell-, tissue-, and organ-specific manner, genes of alkaloid formation seem to be no exception. The corresponding promotors are presumed to be regulated by respective regulatory proteins. This conclusion is important for the interpretation of results obtained with cell suspension cultures. Whereas alkaloid formation is active in differentiated systems (root or shoot cultures), it is usually reduced, or even absent, in undifferentiated suspension cultured cells. It is likely that the corresponding alkaloid genes are just 'switched off.' The production of berberine and sanguinarine in cell cultures seems to be more the exception than the rule.

Alkaloids are stored predominantly in tissues that are important for survival and reproduction, which include actively growing young tissues, root and stem bark, flowers (especially seeds), seedlings, and photosynthetically active tissues. Alkaloid contents in storing organs can be quite high, reaching up to 10% of dry weight in some instances, which is important if the alkaloids are to function as effective defense compounds. In several herbaceous plants, alkaloids are stored in epidermal and subepidermal tissues (e.g., cocaine, colchicine, aconitine, steroidal alkaloids, nicotine, veratrine, buxine, and coniine), which have to ward off small enemies (insects and microorganisms) in the first place. In lupins and broom, QA concentrations are up to 200 mM in epidermal tissue, whereas mesophyll tissue has values below 5 mM. Some plants possess typical alkaloid-storing cells, called 'idioblasts.' These idioblasts have been detected in *Corydalis* (for corydaline), *Sanguinaria* (for sanguinarine), *Ruta* (for rutacridones), *Catharanthus* (for indole alkaloids), and *Macleaya* (for protopine). Short- and long-distance transports are often required to reach these sites of accumulation.

Alkaloid patterns usually vary between the site of synthesis and the sites of accumulation, since a number of secondary substitutions may take place in the latter tissues, or transport may be selective, distributing differing cocktails. In addition, alkaloid profiles of seeds and seedlings often differ from those of the mature plant. Both patterns and concentrations usually change during the development of plants and the annual cycle. In general, alkaloid levels are markedly reduced in senescing tissues, so that shedded leaves are often nearly alkaloid-free. Alkaloid formation and storage may be influenced by environmental stress, such as wounding or infection.

Table 4 Examples for organ-specific biosynthesis of alkaloids

Alkaloid	*Organ*	*Species*
Tropane alkaloids	Roots	*Atropa*, *Datura*, *Hyoscyamus*, *Mandragora*
Nicotine	Roots	*Nicotiana*
Senecionine and other PAs	Roots	*Senecio*
Emetine	Roots	*Cephaelis*
Sanguinarine	Roots	*Sanguinaria*
Betalains	Roots, shoots	*Beta*
Quinine	Stem bark	*Cinchona*
Berberine	Stem and root bark	*Berberis*, *Mahonia*
Caffeine	Green tissue	*Coffea*
Quinolizidine alkaloids	Leaves and other photosynthetic tissues	*Lupinus*, *Cytisus*, *Laburnum*, *Baptisia*
Steroid alkaloids	Roots, tubers, leaves	*Solanum*

Transport and Turnover

A number of alkaloids are synthesized and stored in all parts of plants, whereas others are restricted to a particular organ. Alternatively, alkaloids are synthesized but accumulated in many organs, which usually demands long-distance transport. Theoretically, this transport could proceed sym- or apoplastically. However, the utilization of established transport routes, such as xylem or phloem, seems to be more common. Because it is technically difficult to sample and analyze xylem and phloem sap, only a limited number of appropriate data are available (Table 5). Besides long-distance transport, short-distance and intracellular transports need to be reviewed. In general, alkaloids are synthesized in the cytosol or in membrane-enclosed vesicles (endoplasmic reticulum, mitochondria, and chloroplasts) but are accumulated and sequestered in the vacuole.

Table 5 Evidence for long-distance transport of alkaloids by phloem or xylem

Alkaloid	*Xylem*	*Phloem*	*Occurrence*
Lupanine, sparteine		X	*Lupinus*, *Cytisus*
Cytisine		X	*Laburnum*, *Petteria*, *Genista*, *Spartium*
Matrine		X	*Sophora*
Senecionine (*N*-oxide)		X	*Senecio*
Aconitine	?	X	*Aconitum*
Swainsonine		X	*Astragalus*
Nicotine	X		*Nicotiana*
Hyoscyamine	X		*Atropa*
Scopolamine	X		*Datura*, *Hyoscyamus*

In general, alkaloids are not end products of metabolism but can be degraded, which seems to be plausible because nitrogen is a limited nutrient for plants. As discussed previously, alkaloids stored in seeds are partly degraded during germination and seedling development, and their nitrogen is probably used for the synthesis of amino acids. Degradative pathways have not been worked out yet.

In addition to this developmentally specific recycling, there is evidence that a number of alkaloids are turned over all the time, with half-lives of between 2 and 48 h. Examples are nicotine, QAs, and tropane alkaloids. Alkaloid turnover is often quite substantial in cell cultures: *Lupinus* callus cultures are even able to live on the QA sparteine as a sole nitrogen source for more than 6 months.

How can we explain this phenomenon? A number of alkaloids are defense chemicals (allelochemicals) and affect molecular targets such as receptors of neurotransmitters (tropanes, nicotine, etc.). For this interaction, a correct stereochemical configuration is required. Because alkaloids may oxidize or give rise to racemic mixtures spontaneously, a continuous turnover would make sure that a sufficient concentration of active compounds is always available, similar to the situation of protein turnover.

Functions

Although several alkaloids and other secondary metabolites have been used by mankind for thousands of years as dyes (e.g., indigo and shikonine), flavors (e.g., vanillin, capsaicin, and mustard oils), fragrances (e.g., rose oil, lavender oil, and other essential oils), stimulants (e.g., caffeine, nicotine, and ephedrine), hallucinogens (e.g., morphine, cocaine, mescaline, hyoscyamine, scopolamine, and tetrahydrocannabinol), insecticides (e.g., nicotine, piperine, and pyrethrin), vertebrate and human poisons (e.g., coniine, strychnine, and aconitine), and even therapeutic agents (e.g., atropine, quinine, codeine, and cardenolides), their putative functions have been discussed controversially.

Alkaloid biology is tightly connected with the basic physiology of plants. Many of the features described before would make no sense if these compounds did not have a vital function for the producer. As a common theme, it has been observed that plants that produce seeds rich in energy supplies (carbohydrates, lipids, and proteins) concomitantly accumulate potent chemical defense compounds, often alkaloids, nonprotein amino acids, cyanogenic glycosides, glucosinolates, protease inhibitors, lectins, or other toxalbumins. Their presence in seeds can be mutually exclusive, that is, legume seeds store either alkaloids (e.g., quinolizidines and pyrrolizidines) or nonprotein amino acids, but not both at the same time. During germination, the breakdown of nutrient reserves is a general procedure and usually includes the nitrogenous defense compounds. They serve a double purpose, that is, that of N-storage and that of protection. They are thus degradable and toxic N-storage compounds.

The main function is obviously that of chemical defense against herbivores (insects, other arthropods, and vertebrates), which can be deduced from the fact that many alkaloids have a high affinity for receptors of neurotransmitters that are present only in animals. In some instances, alkaloids play a role (additionally) in the antimicrobial defense (against bacteria, fungi, and viruses) and even in the interaction between plants (allelopathy).

Alkaloids are certainly multipurpose compounds that, depending on the situation, may be active in more than one environmental interaction. For example, QAs are certainly the most important defense chemical in Fabaceae against insects and other herbivores, but they also influence bacteria, fungi, viruses, and even the germination of other plants. In addition, they are employed as degradable N-transport and N-storage compounds.

Alkaloids repel or deter the feeding of many animals (many have a bitter or pungent taste to humans and other vertebrates) or are toxic if ingested. In microorganisms and competing plants, a reduction of growth and antibiosis are usually the visible effects of alkaloid intoxication. How are these diverse effects being achieved? Although most compounds have not been studied in full detail, an impressive number of cellular and molecular targets have been identified that are selectively inhibited or modulated by alkaloids. As a consequence of such interactions, organ malfunctions (heart, lung, liver, kidney, and CNS disorders) result that may impair reproduction and fertility in animals and other organisms or simply kill them.

Because many alkaloids have been shaped during evolution by 'molecular modeling,' many of them are used by humans as medicinal compounds; allelochemicals may have positive effects if used at nontoxic concentrations.

Presence at the Right Concentration at the Right Time and Place

To be effective, alkaloids need to be present at the right time, site, and concentration. Alkaloid metabolism and biochemistry seem to have been optimized and coordinated in most systems to fulfill this prerequisite. An interesting variation can be seen in some plants, where alkaloid formation is enhanced by wounding or microbial attack, that is, in case of emergency, the production of defense compounds is stimulated.

How effective are alkaloidal defenses? In lupins, which normally produce high amounts of QAs, mutants have been selected (the so-called sweet lupins) that accumulate only trace amounts of alkaloids. When both alkaloid-rich and low-alkaloid lupins are planted in the field without any fences and phytoprotectives, a dramatic effect can often be seen (**Figure 2**). Whereas the low-alkaloid lupins were selectively grazed or infested by herbivores, their alkaloid-rich counterparts remained almost undisturbed. More experimental data are certainly needed, but the defensive role of alkaloids seems to be beyond doubt.

Similar to the situation in sweet lupins, in which plant breeders have eliminated the alkaloid trait, also in other crop plants, secondary metabolites, which had evolved to serve as defense compounds, have been bred away or strongly decreased. As a consequence, many crop plants have lost their original resistance to pests and herbivores. Man-made chemistry (i.e., synthetic pesticides) has to be used if these crop plants have to be cultured.

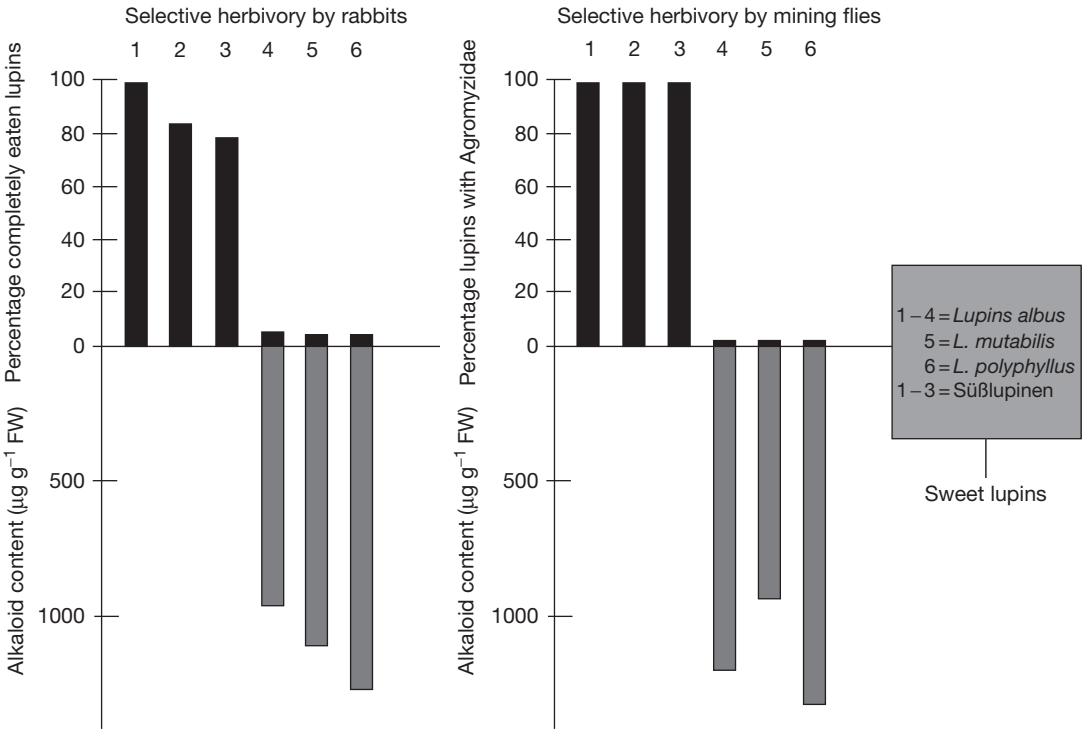

Figure 2 Selective advantage of alkaloids in lupins against herbivores (rabbits and mining flies). Lupins without alkaloids suffer heavily from herbivory, whereas alkaloid-rich lupins are widely protected.

Exceptions to the Rule: Adaptations of Specialists

No defense is absolute. Whereas chemical defense works against the majority of potential enemies, usually a few specialists have evolved during evolution that have become specialized in the toxin-protected ecological niche. This phenomenon can be clearly seen in many insects, which are often highly host plant-specific. Some of these insects take up the dietary alkaloids, store, and exploit them for their own chemical defense or that of their offspring. Others additionally transform the alkaloids into pheromones or utilize them as morphogens. Well-studied examples have been published for pyrrolizidine and QAs. Vertebrate herbivores (humans included) have effective liver enzymes that can detoxify xenobiotics. Often, substances become hydroxylated, conjugated, and then excreted via the feces or the kidney and urine.

Alkaloids: Toxicology and Health Effects

M Wink, Heidelberg University, Heidelberg, Germany

© 2016 Elsevier Ltd. All rights reserved.

Why Alkaloids Are Abundant in Plants

Apparently, most alkaloids play an important role in the ecology of plants or animals. They serve as defense chemicals against herbivores and predators. To a lesser degree, they protect against bacteria, fungi, and viruses or provide a means for plant–plant interactions. To be effective defense chemicals, alkaloids must closely interact with specific targets in herbivores, predators, microorganisms, or competing plants, that is, they must either inhibit or otherwise deregulate important processes that are vital for these organisms. For this purpose, the molecular shape of alkaloids has apparently been optimized during a million years of evolution in a process, which could be termed 'evolutionary molecular modeling.'

While the structures of more than 21 000 individual alkaloids have been reported, rather limited knowledge is available for most of them in terms of biological activities and functions. In this article, the modes of action of the better known alkaloids, especially those found in food plants, are summarized and discussed, considering interactions with organs or complete organisms first and then molecular targets. These interactions are the base for understanding the toxic or antinutritional effects that are observed if humans or animals have ingested alkaloids with their diet.

Toxic and Pharmacological Effects at the Organ Level

Many alkaloids are known for their toxic or adverse effects on animals (Table 1). In many cases, only the toxicity of an alkaloid has been reported evidencing substantial interactions, but the exact mode of action has not yet been elucidated or is rather complex, involving several molecular targets and organs.

In medicine, alkaloids are employed as local anesthetics, narcotics, analgesics, and cardiac, uterine, and respiratory stimulants or to raise blood pressure, to dilate pupils, and to relax the skeletal muscles (Table 2). The use of alkaloids as narcotics and hallucinogens causes major social problems.

Ultimately, the toxic and pharmacological effects (Tables 1 and 2) observed must be the result of interactions of alkaloids with molecular targets present in or on the cells.

Central Nervous System and Neuromuscular Junctions

A remarkable number of alkaloids interfere with the metabolism and activity of neurotransmitters in the brain and nerve cells. A disturbance of metabolism or binding of neurotransmitters and related signal pathways impairs learning and memory, sensory faculties (smell, vision, or hearing), and coordination of bodily functions or produces euphoric or hallucinogenic effects.

Muscle activity (skeletal, heart, etc.) is controlled by acetylcholine (ACh) and norepinephrine (noradrenaline). Any inhibition or overstimulation of neurotransmitter-regulated ion channels will severely influence muscular activity and thus the mobility or organ function (such as the heart, lungs, and gut). When there is inhibition, the muscles will relax; when there is overstimulation, they will be tense or in tetanus, leading to a general paralysis and/or respiratory failure (which is the effect of many of the more toxic alkaloids). Alkaloids that activate (the so-called parasympathomimetics) or inhibit (parasympatholytics) neuromuscular action are tabulated in Table 3. These compounds are usually considered to be strong poisons (Table 1).

Inhibition of the Digestive Process

Food uptake can be reduced by pungent or bitter taste in the first instance. The next step can be the induction of vomiting, which is a common reaction to the ingestion of a number of alkaloids; the alkaloid emetine already implies this activity in its name! Causing diarrhea, or the opposite, constipation, would be another activity that negatively influences the digestive system. Many intoxications with alkaloid-containing plants have diarrhea as one of the symptoms. Another way to interfere would be the inhibition of digestive enzymes or of transport proteins for amino acids, sugars, or lipids.

Modulation of Liver and Kidney Function

Nutrients and xenobiotics (such as secondary metabolites) are transported to the liver after resorption in the intestine. In the liver, the metabolism of carbohydrates, amino acids, and lipids and the subsequent synthesis of proteins and glycogen take place. The liver is also the main site for the detoxification of xenobiotics. Lipophilic compounds, which are easily resorbed from the diet, are often hydroxylated and then conjugated with a polar, hydrophilic molecule, such as glucuronic acid, sulfate, or an amino acid. These conjugates are exported via the blood to the kidney for elimination via the urine. Both organ systems are affected by a variety of secondary metabolites: pyrrolizidine alkaloids (PAs) are activated during the detoxification process and are converted into potent carcinogens, causing liver cancer. Many other metabolic inhibitors, discussed later in the text, are also liver toxins. Many alkaloids are known for their diuretic activity. Increased diuresis would also mean an increased elimination of water and essential ions. Since Na^+ ions are already limited in plant food, long-term exposure to diuresis-inducing compounds would reduce the fitness of a herbivore substantially.

Disturbance of Reproduction

Quite a number of allelochemicals are known to influence the reproductive system of animals, which will ultimately reduce their numbers (and fitness as a species). Antihormonal effects could be achieved by mimicking the structure of sexual hormones, such as coumarins that dimerize to dicoumarols or isoflavones. The next target is the gestation process itself. As outlined in the succeeding text, a number of alkaloids are mutagenic and lead to malformation of the offspring or directly to the death of the embryo. The last step would be premature abortion of the embryo. This dramatic activity has been reported for a number of allelochemicals, including many mono- and sesquiterpenes and alkaloids. Some alkaloids achieve this by the induction of uterine contraction, as do the ergot and lupin alkaloids.

Molecular Targets of Alkaloids

In the following, a number of important cellular molecular targets (Figure 1) have been addressed that are often affected by alkaloids and other plant toxins.

Biomembranes, Membrane Transport, and Neuronal Signal Transduction

Cells can only operate effectively if their biomembranes (cytoplasmic membrane and internal membranes) are intact. Biomembranes are almost impermeable for ions and polar molecules. As an exchange of these molecules must take place between cells and organs, specific membrane proteins, which can be ion channels, pores, or carrier proteins, mediate the controlled flux of these compounds across biomembranes. The biomembranes and the complex transport systems are targets of many natural products.

Steroidal alkaloids, such as solanine and tomatine, which are present in many members of the Solanaceae (including potatoes and tomatoes), can form complexes with the cholesterol present in the biomembranes. While the steroidal moiety 'dives' into the lipophilic interior of the membrane and

Table 2 Pharmacological and medicinal properties of alkaloids

Type	*Alkaloid*	*Activity*
Poison	Pyrrolizidine alkaloids (from *Senecio*, *Heliotropium*, *Crotalaria*)	Conversion to DNA- and protein-alkylating agent in the liver; causing liver cirrhosis, mutations, cancer
	Ergot alkaloids (from *Claviceps purpurea*)	Cause vasoconstrictions, hallucinogenic effects, gangrenous limps; disease named 'ergotism'
Analgesics	Aconitine (*Aconitum*)	Local anesthetic, general paralytic effect
	Morphine (*Papaver somniferum*)	Very effective pain killer (used since ancient times); with addictive properties
	Codeine (*Papaver*)	Pain and cough depression
	Cocaine (*Erythroxylon coca*)	Local anesthetic
Cardiac stimulant	Quinidine (*Cinchona* spec.)	Antiarrhythmic properties at the heart ventricle
	Sparteine (*Cytisus scoparius*)	Antiarrhythmic properties
	Ajmalicine (*Rauvolfia serpentina*)	Antiarrhythmic properties at the heart ventricle
Respiratory stimulant	Nicotine (*Nicotina*), cytisine (*Laburnum*)	Stimulation of respiration is followed by respiratory depression, asphyxia, or even respiratory failure
	Lobeline (*Lobelia* spec.)	Stimulant; used to treat bronchial asthma
	Coniine (*Conium maculatum*)	Used as a potent poison in antiquity (Socrates)
Constriction of blood vessels	Ergot alkaloids (*Claviceps purpurea*)	Used in obstetrics
	Ephedrine (*Ephedra* spec.)	Employed in the treatment of bronchial asthma, cold, sinusitis
	Scopolamine (*Hyoscyamus*, *Atropa*, and *Datura*)	Inhibitor of smooth muscles, for example, dilatator in vessels
Muscle relaxant	Tubocurarine (*Chondrodendron tomentosum*)	Block nAChR[a]; used in surgery
	Hyoscyamine (atropine, *Hyoscyamus*, *Atropa*, and *Datura*)	Antispasmodic at smooth muscles (gastrointestinal tract and bladder)
	Papaverine (*Papaver somniferum*)	Smooth-muscle relaxant
Antiparasitic and antimicrobial activity	Berberine (*Berberis*, *Mahonia*, and *Coptis*)	Intercalates DNA and inhibits parasites and microorganisms
	Emetine (*Psychotria ipecacuanha*)	Intestinal amebiasis, emetic drug
	Boldine (*Peumus boldo*)	Anthelmintic activity
	Quinine (*Cinchona succirubra*)	Antimalarial
Anti-inflammatory activity	Colchicine (*Colchicum autumnale*)	Treatment of acute gout, recurrent gout
Anti-Alzheimer's disease	Physostigmine (*Physostigma venenosum*) Galantamine (*Galanthus nivalis*)	Inhibitor of acetylcholinesterase
Eye treatments	Pilocarpine (*Pilocarpus jaborandi*)	Miotic used in the treatment of open-angle glaucoma
Cancer chemotherapy	Taxol (*Taxus brevifolia*)	Treatment of breast and ovary carcinoma; other malignancies
	Vinblastine, vincristine (*Catharanthus roseus*)	Treatment of lymphomas and other tumors
	Camptothecin (*Camptotheca acuminata*)	Cancer chemotherapy

[a]nAChR, nicotinic acetylcholine receptor.

interacts with the structurally similar cholesterol, the hydrophilic side chain remains outside and binds to external sugar receptors. Since phospholipids are in a continuous motion, a tension easily builds up, which leads to membrane disruption; transient 'holes' occur in the biomembrane, rendering the cell leaky. A similar mechanism has been postulated for saponins, a widely distributed group of natural products, to which the steroidal alkaloids may be assigned. Steroidal alkaloids can also interact with other targets, such as neuroreceptors or even with DNA; malformations have been observed in animal embryos after having been exposed to *Solanum* alkaloids.

Communication between cells is especially important for the nerve cells. Signal transduction in the central nervous system and in neuromuscular junctions is mediated by receptor proteins residing in the membrane, which are directly or indirectly coupled with ion channels. The neurotransmitters involved include, among others, norepinephrine (noradrenaline), epinephrine (adrenaline), serotonin, dopamine, histamine, glycine, γ-aminobutyric acid (GABA), glutamate, and ACh.

Neuroreceptors can be ligand-gated channels, that is, a receptor that is part of an ion-channel complex. When the neurotransmitter binds, a conformational change induces the opening of a Na^+–K^+ channel for microseconds, allowing Na^+ ions (the external concentration is about 145 mmol l^{-1}) to enter the cell following a concentration gradient (the internal Na^+ concentration is between 5 and 15 mmol l^{-1}). The ligand quickly dissociates from the receptor and, in the case of ACh, is hydrolyzed by ACh esterase (Figure 2). Glutamate (*N*-methyl-D-aspartate) and GABA receptors are also ligand-gated ion channels.

More abundant are G protein-coupled neuroreceptors. A prominent one is the muscarinic ACh receptor (AChR); norepinephrine, serotonin, and dopamine receptors also belong to this type. When ACh binds, the receptor changes its conformation, inducing a conformational change in an adjacent G protein molecule. Its α-subunit dissociates and then activates the enzyme adenylyl cyclase, which in turn produces cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). The cAMP molecule, a second messenger, activates protein kinases or Ca^{2+} channels directly.

Quite a number of alkaloids are known whose structures are more or less similar to those of endogenous

Table 3 Examples for alkaloids that bind to neurotransmitter receptors and neurotransmitter-degrading enzymes

Target	*Ligand*	*Alkaloid*	*Occurrence*

(2000). Interference of alkaloids with neuroreceptors and ion channels. In: Atta-Ur-Rahman (ed.) *Bioactive natural products*, pp. 1–127. Amsterdam: Elsevier.

neurotransmitters. They can function therefore as structural analogs. In addition, several plants produce compounds that are identical to animal neurotransmitters, such as ACh and histamine in stinging hairs of *Urtica* or serotonin and dopamine in several species. Targets can be

- the receptor itself through inhibition or overstimulation (Table 3);
- the enzymes that deactivate neurotransmitters after they have bound to a receptor (Table 3);
- transport processes, which are important for the uptake of neurotransmitters into the presynapse or their storage in synaptic vesicles (Table 4); or
- enzymes involved in the biosynthesis of a neurotransmitter.

The stimulation of neurotransmitter-activated ion channels leads to a rapid influx of Na^+ ions, which in turn activates voltage-gated Na^+ and K^+ channels, which are essential for further signal transduction. These Na^+ and K^+ channels constitute another important target for alkaloids (Table 5).

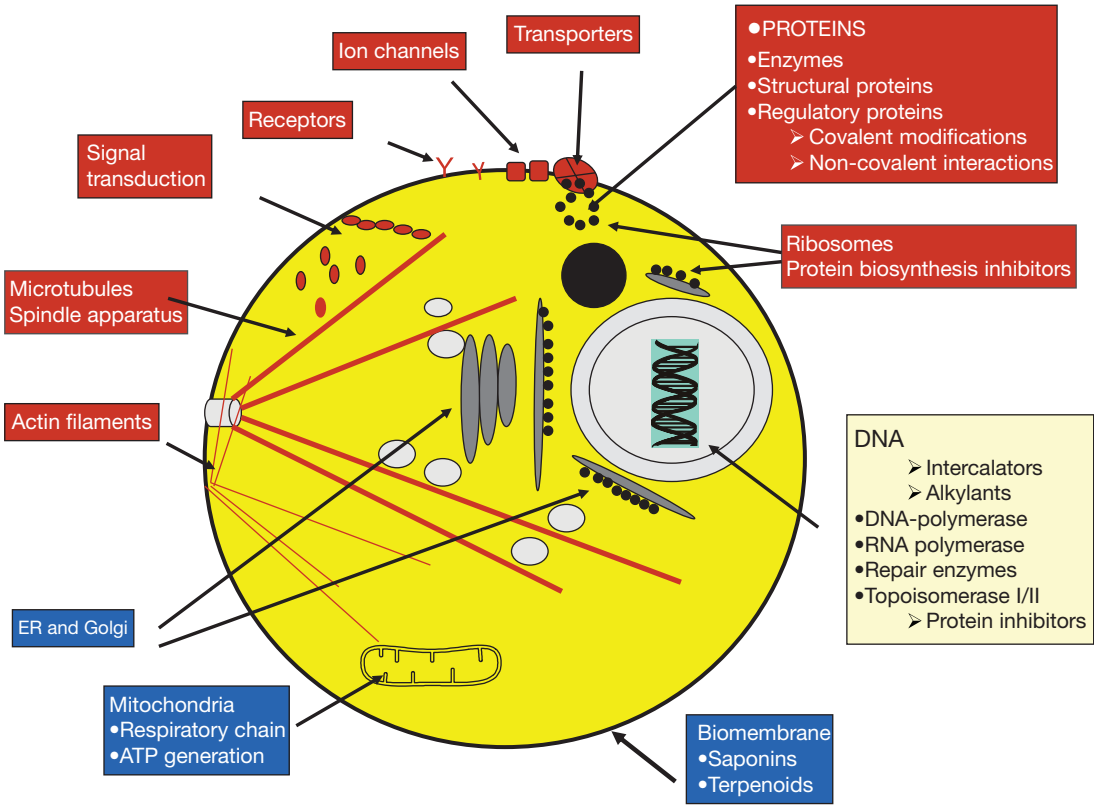

Figure 1 Molecular targets of animal cells that are affected by alkaloids.

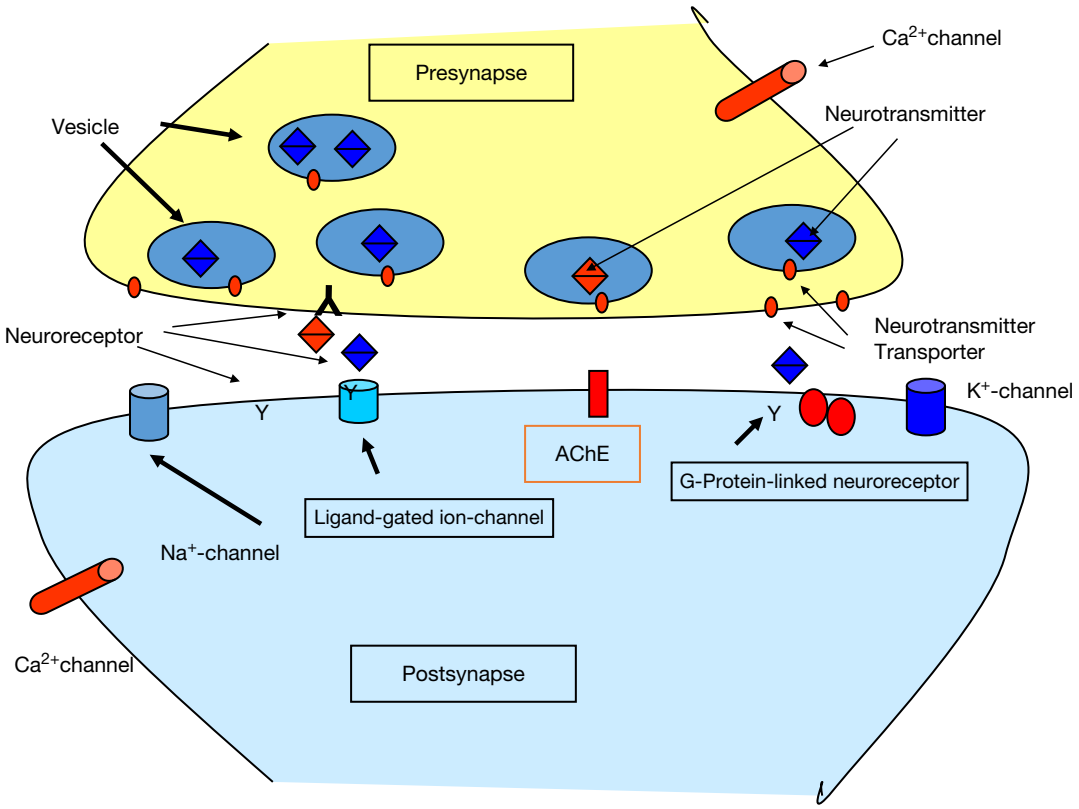

Figure 2 Signal transduction in excitable synapses.

Cells carefully control ion concentrations inside and outside of the cells with the help of specific ion channels (e.g., Na^+, K^+, Ca^{2+}, and Cl^- channels) and of active Na^+, K^+, or Ca^{2+} pumps, such as Na^+/K^+-ATPase and Ca^{2+}-ATPase. Ion gradients and ion fluxes mediated by these channels and pumps are the main elements in the active transport processes, in neuronal and neuromuscular signaling. Cardiac glycosides are potent and well-known inhibitors of Na^+/K^+-ATPase found in plants, some insects, and in the skin of certain toads. A few alkaloids such as harmaline, nitidine, sanguinarine, capsaicin, cassaine, and solenopsin (from ants) inhibit Na^+/K^+-ATPase.

Whereas receptor–ion channel interactions represent the initial part of many signal pathways, key enzymes that produce or inactivate second messengers or amplify the signal can be important targets further down the pathway (Table 6). These enzymes include

- adenylyl cyclase (making cAMP),
- phosphodiesterase (inactivating cAMP),
- phospholipase (releasing arachidonic acid or inositol phosphates), or
- several protein kinases, such as protein kinase C (which is activated by phorbol esters and the alkaloid chelerythrine) or tyrosine kinase (activating other regulatory proteins or ion channels).

Because these targets are almost exclusively found in animals but absent in plants, the development of active compounds directed to these targets appears to be advantageous for the plants producing them. They can store these compounds without risk of being intoxicated by their own toxins.

Table 4 Alkaloids as inhibitors of neurotransmitter uptake (transport into presynapse or into vesicles)

Transporter	*Alkaloid*	*Occurrence*
Norepinephrine	Reserpine	*Rauwolfia*
(Noradrenaline)	Ephedrine	*Ephedra*

[a]Na^+ channel.

DNA/RNA

The genetic information of most organisms is mainly encoded in DNA. Since the integrity of DNA is important for the structure and function of rRNAs, proteins, and enzymes that are important for metabolism, structure, and development of an organism, DNA is a highly vulnerable target. It is not surprising that a number of secondary metabolites became selected during evolution that interact with DNA or DNA-processing enzymes. Some alkaloids are known to bind or to intercalate with DNA (Table 7). Many of these molecules are planar, hydrophobic molecules that fit between the planar stacks of AT and GC base pairs. Other alkaloids act on the level of DNA- and RNA polymerases and DNA topoisomerases, thus impairing the process of replication and transcription.

The effects of DNA-binding or DNA-intercalating compounds can be mutations, which may result in malformations of newborn animals or in the initiation of cancer. When anabasine, coniine, or anagyrine is administered to pregnant cows or sheep, a large proportion of the offspring develop malformations of the legs – the so-called crooked calf disease. Some

alkaloids of the monocot *Veratrum*, such as jervine and cyclopamine, cause the formation of a large central eye, the cyclopean eye, which was probably known to the ancient Greeks and thus led to the mythical figure of the Cyclops.

Other alkaloids are known as carcinogens, such as aristolochic acid from Aristolochia and PAs that are produced by ~3% of the higher plants, especially within the families of Asteraceae and Boraginaceae. Aristolochic acid has a nitro group that can be transformed into reactive intermediates in the intestine. If resorbed, these metabolites can alkylate DNA. PAs are not carcinogenic in their native form, but become so when they are 'detoxified' in the liver: PAs are usually present in the plant as their N-oxides, which are polar compounds that cannot pass biomembranes by simple diffusion. In the intestine, PA N-oxides are reduced by gut bacteria. The free base is then readily taken up by the gut cells and transported to the liver. There, PAs are transformed into alkylating compounds, which covalently bind to DNA and proteins. As a result, mutations and cancer can be initiated.

Protein Biosynthesis

Protein biosynthesis is essential for all cells and thus provides another important target. Indeed, a number of alkaloids have been detected that inhibit protein biosynthesis *in vitro*. Emetine from *Psychotria ipecacuanha* (Rubiaceae) is the most potent plant constituent. Other alkaloids with the same ability include harringtonine, homoharringtonine, cryptopleurine, tubulosine, hemanthamine, lycorine, narciclasine, pretazettine, pseudolycorine, tylocrepine, and tylophorine. Several alkaloids that inhibit protein biosynthesis and are also DNA-intercalating substances can induce apoptosis in cells.

Electron Chains and Other Enzyme Activities

The respiratory chain and ATP synthesis in the mitochondria or photophosphorylation in chloroplasts demand the controlled flux of electrons. These targets seem to be attacked by nicotine, sanguinarine, ellipticine, gramine, alpinigenine, capsaicin, and a few other alkaloids. A multitude of enzymes exist in animal cells and several alkaloids have been reported that interfere with at least one of them.

A recently discovered group of alkaloids are the polyhydroxyalkaloids, such as swainsonine or castanospermine, which inhibit hydrolytic enzymes, namely, glucosidase, galactosidase, trehalase (trehalose is a sugar found in some beetle cocoons and fungi that is hydrolyzed by trehalase), and mannosidase selectively.

Cytoskeleton

Microtubules, which are important for cellular movements, vesicle transport in neurons, or the separation of chromosomes during cell division, are composed of tubulin subunits. Movements and some transport processes are mediated through either the rapid assembly or disassembly of microtubules. The assembly of microtubules is inhibited by colchicine and dimeric indole alkaloids vinblastine and vincristine (important for chemotherapy of certain cancers). These alkaloids thus interrupt cell division. The diterpene alkaloid paclitaxel (Taxol; used in the treatment of ovarian and breast cancer) affects microtubules in the opposite way; the disassembly of tubulin is inhibited by Taxol. As a consequence, Taxol-induced

microtubules are very stable and dividing cells are arrested in the metaphase.

Cell stability, phagocytosis, cell–cell interactions, and cell movements are also controlled by actin filaments, which are rapidly assembled or disassembled from action monomers. Cytochalasin B and latrunculin B bind to the plus end of a growing actin filament, preventing the addition of actin monomers there. Another alkaloid, phalloidin, produced by the fatally poisonous toadstool *Amanita phalloides*, stabilizes actin filaments and inhibits their depolymerization.

Mechanisms of Allelochemical Activities in Antiviral, Antimicrobial, and Phytotoxic Interactions

Circumstantial evidence indicates that some alkaloids protect the producing plant against viruses, bacteria, fungi, and competing plants. A number of antimicrobial alkaloids such as sanguinarine, quinine, or berberine intercalate with viral and microbial DNA or bind to it. These compounds may thus inhibit processes such as DNA replication and RNA transcription, which are vital for the microorganisms. Protein biosynthesis in ribosomes is another vulnerable target, attacked by emetine. The stability of biomembranes can be disturbed by steroidal alkaloids and tetrandrine. Other targets may be electron chains or just metabolically important enzymes. Phytotoxic properties or germination inhibition, which can be observed in plant–plant interactions, can also proceed via the earlier-mentioned mechanisms. But interactions with growth hormones and their metabolism must also be considered.

Target Specificity of Alkaloids

In general, the interactions of a particular alkaloid with a molecular target (as described in the preceding text) suggest a high degree of specificity. A closer look, however, shows that many alkaloids interfere with more than one target. The phenomenon will be explained for two groups of alkaloids: ergot alkaloids and quinolizidine alkaloids (QAs).

Ergot Alkaloids

Ergot alkaloids, such as ergotamine, ergometrine, or ergoclavine, are produced by fungi of the genus *Claviceps*, which lives in close contact with many grasses (family Poaceae) such as the cereal *Hordeum vulgare*. These alkaloids can modulate several receptors of neurotransmitters, such as dopamine, serotonin, and norepinephrine. As a consequence, the pharmacological action of ergot alkaloids is rather broad, ranging from vasoconstriction and uterus contraction to hallucinations. We can explain these activities through structure similarities between the alkaloid and the different neurotransmitters.

Quinolizidine Alkaloids

QAs, such as lupanine, sparteine, or cytisine, are produced by lupins and many members of the Fabaceae. They are bitter for many animals (and plants producing them are therefore avoided as food). If ingested, QAs exhibit a broad level of toxicity: they interact with AChRs as agonists. QAs, like many other alkaloids, occur as complex mixtures in plants. Some QAs preferentially bind to the nicotinic AChR, whereas others tend more to bind to the muscarinic AChR. Some QAs exhibit a prominent cross-reactivity. Additionally, QAs such as lupanine and sparteine inhibit Na^+ and K^+ channels, thus blocking the signal transduction in the nerve cells at a second critical point. A few particular QAs, such as anagyrine, cytisine, and the bipiperidine alkaloid ammodendrine (which co-occurs with QAs in many plants), are mutagenic and lead to malformations (see earlier text).

If we accept the hypothesis that alkaloids were developed as chemical defense compounds through a process of 'evolutionary molecular modeling,' the 'cross-reactivity' described makes sense: any compound that can interfere with more than one target or with more than one group of adverse organisms is likely to be more effective and thus has a better survival value in general than a more selective allelochemical. In addition, herbivores will try to develop tolerance to or resistance against the dietary toxins. If more than one target is affected by a defense chemical, the chances of a herbivore developing specific resistances concomitantly are much smaller than in single-target situations. In conclusion, we can say that nature has obviously tried 'to catch as many flies with one clap as possible' in the selection of alkaloids during evolution.

Medicinal Applications

Because alkaloids can interfere with several molecular targets in animals and microbes, some of them can be used in medicine to treat infections, health disorders, and even cancer.

Important chemotherapeutic alkaloids, used in cancer therapy, include vinblastine and other vinca alkaloids, paclitaxel (Taxol), demecolcine, and camptothecin, Whereas vinblastine, paclitaxel (Taxol), and demecolcine modulate microtubules, camptothecin inhibits DNA topoisomerase I.

Alkaloids that interfere with ion channels can be used as analgesics (aconitine and cocaine) or antiarrhythmic drugs (ajmaline, quinidine, and sparteine).

Alkaloids that modulate receptors of neurotransmitters are interesting as stimulants (caffeine, cathine, cocaine, ephedrine, nicotine, theobromine, and theophylline), hallucinogens (tropane alkaloids, ergot alkaloids, and heroin), muscle relaxants (atropine and tubocurarine), vasodilators (papaverine, ajmalicine, and vincamine), vasoconstrictors (ergotamine), antihypertensives (rescinnamine and reserpine), antitussives (codeine, lobeline, narceine, and noscapine), glaucoma treatment (pilocarpine), or painkillers (morphine).

A few alkaloids that inhibit ACh esterase (such as physostigmine and galantamine) are of medicinal interest to treat Alzheimer's disease.

Some alkaloids have direct cytotoxic effects (because they interfere with DNA) and are used in chemotherapy or as antimicrobial or antiparasitic compounds (such as berberine, quinine, and sanguinarine).

Emetine inhibits protein biosynthesis and is used to treat amebiasis; it is also used as an emetic and secretolytic drug.

It is likely that more alkaloids or derived agents will be exploited in the future when more and diverse molecular targets, which are presently discovered by functional genomics and proteomics, will enter the pipeline of drug development. They remain interesting because they have been selected during evolution as chemical agents that can modulate a multitude of molecular targets.

Allergies: Public Health

ENC Mills, University of Manchester, Manchester, UK

© 2016 Elsevier Ltd. All rights reserved.

What Is an Allergy?

Allergies are a type of adverse reaction resulting from inappropriate immune responses to a variety of environmental agents and can be classified as being either immunoglobulin E (IgE)- or non-IgE-mediated. During the course of normal immune function, the body produces immunoglobulins such as IgA, IgG, and IgM, to many environmental agents, including microbes, dusts, pollens, and dietary proteins. One type of immunoglobulin, IgE, is normally produced in response to parasitic infections like malaria, but in allergic diseases, historically classified as type I hypersensitivity reactions, this antibody repertoire is altered and the body synthesizes larger quantities of IgE to environmental agents like foods, pollens, and dusts. The process of generating an IgE response is termed sensitization and involves complex interactions between immune cells involved in presenting foreign proteins (such as dendritic cells) and those responsible for generating antibody responses (such as B cells and T cells). It takes place in individuals who have a predisposition to becoming allergic and may involve exposure to environmental agents through the skin and the lungs and also by ingestion although exposure to antigens via the gut mucosa is generally thought to induce tolerance.

The IgE becomes bound to the surface of histamine-containing cells, such as basophils and tissue-associated mast cells. On reexposure to the original sensitizing agent in a multivalent form, the cell-bound IgE becomes cross-linked, triggering release of histamine and other inflammatory mediators, which then go on to cause the symptoms of an allergic reaction. Most commonly, the signs and symptoms of an allergic reaction include the following, alone or in combination:

- Skin reactions, such as hives, redness, and swelling
- Itching or tingling in or around the mouth and throat
- Digestive problems, such as diarrhea, stomach cramps, nausea, and vomiting
- Tightening of the throat
- Shortness of breath or wheezing
- Runny nose

In rare cases, a more severe reaction, anaphylaxis, develops. This requires immediate treatment with an epinephrine (also known as adrenaline), and individuals with severe allergies are often provided with the drug in a self-injectable form. It can result in emergency admission to hospital, and in rare cases, reactions can be fatal. The signs and symptoms of anaphylaxis include combinations of the previously mentioned symptoms plus the following:

- Constriction of airways
- Swelling of the throat that makes breathing difficult
- A dramatic drop in blood pressure (anaphylactic shock)
- Rapid pulse
- Dizziness, lightheadedness, or loss of consciousness

A second type of food allergy, which involves the cellular immune system, is celiac disease (CD). First clearly described in the writings of the Greek physician Aretaeus between the first and second centuries CE, the relationship to food ingestion was firmly established by Gee in 1888. Subsequently, Dicke and coworkers established that wheat and rye were the triggers for the condition in the 1950s. An immune-mediated disorder that is largely characterized by chronic inflammation of the small intestinal mucosa, CD is generally characterized by atrophy of the villi and intraepithelial lymphocytosis, although it may also manifest itself in a variety of other ways, either during childhood or later on in adulthood. Symptoms can include diarrhea, abdominal cramping, pain, bloating, and distension. There is a strong genetic component to CD with a link to human leukocyte antigen (HLA) alleles. In particular, HLA-DQ2 and HLA-DQ8 have been shown to be highly associated with CD, although their presence alone is not sufficient for development of CD. Pathogenic T cells recognize gluten selectively in the context of these predisposing HLA molecules.

Prevalence of Food Allergy

The prevalence of food allergy reported in different studies around the world varies, with methodological issues, in particular the method of diagnosis, having a significant impact on the resulting estimates. In general, the lifetime prevalence and point prevalence of self-reported food allergy have been estimated in a recent meta-analysis as being around 17.3% (95% CI: 17.0–17.6) and 5.9% (95% CI: 5.7–6.1), respectively. However, the point prevalence of sensitization to foods is much lower, with 10.1% (95% CI: 9.4–10.8) of the population having food-specific IgE to ≥ 1 food, while sensitization indicated by skin prick testing being lower still at 2.7% (95% CI: 2.4–3.0). The prevalence of food allergy defined by food challenge was lowest of all, at 0.9% (95% CI: 0.8–1.1). There appears to be a geographic variation in prevalence of food allergy across Europe, with rates being higher in Northern Europe. In the United States, the self-reported prevalence of food allergy has been estimated at around 8.0%, with peanut, milks, and shellfish being important foods. In the United Kingdom, peanut has been estimated as causing food allergy in around 2% of school-age children, while in Australia, up to 9% of infants have been estimated to suffer from egg allergy. Infants in Australia from Asian backgrounds are more at risk of experiencing peanut allergy, with 7.7% of infants with both parents born in East Asia having a challenge-proven food allergy, while only 2.3% of infants with both parents born in Australia had a confirmed peanut allergy. As regards the prevalence of severe and fatal reactions, a recent analysis of fatalities in the United States has shown food anaphylaxis to be the least common cause of fatal anaphylaxis in the United States, with 164 fatalities being recorded between 1999 and 2010, and the rate (6.7% of all deaths due to anaphylaxis) is similar to

that defined in Australia and the United Kingdom. Allergies in infancy are dominated by egg and milk, the majority of which are outgrown by school age, and the patterns of food allergies vary around the world and may be related to patterns of food consumption.

The prevalence of CD is highest in Europe with around 1% of the population estimated to suffer from the condition, although it is heterogeneous with 1–2.4% of the population in Finland and 1% of children and adults in the United Kingdom being affected by CD. Interestingly, in the Russian Republic of Karelia, which is a close neighbor of Finland, the prevalence of CD is only 0.2%. Similarly in North Africa, Algeria has the highest reported incidence of CD worldwide of 5.6%, yet the prevalence in nearby Tunisia is one of the lowest reported worldwide at 0.3%. It seems highly probable that much of the variance in incidence relates to differences in diagnosis rather than reflecting true differences in prevalence. There also seems to have been a CD 'epidemic' in Sweden with the incidence rising to almost 3% of children born between 1984 and 1996, which was attributed to changes in infant feeding practices. One consequence of that 'epidemic' is the recommendation of the European Society of Paediatric Gastroenterology, Hepatology and Nutrition that gluten is gradually introduced at the age of 4–7 months during breast-feeding.

Molecules Causing Allergies

In allergies, the immune responses (either IgE binding in IgE-mediated food allergies or T-cell responses in CD) are directed toward target molecules that are known as allergens, which are usually proteinaceous in nature. The sites an antibody recognizes on a protein are known as epitopes and can be either linear (both IgE and T-cell epitopes) or conformational (IgE epitopes only). In the former, only the primary sequence of a polypeptide is involved in recognition by either antibody or a T-cell receptor. However, the structure of conformational epitopes is determined by the three-dimensional structure of a protein, with a number of segments of the polypeptide chain being brought together as a consequence of its tertiary and quaternary structure. IgE responses can also be generated to posttranslational modifications such as glycans that may be attached to the proteins during synthesis. While IgE responses to such glycans are not generally considered to be effective in triggering an allergic reaction, an exception is α-galactose, which has been identified as an important determinant of allergy to meat in individuals who become sensitized to α-galactose after suffering from tick bites. While not necessarily involved in elicitation of allergic reactions, there is evidence that N-linked glycans on certain allergens may play a role in driving sensitization.

The World Health Organization and the International Union of Immunological Societies produced an official list of the molecules that can trigger IgE-mediated allergies. An allergen is termed major if it is recognized by IgE from at least 50% of a cohort of allergic individuals but does not carry any connotation of allergenic potency; allergens are otherwise termed 'minor.' The allergen designation is then based on the Latin name of the species from which it originates, with the first 3–4 letters representing the genus and the second 1–2 the species, followed by an Arabic numeral; for example, Ara h 1 relates to *Arachis hypogea* (peanuts). The numbering was originally consecutive but more recently numbering has been used to denote protein families where possible. Closely related allergen isoforms are denoted by decimals with the first two relating to isoforms with >67% homology, while the second two decimals denote allergens with >90% sequence homology.

As regards triggers for CD, a number of gluten-derived peptides have been identified, which determine the ability of trigger the condition and depend on the following:

(1) The ability of the peptide to resist gastrointestinal digestion sufficiently to allow polypeptides of 15–20 residues to survive in the gastrointestinal tract.
(2) The effectiveness of the digestion-resistant peptide to act as a substrate for TG2. TG2 appears to act in a specific manner, targeting particular gluten peptides.
(3) The binding specificity and affinity for HLA-DQ2 and HLA-DQ8 of a 9-residue peptide.

A number of databases have been developed, which contain information on food allergens and peptide motifs involved in CD.

Treatment of Food Allergy

Currently, there is no cure for either IgE-mediated food allergies or CD and individuals are advised to practice food avoidance. For those at risk of severe IgE-mediated reactions, this advice is supplemented with antihistamines and self-injectable epinephrine (in the United Kingdom, adrenaline) to be self-administered in the event that a problem food is unintentionally consumed. In order to help allergic consumers avoid their problem food, mandatory labeling of a list of certain allergens was recommended by FAO/WHO Codex Alimentarius Commission, which was subsequently implemented around the world. This has significant negative implications for quality of life for both the sufferer and, in the case of children, their parents and relatives. However, accidental exposure to allergens may be difficult to prevent, despite the improvements in food labeling. Thus, food avoidance is not a satisfactory treatment option as the risk of anaphylaxis remains.

Several therapeutic approaches are being developed for IgE-mediated allergies. Since immunotherapy injections for food allergy are associated with a high rate of allergic reactions, alternatives, such as oral immunotherapy (OIT) using foods, are being explored. OIT initially involves patient being treated in hospital with individuals being incrementally exposed to low doses of their allergenic food over the course of a week or two (dose escalation), followed by treatment at home with patients eating a problem food every day over a period of at least 3 years to achieve a fully tolerant state. Other approaches being investigated include delivering the allergens for desensitization via skin patches or using allergen molecules or peptides to desensitize individuals, while medicines based on Chinese herbal medicines may have potential for preventing or treating allergic reactions.

Major Allergenic Foods

Across various populations, allergies to over 100 different foods have now been documented. However, it has been

estimated that the majority of food allergies are caused by the so-called top 8 allergenic foods of both plant and animal origins:

- Egg
- Milk
- Crustacean and molluscan shellfish (such as crab, lobster, shrimp, clams, and squid)
- Fish (such as bass, cod, flounder, and salmon)
- Legumes including peanut, soybean, and lupin
- Tree nuts (such as almonds, cashews, and walnuts)
- Seeds (such as mustard and sesame)
- Cereals containing gluten including wheat, barley, and rye

A summary of these major allergenic foods and their allergens is given in the succeeding text, and a number of databases with more extensive information are given at the end of this article.

Animal Food Allergens

Egg

The major allergens of egg originate from the white and include ovomucoid (Gal d 1) and ovalbumin (Gal d 2), which comprise 10–11% and 50–54% of egg white proteins, respectively. Both proteins are heavily glycosylated with 25% of the mass of ovomucoid comprising carbohydrate. The IgE epitopes of ovomucoid appear to be conformational in newly acquired sensitivities to egg, with linear epitopes being more important in long-standing egg allergy. The epitopes are clustered in seven regions of the protein structure and do not include the regions that are glycosylated. The IgE epitopes of ovalbumin are also resistant to enzymatic digestion and denaturation, and seven IgE-binding regions have been identified, which tend to cluster at the N- and C-terminal regions of the protein. Ovalbumin has also been found in an immunologically active form in the blood of human subjects following consumption of raw egg and can be taken up intact in cell models of the gut epithelium. In general, cooking procedures, such as boiling and baking, have been found to reduce allergenic activity of egg. Other egg white allergens, considered to be more minor, are ovotransferrin (Gal d 3) and lysozyme (Gal d 4). Two allergens have been described in egg yolk, α-livetin (Gal d 5) and a protein of unknown function, Gal d 6. α-Livetin, the serum albumin of hens, may lead to food allergy through previous aerosensitization later in life.

Cow's milk

Both the whey and casein fractions contain allergens, the most common being β-lactoglobulin and α-casein, although other IgE-reactive proteins have been identified. β-lactoglobulin is highly resistant to proteolysis and can be taken up in an intact form by the gut epithelium in cell and animal model systems. IgE epitopes have been identified in four main regions located on the more mobile surface loops of the protein. The major protein fraction of milk, the caseins, is also the major allergens. The caseins possess a loose highly hydrated tertiary structure. As a result of this highly mobile structure, which resembles that of a denatured globular protein in its native state, the allergenic activity of casein is not modified extensively by thermal treatments compared to globular proteins. Thus, linear epitopes are equally available for IgE binding in both the native and the thermally denatured states. Thus, the casein fraction appears to contain thermostable epitopes, with IgE binding being located in around seven different regions of the protein. Boiling milk for short periods of time reduces IgE binding to caseins to only a limited extent, while heating for 2–10 min results either in no difference or in a reduction of about 50–66% of the positive reactions as compared to raw milk; similar observations have been reported with homogenized and pasteurized milk. Baking appears to reduce the allergenic activity of milk, baked goods often being better tolerated in children than liquid milk. There are also indications that hard cheeses, matured for 36 months, may have reduced allergenicity in cow's milk allergic children, possibly because of proteolytic processes. The extensive homologies between mammalian milk proteins from different sources mean that individuals with allergy to cow's milk are usually allergic to goat and sheep milk, although there are instances when individuals are tolerant to cow's milk but allergic to sheep or goat milk.

Fish

The major allergen in fish is the muscle protein parvalbumin, the β-form of which is unique to fish and amphibians. It has been shown to be conserved across fish species, a factor responsible for the cross-reactive nature of allergens in cod, salmon, mackerel, herring, and plaice, among many others. Parvalbumin binds calcium in a calcium-binding motif known as an EF-hand and functions as a calcium buffer protein in fast muscle. Several different isoforms have been identified, with the β-2 isoform of parvalbumin being the form predominantly expressed in muscle tissue, while the β-1 isoform is the predominant isoform in brain tissue, although it is found in a variety of other organs including muscle. IgE-binding epitopes have been characterized in five fish species including sea fish, Atlantic cod (Gad m 1.0101), Baltic cod (Gad C 1.01), Atlantic salmon (Sal s 1.0101), Pacific mackerel (Sco j 1.0101), and the freshwater fish carp (Cyp c 1.0101) with between 3 and 4 main IgE-binding regions having been identified. Like other calcium-binding proteins, parvalbumins are heat-stable, and thus, fish flesh tends to retain its allergenicity after cooking, although in some patients, it appears that it may result in a reduction in allergenicity. The levels of parvalbumin are higher in the flesh of white fish, such as cod, and lower in the muscle of fish such as mackerel, tuna, and swordfish. In some instances, this may mean individuals allergic to white flesh fish may be able to consume fish species such as swordfish. Other potential allergens have been characterized in fish including collagen and enzymes such as aldolase and enolase. Lastly, while not a fish allergen, individuals may react to the presence of the fish parasite, *Anisakis simplex*, to which they are sensitized.

Crustacean and molluscan shellfish

Tropomyosin is the major allergen in crustacean and molluscan shellfish. Many isoforms of this ubiquitous protein have been identified and are expressed in numerous tissues in addition to muscle, reflecting the key role played by tropomyosin in contractile fibers. The proteins have been designated 'pan-allergens' having been identified in various crustacean species including shrimp, lobster, and crab as well as a range of molluscan shellfish, octopus, and squid. The homologous nature

of the proteins explains the cross-reactive allergies frequently observed between, for example, shrimps, lobsters, crab, and inhalant insect allergies, such as those observed with dust mite and cockroaches. However, such homologies do not extend to vertebrate tropomyosins, so there is no cross-reactivity between shellfish and animal muscle tropomyosins. A number of linear IgE-binding epitopes have been identified in a variety of shellfish tropomyosins, with epitopes located in the C-terminal region appearing to be crucial for IgE binding, which are not shared with vertebrate tropomyosin. Informatic analysis has identified regions of the invertebrate tropomyosin sequence, which has a lower probability of forming α-helix than is found in the corresponding vertebrate tropomyosin, suggesting this may play a role in determining their immunogenicity and hence allergenicity. Tropomyosin is a thermostable allergen, and hence, it resists the thermal treatments typically used in food processing, although there is some evidence that Maillard modifications and novel processing approaches such as ultrasound treatment may reduce allergenicity. In addition to being found in cooked meat, tropomyosin also leaches into cooking water. Other allergens identified in crustacean shellfish include arginine kinase (another pan-allergen but thermolabile), troponin C, myosin light chain, sarcoplasmic calcium-binding protein, and triosephosphate isomerase.

Plant Food Allergens

Fresh fruits and vegetables

Allergy to fresh fruits and vegetables is frequently associated with inhalant allergies to substances like birch and grass pollen and latex. After becoming sensitized to the inhalant allergens in pollen and latex, individuals subsequently go on to develop allergies to foods. This is because the foods contain proteins, which are structurally similar to those in pollen, which means IgE developed from, for example, tree pollen proteins cross-reacts to closely related homologues in fruit. Symptoms are often mild and confined to the oral cavity and are collectively known as oral allergy syndrome (OAS), although OAS can occur in any food reaction. The geographic distribution of pollen-related fruit and vegetable allergies is related to the potential exposure to the relevant pollen A.

A major group of allergens involved in such cross-reactive allergies are those belonging to the Bet v 1 family, which includes allergens from a variety of pollens, fruits, and vegetables. Some of the most important include Bet v 1 itself, the major birch pollen allergen, and homologues from Rosaceae fruits such as apple (Mal d 1), cherry (Pru av 1), and peach (Pru p 1) and other emerging allergenic fruits such as kiwi (Act d 8). Homologues are also found in exotic fruits not generally consumed in Europe, which may pose a risk such as sharon fruit and jackfruit. Vegetables have also been identified that contain allergenic Bet v 1 homologues such as celeriac (Api g 1) and carrot (Dau c 1). The IgE epitopes on Bet v 1 and its homologues tend to be conformational in nature, and consequently, food processing procedures, which cause the allergens to unfold, generally result in a loss of IgE reactivity, although this is not so for vegetables such as celeriac. A second group of IgE-cross-reactive allergens involved in pollen–fruit cross-reactive allergies are the profilins, and while found in both plants and animals, where they are thought to play a role in the polymerization of actin, only plant profilins have been described as allergens. The clinical relevance of IgE to profilins is a matter of debate, and it may be that they play an important role in eliciting clinical reactivity only in certain plant foods.

Another kind of fruit and vegetable allergy, generally found in the Mediterranean area, is characterized by much more severe, even life-threatening allergic reactions. These allergies involve the nonspecific lipid transfer proteins (LTPs) and do not seem to be associated with pollen allergy. LTPs have been characterized as allergens in fruits such as apple (Mal d 3), peach (Pru p 3), and grape (Vit v 1) as well as vegetables such as asparagus (Aspa o 1), cabbage (Bra o 3), and lettuce (Lac s 1). They belong to the prolamin superfamily and are highly resistant to gastroduodenal digestion, and while originally identified by their ability to transfer lipids *in vitro*, it seems likely they have a different function in plants. Allergenic LTPs belong to PR group 14 and are generally located in epidermal tissues, where they may function as transporters of cutin and suberin monomers, which are then polymerized to form a waxy layer. LTPs are highly resistant to thermal processing, although removing the outer layers has been shown to reduce the allergenicity of peach products.

Another group of allergens involved in fruit allergy are those involved in the latex–fruit cross-reactive allergy syndrome. This includes the class I chitinases, a group of carbohydrases with a role in protecting plants from pathogens, found widely in plants. These have been identified as allergens in foods such as avocado (Pers a 1), banana (Mus p 1), and chestnut (Cas s 1). Another type of protein involved in IgE cross-reactive allergies between foods and latex is patatin, a storage protein from potato, which, along with other proteins from avocado and banana, has also been shown to be cross-reactive with the latex allergen Hev b 7. Food processing procedures usually, but not always, reduce the allergenicity of these foods such that they can be safely consumed by individuals with fruit/vegetable–latex allergies (Table 1).

Many other proteins have been implicated in allergies to fresh fruits and vegetables and include cupin allergens found in fruit seeds, the highly disulfide-bonded thaumatin-like proteins (TLPs), C-proteases, and a variety of lectins and Kunitz inhibitors. Other less widely found allergens include the flavin adenine dinucleotide-containing oxidase allergen of celery, Api g 5, a M_r 53–57 kDa protein, which is extensively glycosylated, which possesses cross-reactive glycans and a germin-like protein, which has been identified in bell pepper. Many have antifungal and/or antibacterial activity and therefore may have a role in plant protection. Examples of important emerging allergens in fruit include 13 allergens including a TLP (Act d 2), the thiol protease actinidin (Act d 1), and cupin and 2S albumin seed storage proteins found in the seeds of kiwi (Act d 12 and Act d 13, respectively).

Legumes

Allergenic legumes contain many of the same types of allergen that are found in fresh fruits and vegetables, such as allergenic homologues of Bet v 1, which have been identified as allergens in soybean (Gly m 4) and peanut (Ara h 8) together with LTP allergens in peanut (Ara h 9). Other members of the prolamin superfamily, the 2S albumins, are also major allergens in peanut (Ara h 2, 6, and 7), with some evidence that they are allergens in

Table 1 Summary of the attributes of major food allergen families

Protein family	*Structural attributes*	*Biological properties*	*Types of foods*	*Effects of processing*
Animal food allergens				
Tropomyosins	Two-stranded proteins containing 40 uninterrupted heptapeptide repeats that form α-helical coiled coils and form head-to-tail polymers along the length of an actin filament	Regulation of muscle contraction through interactions with actin and myosin	Crustacean and molluscan shellfish	Generally heat-stable and cross-reactive between the various crustacean and molluscan species
E-F hand	The EF-hand motif comprises a loop of 12 amino acid residues flanked on either side by a 12-residue α-helical domain. Allergenic fish β-parvalbumins comprise three EF-hands, two of which bind calcium	Present in high levels in the white muscle of many fish species, it plays a role as a calcium buffer. By binding myoplasmic calcium during contractions, β-parvalbumin reduces the calcium concentration, thus enhancing relaxation	Fish	Holo parvalbumin (which has bound calcium ions) possesses a remarkable stability to heat denaturation unlike the apo form, which is more thermolabile
Caseins	Structurally mobile proteins, caseins comprise several different types, αs1-, αs2-, β- and κ-caseins. αs1-, αs2-, and β-caseins bind calcium through clusters of phosphoserine and/or phosphothreonine residues, forming nanoclusters, which are assembled into the casein micelles found in milk, which are in turn stabilized by κ-casein	Protein source for mammalian off spring and the calcium-binding nanoclusters allow calcium levels in milk to exceed the solubility limit of calcium phosphate	Mammalian milks	The molecular mobility of caseins is not greatly altered by thermal processing and hence IgE epitopes tend to be thermostable
Plant food allergens				
Prolamin superfamily	Contains a characteristic core of eight cysteine residues including a characteristic Cys–Cys and Cys–X–Cys motif (X representing any other residue)			
2S albumins	α-Helical proteins where the pattern of disulfide bonds formed by the core cysteine motif is arranged to give a compact molecule without a lipid-binding tunnel. Synthesized as a single polypeptide chain, they are usually cleaved by proteases posttranslationally to form a large and a small subunit linked by disulfide bonds	Seed storage proteins, which may have additional roles in plant protection	Seeds, including those of legumes (including peanut), and tree nuts	Resistant to thermal processing
Lipid transfer proteins	α-Helical proteins where the pattern of disulfide bonds formed by the core cysteine motif is arranged such that a central lipid-binding tunnel is formed	Diverse functions but allergenic forms are found in epidermal tissues and may be involved in the transport of cupin monomers to the outer layers of fruits and seeds	Fresh fruit and vegetables, seeds, including legumes and cereals, and tree nuts	Resistant to thermal processing
Cereal inhibitors of α-amylase and trypsin	Contain two additional cysteine residues in addition to the conserved core cysteine motif	Inhibit amylases and proteases secreted by pests	Cereal grains	Resistant to thermal processing
Prolamin seed storage proteins	The core cysteine motif is disrupted by the insertion of a repetitive domain comprising motifs rich in proline and glutamine. The repeat motifs contain the celiac toxic motifs	Seed storage proteins	Cereal grains from the Triticeae	The repetitive domain is mobile and is unaffected by heating. Consequently, thermal processing does not modify IgE binding to epitopes located in these regions

(*Continued*)

Table 1 (Continued)

Protein family	*Structural attributes*	*Biological properties*	*Types of foods*	*Effects of processing*
Cupins	β-Sheet-rich proteins, which form a characteristic β-barrel structure			
7S seed storage globulins	Bicupin trimeric proteins, which are usually glycosylated	Seed storage proteins	Seeds, including those of legumes (including peanut), and tree nuts	Thermostable proteins, which have a tendency to form large aggregates following heating
11S seed storage globulins	Bicupin hexameric proteins comprising subunits, which are synthesized as single polypeptides, which are posttranslationally cleaved into an acidic and basic polypeptide linked by an intramolecular disulfide bond	Seed storage proteins	Seeds, including those of legumes (including peanut), and tree nuts	Thermostable proteins, which have a tendency to form large aggregates following heating
Bet v 1 family	A β-sheet-rich protein with a central lipid-binding tunnel	Has a role in plant protection through its capacity to bind plant sterols	Fresh fruit and vegetables, seeds, including legumes and cereals, and tree nuts	The scaffold is thermostable but the protein is unstable in certain plant tissues such as apple, such that its allergenic activity is lost following food processing

soy (Gly m 8) and chickpea. The 2S albumins are usually synthesized in the seed as a single polypeptide chain and then undergo posttranslational processing to yield a small and a large polypeptide chain joined by an intramolecular disulfide bond. The 2S albumins, like the other members of the prolamin superfamily, are highly resistant to thermal processing and are relatively resistant to simulated gastrointestinal proteolysis.

The other major allergens of legumes are the seed storage globulins belonging to the cupin superfamily, including the 7S seed storage globulin of soybean (β-conglycinin; Gly m 5), peanut (Ara h 1), lentil (Len c 1), and pea (Pis s 1) together with the 11S seed storage globulins of soybean (glycinin; Gly m 6) and peanut (Ara h 3). The 11S globulins, sometimes termed legumins, are hexameric proteins of M_r ~300 000–450 000. Each subunit is synthesized in the seed as a single chain of M_r about 60 000, which is posttranslationally processed to give rise to acidic (M_r about 40 000) and basic (M_r about 20 000) chains, which are linked by a single disulfide bond and are rarely, if ever, glycosylated. The 7/8S globulins, also termed vicilins, are somewhat simpler, comprising three subunits of M_r ~40 000–80 000, but typically about 50 000. There is evidence that there is IgE cross-reactivity between the different cupin allergens as a consequence of sequence homology between the proteins. Thus, serum IgE from peanut allergic individuals reacted with both Ara h 1 from peanut and conglutin-β, the 7S globulin from lupin, Lup an 1, reflecting the significant sequence homology between the two proteins. Such cross-reactivity explains clinical observations that individuals with peanut allergy can react to foods containing lupin as a hidden ingredient.

The 7S and 11S globulins are also relatively resistant to thermal processing but are susceptible to pepsinolysis, although a number of lower-molecular-weight polypeptides appear to persist following digestion and retain their IgE-binding capacity.

Other soybean allergens that have been identified include a Kunitz trypsin inhibitor and a member of the cysteine protease family, known as Gly m 1 (Glym Bd 30k). Another soybean allergen, which is of relevance in countries such as Japan, is the M_r 23 kDa protein known as Gly m 28k, which is glycosylated and contains important IgE-reactive glycans also found in a derived 23 kDa peptide. Lastly, allergenic oleosins have been identified in peanut (Ara h 10, 11) together with a lectin, peanut agglutinin. The oleosins are associated with oil bodies where they play an important role in packaging and stabilizing the oil droplet surface, having a portion of the protein structure buried in the oil phase with a second domain on the aqueous facing surface. They may be relevant when considering the allergenicity of edible oils, as they pose a risk of eliciting an allergic reaction, if they find their way into crudely refined oil, which, unlike highly refined oils, has sufficient protein to trigger allergic reactions.

Tree nuts and seeds

Allergenic Bet v 1 homologues have been identified in various nuts and seeds including Cor a 1.04 from hazelnut, while several allergenic LTPs have also been found in nuts and seeds, including those from walnut (Jug r 3) and hazelnut (Cor a 8). However, the major allergens in tree nuts are similar to those found in legume seeds and include other members of the prolamin superfamily, the 2S albumins and the cupin seed globulins. As for legumes, many tree nut and seed 2S albumin allergens comprise two polypeptide chains, including those from Brazil nut (Ber e 1), walnut (Jug r 1), cashew nut (Ana o 3), and almond as well as the seeds of oriental and yellow mustard (Bra j 1 and Sin a 1) and sesame (Ses i 1 and 2). However, the allergenic 2S albumin from sunflower, SFA-8, is a single chain albumin. In many nuts and seeds, both 11S and 7S seed storage globulins have been identified as allergens in tree nuts such as hazelnut (Cor a 11 [7S globulin] and Cor a 9 [11S

globulin]), cashew nut (Ana o 1 [7S globulin] and Ana o2 [11S globulin]), walnut (Jug r 2[7S globulin] and Jug r 4 [11S globulin]), and sesame (Ses i 3 [7S globulin] and Ses 4,5 [11S globulin]), while only the 11S globulins have been identified as an allergen in almond, also known as almond major protein AMP (Pru du 6), and mustard (Sin a 2). Other minor allergens include the oleosins that have been identified as allergens in sesame (Ses i 4,5) and hazelnut (Cor a 12,13).

Cereals

In addition to their role in triggering CD, cereal proteins can cause IgE-mediated allergies, although allergies to wheat products do not appear to be as widespread as allergies to other plant-derived foods such peanut and tree nuts. Thus, the seed storage prolamins of cereals, which can form gluten, have also been characterized as causing IgE-mediated allergies and in particular a condition known as food-dependent exercise-induced anaphylaxis. This is a severe allergic reaction that certain patients experience only if they exercise after eating a problematic food. Allergens involved in this condition include γ- (Tri a 20), α-, and ω-5 (Tri a 19) gliadins. Other seed storage prolamins have also been identified as major cereal allergens, including both the polymeric HMW and LMW subunits of glutenin, as well as the monomeric γ- and an α-gliadins. Cooking appears to affect allergenicity, and one study suggested baking may be essential for allergenicity of cereal prolamins.

Other wheat seed proteins have been implicated as food allergens including several members of the prolamin superfamily. Thus, a number of trypsin/α-amylase inhibitors have been described as allergens, one of which corresponds to a trypsin/α-amylase inhibitor, known as CM3, sensitization to which has been implicated as a cause of atopic dermatitis. Homologous proteins from other cereals have also been shown to be allergens including a M_r 16 000 barley protein found in beer and a M_r 16 000 protein allergen from maize. A number of α-amylase inhibitors with M_r of about 14 000–16 000 including one M_r ~16 000 subunit, termed RA 17, have been described as allergens in rice. Other prolamin superfamily allergens identified in cereals include the LTPs from maize (Zea m 14), spelt, and wheat (Tri a 14). While LTPs are generally resistant to food processing cooking with maize LTP retaining its allergenic activity in cooked foods like polenta, barley LTP retains its allergenicity even after brewing.

Managing Allergens in Foods

In order to support food allergic individuals practicing food avoidance, labeling of certain priority allergenic foods has been made mandatory in many parts of the world, irrespective of the level of inclusion in a recipe. This has been extended in some jurisdictions, such as the EU, from prepacked foods to those sold loose or in catered foods. In some instances, precautionary 'may contain' labels are also applied to warn customers as to the possibility of unintended presence of certain allergenic foods. Such precautionary labels are unregulated, and while best practice guidance is available, it is not always clear how they are applied and can be confusing and difficult for individuals with food allergies to interpret. Approaches are being developed and implemented to effectively manage food allergens in a factory environment, but key pieces of information and tools are still lacking. In particular, identifying levels of food allergens that represent minimal risk of eliciting an allergic reaction would help support allergen management practices. Tools are still lacking that can be effectively used to analyze allergens in foods, both to validate cleaning protocols applied in manufacturing lines and to confirm the absence of allergen residues in finished products. Methodologies have been developed for monitoring allergen levels in products, especially peanuts using immunoassays, particularly enzyme-linked immunosorbent assays, with new methods based on mass spectrometry being developed. Such technology will help support improved ways of managing allergens in factory environments, which will help to minimize the use of precautionary allergen labeling in future.

Aluminum: The Toxicology of

RA Yokel, University of Kentucky Academic Medical Center, Lexington, KY, USA

A Brief History of Recognition of Aluminum as a Toxicant

Aluminum compounds have been used for millennia. The discovery of aluminum (Al) as an element was made in the early 1800s, when it was first isolated as a pure metal. The Hall–Héroult process to isolate elemental Al, invented in the 1880s, enabled inexpensive production of metallic Al. It became widely available in pots and pans in the early twentieth century. Some published their assurance that this was safe. However, by the late 1800s, adverse opinions had been expressed about its use in food storage and surgical applications. Near the end of the nineteenth century, it was demonstrated that Al had the potential to be toxic to the central nervous system. In the early twentieth century, it was recognized that some of Al orally consumed as Al salts is absorbed and distributed throughout the body, and the use of alum (potassium aluminum sulfate) baking powder, based on results of studies, was claimed to be dangerous. A single case report in 1921 of a 46-year-old in England who had been dipping hot metal articles in concentrated nitric acid and was experiencing persistent vomiting, slow and irregular pulse, loss of memory, tremor, jerking movements, and impaired coordination, and whose urine contained a large amount of Al, was attributed to Al poisoning. Although some, but not all, of his signs are consistent with Al intoxication, one cannot draw any firm conclusion from such uncontrolled observations. The highest documented levels of Al inhalation, as flake powder used in explosives by Germans during World War II, led to a fibrotic lung disease (aluminosis). The textbook used by the author's pharmacology course (copyright 1965) assured "Large doses of soluble [aluminum] compounds taken orally produce . . . no systemic effects. Inhalation of dusts of aluminum metals or aluminum oxides leads to no observable toxic effects in animals or man. No entity 'chronic aluminum poisoning' has been identified in human beings." This benign view of Al toxicity started to be changed in the 1970s with two observations. In 1972, patients receiving hemodialysis developed what was later termed the dialysis encephalopathy syndrome (DES), which was shown to be due to Al exposure from contaminated dialysis fluid and consumption of Al-containing phosphate binders. In 1973, a report of greater Al in the brains of victims of Alzheimer's disease (AD) led to the hypothesis that Al is a contributor to this neurodegenerative condition. The aforementioned and other exposures to Al that have resulted in toxicity are discussed in more detail in the succeeding text, clearly demonstrating the potential for Al to toxic. Aluminum has no demonstrated essential function in humans, so one might consider that its exposure only presents a possible downside. However, it is imperative to recognize that, as the father of toxicology, Paracelsus, taught us, "All things are poisons, for there is nothing without poisonous qualities. It is only the dose which makes a thing poison."

Reported Toxic Effects of Aluminum

There have been many studies ascertaining and demonstrating toxic effects produced by Al. This article focuses on results reported from *in vivo* studies of Al's effects because the intact animal and human include the many processes that can influence response to chemical exposure, such as uptake into, distribution within, biotransformation in, and excretion from the organism. It focuses on results obtained from *in vitro* studies for descriptions of the mechanisms of the effects of Al, because molecular response is better studied in reductionist systems such as single cells. It focuses on the toxicity of Al relevant to humans and therefore does not specifically discuss Al toxicity to plants or nonhuman animals.

Many studies have been conducted in animals that have demonstrated effects produced by Al, but the relevance of the results from many of these studies to humans are questionable due to the design of the studies. It is a classical approach in toxicology and experimental pathology, when assessing potential adverse effects, to use high-dose exposures to elucidate the potential effects. Exposure doses are often orders of magnitude greater than anticipated for humans. For example, based on results of a good laboratory practice conducted, double-blind, vehicle-controlled study in which rats were exposed to one of three levels of Al from *in utero* through 1 year after birth in the drinking water, the authors concluded that "concentrations of aluminum in the drinking water that are required to produce minimally detectable neurobiological effects in the rat are about 10,000 times higher than what is typically found in potable drinking water." This raises the question of the relevance of findings of many studies that utilized very large oral Al exposures. To determine if observed effects are relevant to humans, studies subsequent to the initial studies that utilize very large doses should then be conducted with doses that might relate to human exposure and multiple doses, ideally including sufficiently low doses that produce no statistically significant effects, to be able to define the boundary between exposures that produce adverse effects and those that do not. Unfortunately, many of the reported studies do not meet these criteria. Most animal studies employed exposure doses well beyond what humans would experience. Many employed single- or short-duration exposures. A justification may be that the experimental subjects (most often rats or mice) have a much shorter life span than humans, so when extrapolated to humans, the short exposure becomes a significant percentage of the human life span, for example, 1 year in a laboratory rat's life span = ~35 years of the developed world's human life span. Another shortcoming of many animal studies is that only a single dose was studied. Further limitations to many of these studies are the observation of effects at only a single time (as it is well known that short-term and long-term responses can be very different) and the use of exposure routes that are not common for humans (such as intraperitoneal injection).

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00024-6

The route of Al exposure and a person's renal function status greatly affect the potential for Al-induced toxicity. As discussed elsewhere in this encyclopedia, uptake of Al into circulating blood (bioavailability) from oral consumption is ~0.1–0.4%. In contrast, in intravenous Al introduction, as might occur when Al-contaminated medications or parenteral nutrition (PN) (intravenous feeding) are given by that route, all of the Al is administered into circulating blood, creating a much greater potential for toxicity. Bioavailability from the lungs (1.5–2%) is intermediate. Aluminum injected into muscle, in vaccines, is slowly absorbed and may ultimately be 100% absorbed over weeks to months. The kidneys are responsible for eliminating >95% of Al from the body. Reduced, or absent, renal function compromises the body's ability to eliminate Al, creating the potential to accumulate more Al and developing toxicity. Aluminum contamination of dialysis fluids used in hemodialysis presents Al on the opposite side of the membrane used in dialysis, across which Al readily diffuses, and is then complexed by transferrin in the blood. This can result in Al loading of the dialysis patient, who, being unable to readily eliminate Al from the poorly or nonfunctioning kidney(s), accumulates it, to potentially develop sufficient Al levels in the body to be toxic, the DES, discussed later. As good kidney function protects against Al accumulation, when asked by someone if they should be concerned about Al poisoning, the author usually assures them that if they have good kidney function and have typical Al exposure (e.g., they are not receiving Al-contaminated solutions intravenously), they should not worry.

Aluminum Toxicity to the Nervous System

The Dialysis Encephalopathy (Dementia) Syndrome

After hemodialysis became extensively practiced in the early 1970s, some patients developed a slowly progressing encephalopathy that was fatal within 6 months, characterized by dysarthria (a motor speech disorder in which the mouth, face, and respiratory system muscles may become weak, move slowly, or not move at all), myoclonus (sudden, involuntary jerking of a muscle or group of muscles), mental changes, and hallucinations. Symptoms were intermittent and often transiently worsened immediately following dialysis. Increased Al was found in the brain and other organs of affected patients, which was attributed to Al contamination of the dialysis fluids and administration of Al-based phosphate binders. Aluminum in dialysis fluids can diffuse across the dialysis membrane into the patient's blood, where it very strongly binds to transferrin and can then be transported into tissues. Elevated phosphate is a significant problem in chronic dialysis patients, and dialysis does not very effectively remove it. Orally consumed Al, which is poorly absorbed, forms very insoluble Al phosphate in the gastrointestinal tract, enhancing fecal phosphate elimination. As dialysis patients lack good renal function, and therefore good ability to eliminate Al, they accumulate Al, leading to the DES and osteomalacia and anemia, which are discussed later. Implementation of a guideline that limits the Al concentration in dialysis fluids to $<10\ \mu g\ l^{-1}$ has eliminated reports of the DES, except in isolated instances when dialysate Al was inadvertently much higher.

Aluminum and Alzheimer's Disease

The typical neuropathologic signs of AD are neurofibrillary tangles (NFTs), senile plaques (SPs), and cerebrovascular amyloid. Early-onset AD usually has a familial link and accounts for 5–15% of the cases. No specific gene mutations have been associated with late-onset/sporadic forms of AD, which account for the remainder of AD cases. The lack of identified hereditary links for the majority of AD cases suggests environmental factors, such as Al, are likely to interact with other factors to cause this disease. Injection of Al into the brain of rabbits produces a neurofibrillary degeneration that has some similarities, but is not identical, to the NFTs of AD. The neuropathology of the DES is different from that seen in AD. A causative role for Al in AD was suggested in the early 1970s by the observation of elevated Al in the brains of AD victims, determined by graphite furnace atomic absorption spectroscopy. This was followed by many studies, some of which found up to a few-fold higher Al in the brains of AD victims than in controls and some of which did not. Many studies with microprobe techniques that are able to determine the Al concentration within a cell, NFT, or SP, as well as Al-selective stains, have also produced mixed results. Elevated Al in the AD brain would not prove that it causes AD, as the neuronal degeneration of AD may result in Al accumulation.

Many epidemiological studies have been conducted to compare the incidence of AD and other dementias in relation to the concentration of Al in drinking water. The results of some of these studies show a positive correlation; the results of some do not. However, focussing on drinking water as an Al source that might contribute to AD may be ignoring the primary source of Al for typical humans, given that ~95% of oral Al consumption comes from foods and the absorption of Al from foods is not greatly different than that from water. Only a few, generally small, published studies have addressed a potential association between Al in food and AD. A small epidemiological study showed a significantly increased incidence of AD associated with consumption of pancakes, waffles, biscuits, muffins, corn bread, and corn tortillas. These are baked goods that often have higher Al amounts than other foods due to the use of acidic sodium aluminum phosphate to make the baked goods rise. Dietary intake of Al was shown to be higher among Chinese with AD than controls. Aluminum absorption was greater among those with AD than those without. These do not demonstrate a cause–effect relationship, but like many of the animal studies, suggest there may be a link that requires more rigorous investigation. The lack of AD pathology in DES victims, lack of increased progression of DES survivors to develop AD, and lack of epidemiological studies demonstrating a positive relationship between occupational Al exposure and AD are some of the observations that have convinced most of the lack of a significant role of Al in the etiology of AD. In the opinion of this author, until all of the causative factors contributing to AD are identified, it will be very difficult to totally dismiss Al as a contributor.

Aluminum Neurobehavioral Toxicity

Many animal studies have demonstrated the ability of Al to produce neurobehavioral toxicity. Increased age has been

shown to increase susceptibility. However, as noted in the preceding text, animal studies have generally used Al doses, and sometimes routes of administration, that do not directly relate to human exposure. Such studies create models to study Al-induced toxicity and can be used by risk assessors to set exposure limits for regulatory purposes, but it is difficult to predict human response to Al from the results. Numerous studies have shown reductions in performance of many neurobehavioral and psychometric tests among those occupationally exposed to Al, such as Al foundry and production workers but particularly Al welders. Performance decrements relate well to urine Al concentration.

Aluminum Toxicity to the Musculoskeletal System

Aluminum-Induced Bone Disease

Aluminum accumulation in bone can produce a low-turnover bone disease, manifested as osteomalacia (softening of the bones due to a defect in the bone-building process) and an adynamic bone disease (characterized by a reduction of the cells that resorb bone tissues (osteoclasts) and cells that deposit new bone tissue (osteoblasts), resulting in markedly reduced bone turnover). Patients with Al toxicity who have this condition may complain of generalized bone and joint pain and muscle weakness. Aluminum interferes with parathyroid hormone synthesis and function. In osteomalacia, Al is localized at the mineralization front, where it disrupts bone mineralization by inhibiting calcium accumulation and osteoblast activity and increases bone resorption, which results in an increase of nonmineralized bone that can lead to painful fractures. In adynamic bone disease, Al decreases osteoid (a fibrous protein matrix) formation and bone mineralization (deposition of calcium into the matrix). The joint symptoms may reflect Al deposition within the joint. High Al concentrations have been observed in the synovial fluid of patients taking Al-containing phosphate binders, perhaps reflecting a general increase of Al in their bodies.

Macrophagic myofasciitis is a rare inflammation of muscle tissues manifested as a delayed onset of diffuse muscle pain and muscle weakness at the site of the intramuscular injection of Al hydroxide-containing vaccines. It is accompanied by fever, chronic fatigue, and cognitive dysfunction (memory impairment, difficulties maintaining attention, and mood disturbances). It is accompanied by formation of Al-loaded macrophages at the injection site that form a granuloma. Genetic susceptibility has been suggested to contribute to this and other similar adverse outcomes of Al-containing vaccines.

Aluminum Toxicity to the Hematopoietic System

A microcytic (small red blood cell) hypochromic (reduced hemoglobin content) anemia can occur in patients who have compromised or no renal function and have prolonged exposure to excessive Al via dialysis fluids or who consume large amounts of Al-based phosphate binders. Anemia may precede or occur with lower Al exposures than Al-induced osteomalacia or encephalopathy. This anemia is associated with Al accumulation in the bone marrow, is resistant to iron, and is due to impaired red blood cell integrity, disruption of a step in the hemoglobin synthesis pathway, and reduced iron absorption and delivery to cells. Al-induced anemia has been largely avoided by the use of non-Al-based phosphate binders and maintenance of Al concentration in dialysis fluids at $< 10\ \mu g\ l^{-1}$. Anemia has also been reported among those who practice ancestral geophagy (consumption of clay, which is primarily aluminum and calcium silicate), illustrating the ability of long-term high-dose Al consumption to induce anemia.

Aluminum Toxicity to the Respiratory System

Occupational exposure to high levels of Al has been associated with lung fibrosis from stamped Al powder, asthma from Al salts and welding fumes, and increased oxidative stress.

Exposure to Al-containing minerals that contain silica, such as bauxite (the primary natural source of Al), can lead to lung fibrosis (Shaver's disease). Stamped pure Al powder can also lead to a lung fibrosis (aluminosis) manifested as coughing, fibrosis, lung atrophy, and secondary emphysema.

Aluminum Toxicity to the Reproductive System

Daily intraperitoneal injection of Al (as the nitrate) to male mice before mating reduced the pregnancy rate and sperm counts and produced histological changes in the males when the daily dose was $100\ mg\ kg^{-1}$ (equivalent to $7\ mg\ kg^{-1}$ Al) or greater. Absorption of soluble salts, such as Al nitrate, from the peritoneal cavity is generally complete after intraperitoneal injection. The potential for Al to produce reproductive toxicity was assessed in two-generation studies in rats comparing three concentrations of Al sulfate or Al ammonium sulfate in their drinking water before and during mating and for the females, throughout pregnancy. Based on the observed reduced body weight gain and delayed sexual development in the first-generation female offspring, the lowest-observed-adverse-effect levels for Al sulfate and Al ammonium sulfate were determined to be 31 and $36\ mg\ kg^{-1}\ day^{-1}$, respectively, of Al. This is 200–500-fold greater than the typical daily oral Al intake by humans of $5–10\ mg\ day^{-1}$, which results in $< 1\%$ absorption of Al. These studies suggest reproductive toxicity from Al would not be expected from typical Al intake or intake that is several orders of magnitude greater.

Embryotoxic, Teratogenic, and Developmental Aluminum Toxicity

Oral administration of Al hydroxide to rats at doses far exceeding human Al intake did not produce significant embryotoxicity or teratogenicity. Addition of citrate, which increases Al absorption, resulted in delayed ossification, skeletal variations, and cleft palate, but the amount of Al was $\sim$1000-fold greater than typical daily Al intake. Intraperitoneal injection of Al chloride to male mice for 2 weeks produced reversible reduced fertility, decreased testes weight, and spermatogenic impairment. There were greater postimplantation losses, fetal mortality, bleeding, and decreased body weight, but no fetal abnormalities, in the

offspring. These effects were seen at doses 100-fold or greater than the typical daily Al intake, given by a route that probably eventually results in 100% absorption. Prenatal stress during intraperitoneal Al injections resulted in skeletal anomalies and defects, but this was not seen when Al was given orally.

Studies in mice that consumed a diet containing Al lactate from conception throughout lactation showed increased grip strength, which was not Al exposure-level-dependent, whereas some other studies showed reduced grip strength or no effect. A double-blind study was conducted following good laboratory practice. It exposed rats to 30, 100, or 300 mg kg^{-1} day of Al, as the citrate, in their drinking water from day 6 of gestation and to 1 year after birth and assessed multiple behavioral, cognitive function, clinical chemistry, hematology, and neuropathology endpoints. Renal pathology, impaired grip strength, and splayfoot were observed. Many end points showed no effect of the Al intake. The authors concluded that "concentrations of aluminum in the drinking water that are required to produce minimally detectable neurobiological effects in the rat are about 10,000 times higher than what is typically found in potable drinking water." A two-generation study conducted in rats given 50, 500, or 5000 ppm Al in their drinking water measured many end points of reproductive activity, offspring viability, histology, and behavior. The no-observed-adverse-effect level was calculated to be 5.35 mg kg^{-1} day^{-1} or ~50–75-fold greater than the typical daily oral Al intake. The results of these studies suggest a lack of concern for oral Al intake during pregnancy and lactation with the possible exception to avoid massive Al consumption during pregnancy.

On the other hand, intravenous administration introduces Al into the blood, ~300–1000-fold more efficiently than when taken orally, presenting a much greater risk. When this occurs in the presence of reduced ability to eliminate Al, as occurs due to the Al contamination of PN solutions given to premature infants, it presents an even greater risk. One manifestation is the potential for Al-induced developmental delay. This was demonstrated in 18-month-olds who received standard PN solutions as premature infants compared with age-matched infants who received PN solutions containing less Al, as discussed in section '**Aluminum Contamination of Intravenous Solutions**.'

Aluminum and Autism Spectrum Disorder

There has been an increase in the number of immunizations received by preschool children in the United States and diagnosis of autism spectrum disorders. The role of Al as an adjuvant in vaccines is discussed in section '**Aluminum as an Adjuvant**.' Although some have suggested that there is a cause and effect relationship between these two observations and shown positive correlation between these two increases, there is little peer-reviewed published literature supporting this relationship. The World Health Organization's Global Advisory Committee on Vaccine Safety, the US FDA, and Health Canada do not state a concern about this possible relationship. Like the proposed relationship between Al and AD, until the cause or, most likely, contributing factors to autism spectrum disorder are definitively identified, this controversy will not be resolved to the satisfaction of those who are impacted by these and similar neurodegenerative and neurobehavioral diseases and disorders.

Aluminum Toxicity to the Dermal System (Skin)

Application of Al to the skin can produce irritation, which is dependent on the chemical form (species) of Al. An animal study showed 10% Al chloride and nitrate produced epidermal changes and damage, whereas Al chlorhydrate (as used in antiperspirants), sulfate, hydroxide suspension, and basic acetate suspension did not. There is little documentation of skin irritation from occupational Al exposure. Contact sensitivity to Al can manifest as irritation, soreness, and recurrent eczema from topical antiperspirant application, which is rare, and as sensitization from Al injection (see section '**Aluminum as an Adjuvant**'). Contact sensitivity can be diagnosed using patch testing.

Aluminum Toxicity to the Liver

Numerous animal studies have shown the development of Al-induced effects indicative of liver toxicity. The effects included an increase in the blood of enzymes that are released from damaged liver cells (ALT and AST), increased triglyceride and cholesterol in the liver indicative of fatty degeneration, and increased lipid peroxidation and decreased catalase (an enzyme that catalyzes hydrogen peroxide, thereby protecting against oxidative damage), which indicate oxidative stress and organ damage. However, there are few reports of significant liver toxicity in humans. A population that is highly susceptible to Al toxicity, parenterally fed premature neonates, is prone to cholestatic hepatitis (reduced bile flow and occasionally gallstones). Elevated Al in the PN solutions (see section '**Aluminum Contamination of Intravenous Solutions**') has been associated with this, but the role of Al and other contributors to cholestatic hepatitis in this population has not been well determined.

Aluminum as an Adjuvant

Aluminum is used as an adjuvant in vaccines and hyposensitization treatments to adsorb/precipitate toxins and toxoids, to enhance their antigenic properties, and to reduce their rate of absorption from the injection site and elimination from the body. Injection of Al as an adjuvant probably induces immune activation. When injected, Al can produce immune system induction (which enhances the toxoid response), inflammation, accumulation of macrophages at the injection site, and formation of granulomas (containing macrophages and other cells, which become persistent itching nodules in ~1% of children receiving Al-adsorbed vaccines) and sterile abscesses at the injection site. These responses are more common with Al hydroxide than Al phosphate adjuvants and more common with subcutaneous than intramuscular injection.

Aluminum and Cancer

In vitro studies have shown the ability of Al to bind to DNA and to induce DNA damage and inhibit repair of radiation-induced

DNA lesions. It has been suggested that the underarm use of Al-containing antiperspirants increases the risk of breast cancer in women. However, several epidemiological studies have not found support for this suggestion. There is no good evidence of increased cancer incidence among workers occupationally exposed to Al, in the absence of known cancer risk factors. On the other hand, an increased incidence of cancer among Al production workers has been well demonstrated, which is believed to be due to non-Al compounds, particularly polycyclic aromatic hydrocarbons, some of which are known carcinogens.

Exposures Leading to Aluminum Toxicity

Aluminum Contamination of Intravenous Solutions

The population that is perhaps the most susceptible to Al accumulation and toxicity is premature infants who receive their nutrients and fluids intravenously, for example, who receive their nutrients and fluids intravenously as PN. Premature infants have immaturely developed kidneys and a high requirement for calcium for their developing skeletal system. One of the components of PN solutions is calcium, generally introduced into the PN solution as calcium gluconate. Calcium gluconate is routinely contaminated with Al, due to its storage in glass vials that contain 2–5% Al. The gluconate ion binds Al well, leaching it out of the vial over time. Aluminum accumulation in this population has been shown to cause cognitive deficits and reduced bone density and may contribute to a rickets-like condition and liver problems. The US Food and Drug Administration adopted a labeling requirement for Al in large- and small-volume parenterals used to prepare total PN solutions. This has not solved the problem because it does not inform the user of the actual Al concentration in the small-volume parenteral product at the time of its use nor demand a reduction of Al in these parenteral products.

The preparation of drugs in Al vessels for intravenous self-administration by recreational drug users and inhalation of heroin volatilized from Al foil has resulted in the signs observed in dialysis encephalopathy and elevated Al in the body and urine.

Nonintravenous Al Introduction

Implanted medical devices (prosthetics) containing Al

There are a few reports of dialysis encephalopathy-like signs and elevated brain Al following introduction of an Al-containing cement into the brain that came into contact with the cerebrospinal fluid (CSF), presumably resulting in dissolution of Al from the cement and, via the CSF, its uptake into the brain.

Bladder irrigation

Severe hemorrhagic cystitis (blood in the urine), caused by radiation, chemotherapy, cancer, or other conditions, has occasionally been treated with 1% alum irrigation (an astringent). Some patients with renal insufficiency or failure developed Al-induced encephalopathy. This illustrates the potential for massive amounts of Al administered acutely to disrupt brain function.

Occupational Exposure to Aerosolized Al

Occupational Al exposure can occur during refining and welding and in industries that use Al products and can result in exposure to airborne Al concentrations 1000-fold greater than the general population. The highest occupational Al exposure occurs for those engaged in Al powder production and Al welding.

Asthma and reversible bronchial obstruction are fairly common among those engaged in Al production (in smelters, termed potroom asthma) and production of Al salts, usually due to exposure to irritant airborne particulates and fluoride fumes.

Food and Beverages

The main source of Al intake for typical humans is the diet. Aluminum, being ubiquitous and a major component of the Earth's crust, is taken up into plants. Numerous plants, such as the tea plant, are hyperaccumulators of Al, depositing it into the leaves and other plant parts. For those who consume considerable tea, this beverage can provide up to 50% of a typical human's daily dietary Al intake. For others, a significant source of Al in the diet is added Al salts, as approved food additives, such as acidic and basic sodium aluminum phosphate (used as a leavening agent in baked goods and emulsifier in cheese, respectively) and sodium aluminosilicate (used as an anticaking agent in salt and artificial dairy creamer), among many other Al salts and applications. Although much attention has been paid to the potential link between Al in drinking water and AD and other dementias (see preceding text), drinking water typically contributes only a few percentage of the daily intake of Al in foods and beverages.

Nanoscale Al

There is much interest in nanoscale materials, including Al nanoparticles. As novel nanomaterials are being developed, some are being tested for their potential toxicity. Uptake by the lungs is the route of most concern for unintended exposures. The amount of Al nanomaterial that reaches the lungs influences the magnitude of the response. Most airborne nanomaterials form agglomerates with themselves or other airborne particles so that the size of the particles taken up is greater than their primary size, which influences how deeply they enter the lungs. The most common adverse effect of NPs is oxidative stress and inflammation. Shape and surface area are major factors influencing nanomaterial effects. As with other fiber-like materials, there is increased toxicity as the aspect ratio (length/diameter) of Al nanorods increases. The distribution of Al nanomaterials out of the lungs to other organs is very low, as is generally seen with quite insoluble nanomaterials. The absorption of nanomaterials from the gastrointestinal tract (bioavailability) is generally very low.

Nanoclays (which are primarily composed of Al and silicon), for example, montmorillonite, are used in polymers for food packaging and storage to improve water vapor and gas barrier properties by creating a tortuous path and increasing mechanical strength. The US FDA considers nanoclays as Generally Recognized as Safe. The primary concern about

their use in food packaging is migration out of the clay–plastic nanocomposite. *In vitro* studies have demonstrated the potential for nanoclays to be cytotoxic, but long-term exposure studies at concentrations relevant to human exposure are lacking.

Properties and Sources of Aluminum

Properties

Elemental aluminum (Al), which does not exist naturally, is soft, light, and malleable. Exposure to water, oxygen, and other oxidants leads to formation of Al oxide that provides a few nm thick surface film, for example, on the 0.18 mm thick household Al foil, that has high resistance to corrosion and is virtually insoluble from pH 4.5 to 8.5. In aqueous solution, in the absence of cationic ligands that bind to it, its chemical form (species) is pH-dependent. The Al^{3+} ion predominates below pH 5.5, as Al $(H_2O)_6^{3+}$. As the pH increases, $Al(OH)^{2+}$, $Al(OH)_2^+$, $Al(OH)_3$, and $Al(OH)_4^-$ predominate at pH 5.5, 6, 6.2, and above 6.2, respectively. $Al(OH)_3$ (gel) has the lowest solubility, at pH 6.2. As a Lewis acid (electron pair acceptor and electrophile), it strongly complexes with multidentate carboxylate- and hydroxyl-/keto-containing ligands, for example, carboxylic acids such as citrate. The chemical species of Al has a great impact on its kinetics and effects. The effective ionic radius of Al^{3+} is sufficiently similar to that of Fe^{3+} to engage in some of the same chemical and metabolic processes. Aluminum binds particularly strongly to phosphates, giving it the potential to bind with DNA, ATP, and many other biomolecules.

Elemental Al and its compounds have extensive applications. They are used in water purification, sugar refining, and brewing. They are incorporated in personal care and medical products including antacids/antiulcerative medications (which are also used as phosphate binders), buffered analgesics, antiperspirants, acne-treating products, toothpastes as an abrasive and to reduce sensitivity, astringents and rash products, antidiarrheal agents, vaginal douches, cosmetics, and as an adjuvant in some vaccines to increase their antigenic properties.

Natural Occurrence

Aluminum is the third most common element, and most common metal, of the Earth's crust, comprising 8%, mainly as silicates, oxides, and hydroxides. It is ubiquitously distributed throughout the environment. In contrast to its abundance in the Earth's crust, most natural waters contain very little dissolved Al. Its average concentration in lakes, rivers, groundwater, coastal sea water, and open ocean water is ~0.15, 0.4, 0.1, 0.001–0.007, and 0.001 mg l^{-1}, respectively. Increased acidity and organic matter can increase Al concentration. The World Health Organization (WHO) stated large and small water treatment facilities should be able to produce water that has $\leq$0.1 and $\leq$0.2 mg l^{-1} Al, respectively. The EU *indicator parameter* directive for Al in drinking water is 0.2 mg l^{-1}. Failure indicates there may be a problem with the supply. The US Environmental Protection Agency has as a nonmandatory standard for Al a maximum contaminant level of 0.05–0.2 mg l^{-1}. Colored water is a noticeable effect above this level. Canadian guidance levels, based on operational considerations, are $<$0.1 mg l^{-1} for conventional water treatment plants (using Al-based coagulants) and $<$0.2 mg l^{-1} for other types of treatment systems.

Aluminum is present in food naturally, as a food additive, and can be taken up through contact during food processing, preparation, and storage. The Al content of foods is highly variable, depending on the food product; the site of its growth, if the plants are Al-tolerant varieties; and food processing and storage. Contamination of food with soil that typically contains 5–10% Al can significantly increase the food Al content, for example, spinach and lettuce, although the Al may not be in a readily absorbable form. Most plants, and plant-eating animals, contain little Al, due to its very low oral bioavailability and limited transfer to eggs and milk (see the succeeding text). Some plants accumulate Al and deposit it in their leaves. The tea plant accumulates and concentrates Al, accounting for the higher Al concentration in tea infusion than other beverages. Some spices contain considerable Al, illustrated by paprika and pepper. Addition of Al as a food additive can greatly increase its food content, illustrated by baking powder, cake and pancake mixes, cakes and pancakes, and cheese containing sodium aluminum phosphate (SALP). The following discusses these points in more detail.

Aluminum in unprocessed beverages and foods

Table 1 shows median Al concentrations for representative beverages and foods. The values in Tables 1 and 2 are from studies published since 1985 and are based on multiple reported values for each entry in the table. Most unprocessed foods contain $<$5 mg kg^{-1} Al. The Al concentrations in paprika and pepper (Table 1), as examples of spices, are based on their dry weight, whereas most food Al concentrations are based on wet weight. Spices generally have much higher Al concentrations than other unprocessed foods but are consumed in much smaller amounts.

Anthropogenic Sources: The Addition of Aluminum Compounds to Beverages and Foods

Many governmental bodies permit the use of Al compounds as food additives (intentionally added to food for a functional purpose, up to a few percentage). In the United States, Al salts had been used in foods prior to 1958 when the Food Additives Amendment of the US Food, Drug and Cosmetic Act was amended to require pre-market approval of substances intentionally added to food. Exceptions were granted when the use of the substance was generally recognized as safe (GRAS) or was excepted from the definition of food additive, e.g., is a color additive. In 1959, the US Food and Drug Administration published a list of substances considered GRAS for use in foods that included Al salts. A 1975 review of the GRAS status of Al concluded "There is no evidence in the available literature

on... acidic sodium aluminum phosphate [and other Al forms]... that demonstrates, or suggests reasonable grounds to suspect, a hazard to the public when they are used at levels that are now current or that might reasonably be expected in the future." It was noted that care should be taken by patients with kidney disease when consuming food containing high levels of Al salts. This was prior to elucidation of the role of Al in dialysis encephalopathy or the controversial role of Al in Alzheimer's disease. Many governmental bodies legislated acceptable Al compounds as food additives. International Numbering System numbers are assigned by the Codex Alimentarius Commission to allow each food additive to be uniquely identified, for example, 541 for acidic and basic SALP and 554 for sodium aluminosilicate (SAS) (AKA: sodium silicoaluminate). On packaging in the EC, approved food additives are written with a prefix of 'E.'

Table 2 shows median Al concentrations for representative processed beverages and foods. The higher Al content of soy-based infant formula (Table 2) derives from the higher Al content of soybeans than cow milk (Table 1). Al-containing food additives used in the greatest amounts include acidic SALP in self-rising flour as an acidifying and leavening agent (by reacting with sodium bicarbonate to produce carbon dioxide); basic SALP in processed cheese, cheese food, and cheese spread as an emulsifying agent to provide a soft texture and easy melting characteristics; and SAS as an anticaking agent. Acidic SALP accounts for the increase of Al in biscuit, cake mix, cake, baking powder, pancake mix, and pancake; basic SALP for the increase of Al in frozen pizza cheese; and SAS for the Al in powder nondairy creamer and the increase in single-serving salt packets (Table 2). Aluminum is permitted in lakes (water-soluble artificial colors adsorbed onto alumina), which typically have an Al content of 25%. Canada, the European Union, the United Kingdom, Australia, New Zealand, India, China, Japan, Taiwan, and South Africa generally permit similar Al-containing food additives as the United States.

The contribution of processing to aluminum in beverages and foods

Many countries permit the use of Al compounds in food processing, packaging, and storage. Most countries, and the EC, do not have specific requirements for light metal alloys in contact with food. Aluminum has been used in cookware since ~1890 due to its heat conductivity. The Al surface oxidizes to form a layer of Al oxide that resists corrosion. Many studies conducted from 1890 to date have shown that Al can be solubilized by beverages and foods. Table 3 shows published results of studies that directly compared beverages and foods processed or prepared in Al compared to non-Al containers. The values are percentages to illustrate the relative magnitude of effect and as such do not inform about the absolute magnitude, for example, the amount of mobilized Al. Differences among studies that investigated similar beverages or foods and process conditions might be due to different initial Al levels. Processing and preparation of beverages and foods in Al containers routinely increased their Al content compared to steel, stainless steel, enamel, Teflon®, glass, or even containers made of clays, which are Al silicate complexes. The lack of consistency between old and new Al containers may be due to more Al release from a new container whose surface is not oxidized and more release from an older container with a pitted surface, vessel manufacture and surface coating, extent of use or cleaning prior to their study, and the food under study. Acidic and alkaline (the latter are much less common) foods mobilize more Al, which relates to increased Al solubility as the pH deviates from circumneutral pH (see section '**Properties**'). Similar to the results with canned mushy peas, tomatoes, and rhubarb, many other studies found an increase of Al in

Table 2 Aluminum concentration in some representative processed beverages and foods

prepared foods compared to the food before preparation. Sodium chloride (table salt) can increase Al mobilization from Al cookware, illustrated by peas cooked with salt in an Al pan for 10, 20, and 30 min, which had 200%, 406%, and 438% as much Al as when salt was absent.

The conclusion of a review conducted in 1939 was that Al is safe and harmless as a material for cooking and household utensils in contact with food. The US FDA came to a similar conclusion in 1991. However, serum Al and urine excretion were significantly greater in people with chronic

Table 3 Aluminum in beverages and foods processed/prepared in aluminum compared with nonaluminum containers

renal insufficiency who used Al rather than stainless steel kitchen utensils for 3 months, suggesting a potential risk to this susceptible population.

The roles of aluminum in beverage and food packaging and storage

Metallic Al and its salts have many roles in food packaging and storage. Most soft drinks and beer are packaged in Al cans, which are lined with a polymeric coat to prevent Al-beverage contact. Approximately seven billion Al foil containers are produced annually, as packaging and food trays for many food types and pharmaceuticals. Aluminum borate is an antistatic and antifogging agent for olefin polymers intended as food-packaging materials. Aluminum-containing clarifying agents are used in polyethylene and polypropylene copolymers intended for food contact. Aluminum and Al oxide polymer films are used as barriers in food packaging. Nanoclays are included in the polymer matrices (e.g., polyethylene and polypropylene) in packaging intended for food contact to enhance their barrier (reducing air and water vapor passage) and mechanical (increasing strength up to 100-fold) properties. Nanoclay incorporation in polylactic acid plastics used for food packaging enhances biodegradation.

The contribution of aluminum in packaging and storage to aluminum in beverages and foods

Table 4 has examples of the influence of Al packaging and storage on the Al concentration of the packaged contents. Tap water (pH 8.2) that originally had 0.053 mg l^{-1} Al increased to 0.16 mg l^{-1} after storage for 32 h in a new Al bottle. When stored in an old Al bottle, the Al concentration increased more (Table 4). Storage of beer at room temperature in Al cans increased its Al content over time, whereas storage at 4 °C did not. Storage of tomato puree in an Al pan for 72 h at 4 °C increased the Al concentration 31-fold. Addition of salt increased the Al by 10%. Storage of tamarind in an Al pan for 72 h at 4 °C increased the Al concentration 17-fold. Addition of sugar increased the Al by 16%. The Al concentration in grapefruit juice increased 6-fold when stored at 50 °C for 12 weeks; increased ~14-fold in cola and lemon drink, ~9-fold in lemon–lime drink, and ~26-fold in orange drink stored in Al cans for 12 months; and increased ~30-fold in a soft drink

Table 4 Aluminum in beverages and foods package and/or stored in aluminum compared with nonaluminum packaging/storage materials

Beverage or food	As a percentage of non-Al storage/packaging material

Mackerel in white wine stored 2.5 years in Al versus steel can	93
Liver paste, stored 2.5 years in Al versus steel can	96

stored in an Al can for 48 months. The mobilization of Al during the processing and storage in contact with Al is greatest for acidic beverages and foods (Tables 3 and 4) (e.g., tomato pH ~4.5 and rhubarb ~3.2), consistent with the chemical species of Al as a function of pH; solubility increases below pH 6.2. It has been estimated that typical food processing and storage do not contribute more than 2 mg day^{-1} of Al to daily Al intake in foods. Compared to daily Al intakes of 3.6–9 mg of Al in beverages and foods (see section 'Aluminum Consumption'), this represents ~20–50% of daily Al intake.

Aluminum Consumption

Human Al exposure is mainly from food, water, airborne dust, antiperspirants, immunizations, allergy injections, and antacids. Foods and beverages are the largest single source of Al for the typical human, in the absence of occupational exposures or chronic use of Al-containing pharmaceuticals. Food additives provide a significant percentage of daily Al intake. Among the food additives, SALPs are the main contributors. Drinking water, based on daily average consumption of 1.4 l, provides ~0.1 mg, or ~2% as much as food.

More than 50 studies conducted since the mid-1980s in Australia, Brazil, Canada, China, East Germany, Finland, France, Germany, Hungary, India, Italy, Japan, the Netherlands, Portugal, Slovenia, Spain, Sweden, Switzerland, Taiwan, Turkey, the United Kingdom, and the United States have reported daily dietary Al intakes. The intakes were based on total diet studies, market basket surveys, dietary records, and calculations based on food consumption and Al levels and duplicate diets and portions. Aluminum intake by males generally exceeded that of females. The median daily Al intake by adults in these studies was 4.8, teenagers 8.6, children 6, and infants (<2 years old) 0.7 mg day^{-1}. Reported intakes were highest in China, Japan, and Taiwan (~9 mg day^{-1}). Aluminum intake by adults was higher in the United States and Canada (8.5 mg day^{-1}) than Europe (3.6 mg day^{-1}), probably because there are fewer approved Al food additives and lower minimum permissible levels in the EU than the United States, less Al is added to cereal grain products as raising agents, and basic SALP is not permitted to be used in processed cheese. Total Al intake generally relates to total food intake, partially explaining the greater Al intake in teenagers than adults. Another contributor is food selection. Teenagers eat more prepared foods that have Al-containing food additives.

Aluminum intake in food is ~50-fold greater than from drinking water. As tea contains more Al than other beverages, its consumption can contribute 50% of the daily Al intake in those who consume considerable amounts of this beverage, when other sources do not provide larger than typical amounts of Al.

In 2008, the Agency for Toxic Substances and Disease Registry set the minimal risk level for intermediate (15–364 days) oral Al intake at 1 mg $kg^{-1}day^{-1}$. In that year, the European Food Safety Authority Panel on Food Additives, Flavourings, Processing Aids and Food Contact Materials of the European Commission lowered its tolerable weekly intake to 1 mg kg^{-1} body weight per week. The Joint Food and Agriculture Organization of the United Nations/World Health Organization Expert Committee on Food Additives in 2011 established a provisional tolerable weekly intake for Al of 2 mg kg^{-1} body weight per week, raised from the previous 1 mg kg^{-1}, which applies to all Al compounds in food, including food additives. There were recommendations from the thirty-sixth session of the Joint FAO/WHO Food Standards Programme in 2013 to eliminate some approved uses of Al as a food additive.

Aluminum Absorption, Distribution, and Elimination

Bioavailability

The typical routes of Al uptake are by inhalation and through the gastrointestinal tract. The percentages of Al absorbed from the lungs and gastrointestinal tract are 1.5–2 and ~0.1–0.4, respectively. Results from one small study suggest up to 0.012% of Al is absorbed from underarm application. Aluminum injected in vaccines is slowly absorbed as it dissolves and may ultimately reach 100%. Aluminum, as a contaminant of dialysis fluid, extensively distributes from dialysis fluid into blood due to its strong binding to the plasma protein transferrin. Limited results suggest Al might enter the brain from the nasal cavity by uptake into nerve endings involved in smell.

Absorption of Al from the gastrointestinal tract is increased by citrate, and other carboxylic acids to a lesser extent; soluble Al forms; low iron, calcium, or sodium status; and uremia. In contrast, silicon-containing compounds appear to reduce its absorption and/or enhance its elimination in urine, the primary route of excretion (see section 'Aluminum Excretion').

Aluminum Biokinetics in Blood

The upper range of the blood Al concentration in normal humans has been stated to be 3–5 μg l^{-1}. There has been considerable variability in normal values reported in the past decade, with mean values from 1 to 15 μg l^{-1}. The differences probably reflect differences in diet, environment, occupation, and sampling and analytic methods. Given this is very low and Al is ubiquitously present, much attention must be paid to collection, storage, and handling of blood samples to avoid contamination. In addition to enhancing Al absorption, citrate enhances its distribution out of the blood and into tissues and its excretion by the kidney.

Aluminum Tissue Deposition and Body Retention

Aluminum distributes unequally throughout the body. The normal human has ~60 mg of Al, with ~60%, 25%, 10%, 3%, 1%, 0.3%, 0.25%, and 0.2% in the bone (which provides a depot, discussed later in text), lung, muscle, liver, brain, heart, kidney, and spleen, respectively. Aluminum localizes at the mineralization front and in osteoid of the bone, contributing to a low turnover bone disease. Aluminum in the lung may be from particle inhalation, occupational exposure, and distribution from the blood. Insoluble particles trapped in the lung remain there a long time. With continuous intake, Al accumulates in the body, resulting in increased Al concentrations in the brain, bone, and serum with age. Hair Al concentration as an indicator of Al body burden has not been validated.

The whole-body Al half-life was estimated to be ~50 years in one human who received an intravenous injection of Al citrate. Given the large percentage of Al in bone, it probably drives the Al concentration and elimination half-life throughout the body. Increased bone turnover, in children or geriatrics, may accelerate bone Al release.

Aluminum Excretion

The kidneys provide the primary route of Al excretion, accounting for >95% of excreted Al, presumably by glomerular filtration of Al citrate. Reduced or no renal function creates the risk of Al accumulation and toxicity. Susceptible populations include those receiving dialysis, premature neonates receiving parenteral nutrition (all fluid and nutrition given intravenously), and infants receiving soy-based infant formula. Bile (feces) accounts for most of the remaining excreted Al, although it is also eliminated in saliva, sweat, semen, and hair.

Methods for Aluminum Detection and Quantification in Water; Food Constituents, Additives, and Contaminants; and Biological Samples

Aluminum ions in water can be quantified by reaction with pyrocatechol violet and spectrometric measurement of the resulting colored complex. Many methods using similar chromogenic agents have been developed to measure Al in water and simple aqueous solutions with low microgram per liter detection limits. Quantification of Al in more complex materials, such as beverages, foods, and biological samples, usually requires converting the materials to a homogenous liquid (if not originally as such). Aluminum quantification is usually conducted using inductively coupled plasma atomic emission spectroscopy (ICP-AES) or the more sensitive graphite furnace (flameless or electrothermal) atomic absorption spectroscopy (GFAAS) and inductively coupled plasma atomic mass spectroscopy (ICP-MS). Detection limits are 5 $\mu g\ g^{-1}$ and 10 $\mu g\ l^{-1}$ for ICP-AES and $< 1\ \mu g\ l^{-1}$ or $\mu g\ g^{-1}$ for GFAAS and ICP-MS, to as low as 0.01 or less.

There are numerous methods to localize Al in histological sections, at the light or electron microscopic level. For experimental purposes, the use of the rare isotope ^{26}Al, and its quantification by accelerator mass spectrometry, enables the determination of picogram per liter Al.

Biological monitoring of Al exposure and potential excessive body burden can be conducted with urine that is thought to indicate recent exposure and blood plasma that better reflects the Al body burden and long-term exposure. Reliable quantification of Al in blood is quite difficult because the blood Al concentration of the normal healthy human is very low (see preceding text) and Al is ubiquitous. Sample contamination is very easily encountered. However, neither urine nor blood is a good predictor of the Al body burden, which is better estimated by bone Al, the desferrioxamine challenge test, or combined measurement of serum parathyroid hormone and the desferrioxamine test. Desferrioxamine is a chelator that binds Al, iron, and many other trivalent metals and can increase their levels in blood serum and urine when they are present in excess.

Amaranthus

Amaranth is an edible plant that has been used by humans for over 4000 years. The origin of amaranth domestication is unknown; diverse tropical and subtropical climates possess indigenous amaranth species, which have facilitated amaranth cultivation around the world, both before and during domestication.

Amaranth is classified within the Dicotyledoneae in the *Amaranthaceae*, which includes more than 70 genera. The genus *Amaranthus* possesses more than 60 species, the majority of which are from the American continent. The large number of varieties is reflected in its common and vulgar names: *amaranto* (Spanish and Portuguese); *kiwicha, achita, coyo, achis,* and *qamaya* (Peru, Quechua); *coimi, millmi,* and *inca pachaqui o grano inca* (Bolivia); *sangorache, ataco,* and *quinua de castilla* (Ecuador); *millmi* (Argentina); *alegría* and *huanthi* (Mexico); *rejgira, ramdana,* and *eeerai* (India); and *een, choy, yin choy, in-tsai, hsien tsai,* and *xian ca* (China).

The most cultivated *Amaranthus* spp. are cited in Table 1. Species division is based on their method of utilization: into grain, vegetable, ornamental, and weedy amaranths.

Three species of amaranth are the most used for grain production, *A. cruentus* L., *A. caudatus* L., and *A. hypochondriacus* L. Vegetable amaranth are found in two major species, *A. tricolor* L. and *A. lividus*.

Leaf color can be green, yellow, orange, or red, due to the presence of betacyanin. Inflorescence morphology is very variable but is usually prominent, being displayed at the apex of the stem. The seeds, considered pseudocereals (nongrasses), are small and lenticular (disk-shaped), averaging 1–1.5 mm in diameter. One to three thousand seeds per gram are common. Seed color varies from pale ivory to black. Figures 1–3 show common amaranth species and crops in the *Cerrado*, a central region in Brazil.

Sources, Production, and Consumption

Great importance is attributed to amaranth in the pre-Hispanic period. The plant played a role in ancient religions, being used to celebrate the gods of earth, fire, and rain in Mexico and to prepare drinks associated with fertility rituals in Peru. Spanish colonization of the Americas in the 1500s banished amaranth production, in an attempt to eradicate these and other pagan ceremonies. However, by the 1700s, amaranth cultivation had spread throughout Europe, being used mainly as an herb and ornamental.

Currently, amaranth is an underutilized crop. Amaranth production levels worldwide are not known. It is more commonly cultivated in Mexico, Peru, and other Andean countries and grown on a small scale in some other South and Central American countries, aimed at grain production. Amaranth is also grown and consumed as grain or vegetable crop in Australia, Africa, and Asia and especially in Nepal and by inhabitants of mountainous regions of northern and southern India, where it is the most commonly consumed as a green leafy vegetable. Researchers have verified that amaranth is the second most preferred indigenous vegetables for the Sudanese people.

The production of amaranth has been promoted around the world, mainly due to its many interesting characteristics, such as fast growth (in about ninety days). Unlike other green vegetables, it is cultivated during the summer months, when no other market leafy vegetables are available. This makes it possible to use in grain crop rotation systems. Amaranth can also grow under varied soil and agroclimatic conditions. Amaranth culture can be employed under different production systems, ranging from direct seeding, transplanting, irrigated or rain-fed conditions, interspersed, as edges around other cultures, to monoculture, depending on the environmental conditions and location. Good results have been obtained at sea level and in tropical areas. Although the plant is susceptible to cold and excessive moisture, it is resistant to water deficit and heat. Recent research indicates that under optimal soil, moisture, and temperature culture conditions, yields can reach 5000 kg ha^{-1}, although average yields are within the range of 1000–2500 kg ha^{-1}.

Amaranth grown conventionally brings around $ 0.40 per pound, while organic amaranth may sell for $0.65 per pound or more. Thus, with high productivity, amaranth gross returns can easily surpass commodity crops. In addition, productivity keeps increasing due to improvements in available technology, derived from research, as well as new varieties, harvest mechanization, breeding, and agroindustry development. Projects worldwide are aimed at contributing to the improved livelihood of resource poor communities through increased grain amaranth production, increased use as food, and the introduction of value-added products. Currently, many farmers seem more interested in growing the crop for sale than home consumption. Nonetheless, two expensive problems involve seed cleaning and transportation to market. If the harvested seed contains considerable extraneous material, cleaning and drying should be done as fast as possible. After that, the grain should be stored at about 10–12% relative humidity.

On small, family properties, amaranth can be prepared using low-energy techniques. The grain can be boiled in water, toasted, or parched lightly, sprouted, popped, or puffed like popcorn. Milling for household consumption may pose a problem, requiring the installation of mills in communities to facilitate this task. However, industrial grinding or milling of the grain is very feasible, and its flour can partially substitute other flours to generate several products, such as biscuits, cakes, and bread. For bread production, though, adjustment is necessary because the grain has no gliadin to form a gluten structure. On an industrial scale, quality products can be

produced with amaranth flour, generating expanded products, such as snacks. Besides that, flakes, cereal bars, or fermented products, such as an alcoholic drink, can be produced. A water extract can used to produce a nonalcoholic amaranth drink. Leaves usually are used as boiled greens or in salads.

Chemical Composition and Analyses

Both the leaves and seeds of amaranth possess high nutritional value. Ash, protein lipid, fiber, and carbohydrate contents of amaranth leaves are about 14%, 18%, 5%, 9%, and 52%, respectively. They also possess appreciable amounts of vitamins and low levels of toxicants, especially after thermal processing.

The National Research Council of the United States considered amaranth grain as one of the most promising foods of the millennium, and the US National Academy of Sciences encourages commercial exploitation of the grain due to its high nutritional quality. Seed lipid content is about 6–8% and a lipid profile similar to that of cereals. Amaranth differs mainly by the presence of squalene in the unsaponifiable fraction. Starch and fiber contents are 50–60% and 8%, respectively. In addition, the seed possesses a high soluble fiber content, as compared to cereals. Another advantageous factor favoring amaranth consumption is the availability of amino acids that are limiting in cereals and legumes, such as lysine and methionine. Finally, the protein content of amaranth grain is comparatively high (13–18%) and its amino acid composition close to the optimum for human consumption.

The mineral and vitamin contents of amaranth are also considerable. Calcium, phosphorus, and iron contents are high, relative to cereals. In addition, amaranth's content of antinutritional factors such as phytate is negligible. The pseudocereal also possesses antioxidant compounds, such as tocotrienols, tocopherols, flavonoids, and other phenolic compounds.

Due to its interesting composition, several compositional and physicochemical tests have been performed on amaranth leaves, grain, and their by-products. The identification and quantification of vitamin, lipid, carbohydrate, protein, peptide, phenolic content, and other organics usually involve the use of chromatographic methods, combined with mass spectrometers. Mineral analyses involve spectrophotometric methods, such as atomic absorption and flame atomic emission.

Chemical and physicochemical analyses may be accompanied with assessment of nutrient bioavailability. In this regard, genomic, transcriptomic, and proteomic methods have been used to determine specific effects of its components on biological systems. For food safety, PCR is one of the most used methods, specifically to detect for gluten contamination.

Availability, Absorption, Metabolism, and Health Effects

Besides these nutritional characteristics, studies have shown that the introduction of amaranth into the diet may prevent or diminish the risk of diseases by presenting several biological effects, possessing antidiabetic, cholesterol-lowering, antioxidant, antitumoral, and antimicrobial effects.

Antinutritional Factors and Bioavailability

Oxalates are present in the leaves of cooked amaranth (*A. gangeticus* or *A. tricolor*) and could inhibit the absorption and bone deposition of calcium as demonstrated in young rats. Amaranth grains (*A. cruentus*, *A. hypochondriacus*, and *A. hybrid*) contain 4–5 times more oxalate than cereals and legumes, averaging 229 mg 100 g^{-1}, of which 80% were insoluble. Oxalate reduces the bioavailability of calcium and magnesium by complexing with these minerals, preventing their absorption. Moreover, this contributes to the formation of kidney stones.

In order to reduce the intake of soluble oxalate, cooking of the grain prior to consumption is essential.

Cooking and popping of *A. cruentus* and *A. caudatus* decreased the presence of antinutritional factors such as phytates, trypsin inhibitors, and increased nutrient bioavailability. In contrast, the same processes decreased concentrations of phenolic compounds, of which popping had the lesser effect.

Antidiabetic Effects

Studies with different amaranth leaves have shown positive effects in terms of reducing hyperglycemia. Methanol extracts from *A. caudatus* inhibit α-amylase under *in vitro* conditions. These extracts contain flavonoids, saponins, alkaloids, carbohydrates, proteins, peptides, amino acids, and phenolic compounds. The latter accounted for 48% of the organic constituents. The same inhibition was observed by ethanol extracts from raw and processed (bleached) *A. cruentus* leaves. Inhibition of amylases reduces the bioavailability of carbohydrates, thus contributing to the reduction of glucose levels in blood. Therefore, glycated hemoglobin decreased, as well as α-glucosidase inhibition, related to the phenolic content of amaranth leaves. A hypoglycemic effect of methanol extracts was observed, from *A. caudatus*, *A. spinosus*, and *A. viridis* leaves, on diabetic rats, depending on extract concentration. In spite of these potential beneficial effects, the antidiabetic role of amaranth is still controversial, especially because the compound class responsible for such effects has not been established.

Conflicting results have been obtained from studies concerning the potential antidiabetic effects of amaranth grain. Peptides were found in grain amaranth (*A. hypochondriacus*) that interact with dipeptidyl peptidase IV, a regulator of the glucose levels, inhibiting its action through hydrophobic interactions and hydrogen bonds. The effect of oil and grain amaranth (*A. esculentus* L.) on diabetic rats showed that supplementation with oil and grain reduces their glucose levels. The mixtures of amaranth grain with chapatti (a common Middle East bread wheat) was considered of low or medium glycemic index (GI), depending on amaranth proportion. On the other hand, the glycemic response of normal volunteers following ingestion of extruded amaranth (*A. cruentus* L.) showed an effect similar to that of white bread and a greater capacity than the control to stimulate insulin production. Although grain amaranth has high dietary fiber content, it was not enough to reduce the glycemic response. Grain processing may expose starch matrix and facilitate its gelatinization, which in turn increases susceptibility to enzymatic digestion.

Cholesterol-Lowering Effect

Several studies have evaluated the influence of diet changes on the plasma levels of total cholesterol and its fractions. For many decades, amaranth has been investigated about its beneficial effects in this regard. Initially, the fractions suspected responsible for this effect were amaranth's protein and lipid moieties. Whereas the data on amaranth protein effect have been consistent, results from the lipid fraction seem controversial. The effect of amaranth oil on patients with heart disease and both obese and hypertensive was a reduction in the blood cholesterol levels. Squalene and phytosterols in the oil might be involved in this decrease. However, studies of the effect of amaranth oil and squalene on hamsters subjected to a hypercholesterolemic diet showed that the lipid fraction of *A. cruentus* did not reduce the levels of serum cholesterol or triglycerides. On the other hand, they increased bile acid excretion in the feces, indicating a possible decrease of the solubility of cholesterol micelles. Phytosterols and their corresponding saturated sterols reduce the absorption of cholesterol through the inhibition of its solubility in the intestinal lumen and thus decrease plasma LDL-c (low-density lipoprotein cholesterol). Supplementation with amaranth oil and grain in diabetic rats was effective in lowering total cholesterol, very low-density lipoprotein, and plasma triglycerides but had no effect on high-density lipoprotein particle of cholesterol levels and LDL-c. In the liver, there was a decrease in both triglycerides and supplemental grain showed an effect in lowering cholesterol.

The first consistent studies on amaranth grain in reducing cholesterol in mammals were performed with extruded amaranth in rabbits. In these studies, amaranth without oil reduced total cholesterol of hypercholesterolemic rabbits by 50%. Pure amaranth protein, without any other major component as fiber or oil, was found to produce the equivalent reduction in hamsters. Amaranth protein was then tested in hypercholesterolemic patients, and a decrease in their plasma cholesterol levels was observed. The protein dosage was critical for this effect to be observed. When insufficient protein (< 10 g day^{-1}) is used, the effect may be not relevant. However, when it amounts to around 25 g day^{-1} or more, the effect is substantial (around 4.5% decrease in blood cholesterol) that represents a significant reduction in the cardiovascular risk.

The mechanisms of serum cholesterol reduction associated with the consumption of amaranth protein are still poorly understood. One possibility is by the inhibition of the micellar solubilization of cholesterol in the lumen due to the considerable hydrophobic amino acid content of the samples. Peptides derived from hydrophobic amino acids, such as the hypocholesterolemic IAEK (lactostatin), found in soybeans, inhibit cholesterol absorption. There is also the possibility of peptides absorbed into enterocytes and transported to the liver to inhibit the cholesterol synthesis pathway. In fact, reports on the inhibition of liver HMGR (HMG-CoA reductase), a key enzyme of cholesterol synthesis, by the ingestion of amaranth protein, and the ability of peptides from amaranth to inhibit HMGR *in vitro*, support this mechanism.

Antioxidant Effect

Oxidative stress is related to cellular aging and neurodegenerative, cardiovascular, liver, and other diseases. The antioxidant effect of methanol extracts of grain amaranth (*A. hypochondriacus*) on the liver of rats intoxicated with ethanol showed interesting results. The group that ingested alcohol, in combination with amaranth extracts, had a decrease in malonaldehyde (MAD) concentrations and an increase in the activity of superoxide dismutase (SOD). Both effects were observed in serum and in the liver. Other enzymes involved in oxidative stress, such as catalase and glutathione peroxidase (GPx), hardly changed. Stimulation of gene transcription for Cu–Zn SOD was demonstrated, and the *in vitro* extract was able to inhibit lipid peroxidation and to act as a free-radical scavenger. The addition of grain amaranth (*A. cruentus*) to the diet together with fructose reduced the concentrations of MAD, SOD, GPx3, and lipid peroxidation in

plasma and various rat tissues. The grain was more effective on lung and heart tissues.

When one compares the total phenolic content, antioxidant activity, and inhibition of lipid oxidation between raw and processed amaranth (*A. cruentus*) (extruded, roasted, boiled, and popped), it is found that the ethanol extracts from cooked amaranth were able to inhibit lipid oxidation more effectively as compared with the extracts from distinct processed cereal and pseudocereal grains. Among the processed grains, only the extracts from the roasted grains had a lower antioxidant activity index in relation to the raw grain. Although processing reduced the total phenolic content, this did not affect the antioxidant capacity, highlighting the participation of other compounds in this property.

The peptides from amaranth albumin, globulin, and glutelin (*H. mantegazzianum*) showed significant scavenging capacity, but glutelin fraction exhibited the greatest effect. Molecules smaller than 0.5 kDa had the greatest antioxidant effect. Peptides with molecular masses below 0.25 kDa showed no effect. Amaranth proteins were effective sources of antioxidant peptides when this activity is detected using ORAC and $ABTS^{+}$ methods.

Antihypertensive Effect

Inhibitors of the angiotensin-converting enzyme (ACE) have an important role in the regulation of blood pressure. The enzyme promotes the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. On the other hand, a vasodilator acts by inactivating bradykinin.

The ACE inhibitory activity of amaranth, quinoa, and buckwheat grains was studied, and it was found that these species inhibited the enzyme's activity by 8.8%, 23.3%, and 22.8%, respectively. Even though amaranth had the least effect, its effect was higher than those of rice and wheat. This activity of amaranth is due to its bioactive peptides found in glutelin.

The ACE inhibition by peptides of amaranth 11S globulin showed that the tetrapeptides, ALEP and VIKP, were effective inhibitors of the enzyme. A three-dimensional model was built of globulin, and its peptides were mapped by computer. The inhibitory activity on ACE by peptides from the 7S globulin showed that the effect was similar to that of 11S globulin. The better results were observed with the peptides obtained with protein hydrolysis by alkalase.

Other Beneficial Effects

Amaranth can affect cell replication. The effects of a lunasin-like amaranth peptide on histone acetylation showed a dose-dependent inhibitory effect upon acetylation of the core histones H3 and H4. These histones are involved in DNA packing and unraveling, being their lysine residues' acetylation the mechanism by which unraveling and replication of DNA are promoted. Therefore, substances that inhibit this acetylation will have a potential anticarcinogenic effect. Interruption of deacetylation–acetylation processes leads to cell death. In a maximum utilized concentration of lunasin-like peptide from amaranth (1000 nM), acetylation of H3 and H4 by the histone acetyl transferase was inhibited up to 77% and 70%, respectively. Amaranth lunasin acts in various ways to inhibit uncontrolled cell replication. One of these involves competition with histone acetyltransferases on H3 and H4. This peptide presents high content of methionine and cysteine.

Amaranth peptides have antimicrobial activity. By measuring the effect of the antifungal peptide, Ar-AMP, of amaranth (*A. retroflexus*) against several funguses, the observed growth inhibition was greatest against the *Fusarium culmorum* fungus in a dose-dependent manner. Significant antihelminthic effects were also observed when using amaranth peptides. The initial methanol extracts of the species *A. spinosus*, *A. caudatus*, and *A. viridis* had the greatest effect in inducing rapid helminth mortality.

The effect of supplementation with amaranth (*A. viridis* L.) on analgesia in mice was reported. It was found that a dose of 400 mg kg^{-1} of amaranth per mouse weight reduced pain by 60.5%, similar to the effect of aspirin.

Conclusion

In conclusion, amaranth cultivation and consumption have increased in the past few decades, especially due to three factors: rediscovery of the crop, development of new agronomic technologies, and increased demand for healthy food products. Amaranth contains several compounds that act beneficially, protecting, modulating, inhibiting, or stimulating activities in human cells and tissues or even modulating human genome. Further studies are necessary to elucidate the biochemical pathways of amaranth bioactive substances and evaluate their bioavailability in processed food. In the future, data may allow the establishment of dietary references for amaranth intake and its products for consumption, improving human health.

Amino Acids: Determination

Introduction

Proteins and peptides contribute to many relevant functions in an organism and, in fact, constitute key elements for the survival of animals and humans. Proteins are naturally constituted by 23 amino acids, which act as basic components of the polymeric structure. Some proteins or peptides contain also 'nonstandard' amino acids that are formed by posttranslational modification during protein synthesis and that are essential for the function or regulation of that protein.

Once foods are ingested, its proteins are hydrolyzed and small peptides and amino acids are released by enzymatic digestion and absorbed into the body. So, protein quality in a particular food strongly depends on its amino acid content and digestibility. Amino acids participate in many biochemical pathways for growth, maintenance, and metabolic activity of cells and organs, and its requirements vary, depending on the stage of life and the quality of proteins. Thus, the knowledge of the amino acid profile or the essential amino acids contents in foods and the limiting amino acids in a protein is very important for the characterization of their biological value and how their nutritional benefits may be affected by food processing or during storage. There are many available methods for the analysis of amino acids in foods that are summarized in this article.

Methods for the Analysis of Amino Acids in Foods

The choice for the methodology for the analysis of amino acids in foods depends on many factors such as the nature of the matrix because the presence of proteins, sugars, starch, or fat could interfere with amino acid extraction or analysis. Also, the choice will depend on the amino acid concentration and the required sensitivity level, but, except in some cases, it is not a limitation since sample size is usually more than enough. Finally, the technique of choice will depend on the availability in the laboratory. The simplest aim in the analysis of amino acids is to determine the total amino acid content. This analysis mainly quantifies free amino acids and some small peptides and is based on the reaction of the α-amino group with reagents like *o*-phthaldialdehyde (OPA), cadmium–ninhydrin, fluorescamine, and trinitrobenzene sulfonic acid that are the most used. These reagents contribute to a better ultraviolet response of amino acids at a higher wavelength or confer them visible or fluorescent characteristics. This global determination has a wide number of applications such as obtaining a proteolysis index for controlling the progress of food protein hydrolyzates or controlling manufacturing processes of some food products like cheese, meat products, and anchovies. Methods for this analysis generally include the precipitation of proteins, reagent addition, and colorimetric, UV absorption, or fluorescent determination of the amine nitrogen in the supernatant.

In most cases, the goal is focussed on determining the amino acid profile by analyzing the individual content of each amino acid, but such profile will vary, depending on whether they are in free form to obtain the free amino acid profile or come from protein hydrolysis constituting the total amino acid profile that may include also free amino acids present in the sample. The three described possibilities for the analysis of amino acids in foods are summarized in Figure 1.

Sample Preparation

The treatment of samples differs depending on the analytic purpose as mentioned earlier. In the case of free amino acids, some or all of the following processes may be required: extraction, cleanup, and derivatization, before or after the amino acid separation. In the case of total amino acids, additional protein hydrolysis is required. Once these stages are performed, amino acids can be separated and quantified. In this section, sample extraction and methods for sample cleanup and protein hydrolysis are described.

Free Amino Acids

Figure 2 shows a flowchart with the steps for the determination of free amino acids. The steps are described in detail in the following.

Extraction

This stage must be performed in the case of nonsoluble solid matrices (fish, meat, cereals, etc.) and is usually achieved by homogenization of the ground or milled food sample in an appropriate solvent. A dilute solution (0.1 N) of hydrochloric acid, or even water, is the typical extraction solvent to be used. In some cases, stronger acid concentrated solutions such as 4% of 5-sulfosalicylic acid (SSA) and 5% of trichloroacetic acid (TCA) or rich alcohol-containing solutions (>75%) such as ethanol and methanol have been successfully used as extraction solvents with the additional advantage that proteins are not extracted and, then, there is no need for further cleaning up of the sample. In the case of liquid food samples like milk or drinks, in general, no extraction is needed.

Once homogenized, the solution is centrifuged (10 000 g at 4 °C) to separate extracted (supernatant) from nonextracted (pellet) materials and filtered through glass wool to retain any fat material on the surface of the supernatant.

Sample cleanup

Sample cleanup consists in the isolation of amino acids from other extracted compounds (proteins, carbohydrates, and fats) as much as possible. The most common requirement is the separation of amino acids from proteins, a process known as deproteinization, which can be achieved through different chemical or physical methods. To this aim, concentrated strong acids like SSA, perchloric acid, trifluoroacetic acid (TFA), TCA, picric acid (PA), and phosphotungstic acid and organic solvents like methanol, ethanol, and acetonitrile (by

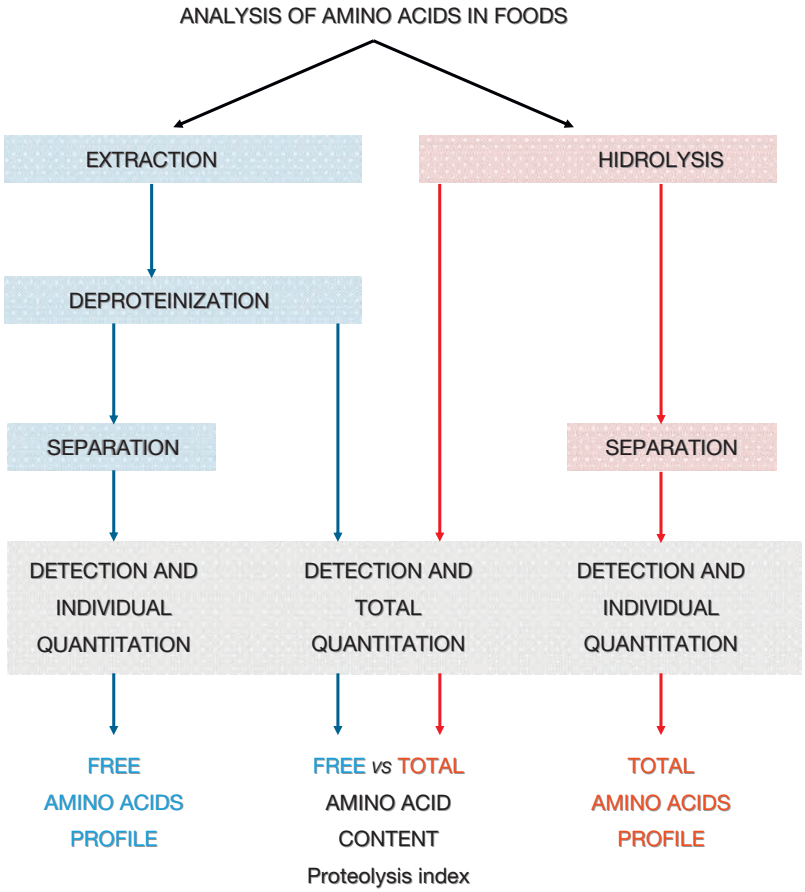

Figure 1 Flowchart showing the three general types for the analysis of amino acids in foods.

mixing two or three volumes of organic solvent with one volume of extract) are used. Under these conditions, proteins precipitate by denaturation, while free amino acids remain in solution. Some physical methods consist in the centrifugation through cutoff membrane filters (1000, 5000, 10 000, and 30 000 Da) that allow free amino acids through while retaining large compounds. All these methods give a sample solution rich in free amino acids and free of proteins.

Sample cleanups using cation-exchange resins (Amberlite, Rexyn, Biorex, Dowex, etc.) and C-18 minicolumns (Sep-Pack™ from Waters, Bond-Elut™ from Varian, etc.) have also been used. Cation-exchange supports retain amino acids under acidic conditions, while other interfering compounds, such as carbohydrates, are washed off the column. Amino acids are afterward eluted with a strong volatile base that will be removed by evaporation. C-18 minicolumns operate in a similar way to reverse-phase chromatographic columns, and thus, when the sample is percolated through the minicolumn, amino acids are eluted, while lipids, proteins, and peptides are retained. This is not a very feasible method because some hydrophobic amino acids may be retained while some polar proteins may elute together with the amino acids.

Total Amino Acids

The determination of the total amino acid profile can give information on the nutritional value of foodstuffs. Prior to the analysis, proteins must be hydrolyzed into their constituent amino acids (see Figure 1). The main hydrolysis methods are described in the following.

Acid hydrolysis that is based on acid digestion is the most common method for hydrolyzing proteins. Typically, samples are treated with concentrated (6 N) hydrochloric acid in a conventional oven (110 °C for 20–96 h or at 145 °C for 4 h) or in a microwave oven (at shorter times, usually <20 min). These temperatures in such acidic and oxidative media can degrade some amino acids, and thus, the elimination of oxygen by keeping a nitrogen atmosphere in sealed vials during hydrolysis in order to minimize degradation is strongly recommended.

Hydrolysis may be improved by optimizing the temperature and time of incubation and with the addition of amino acid oxidation protective compounds like 1% phenol and 0.1% sodium sulfite that prevent losses of the most labile amino acids like tyrosine, serine, threonine, and methionine. Indeed, protective agents improve the recovery of nearly all amino acids except tryptophan and cysteine.

Tryptophan is especially labile in samples having a high content in carbohydrates. Alternative hydrolysis with 4 N methanesulfonic or mercaptoethanesulfonic acid in samples with up to 20% of sugar content has been reported to improve tryptophan recoveries. Many authors recommend alkaline hydrolysis with 4.2 M of NaOH, KOH, LiOH, or BaOH, for 18 h at 110 °C for a better tryptophan determination, even in samples with a large amount of sugars (70–85%).

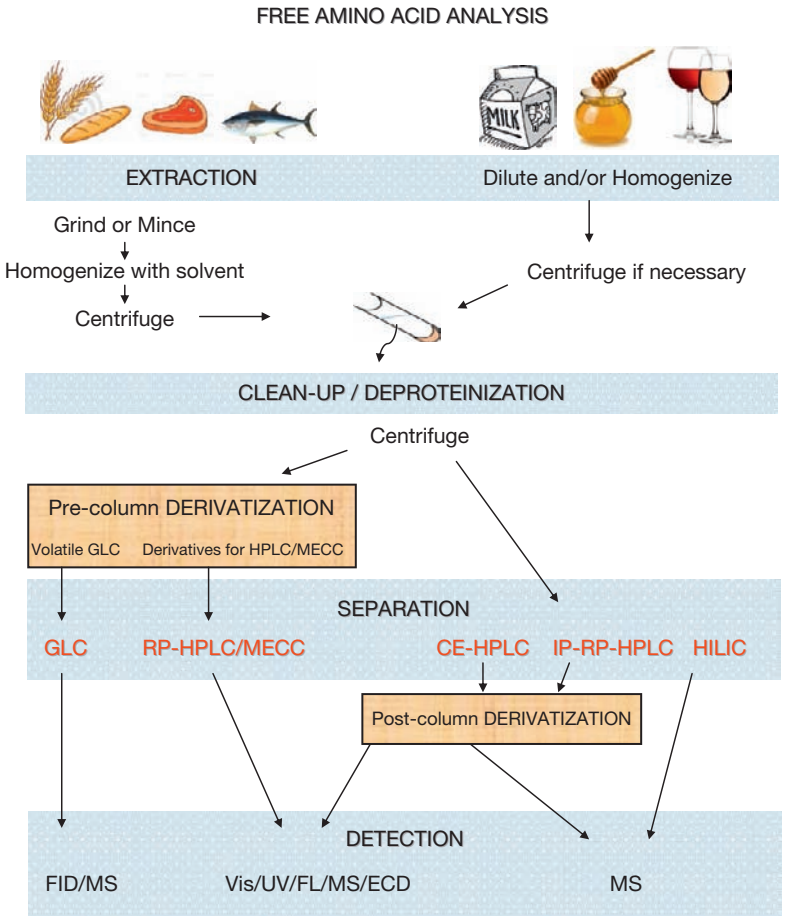

Figure 2 Flowchart showing the main steps and procedures for the analysis of free amino acids in foods.

Cyst(e)ine is partially oxidized during acid hydrolysis yielding several adducts, which makes its analysis difficult. The performic acid oxidation of cysteine to cysteic acid or the use of alkylating agents (3-bromopropylamine, 4-vinyl pyridine, iodoacetic acid, and 3,3′-dithiodipropionic acid) to stabilize cysteine before hydrolysis improves cysteine recovery.

Finally, glutamine and asparagine are deamidated during hydrolysis and are codetermined with glutamic and aspartic acids, respectively.

Derivatization

Once amino acids are extracted, cleaned up, or hydrolyzed, they must be separated from each other for their individual analysis. Before or after this separation, amino acids are usually derivatized to improve their separation or to enhance their detection. Several types of derivatives are obtained depending on the chosen separation and/or the detection technique.

Derivatives for Gas Chromatographic Separations

The conversion of amino acids into a volatile and thermostable molecule by means of substitutions in their polar moieties by nonpolar groups makes them apt to gas chromatographic (GC) analysis. Original reactions consisted in two stages: an esterification with an acidified alcohol (methanol, isopropanol, isobutanol, *n*-propanol, *n*-butanol, or isoamyl alcohol) followed by N-acylation using TFA anhydride, pentafluoropropionic anhydride, or heptafluorobutyric anhydride or silylation.

Silylation is the most prevalent derivatization technique. The products are generally more volatile and more thermally stable, and, in opposition to acylation, silylation normally does not require a purification step, and the derivatives can be injected directly into the GC. Nowadays, the silylating reactions have improved with the use of *N*,*O*-bis(trimethylsilyl) trifluoroacetamide or *N*-methyl-*N*(tert-butyldimethylsilyl)trifluoroacetamide that may permit a one-step derivatization procedure, with formed derivatives more stable to moisture. They constitute the basis of a methodology marketed by Sigma-Aldrich/Supelco (Bellefonte, PA, USA). There are a wide range of reagents available for the silylation of amino acids, which differ in their reactivity, selectivity, and secondary reactions and the nature of the reaction products. All these reactions require in more or less extent a water-free medium.

The use of alkyl chloroformates (methyl chloroformate, propyl chloroformate, etc.) allows the direct derivatization in aqueous solution even without prior removal of proteins. These derivatives are stable for up to 1 day at room temperature and for several days if refrigerated. The formed amino acid

derivatives will be afterward extracted with an organic solvent that will be injected directly into the gas or liquid chromatographs. This method is the basis of a commercially available procedure offered by Phenomenex (Torrance, CA, USA) and registered under the name EZ:faast kit.

Derivatives for Liquid-Media Separations

The derivatization of amino acids to be analyzed in liquid media like capillary zone electrophoresis (CZE) or high-performance liquid chromatography (HPLC) has another goal, that is, to enhance their detection by acquiring spectroscopic or electrochemical characteristics. By labeling the amino acids with reagents that allow ultraviolet absorption or add fluorescent properties to the molecule, not only sensitivity but also selectivity is improved in the detection.

With regard to derivatization for liquid chromatographic amino acid analysis, the derivatization reaction can be done after (postcolumn derivatization) or before (precolumn derivatization) the separation of the amino acids.

Postcolumn derivatization is achieved by the introduction of a suitable derivatizing reagent into the effluent system from the column, the flow of the combined liquids through a mixing manifold followed by a reaction coil, and the introduction of the derivatized amino acids through an on-line detector system. The reagents that have been usually employed for postcolumn derivatization are ninhydrin, for visible detection, and fluorescamine or *o*-phthalaldehyde, for fluorescence detection.

When using precolumn derivatization, the molecule formed improves sensitivity and selectivity for the detection, and also the derivatizing agent confers hydrophobicity to the amino acid molecule, making it suitable for separation by partition chromatography on a reverse-phase (RP) column. The most usual derivatizing agents are described in the following.

Phenylisothiocyanate (PITC). The methodology involves the conversion of primary and secondary amino acids to their phenylthiocarbamyl (PTC) derivatives, which are detectable by UV (λ 254 nm). The PTC amino acids are moderately stable. Sample preparation is quite laborious because it includes several drying steps. A 20 min reaction time is recommended for a complete reaction. PTC cystine shows a poor linearity that makes the quantitation of free cystine nonfeasible with this method. The selection of the column is critical for achieving a good resolved separation, especially when the analysis of physiological amino acids is pursued.

This method is available as a commercially prepackaged system named 'Pico-Tag' (Waters Associates, Milford, MA), which includes the analytic column, standards, and solvents. Until recently, PITC was one of the preferred precolumn derivatizing agents to analyze both physiological and hydrolyzed amino acids from foods and feeds by HPLC.

4-Dimethyl-aminoazobenzene-4′-sulfonyl chloride. The detection of the amino acid derivatives is by absorption in the visible range presenting a maximum from 448 to 468 nm. The high wavelength of absorption makes the baseline chromatogram very stable with a large variety of solvents and gradient systems. Derivatives are very stable (weeks) and can be formed from both primary and secondary amino acids. The reaction time is around 15 min at 70 °C. Reaction efficiency is highly matrix-dependent and variable for different amino acids, being especially affected by the presence of high levels of some salts (chloride). By-products originating from an excess of reagent must be minimized because they absorb at the same wavelength and appear in the chromatogram. The commercial 'System Gold/Dabsylation Kit' uses this technique (Beckman Instruments).

1-Dimethylamino-naphtalene-5-sulfonyl chloride (Dansyl-Cl). Dansyl-Cl reacts with both primary and secondary amines to give a highly fluorescent derivative (λ_{ex} 350, λ_{em} 510 nm), also detectable at UV (λ 250 nm). The dansylated amino acids are stable up to 7 days at −4 °C, if protected from light. The reaction time ranges from 1 h at 40 °C to 2 min at 100 °C. However, the reaction conditions (pH, temperature, and excess of reagent) must be carefully fixed to optimize the product yield and to minimize secondary reactions. This methodology reveals excellent linearity for cystine and also cystine-containing short-chain peptides.

9-Fluorenylmethyl chloroformate (F-MOC). This reagent yields stable derivatives (days) with primary and secondary amines. The derivative is fluorescent (λ_{ex} 265 nm and λ_{em} 315 nm). The reaction time is fast (45–90 s) and does not require any heating. The major disadvantage is the presence of the hydrolyzed reagent that is highly fluorescent and may interfere in the chromatogram. In order to avoid such trouble, it must be extracted with pentane or diethyl ether, as proposed in the automated AminoTag™ method (Varian Associates Ltd.), or converted into a noninterfering adduct prior to injection by reaction with a very hydrophobic amine such as 1-adamantylamine that gives a late-eluting noninterfering peak.

o-Phthaldialdehyde (OPA). This reagent reacts with the primary amine of amino acids in the presence of a mercaptan cofactor to give highly fluorescent derivatives (λ_{ex} 230 or 330 nm and λ_{em} 455 or 470 nm). OPA derivatives can be detected by UV absorption (λ 338 nm) as well. The choice of mercaptan can affect derivative stability, chromatographic selectivity, and fluorescent intensity; ethanethiol, 2-mercaptoethanol, and 3-mercaptopropionic acid are those most frequently used. The derivatization is fast (1–3 min) and is performed at room temperature. Derivatives are not stable, but this problem is overcome by standardizing through automation the time between sample derivatization and column injection. Some methods have been patented and commercially marketed (AutoTag OPA™, Waters Associates, Milford, MA, and AminoQuant™, Agilent Technologies, Palo Alto, CA). One of the main disadvantages of this procedure is the inability of OPA to react with secondary amines and thus it does not derivatize proline or hydroxyproline. This drawback can be overcome by combining OPA with other derivatization methods such as that based on F-MOC, which should take place sequentially. This is the basis of the AminoQuant system™ developed and marketed by Agilent Technologies (Palo Alto, CA). On the other hand, the cysteine yield is low and variable and several methods to improve its analysis will be described later.

6-Aminoquinolyl-N-hydroxysuccinimidyl carbamate (AQC). This reagent reacts with primary and secondary amines yielding very stable derivatives with fluorescent properties (λ_{ex} 250 nm and λ_{em} 395 nm), which are easily separated by RP HPLC. The main advantage of this reagent is that the yield and

reproducibility of the derivatization reaction are scarcely interfered by the presence of salts, lipids, and other compounds naturally occurring in food. The excess of reagent is consumed during the reaction to form aminoquinoline, which is only weakly fluorescent under the amino acid derivative detection conditions and does not cause any interference in the chromatogram. Reaction time is short (1 min), but 10 min at 50 °C would be necessary if a tyrosine monoderivative is required, because both mono- and diderivatives are the initial adducts from tyrosine. The fluorescence of the tryptophan derivative is very poor. Derivatives are very stable (1 week at room temperature). The methodology has been commercialized as a prepackaged kit by Waters Corporation as 'AccQ Tag.'

Derivatization reagents specific for cysteine are the Ellman's reagent 5,5′-dithio-bis-nitrobenzoic acid and 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole, which react with cysteine giving a product showing a maximum of absorbance by 420 nm. These reagents are highly specific for cysteine and do not need a posterior chromatographic separation. Other reagent is *N*-(1-pyrenyl)maleimide, which reacts with free sulfhydryl groups to form fluorescent derivatives (λ_{ex} 230 nm; λ_{em} 376 nm) that will be separated by RP HPLC. A prederivatization sample treatment with dithiothreitol was suggested to reduce the cystine disulfide bonds and thus quantify it from the total cysteine determination.

Derivatives for laser-induced fluorescence (LIF) detection are fluorescein isothiocyanate, 3-benzoyl-2-quinolinecarboxaldehyde, and 4-fluoro-7-nitro-2,1,3-benzoxadiazole. LIF constitutes an alternative to fluorescence when looking for more selective and sensitive detectors for HPLC or micellar electrokinetic capillary chromatography (MECC), with a wide linear dynamic range (3 orders of magnitude) to cover new high sensitivity applications.

Some derivatization reagents permit the separation of racemic mixtures (D- and L-amino acids) by RP HPLC and MECC. It is the case of fluorescent chiral reagents like OPA plus *N*-isobutyryl-L-cysteine or *N*-isobutyryl-D-cysteine, OPA plus 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranose, R(−)- and S(+)-4-(3-isothiocyanatopyrrolidin-1-yl)-7-(*N*,*N*-dimethylaminosulfonyl)-2,1,3-benzoxadiazoles, and 1-fluoro-2,4dinitrophenyl-5-L-alanine amide (Marfey's reagent). The quantitation of D-amino acid isomers is used as an indicator of the geographic origin of some foods, as a marker of the correct heat or alkali treatment, or as an index of microbial quality.

Derivatization reagents for electrochemical detection (ECD) are molecules with electroactive functional groups. All of them also have spectroscopic properties. The most used are OPA/mercaptoethanol or OPA/sulfite, 6-AQC, PITC, and naphthalene-2,3-dicarboxaldehyde. Sensitivity is of the order of fluorescent derivatives.

Separation

The analysis of individual amino acids needs a previous separation of each other unless a very selective detection is used. The separation of the individual amino acids in a mixture requires very efficient separation techniques as is liquid chromatography or GC or capillary electrophoresis.

Liquid Chromatographic (LC) Methods

Cation-exchange method

The separation is based on the amino acid charge. The most widely used is cation-exchange chromatography, which is based on the underivatized amino acid separation using cation-exchange resins as the stationary phase and citrate buffers as the mobile phase. After separation, amino acids react with ninhydrin, to obtain colored derivatives, or with either OPA or 4-fluoro-7-nitrobenzo-2,1,3-oxadiazole to obtain highly fluorescent derivatives with enhanced sensitivity.

There are many manufacturers (Beckman, Biotronik, Dionex, LKB, Pickering, etc.) who offer integrated commercial systems including the column, buffer system, and an optimized methodology having the advantage of the ease of use and reliability. The advantage of this method is the accurate results that make it as a reference method for amino acid analysis. Main drawbacks of this methodology are the high cost of the ion-exchange amino acid analyzer and its maintenance, the very complex mobile phase composition, and the long time of analysis.

Reverse-phase HPLC

RP HPLC separates the amino acids based on their hydrophobicity. This technique is widely used and has the advantage of requiring standard equipment able to be shared by different types of analysis. In this case, the previous amino acid derivatization not only is necessary to confer hydrophobicity to the amino acid molecule, making it apt for partition based on chromatography, but also allows the spectroscopic (ultraviolet or fluorescent) detection of amino acids.

If the choice of the derivative reaction is a challenge, the choice of the RP column is not an easy subject because of the great variability of commercially available RP columns. The most used column packaging consists of alkyl-bonded silica particles, mainly octadecylsilane. However, the selectivity obtained with this same stationary phase in columns from different manufacturers is different due to the particular chemistry employed in their manufacture.

Mobile phase composition combines an aqueous buffered phase with an organic phase constituted by acetonitrile and/or methanol and/or tetrahydrofuran. The buffer may be constituted by acetate or phosphate, but in the case of using mass spectrometry (MS) detection, volatile solvents like acetic and formic acids should be used. A finely adjusted gradient elution is often necessary when the overall amino acid profile from hydrolyzed and, especially, physiological amino acids has to be analyzed. Figure 3 shows a typical chromatogram of PTC-free amino acids from Spanish dry-cured ham.

Ion-pairing method

This procedure is applied to direct analysis of native (underivatized) amino acids. Ion-pairing (IP) technique consists in an RP HPLC where a contraion (ion with opposite charge to the amino acid ones) is added to the mobile phase in order to obtain an ion pair with charged amino acids with enhanced retention. The IP complexes are separated by RP as neutral molecules and ultraviolet or fluorescence detection after OPA or fluorescamine postcolumn derivatization. The most used ion-pairing reagent is lauryl sulfate. This technique has not

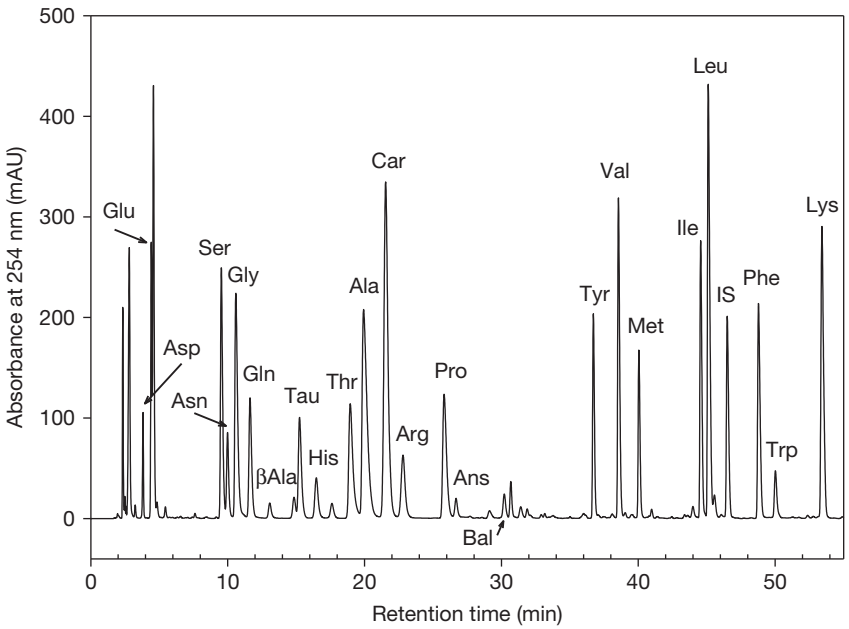

Figure 3 Reverse-phase HPLC chromatogram of free amino acids from dry-cured ham after PITC derivatization. Tau, taurine; Car, carnosine; Ans, anserine; Bal, balenine; IS, internal standard norleucine (unpublished data).

many adepts because of its complexity and lack of advantages when compared with other techniques. The current development of MS has reactivated the use of ion-pairing chromatography on amino acid analysis. Due to the requirements of MS, volatile ion-pairing reagents like perfluorinated carboxylic acids are used.

Hydrophilic-interaction chromatography

Hydrophilic-interaction chromatography (HILIC) employs polar stationary phases such as bare silica; amide, amino, hydroxyl, or zwitterionic on silica; and polymeric supports and RP-type solvents, but in this case, things work as normal phase when higher content of water implies greater elution strength. An initial mobile phase with a high content of organic solvent (mainly acetonitrile) is used to promote hydrophilic interactions between the analyte and the polar stationary phase. Under these conditions, polar solutes are retained, and with the aid of gradients in which the water amount is increasing, compounds will be gradually eluted. Volatile salts, ammonium acetate, and ammonium formate are used to provide some ionic strength to the system and to adjust the pH of the mobile phase with the advantage of being compatible with MS detection. This combination HILIC–MS, using narrow-bore columns (2.1 mm), permits the analysis of native (underivatized) amino acids as happened with IP–RP-HPLC method but with no need of IP reagents.

Micellar Electrokinetic Capillary Chromatography (MECC or MEKC)

The technique of CZE is an extremely efficient technique for separations of charged solutes. The high efficiency, the speed, and the low requirements of the sample amount make this technique very interesting when compared with classical electrophoresis and chromatographic techniques. The difficulty of separating amino acids by this technique relies on their structure. Amino acids constitute a mix of basic, neutral, and acidic constituents, and even though a particular pH can significantly improve the resolution of one kind, it is likely to cause overlap with the others. The primary limitation of CZE is its inability to separate neutral compounds each other. A modified version in which surfactant-formed micelles (sodium dodecyl sulfate, dodecyltrimethylammonium bromide, Tween 20, and octylglucoside) were included into the running buffer to provide a two-phase chromatographic system for separating neutral compounds together with charged ones has been developed. This technique has also been termed MECC. With few exceptions, it is used to derivatize the amino acids (Dansyl-Cl, PITC, phenylthiohydantoin, and OPA), to improve separation, and to enhance detection.

Nevertheless, separation of amino acids with this technique has not reached the resolutive power obtained through HPLC methods. The reported applications are limited to a reduced number of amino acids separated in the same electropherogram. For this, the use of MECC for the analysis of amino acids in food has not gained widespread being more restricted to clinical diagnosis, neuroscience, or metabolomic studies, in which very specific, feasible, and sensible methods are generally required, in which the sample amount in some cases is scarce, and where the economic cost is not so important in relation to the obtained benefits. Even though the current trend to miniaturizing analytic techniques suits well with the CE methodologies, the applications are more directed toward biomedical and space exploratory issues than to food.

GC Methods

Since the development of RP HPLC in 1990s, the use of GC for the analysis of amino acids was dropped. Recently, the emergence of new and improved derivatives of amino acids

(described earlier) and the wide dissemination of MS detection that can be interfaced efficiently with GC instruments have revived its use for analyzing complex mixtures of amino acids.

The very high-resolution capacity, especially since the capillary columns appeared, is the main advantage of GC in relation to the LC techniques. This high-resolution capacity allowed the separation of complex mixtures of protein plus nonprotein amino acids from food samples or the simultaneous analysis of amino acids and other food components like amines, organic acids, and sugars. GC is not very expensive because no solvent is used, and the equipment is very versatile and naturally available in an analytic laboratory. The connection with MS detectors greatly increases not only its specificity and efficiency but also its price.

Detection Techniques

Separated amino acids peaks should be detected for their quantification. There are some selective detectors for GC systems and others for liquid systems (flow injection analysis (FIA), HPLC, and MECC), while MS may be used with either gas or liquid systems.

Among the detectors specific for GC, the flame ionization detector (FID) is a universal detector and is the most widely used, while thermionic N-P or flame photometric detector is selective toward organic compounds containing phosphorous and nitrogen like phosphoserine, phosphothreonine, and phosphotyrosine being much more sensitive than FID for such compounds. The main advantage of these detectors is their high sensitivity and wide linear range.

Detectors more used for liquid systems are spectroscopic or electrochemical.

Amino acids, in their native form, absorb at 210 nm, which is a very unspecific detection wavelength. Only three amino acids (phenylalanine, tyrosine, and tryptophan) possess a chromophore moiety, which confers a suitable maximum absorbance for more specific ultraviolet detection (280 nm for tyrosine and tryptophan and 254 nm for phenylalanine). Tryptophan also possesses native fluorescence ($\lambda_{ex} = 295$ nm, $\lambda_{em} = 345$ nm) that facilitates a more selective detection. Apart from these, the spectroscopic detection of amino acids requires their previous derivatization to obtain a visible or ultraviolet-absorbing or fluorescent molecule. A wide explanation of the different possibilities in pre- or postcolumn derivatization was given earlier.

ECD is based upon the electrical properties of a solution of analyte when it forms part of an electrochemical cell. Only amino acids with aromatic rings or sulfur-containing side chains are enough electrochemically active to be detected by this method. Other amino acids need an electrochemically active compound to be attached to them (some of them were mentioned earlier).

MS is based in the conversion of components of a sample into rapidly moving gaseous ions that can be resolved on the basis on their mass-to-charge ratios that is characteristic of each ion and allows its identification. The identification of the proteinogenic amino acids may not be a problem, but this detector increases its value in the analysis and identification of nonprotein amino acids in complex matrices. Despite the high cost of purchase and maintenance of mass spectrometers, their use for analysis in food industry and/or food control is each time more often.

MS detectors were firstly connected to GC equipments. A good compatibility between both techniques, especially when capillary columns were available, permitted the rapid development and the onset of these complementary techniques.

Due to its high specificity, MS detectors coupled with HPLC or MECC do not require amino acids derivatization, an additional advantage, which means a minor sample manipulation and, due to its high specificity, a reduction of the problems related to the analysis of coeluted peaks. In these cases, volatile solvents and running buffers should be used. One of the main requirements for samples to be analyzed by MS is that analytes, amino acids in this case, must be ionized. The atmospheric pressure ionization by either microwave-induced plasma ionization, electrospray ionization, or chemical ionization has shown to be optimal interfaces between LC or MECC and tandem mass (MS/MS) detectors for the analysis of amino acids in biological samples.

Introduction

Transcription and translation are the backbone of molecular biology that carries the information from DNA (genes) to mRNA to synthesize more than 20 000–25 000 proteins (in more than 200 different cell types) using the 20 standard L-amino acids (AA) present in proteins universally.

In living organisms, there are about 300 of nonstandard AA (not all of them are found in the proteins, but have specific functions). Almost all of that nonstandard AA emerge from posttranslational enzyme modifications of standard AA (e.g., 4-hydroxyproline and 5-hydroxylysine in the collagen, desmosine in elastin as a derivative of four lysine residues, and γ-carboxyglutamate as constituent of a blood-clotting protein).

The exceptions are two nonstandard AA, designated as 21 and 22: selenocysteine (found in archaea, eubacteria, and animals, including mammals) and pyrrolysine (found in certain archaea and eubacteria). Both selenocysteine and pyrrolysine are encoded by RNA codons that signify a command to stop translation of mRNA into protein (UGA for selenocysteine and UAG for pyrrolysine) and incorporated directly into these proteins during the normal process of translation (there is a specific tRNA for these AA).

From 1806 when the first AA (asparagine) was discovered from asparagus shoots to 1938 when Rose discovered threonine, the last of the 20 AA, the interest for AA permanently increased in chemistry, biology, and medicine, from physiology to pathology, nutrition, metabolism, and especially the role that AA play in the regulation of fundamental cellular processes.

Sources of AA and Nutritional Requirement

While most bacteria and plants can synthesize all 20 AA, mammals can only synthesize 10. Those that can be synthesized and are not needed in the diet are called nonessential AA, and those for which a synthetic pathway does not exist and must be obtained from food (Table 1) are called essential AA. The latter are also essential for maintaining nitrogen balance and are indispensable in growth, whereas the former are not essential (dispensable) to mammals, birds, and fish. In some cases, this is a rough division. The fact that a synthetic pathway exists for a given AA does not necessarily mean it will be synthesized in sufficient amounts to satisfy the normal requirement (arginine, proline, and glycine). For example, arginine biosynthetic pathways do not have the capacity to compensate for depletion or inadequate dietary supply in adult rats and humans to meet the metabolic demand under certain conditions (e.g., normal growth and development of children, pregnancy, lactation, burns, injury, infection, and stress). Thus, with regard to dietary requirements, L-arginine is classified as a semiessential or, better, a conditionally essential AA.

In different organisms, the need for AA and their sources are widely different, especially in eukaryotes. Not only can most microorganisms synthesize all AA, but also they can uptake them from the environment and use in metabolic processes, including oxidation and energy production. Plants synthesize all AA, use them for synthesizing proteins and other important biomolecules, and almost never (except in stress conditions) use as an energy source. Animals can only synthesize nonessential AA. They do not store AA as glucose or fatty acids and use them in the biosynthetic processes, depending on conditions (e.g., during starvation, skeletal muscle AA become the principal source of substrates for gluconeogenesis in the liver). Besides that, herbivores satisfy most of their energy demand (90%) through oxidizing AA, while that contribution is much smaller with carnivores, including humans (15%), and strongly depends on the presence of proteins in the diet.

Digestion and Intracellular Degradation of Proteins

Dietary proteins are an important source of AA in humans. Degradation of ingested proteins occurs in the gastrointestinal tract by the action of proteolytic enzymes (proteinase) that break the long polypeptides of proteins into shorter fragments (peptides) and finally into AA. The proteolytic digestion was initiated in the stomach (pepsin) where the proteins are only partially digested and continues in the small intestine, mainly with proteolytic enzymes secreted by acinar cells of the pancreas as inactive precursor (trypsinogen, chymotrypsinogen, proelastase, and procarboxypeptidase). After activation in the small intestine (duodenum), together with proteinases secreted by enterocytes (epithelial cells of the small intestine), pancreatic proteases convert proteins into free AA, which are easily absorbed by the cells of the intestinal epithelium.

Both enterocytes and other cells in the body uptake AA by specific transporters in the plasma membrane. The transport of AA is an energy-requiring process. The fact that there are ten transporters for twenty AA suggests that some of these carry more than one AA. Distribution and properties of transporters are highly specific for the cells and tissues.

All cellular proteins have specific half-lives, including transcription factors, structural proteins (membrane), or enzymes. Some time, the half-lives of proteins depend on the lifetime of a cell (110 days for hemoglobin in the erythrocytes) and generally vary from 30 to 60 s to a few months. In addition, all abnormal or modified (oxidatively) proteins are promptly degraded in the cells by ATP-dependent cytosolic systems, in both bacteria and eukaryotes and lysosomal–autophagic and ATP-dependent ubiquitin–proteasome systems in eukaryotic cells. This is a very important source of AA in humans, and if a variable, it contributes to the overall pool of AA of more than the amount of food ingested (adult humans normally turnover about 2% of their proteins per day).

In addition to the two earlier-mentioned sources, hydrolysis of the digestive enzymes secreted by the small intestine and

pancreas and from dead microorganisms in the intestine (especially in the colon) contributes to the total pool of AA in the organism.

Metabolism of AA: Catabolism and Anabolism

Oxidative Transdeamination of AA

The metabolism of AA is strongly coupled with the metabolism of amino groups. The main chemical characteristic of AA, the presence of the α-amino group (α-NH_2), is one of the key features in their catabolism and anabolism. In the first case, a metabolic strategy is to remove the 'excess' of amino groups because ammonia is toxic and, in the second case, to provide a source of amino groups not only for the biosynthesis of AA but also for other important biomolecules, particularly nucleotides.

Table 1 Essential and nonessential AA in humans

Essential	*Nonessential*
Arginine	Alanine
Histidine	Asparagine
Isoleucine	Aspartate
Leucine	Cysteine
Lysine	Glutamate
Methionine	Glutamine
Phenylalanine	Glycine
Threonine	Proline
Tryptophan	Serine
Valine	Tyrosine

Catabolism (oxidative degradation) of AA normally occurs in our cells, and its intensity increases when we consume food rich in protein (overcomes the need for protein synthesis) or in pathological conditions when cellular proteins (e.g., muscle proteins) were used as fuel (starvation and untreated diabetes).

Different organisms have a variety of strategies for the excretion of the excess amino groups. It depends on the type of habitat and water availability. Thus, the main excretory form of nitrogen in most microbes and aquatic vertebrates is ammonia (as ammonium ion (NH_4^+)), urea for many terrestrial vertebrates and sharks, and uric acid in birds and terrestrial reptiles.

In humans, the liver is the major organ for catabolism of AA. The overall process involves three major steps: transamination in the cytoplasm of hepatocytes, oxidative deamination in the mitochondria of hepatocytes, and degradation of the corresponding α-keto acid analogs of AA (Figure 1).

The metabolic strategy of transamination reactions is to channel amino groups into only a few products. Enzymes that catalyze the transamination reactions are named transaminases (aminotransferases). All transamination reactions are freely reversible and all transaminases have the same prosthetic group, pyridoxal phosphate. The most common acceptor of α-amino groups in transamination reactions is a α-ketoglutarate. Thus, the amino groups of different AA are channeled to glutamate (e.g., alanine aminotransferase catalyze the transfer of α-amino group of alanine to α-ketoglutarate giving glutamate and pyruvate as a corresponding α-keto analog) (Figure 1).

Glutamate in hepatocytes is transported from the cytoplasm into mitochondrial matrix via the glutamate–aspartate transporter of inner mitochondrial membrane. Then, glutamate

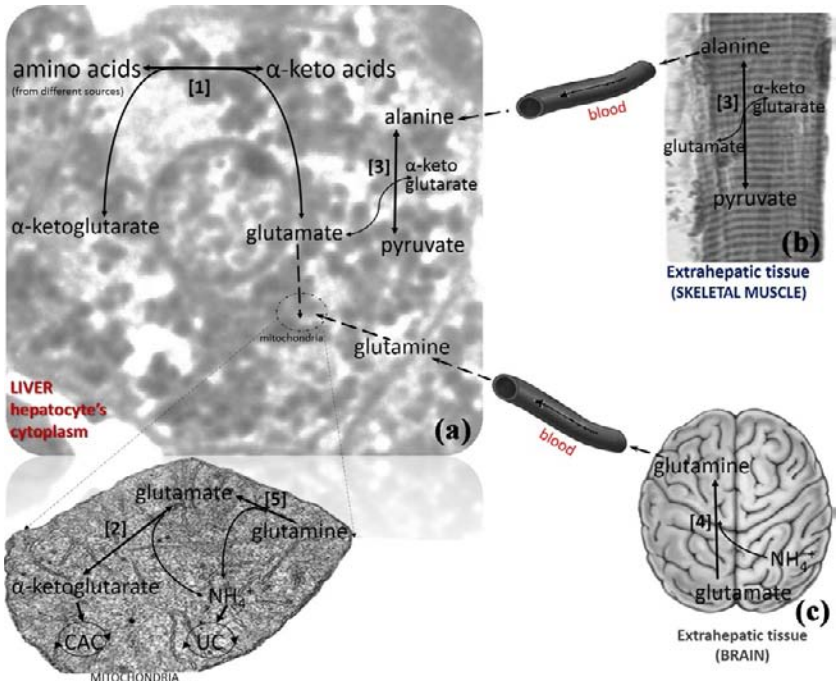

Figure 1 Metabolic flow of amino groups. (a) Transamination and oxidative deamination reactions (transdeamination) in liver cytoplasm and mitochondria (enlarge detail: liver mitochondria). Transporting route of ammonia from extrahepatic tissues in the form of (b) alanine (e.g., the muscle) and (c) glutamine (e.g., the brain). (1) Aminotransferases (transaminases), (2) glutamate dehydrogenase, (3) alanine aminotransferase, (4) glutamine synthetase, (5) glutaminase. CAC, citric acid cycle; UC, urea cycle.

undergoes oxidative deamination catalyzed by enzyme glutamate dehydrogenase. The first product of glutamate deamination is ammonium ion that enters the urea cycle (including ammonia from extrahepatic tissues and ammonia that leads to the liver via the portal vein from the intestine). Urea cycle takes place in the liver, starting in the mitochondria of hepatocytes, the only place where free ammonia is released. The second product, α-ketoglutarate, goes to the citric acid cycle, where it can be completely oxidized or be used in gluconeogenesis for the synthesis of glucose. Glutamate dehydrogenase reaction is a readily reversible (Figure 1).

Because ammonia is toxic to animal tissues, especially the brain, the excess is transported from extrahepatic tissues in the bloodstream in the form of glutamine. In the extrahepatic tissues, the enzyme glutamine synthetase catalyze the reaction of synthesis of glutamine from glutamate and NH_4^+. Glutamine is transported through the blood to the liver (also intestine and kidneys) where in the mitochondria of cells of these tissues, the amide nitrogen of glutamine is released as ammonium ion by enzyme glutaminase. In the second way of the ammonia transport in nontoxic form from the muscle and some other extrahepatic tissues to the liver, alanine serves as a carrier. Alanine aminotransferase in the muscle catalyzes conversion of pyruvate to alanine with glutamate as the amino group donor. In the liver, the same enzyme (alanine aminotransferase) catalyzes the reverse reaction, converting alanine to pyruvate with α-ketoglutarate as the amino group acceptor (Figure 1). In that way, a metabolic burden is transferred from the muscle to the liver, where the ammonia transferred from the muscles enters urea cycle, and pyruvate is used in gluconeogenesis (glucose–alanine cycle).

Pathways of AA Catabolism and Anabolism

Catabolism and anabolism of AA have some common characteristics. The same coenzymes are used in both paths. The final products of catabolic pathways and metabolic precursors of anabolic pathways are intermediates of glycolysis, citric acid cycle, and pentose phosphate pathway.

In catabolism, the next step (after deamination) is oxidative degradation of α-keto acid analogs of AA. They are oxidized to CO_2 and H_2O in the mitochondria of the liver, small intestine, muscle, and kidney. These tissues play the major role in catabolic processes, with dominant participation of the liver.

Catabolic pathways of 20 AA are a classic example of convergent metabolic pathway. All individual pathways flow into citric acid cycle across six common intermediates: acetyl-CoA, pyruvate, α-ketoglutarate, succinyl-CoA, fumarate, and oxaloacetate. In this way, many catabolic pathways of AA are simplified, but functionally integrated with the energy metabolism of glucose and fatty acids (Figure 2).

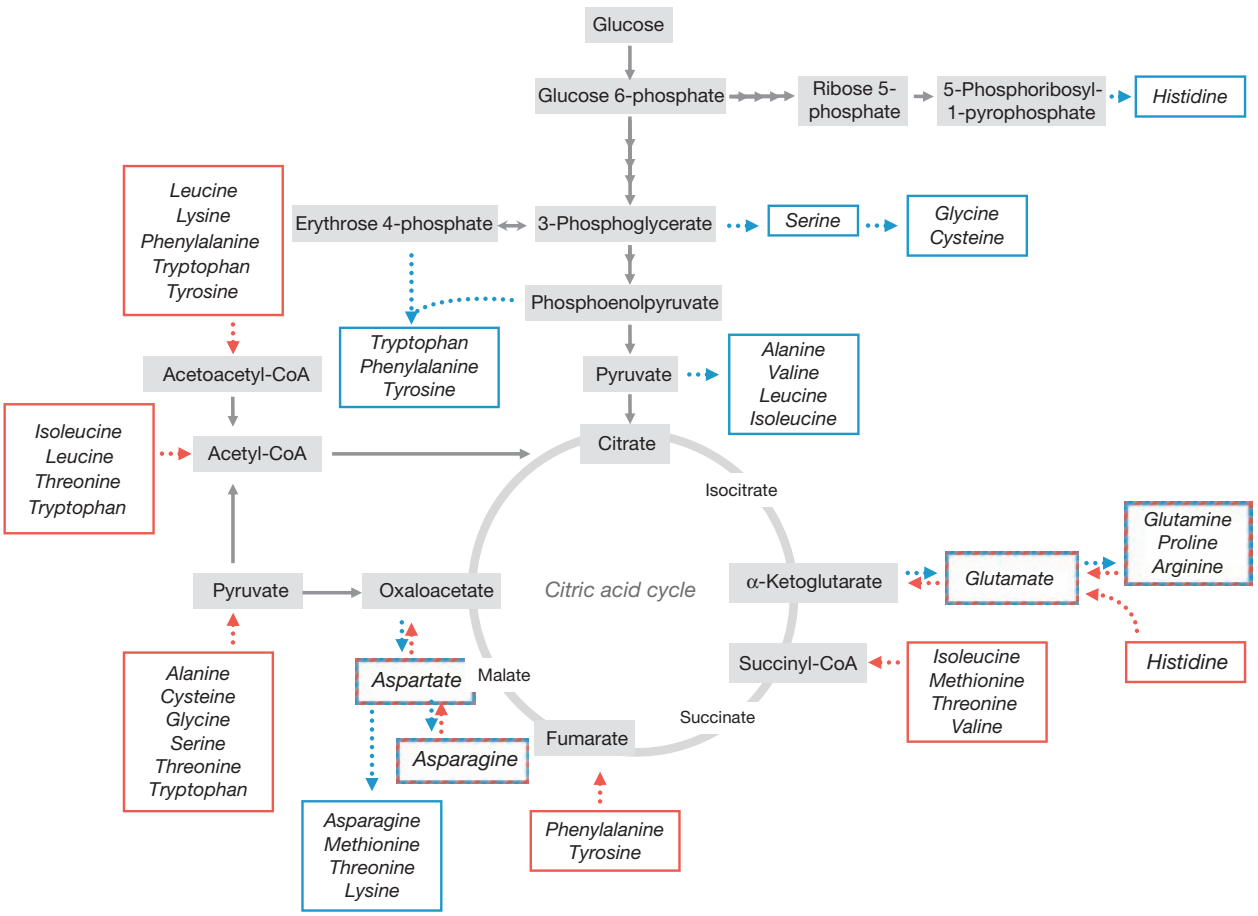

Figure 2 General scheme of AA catabolism and anabolism (red arrows represent catabolic and blue arrows anabolic pathways).

Complete oxidation of AA contributes to the production of ATP (in this case, CO_2 is the end product). This contribution is variable and depends on the presence of AA in the diet. If the amount of AA exceeds the needs for protein synthesis and ATP production, their carbon skeletons are diverted to other products: *de novo* synthesis of glucose (gluconeogenesis), fatty acids, or in specific conditions ketone bodies (ketogenesis).

Some AA gives only one final intermediate (e.g., asparagine and aspartate give only oxaloacetate and lysine and leucine only acetyl-CoA), but some more than once, reflecting different catabolisms of their carbons (e.g., phenylalanine and tyrosine give both fumarate and acetyl-CoA and threonine gives succinyl-CoA, pyruvate, and acetyl-CoA).

Those AA that are completely or partially degraded to acetyl-CoA (or acetoacetyl-CoA) can participate in ketogenesis, contributing to the synthesis of ketone bodies. These AA are referred to as ketogenic. Similarly, those AA that give the remaining five products (pyruvate, α-ketoglutarate, succinyl-CoA, fumarate, and oxaloacetate) are called glucogenic AA, since they can be converted to glucose, by gluconeogenesis. This division is not exclusive. Some AA are also ketogenic and glucogenic. Only leucine and lysine are solely ketogenic AA, because they are broken down to acetyl-CoA only (recall that carbons of fatty acids do not contribute directly to gluconeogenesis because they break down entirely to acetyl-CoA, but indirectly contribute, providing energy in the form of ATP for glucose synthesis). In uncontrolled diabetes mellitus and prolonged starvation, tissue (muscle) proteins are degraded, and AA are used to provide precursors for gluconeogenesis and ketogenesis.

Such as the catabolism of AA is a convergent process, anabolism is an example of divergent metabolic process, with the starting points in the glycolytic (3-phosphoglycerate, phosphoenolpyruvate, and pyruvate), citric acid cycle (oxaloacetate and α-ketoglutarate), and pentose phosphate intermediates (ribose 5-phosphate and erythrose 4-phosphate) (Figure 2).

As we mentioned earlier, there are great variations in the degree of AA synthesis in different organisms. In contrast to bacteria and plants, humans can synthesize only a half of the twenty, that is, nonessential AA. Humans get the second half, essential AA, by food intake. Their synthetic pathways are complex, specific in different organisms, contrary to nonessential AA, which are synthesized in a few (often one) simple steps.

One of the important determinants of anabolism of AA is the incorporation of nitrogen (amino group) in biosynthetic intermediates. Glutamate and glutamine have major roles in these processes: glutamate via transamination reactions, with pyridoxal phosphate as a prosthetic group, and glutamine in the reactions catalyzed by enzymes glutamine amidotransferases. Please do not confuse that with glutaminase in the mitochondria that catalyzes the release of free ammonium ion and glutamate from glutamine; amidotransferases have two domains: One binds glutamine and the other domain is the acceptor of gamma-amido nitrogen of glutamine.

The second equally important determinant of AA metabolism is the transfer of one-carbon group in different oxidation states: in most oxidized state (CO_2) with biotin as a cofactor, intermediate states (methylene, methenyl, formyl, formimino, and also methyl groups) with tetrahydrofolate as a cofactor, and *S*-adenosylmethionine, which is the predominant cofactor for transfer one-carbon unit as the most reduced state – methyl group.

Organ and Interorgan Specificity of AA Metabolism

Although the liver is the central site of AA metabolism, these processes are important and occur in all other tissues. Moreover, the cooperation between the tissues is essential for the integration of the metabolism of AA. We will focus only on some illustrative cases.

Catabolism of branched-chain AA (BCAA) (leucine, isoleucine, and valine) does not primarily occur in the liver, but in the muscle, adipose tissue, kidney, and brain, because these extrahepatic tissues contain the enzyme branched-chain aminotransferase, which is absent in the liver. The products, corresponding three α-keto acids, are either oxidized in the myocytes (the branched-chain α-keto acid dehydrogenase complex catalyzes oxidative decarboxylation to CO_2 and acyl-CoA derivative) for ATP production or released into the blood and oxidized in the liver.

Quantitatively, the muscles (40% of the body mass) contribute most to the metabolism of BCAA. On the other hand, BCAA could have cell-signaling properties on protein metabolism, predominantly in the muscle. Namely, the administration of BCAA or leucine alone induces anabolic effect in humans via a reduction in protein breakdown without increasing protein synthesis.

The separation of BCAA metabolism in the muscle (and other extrahepatic tissues) allows the segregation of that part of the nitrogen metabolism, bypassing the channeling of amino groups to urea cycle in the liver. In that way, the amino group of BCAA transamination reactions in the muscles is used for the synthesis of glutamine, over α-ketoglutarate and glutamate. The same metabolic pattern of BCAA in the adipose tissue, directed to glutamine, opens a new and remarkable function of adipocytes: providing glutamine for immune cells (lymph nodes in adipose tissue) and for rapidly proliferating cells in the bone marrow (very rich in adipocytes).

The small intestine not only is a place of digestion and absorption of AA from food but also, in varying degrees, has an important role to play in their catabolism and also for uptake and catabolism of AA from the circulation. Some AA are metabolized to a great extent in the enterocytes of the small intestine, particularly glutamine, glutamate, aspartate, asparagine, proline, and arginine. The physiological significance of their catabolism is to provide ATP, not only in the small intestine but also in epithelial cells of colon. This provides support for the epithelium of the digestive tract for digestive and absorptive functions, maintenance of the cell structural integrity, and physical barriers. On the other hand, the metabolism in the small intestine provides a constant concentration of AA in circulation, especially those that are neurotransmitters (e.g., glutamate and aspartate).

Enterocytes of the small intestine have a special place in the interorgan metabolism of arginine, either taken from the lumen and circulation or synthesized from glutamine, glutamate, and proline. In enterocytes, arginine is metabolized to citrulline. Citrulline, as the only product, is released into the

bloodstream and taken up by virtually all extraintestinal cell types (except hepatocytes), where it is converted back into arginine. Quantitatively, the kidneys contribute most to this process. Arginine, synthesized in the kidney, is released into the circulation. Such interorgan arginine metabolic profile avoids the liver and degradation in the urea cycle. In this manner, a constant level of arginine is maintained in the bloodstream and is available for the other cells.

Functions of AA

Besides the well-known role they play in the regulation of the metabolism (e.g., urea synthesis, transfer of reducing equivalents from the cytoplasm to mitochondria and vice versa, nutrient transport, activation of lipolysis and glucose oxidation, methylation of DNA and proteins, and one-carbon transfer), AA are precursors of many specialized biomolecules and play an important role in the regulation of several physiological processes. In recent years, there has been growing interest in the role of AA in the regulation of growth, reproduction, immunity, digestive functions, lactation, blood flow, cardiovascular function, thermogenesis, osmoregulation, appetite, apoptosis, aging, antioxidant defense, synthesis of neurotransmitters, spermatogenesis, hormone secretion, etc. AA enhance insulin secretion from pancreatic β-cells (leucine and phenylalanine), stimulate β-cell neogenesis through the activation of the transcription factors (arginine), and participate in the activation of insulin signaling pathway (leucine).

AA achieve many of these functions by participating in cell signaling via kinases: mammalian target of rapamycin, AMP-activated protein kinase, cGMP-dependent protein kinase, cAMP-dependent protein kinase, and mitogen-activated protein kinase or G protein-coupled receptors. In addition, AA may enhance the transcription of many genes containing an AA response element (particularly in a state of deficiency), directly participate in the regulation of gene expression, alter the levels and biogenesis of micro-RNA, and alter cell redox status and synthesis and bioavailability of gasotransmitters.

AA and Redox Biology

AA play an important role in maintaining the redox balance of the cells, tissues, and whole organism. Studying oxidants, antioxidants, the redox active molecules, and redox regulation is important in both physiological and pathological conditions. With a lot of reasons, we can talk about the development of a new scientific discipline, redox biology. We will consider some important aspects of redox biology in which AA are key players.

Cysteine, Selenocysteine, Glutathione, and Glutathione Peroxidase

Cysteine is a naturally occurring AA that is found only in small quantities in most proteins. It is the only AA that contains thiol in its side group. So, cysteine is an important source of sulfur in human metabolism, and although it is classified as a nonessential AA, it may be essential for infants, the elderly, and individuals with certain metabolic diseases. Thiol group is a responsible for a number of important functions of cysteine, such as allowing the formation of disulfide bonds that are crucial to defining the structures of many proteins, stabilizing extracellular proteins, conferring proteolytic resistance, and enabling catalytic properties of enzymes.

Like most thiols, cysteine undergoes a variety of redox reactions. Oxidation by removal of hydrogen of cysteine produces the previously mentioned disulfide cysteine. This reaction is reversible, as reduction of this disulfide bond regenerates two cysteine molecules. More aggressive oxidants produce sulfinic acid or sulfonic acid. The cysteine thiol group is also nucleophilic and thus can undergo addition and substitution reactions.

Due to its ability to undergo redox reactions, cysteine has antioxidant properties and it has been shown that cysteine itself is the major extracellular antioxidant. Further examples of cysteines' critical role in redox balance can be found in other enzymatic systems including the multiple enzymes involved in the maintenance of peroxiredoxins, glutaredoxins, and thioredoxins among others. The natural role of cysteines as redox sensors is further witnessed by the observation that throughout evolution, cysteines are found in transcriptional regulators that are modulated by oxidative stress such as redox-sensitive transcriptional activator (OxyR) and the nuclear factor erythroid 2-related factor 2/kelch-like ECH-associated protein 1 (Nrf2/Keap1).

Cysteine is also a major determinant of intracellular redox conditions. Namely, along with glutamic acid and glycine, cysteine is a precursor of glutathione (GSH), which is the body's most important low-molecular-mass intracellular antioxidant.

Compared to cysteine, GSH is less susceptible to oxidation, which makes it an ideal candidate for the maintenance of the intracellular redox state. There are two forms of GSH: reduced (thiol, GSH) and oxidized (disulfide, GSSG). The reduced form of GSH is dominant in the cell, while the oxidized form makes up $<1\%$ of the total food daily intake GSH.

Biological activity of GSH is enabled by cysteine's thiol group that serves as proton donor. Apart of maintenance of cell redox milieu in reduced state, GSH–GSSG redox couple achieved an essential role in the regulation of the function of many proteins by modification of the cysteine residues. Specifically, it regulates the formation of reversible intra- and intermolecular disulfide bonds directly or indirectly through the process of protein *S*-glutathionylation. *S*-glutathionylation is a reversible posttranslational modification of proteins, achieved by the formation of disulfide bonds between cysteine motif in the protein and the cysteine in GSH, which can lead to change in protein function, localization, and stability.

Taking into account the fact that GSH is less susceptible to oxidation of cysteine, GSH plays an important role in the storage and transportation of this AA. This role of GSH is achieved through the so-called saving cycle, in which outside of the cell, γ-glutamyl transpeptidase catalyzes the transfer of γ-glutamyl GSH motif on one of the AA. The remaining cysteinylglycine may be decomposed to the extracellular cysteine and glycine by cysteinylglycine dipeptidase or transported as such in the cell, rehydrolyzed, and used for the synthesis of GSH.

Although the level of intracellular cysteine depends on the type of tissue and the diet, the level of cysteine is constantly

lower than the level of glutamate and glycine, and due to that, the cysteine is limiting AA for the GSH synthesis. The liver is unique in that it has the ability to convert methionine to cysteine in its path known as transsulfuration. Also, the liver is supplied with cysteine from the proteins in nutrition. For other tissues, a major source of cysteine represents GSH and GSSG from plasma.

The analog of cysteine having the same structure as that of cysteine, but in which sulfur atom is replaced by selenium forming selenium-containing selenol group in place of the sulfur-containing thiol group, is designed as selenocysteine. It is the twenty-first proteinogenic AA with a lower pK_a and a higher reduction potential than cysteine. These properties make it very suitable in proteins that are involved in antioxidant activity, such as glutathione peroxidases (GSH-Px) and thioredoxin reductases. It is also present in a number of enzymes like tetraiodothyronine 5′-deiodinases, formate dehydrogenases, glycine reductases, selenophosphate synthetase 1, methionine-*R*-sulfoxide reductase B1, and some hydrogenases. Proteins having more than one selenocysteine residues are called selenoproteins; those with catalytic activities that depend on selenocysteine's biochemical activity are called selenoenzymes.

There is no single free pool of selenocysteine AA that exists within cells to be used. So, it means it is an essential AA that is needed to be provided through food.

The first selenoprotein identified in mammals is GSH-Px, an enzyme that protects the cell from oxidative damage by catalyzing the reduction of H_2O_2, lipid peroxides, and other organic peroxides, using GSH as the reducing substrate. There are five types of mammalian selenium-containing GSH-Px, which catalyze oxidation of the reduced selenocysteine residue by hydroperoxide forming a selenic acid, which is further converted to a selenyl sulfide by GSH. An additional GSH reacts with the enzyme and regenerates the reduced selenol.

AA and Gasotransmitters

Gasotransmitter refers to a gaseous messenger molecule involved in any signaling process. Molecular mechanisms whereby they signal to their targets, by chemically modifying intracellular proteins and affecting cellular metabolism in an immediate fashion, are the most remarkably unique feature of gasotransmitters. The first identified gasotransmitter is nitric oxide (NO), while recently, carbon monoxide (CO) and hydrogen sulfide (H_2S) have been established as members of the gasotransmitter family. Their signaling involves a diverse range of biological targets and the cellular effects resulting from these molecular interactions are clearly seen in cardiovascular, neuronal, gastrointestinal, immune, and genitourinary systems.

NO, CO, and H_2S are produced in human cells from L-arginine, heme (glycine), and L-cysteine by specific enzymes: NO synthases (NOS); heme oxygenases (HO); and cystathionine-β-synthase, cystathionine-γ-lyase, and 3-mercaptopyruvate sulfurtransferase, respectively. It has been shown that the aforementioned (and other) AA not only act as precursors for gasotransmitter production but also regulate their production. For example, as an important substrate for arginine synthesis, glutamine has an important influence on whole body NO synthesis. Besides, glutamate and glycine activate neuronal NOS-dependent NO synthesis, through binding the different sites of *N*-methyl-D-aspartic acid receptor and increase in Ca^{2+} influx. The stimulatory effect of gamma-aminobutyric acid on NO synthesis has been shown in both hypothalamic neurons and ischemic brains. In contrast, reduction of NO synthesis has been shown by homocysteine in endothelial cells, glycine in endotoxin- or cytokine-challenged liver cells, and taurine in various cell types including hepatocytes, macrophages, and glial cells.

Apart from regulating NO synthesis, arginine is a key physiological regulator of CO production. Precisely, it was shown that dietary L-arginine increases the expression of HO3 in white adipose tissue in diet-induced obese rats and HO1 expression in vascular smooth muscle cells. Glutamate and sulfur AA increase CO production in multiple cell types, as well as the second product of glutamine catabolism, alanine. The same holds true for glutamine and taurine, whereas their stimulatory effects were seen mostly on intestinal epithelial cells and macrophages, respectively.

Considering that cysteine is a precursor for H_2S synthesis, it is reasonable that high intakes of diet enriched by cysteine increase production of this gasotransmitter. However, similar results were reported for taurine- and arginine-supplemented diet. The effects of glutamate on H_2S synthesis, at least in neuronal tissue, are bidirectional and concentration-dependent: Elevated levels of glutamate inhibit H_2S synthesis and low concentration of glutamate stimulates H_2S synthesis. In addition, intracellular glycine has been shown to modulate H_2S production, through the synthesis of GSH.

L-Arginine

Owing to more than 100-year-long physiological and nutritional studies on L-arginine, today, we know that this AA is involved in the regulation of multiple areas of human physiology. Apart from L-arginine per se, products of its metabolism such as NO, creatine, polyamines, agmatine, and urea, in addition to L-arginine per se, also play significant roles in the regulation of fundamental physiological functions. L-arginine participates in regulating protein synthesis, gene expression, micro-RNA levels, cell signaling, blood flow and capillary remodeling, nutrient transport and metabolism, antioxidative response, hormone secretion and synthesis, and mitochondriogenesis. In neural tissue, L-arginine regulates neurological functions and behavior, synthesis of neurotransmitters, and neuroprotective reactions. In the digestive system, L-arginine regulates gastrointestinal empting and the motility of the small intestine, as well as intestinal microbial growth and metabolism. Well-known roles of L-arginine in the cardiovascular system involve the regulation of blood pressure and vascular reactivity and setting of intimal hyperplasia. Importantly, it has been shown that numerous health disorders are characterized by reduced concentrations of L-arginine in plasma and/or various tissues and failure of its metabolic effects.

So, it is not surprising that dietary supplementation of L-arginine has multiple beneficial effects in the treatment of various diseases. To date, the favorable effects of exogenous L-arginine have been documented in many developmental and health problems including male and female infertility, injuries

and trauma, wound healing, immunomodulation, HIV/AIDS, athletic performance, cancer, and gastrointestinal and cardiovascular diseases. Both experimental and clinical studies clearly show favorable effects of L-arginine in diabetes. Accordingly, we reported recently that 12 days of oral supplementation with L-arginine had multiple beneficial roles in the diabetic pancreas resulting in endocrine pancreatic cell neogenesis.

L-arginine has beneficial effects on fuel homeostasis, including stimulation of glucose and fatty acid oxidation in insulin-sensitive tissues; inhibition of glucose, triacylglycerol, and LDL synthesis in target tissues (liver and adipose tissue); and enhancement of lipolysis in adipocytes. Thus, L-arginine supplementation is clearly a novel effective treatment for the prevention and treatment of obesity and metabolic syndrome.

Anemia: Causes and Prevalence

Defining Anemia

Anemia is defined as an insufficient mass or altered morphology of red blood cells to meet the physiological needs of the body. Hemoglobin is the protein responsible for carrying 97% of the oxygen from the lungs to the peripheral tissues. Its decreased concentration leads to anemia, with less cellular oxygenation as a direct consequence. At a public health level, anemia is defined as hemoglobin concentration <5th percentile of the distribution of hemoglobin from a normal population, for the same sex, age, and physiological condition. The criteria to define the cutoffs for anemia were first established in the early 1960s considering population data of individuals <60 years of age. Later, in 1989, in light of new data from the Second National Health and Nutrition Examination Survey (NHANESII), the cutoffs were updated and validated to define anemia in different age groups, changing the established cutoffs for the school-age population (from 12 to 11.5 g dl^{-1}). Cutoffs established by the World Health Organization (WHO) to define anemia and its severity are still in force (Table 1). There has been no change or update of these to define anemia, despite growing evidence that the distribution of hemoglobin differs during the first 3 months of pregnancy and according to race and population >60 years of age.

For pregnant women, the increase in plasma volume as a result of hormonal changes of pregnancy demands an increased supply of iron for adequate production of red blood cells due to the increased blood volume. Several authors have reported the need to have valid cutoffs for each stage of pregnancy in order to promptly identify pregnant women at risk; however, there has been no consensus to date.

Data derived from various studies have shown that hemoglobin levels in the black population are less ($\approx$1 g l^{-1}) compared to the white population for each gender, and that this variation is not attributable to sociodemographic or economic conditions, health behaviors, or nutritional status. Anemia is three times more common in the black population than in the white population. WHO-defined anemia has been associated with an increased risk of death in both black and white populations, but hemoglobin thresholds for predicting mortality in older adults were 7 g l^{-1} below the WHO criteria in the black population, whereas in the white population thresholds were 4 g l^{-1} above the WHO cutoffs for anemia. It has been documented that at least one-third of the racial difference in hemoglobin concentration can be explained by α-thalassemia.

Epidemiology of Anemia and Iron Deficiency

Data collected by the WHO during the period from 1993 to 2005 on the status of anemia worldwide revealed that the region with the highest prevalence in the preschool population is Africa with 67.6%, followed by southeast Asia and the Oriental Mediterranean with a prevalence of 65.5% and 46.7%, respectively. A lower prevalence is reported in regions of the Americas (29%), Western Pacific (23.1%), and Europe (21.7%).

Kassebaum et al. gathered information from 187 countries to estimate the global burden of anemia in 2010, classified as mild, moderate, and severe anemia. Estimates of the prevalence of anemia were 50–80%, of which 10–20% had moderate to severe anemia. The prevalence was higher in persons with low socioeconomic status, low weight, and women who recently gave birth. In the study period (1990–2010), the prevalence decreased from 40.2% to 32.9%.

Worldwide, the three most common forms of micronutrient deficiencies are iron, vitamin A, and iodine deficiency. Together these affect at least one-third of the world population, most of whom live in developing countries. Iron deficiency is the most prevalent of the three.

Black et al. estimated an overall prevalence of anemia due to iron deficiency, with 18.1% in children <5 years of age and 19.2% in pregnant women. On the other hand, the prevalence of severe anemia was 1.5% in children <5 years of age and <1% in pregnant women.

Main Causes of Anemia in the Population

The terms 'iron deficiency' and 'iron-deficiency anemia' are often used synonymously, although they are, in fact, not the same conditions. The causes of anemia are multifactorial; the most common is iron deficiency, according to data of the Global Burden of Disease. Parasitic infections (hookworm, schistosomiasis) and malaria contribute to explain the second cause of anemia, whereas hemoglobinopathies and anemia inflammation rank as the third cause of anemia (13% of all causes), being present in higher-income countries. Table 2 summarizes the main causes of anemia in the population.

Nutritional Deficiencies

Nutritional deficiencies represent a deficit of nutrients needed for the formation of red blood cells. This group includes anemia due to vitamin B12 and folate deficiencies, both characterized by defective DNA synthesis (megaloblastic anemias); and iron-deficiency anemia in which heme synthesis is impaired.

Iron Deficiency

Iron is essential in the synthesis of hemoglobin and is also involved in many bodily functions, including the respiratory chain, phagocytosis, prostaglandin synthesis, and cytochrome P450, among others.

Due to the redox capacity of iron, it plays a crucial role in oxygen transport. Much of the intracellular iron is used in the mitochondria for heme synthesis. Heme iron is synthesized by

Table 2 Causes of anemia

Direct causes	*Components (in order of importance)*
Poor, insufficient, or abnormal red blood cell production	Poor dietary intake and/or absorption of iron
	Poor dietary intake and/or absorption of vitamins (A, B12, folic acid, and possibly B6, C, and riboflavin) and copper
	Increased needs for nutrients due to growth or disease (diarrhea), HIV/AIDS
	Other infectious diseases (tuberculosis, malaria)
	Chronic inflammation
	Chronic diseases and medical treatments (cancer, HIV/AIDS, kidney diseases)
	Genetic blood diseases (sickle cell disease or trait, thalassemia)
Excessive red blood cell destruction	Malaria
Excessive red blood cell loss	Helminth (worm) infections (hookworm, schistosomiasis)
	Bacterial or viral infections (peptic ulcers, gastritis, diarrhea)
	Reproduction (excessive blood loss during menstruation, delivery, and postpartum period; multiple pregnancies, shortened postpartum amenorrhea)
	Contraceptive methods (intrauterine devices)
Contributing causes	*Components*
Knowledge and behavior	Poor knowledge among health workers about anemia, iron supplementation, and other anemia prevention and control interventions
	Poor knowledge among vulnerable groups about the importance of anemia
	Prevention and control interventions
	Cultural taboos or biases (e.g., women eating after others eat)
	Practices that restrict food intake, including poor infant breastfeeding practices and inadequate introduction of complementary foods
	Poor compliance with recommended behaviors (iron supplementation; malaria, tuberculosis, and other medication regimens; use of family planning; use of sanitation facilities; HIV prevention behaviors)
Environmental lack of access to services	Contamination due to heavy metals (lead)
	Low use of antenatal and other services providing iron supplements
	Lack of trained midwives to manage bleeding during delivery
	Lack of access to sanitation services that mitigate helminth infestation
	Lack of access to bed nets to prevent malaria transmission
Poverty	Lack of income to buy foods with adequate amounts of absorbable iron or to obtain iron supplements, malaria treatment, insecticide-treated bed nets, shoes to prevent helminth infection, and other preventive commodities or services

Adapted from Galloway, R., International Nutritional Anemia Consultative Group (INACG). (2003). *Anemia prevention and control: what works. Part I. Program guidance*. Washington, DC: USAID.

a sequence composed of eight reactions in the mitochondria and cytoplasm, with the final reaction being Fe^{2+} inserted into protoporphyrin IX by ferrochelatase. Heme iron is essential in the formation of hemoglobin. The core is fixed into the oxygen to be transported to tissues. Consequently, iron deficiency results in low red blood cell production, giving a hypochromic and microcytic appearance to erythrocytes. The most common cause of iron deficiency is the inadequate intake of iron (heme iron) coupled with a high intake of absorption inhibitors (phytates, tannins).

Deficiency of Vitamin B12 and Folic Acid

Vitamin B12 and folic acid share many metabolic pathways. Deficiency of one alters the metabolism of the other in the formation of red blood cells. Hematologic effects of deficiency

of these vitamins are identical. Macrocytic anemia is due to megaloblastic changes in the bone marrow; however, megaloblastic anemia can occur without macrocytosis. It is a common condition in elderly persons because it occurs as a result of vitamin B12 malabsorption due to impaired production of the intrinsic factor of parietal cell gastric atrophy. In malnourished individuals, it is estimated that less frequent causes of anemia are associated with vitamins A, E, B2, B3, B6, C, and zinc and copper deficiency.

Anemia Due to Malaria and Parasitism

Malaria contributes to iron-deficiency anemia by causing intravascular hemolysis, and also causes an immune response that suppresses erythropoietin through rupturing, phagocytosis, and hypersplenism. Extensive geographic overlap of hookworm and malaria yields a high prevalence of coinfection, which may increase additively the risk of anemia.

Hookworms (*Necator americanus* and *Ancylostoma duodenale*) reside in the small intestine of infected individuals, where they attach to the villi and feed on host blood. Heavily infected patients are unable to maintain adequate iron stores and become anemic. WHO currently recommends that school-age children living in areas of high prevalence of soil-transmitted helminths (hookworms, Ascaris lumbricoides, and Trichuris trichiura) receive treatment with either albendazole or mebendazole.

Inflammation; or Anemia of Chronic Disease

Human hepcidin is a 25-amino acid peptide synthesized by the liver, induced by infection and inflammation. Hepcidin regulates expression of ferroportin and ceruloplasmin. Both proteins are responsible for exporting iron from the basolateral membrane (enterocyte and polarized cells, respectively). The link of hepcidin with ferroportin causes internalization and degradation of ferroportin, affecting the export of iron from the enterocyte into the systemic circulation. Inflammatory anemia is characterized by decreased serum iron and the iron-binding capacity by transferrin, indicating an impairment of mobilization of iron reserves. The link among infections, hypoferremia, and inflammatory anemia suggests that the last two are part of the host response to infection. Because most of the iron in the transferrin compartment is intended for bone marrow, hypoferremia resulting from the excess of hepcidin reduces the amount of iron available for hemoglobin synthesis and erythrocyte production.

Anemia of Chronic Renal Disease

In the absence of disease, erythropoiesis is controlled by a negative feedback system. The rate of change of the concentration of erythrocytes is the difference between the rate of its production and destruction. Erythropoietin, along with the colony-forming units, is responsible for the differentiation and proliferation of erythroid progenitors in the bone marrow to increase red blood cell mass. This hormone is produced by the juxtaglomerular apparatus of the kidney cortex. The basal rate of red blood cell production is decreased in patients with chronic renal disease (CRD) so that anemia is proportional to the severity of renal function. Anemia of CRD develops early and worsens as renal failure progresses.

Consequences of Anemia

Iron deficiency has been shown to have adverse effects on physical capacity, work performance of adolescents and adults, immune status, and morbidity from infections of all age groups. Iron deficiency anemia reduces the body's ability to regulate the internal temperature by altering the production of hormones involved in energy metabolism, affecting the synthesis of neurotransmitters and thyroid hormones related to muscle and neurological functions involved in regulating body temperature. It also impairs cognitive performance and behavior at any age. In general, these effects are corrected by iron supplementation, but if moderate to severe iron deficiency occurs in infancy, the effects on cognition may not be reversible.

In addition to the obvious and direct health effects, the existence of iron deficiency and anemia has profound implications for economic development and productivity, particularly in terms of the potentially huge public health costs and loss of formation and quality of human capital. Anemia is a prevalent and often underdiagnosed and untreated condition, but one that has important substantial consequences for subjects with the condition, diminishing their quality of life as well as resulting in economic consequences for the health sector.

Recently, the Global Burden of Disease estimated that anemia was responsible for 68.3% of YLDS (years lived with disability) in 2010 and accounted for 8% of all disabilities, with women and preschool children carrying the highest burden.

In terms of disability-adjusted life years (DALYs), iron-deficiency anemia accounts for 25 million lost DALYs, or 2.4% of the overall total. Annually, iron-deficiency anemia leads to 134 000 deaths of children and indirectly leads to 841 000 maternal and perinatal deaths. Anemia is a risk factor for perinatal (591 000) and maternal (115 000) deaths globally; 18.4% of maternal and 23.5% of perinatal deaths are attributable to anemia. Combined with the direct impacts of iron-deficiency anemia, the total deaths are 841 000 annually. In the United States, patients with anemia have an average cost two times higher than nonanemic patients. Anemic patients most frequently use health services and represent higher costs ($14 535 vs. $9451 $p < 0.001$) when compared with nonanemic patients having the same pathological condition. Average annualized per-patient costs were $14 535 for anemic patients (55% outpatient, 33% inpatient, 13% pharmacy), 54% higher than the $9451 average cost for nonanemic patients (45% outpatient, 36% inpatient, 19% pharmacy).

Particular Effects on Women

Anemia is associated with increased mortality and adverse outcomes in a variety of physiological and pathological conditions. In women of childbearing age, iron demand is high due to menstrual losses as well as during pregnancy. Iron requirements are greater as pregnancy progresses. Approximately 1200 mg of iron are required from the time of conception until delivery throughout pregnancy, because the iron stores of the mother must meet the needs of the developing fetus and accommodate blood loss at delivery. The red cell

mass increases 350–450 ml during this period; ~80% of the maternal iron is used for the production of hemoglobin, and 30% for the accumulation of iron stores. Beyond the first year, iron intake or stores must remain sufficient to support the ongoing growth and increased red cell mass.

It has been documented that women with insufficient prepregnancy iron stores increase their risk of anemia during pregnancy and also have less capacity for physical activity, increased susceptibility for infections, and less interaction with their children. During pregnancy, iron-deficiency anemia increases the risk of premature birth and low birth weight, reducing infant iron stores.

Under conditions of no maternal anemia, the fetus accumulates iron during the last weeks of pregnancy to meet and satisfy the iron demands of the infant for the next 6 months postpartum, being fed only with breast milk during this period. Inadequate maternal iron reserves also result in low reserves of the newborn. In anemic women, the fetus will develop limited reserves of iron, therefore being likely to develop iron deficiency in the first months of life, which is characterized by rapid growth.

Pregnant women with anemia are 3.5 times more likely to die from complications during childbirth and the postpartum period than are nonanemic women. Low maternal hemoglobin level has been found as a strong predictor of perinatal mortality due to placenta previa and abruption placenta. Perinatal mortality was nearly 50%; of these were stillbirths in women from Ethiopia.

Particular Effects on Children

Anemia and iron deficiency in children <2 years of age is of great interest and concern because at this critical stage of growth, a higher intake of iron is required and is often not provided by diet. Neurobehavioral effects are of greatest concern because they persist long after treatment with iron and resolution of anemia. Iron deficiency in utero appears to have direct effects on indicators of brain maturation in premature infants.

Iron requirements during the first 2 years of life gradually increase to meet the demands of multiple roles in brain development and in the immune and endocrine systems. In this regard, there is ample evidence in the literature that iron deficiency in children is associated with adverse effects on psychomotor, cognitive, and social-emotional development, as well as increased susceptibility to infections, persisting after treatment of anemia and iron deficiency resolution.

Although the causal link between iron deficiency and adverse child development is unclear, evidence from animal studies suggests that iron deficiency may affect neurological development through brain functions, specifically myelination, dopamine and norepinephrine metabolism, and neuronal energy metabolism. The evidence of a causal effect of lack of iron on behavior comes from animal studies in which the environment is controlled and differences in iron status are experimentally induced. Studies in both monkeys and rats document behavioral differences in infancy and later on that relate directly to findings in the human infant. Recent studies of iron deficiency during brain development in nonhuman primates show different behavioral consequences depending on the timing of iron deficiency relative to brain developmental stages, and the potential for long-lasting changes in brain iron regulatory systems. Iron deficiency caused long-term diminished protein levels of four factors critical for hippocampal neuron differentiation and plasticity, including CamKII alpha, Fkbp1a (Fkbp12), Dlgh4 (PSD-95), and Vamp1 (synaptobrevin-1). Iron deficiency altered gene expression in the mammalian target of rapamycin pathway, and during late fetal and early postnatal life, iron deficiency alters the levels and timing of expression of critical genes involved in hippocampal development and function.

Iron has multiple roles in the neurotransmitter system and can affect behavior through its effect on dopamine metabolism. This interaction between iron deficiency and dopamine metabolism is highly relevant for early cognitive development because dopamine clearance has strong effects on attention, perception, memory, motivation, and motor control. Low cerebral iron may interfere with myelination and dopaminergic function, potentially disrupting sleep cycles, motor control, learning, and memory. Iron deficiency during the perinatal period is associated with altered expression of genes critical for hippocampal development and function.

Children with chronic, severe iron deficiency in infancy continue at a behavioral disadvantage relative to their peers at school entry. Sustained differences in mother/child interaction might contribute to the long-lasting behavioral and developmental alterations reported in children with chronic, severe iron deficiency in infancy.

Some studies have found that infants with chronic, severe iron deficiency compared with those with a healthy iron status are more likely to be fearful, hesitant/wary, unhappy, inactive, easily fatigued, in close contact with their mothers, or lower in vocalization. Unfortunately, the effects of anemia during the first 2 years of life are nonreversible. Neurocognitive complications of iron deficiency during critical pre- and postnatal periods of brain development are difficult to remedy, persisting into adulthood. Derived from this evidence of adverse physical and mental health effects of the child, prevention of perinatal iron deficiency and promotion of neural plasticity in individuals exposed to poor iron status during critical stages of development require more attention.

Programs for the Prevention and Control of Anemia and Iron Deficiency

Globally, there are various ways to control and treat anemia at the population level. Some of them include iron supplementation, food fortification, and control of parasitic diseases, as well as promoting increased intake of bioavailable iron, decreasing its losses, and increasing reserves in newborns by late clamping of the umbilical cord.

Iron Supplementation

Pharmacological iron supplementation can be used to treat iron-deficiency anemia in persons who suffer from the condition or to prevent anemia in susceptible groups such as children <5 years of age, women of childbearing age, adolescents, and pregnant women. The therapy generally requires a daily

dose, whereas preventive treatment is given weekly or intermittently.

The evidence shows that daily iron supplementation in children 4–23 months of age is effective in reducing iron-deficiency anemia. A systematic review of 55 clinical trials administering oral and parenteral iron or through fortified food to children found that, on average, iron supplementation improves hemoglobin concentration ($0.74\,g\,l^{-1}$) and decreases the prevalence of anemia. A systematic review carried out in 2009 showed results on the type and frequency of intermittent iron supplementation in populations where malaria is endemic. Despite the fact that intermittent supplementation was effective in reducing the risk of anemia and iron deficiency in children <12 years of age, a daily supplementation scheme was more effective. Therefore, the authors conclude that an intermittent scheme can be effective in populations where the daily scheme daily has not been implemented or has failed.

In nonpregnant women of childbearing age, a systematic review assessed intermittent iron supplementation (1, 2, or 3 times a week on nonconsecutive days), and found that it improves hemoglobin and ferritin in addition to reducing the risk of anemia by 27%. In this same review, a comparison of intermittent supplementation with daily supplementation was performed. It was found that women who received intermittent supplementation had a higher risk of anemia, although the average final concentration of hemoglobin did not differ between comparison groups.

In pregnant women, iron supplementation has been found effective in outcomes such as iron deficiency at term and hemoglobin concentrations in pregnancy; however, the pattern of daily supplementation has also been associated with side effects, especially at doses >60 mg iron. An alternative scheme is supplementation with iron compounds alone or in combination with other vitamins and minerals intermittently (1–3 times a week), as these have fewer adverse effects.

Food Fortification

Food fortification has been recognized as one of the most effective measures for the control of micronutrient deficiency at the population level, where the fortification of staple foods such as maize, wheat, and rice, or condiments like salt, curry, and soy sauces, has been proposed. In Egypt, a program of fortification of wheat flour with iron (ferrous sulfate) and folic acid implemented since 2008 in low-income groups estimated that 50 million people consume ≈12 mg iron and 600 μg folic acid daily by eating fortified bread.

There are different forms of iron for food fortification such as ferrous sulfate (water-soluble) and ferrous fumarate (soluble in weak acid), which are highly bioavailable. Ferrous sulfate is cheaper, so it is widely used for flour fortification. But it causes rancidity during storage, which is an unfortunate consequence. Ferrous fumarate may produce less damage in foods. Other iron compounds are the iron soluble in strong acids such as elemental iron, pyrophosphate, and ferric orthophosphate, which have less of an effect on the food but have minimal bioavailability in humans. Fortification of cereal, salt, and sauces has been successfully achieved by EDTA iron, which contains iron protected that enhances the absorption of dietary nonheme iron. Likewise, encapsulated iron as ferrous salt has very little reaction to food and has high bioavailability, but is a little more expensive.

The effectiveness and sustainability of fortification programs is a challenge in developing countries due to the necessity of infrastructure and various resources for their implementation. A major limitation that occurs in some countries is inadequate food fortification; for example, in Ghana and South Africa, a low addition of iron in wheat flour by millers was detected, making the desired reduction of deficiency unlikely. Another limitation of fortification is that persons who need it the most have little access to it. A clear example of this problem is the fortification of wheat flour in Guatemala. It was observed that vulnerable groups did not consume fortified products despite the availability of fortified corn flour, which is a highly consumed product. Therefore, any fortification program that is developed should take national context into account.

Iron Fortification of Foods

One strategy that has been successful in combating anemia in infants >6 months of age is home supplementation with micronutrient powders known as 'Sprinkles.' These preparations have iron encapsulated in a lipid layer that prevents adverse effects on both taste and appearance of food. This form of supplementation consists of single-dose packets of micronutrient powder and is added to childrens food at the time it is served. It has no smell or taste. In clinical trials, its effectiveness has been shown to control anemia compared with liquid supplements of ferrous sulfate. In 2011, a review of eight studies of powder micronutrient supplementation containing iron showed that home fortification with micronutrients reduced anemia by 31% and iron deficiency by 51% compared with the control group. Other studies found no difference comparing the powder micronutrient with daily iron supplementation in anemia or hemoglobin.

Control of Parasitic Infections

Deworming is a proven strategy to prevent iron deficiency caused by hookworm in children and pregnant women. In a 12-month clinical trial, 10 mg iron and/or 500 mg mebendazole were administered daily every 3 months in children 6 to 71 months of age in Zanzibar. It was found that the administered dose of iron had no effect on growth retardation, hemoglobin concentration, or mild to moderate anemia (hemoglobin <110 or $<90\,g\,l^{-1}$, respectively); however, it significantly improved serum ferritin and erythrocyte protoporphyrin. In children <24 months of age, treatment with mebendazole also reduced moderate anemia. Finally, a systematic review in 2007 showed that deworming increases hemoglobin and reduces the prevalence of anemia.

Late Clamping of the Umbilical Cord

Cord clamping is a strategy to prevent iron deficiency and is especially important in children <6 months who need enough iron stores until they start complementary feeding at 6 months of age. Delayed clamping for 2 min after birth ensures reserves,

preventing iron deficiency. It has also been associated with a lower prevalence of neonatal anemia. A review of studies of delayed umbilical cord clamping compared with early clamping found higher hemoglobin levels in infants with late clamping, but also a greater need for phototherapy for jaundice. Although hemoglobin levels were not maintained after 6 months of age, higher levels of ferritin were found at this age.

Nutritional Recommendations

One of the main causes of iron-deficiency anemia is the low consumption of foods rich in this nutrient. These foods are mainly of animal origin and include meat, fish, and poultry; therefore, poor families often consume small amounts of these foods.

In general, nutritional recommendations should be adapted to the national or local context because there may be variations in diet, food availability and access, seasonality, and so on. Bioavailability of iron in foods should be noted because bioavailability of iron in food is strongly influenced by substances that promote or inhibit its absorption.

Inhibitors of iron absorption are phytates present in cereals, refined flour, legumes, nuts, and seeds; foods rich in inositol; tannins; tea, coffee, cocoa, herbal teas, and some vegetables; and calcium in milk and dairy products. Certain methods of preparation such as fermentation can reduce the phytic acid that inhibits iron absorption.

Promoters of iron absorption are ascorbic acid or vitamin C in fruits, juices, potatoes, and other tubers, plus green leafy vegetables, cauliflower, and some fermented or sprouted foods. The heme iron in meat, poultry, fish, and seafood is absorbed by a different mechanism than nonheme iron and has a high bioavailability.

In order to improve the bioavailability of dietary iron, it is important to avoid eating inhibitors of iron absorption in conjunction with iron-rich foods.

Recommendations to improve the absorption of iron from food:

- Drink coffee or tea at least 1 or 2 h after a meal.
- Include fruit juices in the diet, such as orange juice, or other sources of ascorbic acid (vitamin C).
- Consume dairy products as snacks between meals instead of during a meal.
- Eat foods containing iron-absorption inhibitors with low iron content such as cereal, tortilla, or bread accompanied by milk, because this can provide sufficient calcium without impeding the absorption of iron.

Furthermore, exclusive breastfeeding for 6 months covers almost all the nutritional needs of children born at term; however, this recommendation is always given when the mother is well nourished. Children born with normal weight from well-nourished mothers can have adequate iron stores in the liver and therefore are at lower risk for anemia. However, children with low birth weight, premature infants, or infants born to mothers with iron deficiency (even those born with normal weight) have a higher risk of iron deficiency, hence the recommendation to improve the diet of the mother during pregnancy. A scheme has been proposed for home supplementation with micronutrient fortification in children ages 6–23 months (Table 3). In the case of children with low birth weight, supplementation is recommended starting at 6–8 weeks of age.

During the stage of weaning or supplementary feeding, fortified foods should be chosen versus iron supplementation, especially in areas where the prevalence of infectious diseases and malaria is high. It is important to note that before supplementation, the nutritional status of children <5 years old should be assessed – along with measures existing in the community for controlling iron deficiency – to ensure that the daily iron requirements are not exceeded. It must be taken into consideration that if iron supplementation is administered, adverse effects such as stunting may occur. Therefore, we must prioritize the consumption of fortified foods in order for infants to receive the necessary nutrients. Iron supplementation is recommended at a dose of 2 mg kg^{-1} body weight in children 6–23 months of age in areas where the prevalence of anemia in children <1 year of age is >40%, or where the consumption of iron-fortified foods is low. Likewise, if consumption in children (>6 months) of food of animal origin is very low or nonexistent, it is necessary to provide vitamin and mineral supplementation, particularly iron.

Women of childbearing age should be aware that pregnancy demands high amounts of iron for the development of the fetus and placenta and increased blood volume. Added to this, childbirth is accompanied by variable blood losses. When pregnancy occurs in adolescence, iron demands are even greater because it combines the demands of growth and of

Table 3 Home fortification scheme with multiple micronutrient powders for children 6–23 months of age

Dose of micronutrients	*Iron*: 12.5 mg of elemental iron, preferably with ferrous fumarate capsules (12.5 mg of elemental iron is equal to 37.5 mg of ferrous fumarate, 62.5 mg of ferrous sulfate heptahydrate of 105 mg of ferrous gluconate) *Vitamin A*: 300 μg of retinol *Zinc*: 5 mg of elemental zinc, preferably zinc gluconate
Special conditions	In malaria setting, additional pharmacological treatment is recommended
Frequency	One dose daily
Duration and interval between intervention periods	Minimum of a 2-month period followed by a period of 3–4 months without supplementation; use of micronutrients is initiated each 6 months
Target group	Children 6–23 months of age, beginning at the same time as cessation of breastfeeding
Scenario	Populations where the prevalence of anemia in children 2–5 years of age is 20% or higher

Adapted from World Health Organization. (2011). *Use of multiple micronutrient powders for home fortification of foods consumed by infants and children 6–23 months of age*. Geneva: World Health Organization.

pregnancy, resulting in a high risk for anemia. The postpartum period is the ideal time to recover iron reservoirs because amenorrhea during this time (due to breastfeeding) reduces iron loss. Hence, the promotion of exclusive breastfeeding for 6 months, followed by breastfeeding up to 2 years of age, may contribute to controlling iron-deficiency anemia in women of childbearing age. Another important measure is to allow at least 2 years between pregnancies in order for women to recover iron stores. However, one should keep in mind that iron supplementation helps to control anemia, and eating foods rich in iron is also necessary.

WHO recommends daily oral supplementation of iron and folic acid as part of prenatal care in order to reduce the risk of low birth weight, anemia, and iron deficiency (Table 4); likewise, it suggests a supplementation scheme for menstruating women (Table 5).

With respect to the preschool and school-age populations, an intermittent supplementation scheme proposed by the WHO to improve iron status and reduce the risk of anemia is shown in Table 6.

In regard to regular deworming for helminths, it is recommended that in areas where the prevalence among school children is >50%, the process should be carried out every 6 months both in preschool and school-age children as well as in women of childbearing age. Where the prevalence among school-age children is between 20% and 50%, deworming is recommended once a year. The WHO-recommended dose is 200 mg of albendazole for children <2 years of age and 400 mg for the remaining population or administration of 500 mg of mebendazole.

In the general population, if the amount of absorbable dietary iron will not immediately improve anemia, pharmacological

Table 4 Scheme of daily supplementation with iron and folic acid in pregnant women

Composition of the supplement	Iron: 30–60 (if prevalence >40%) mg of elemental iron[a] Folic acid: 400 μg (0.4 mg)
Special conditions	60 mg of elemental iron if anemia is a severe public health problem (40% or higher) Anemia in clinical setting: 120 mg of elemental iron plus 400 μg of folic acid In malaria settings: additional pharmacological treatment
Frequency	Daily
Duration	During pregnancy. Supplementation should begin as soon as possible in pregnancy
Target group	Adolescent and adult women
Scenarios	All scenarios

[a]30 mg of elemental iron equivalent to 150 mg of ferrous sulfate heptahydrate, 90 mg of ferrous fumarate, or 250 mg of iron gluconate.
Adapted from WHO. (2012). *Guideline: daily iron and folic acid supplementation in pregnant women*. Geneva: World Health Organization.

Table 5 Scheme of intermittent supplementation with iron and folic acid in menstruating women

Composition of the supplement	Iron: 60 mg of elemental iron[a] Folic acid: 2800 μg (2.8 mg)
Special conditions	Anemia in clinical setting: 120 mg of elemental iron plus 400 μg of folic acid In malaria settings: additional pharmacological treatment
Frequency	Once weekly
Duration	3 months of supplementation followed by 3 months without supplement; reinstate supplementation after this period
Target group	All menstruating adolescent and adult women
Scenarios	Populations where the prevalence of anemia among nonpregnant women of reproductive age is 20% or higher

[a]60 mg of elemental iron equivalent to 300 mg of ferrous sulfate heptahydrate, 180 mg of ferrous fumarate, or 500 mg of iron gluconate.
Adapted from World Health Organization. (2011). *Guideline: intermittent iron and folic acid supplementation in menstruating women*. Geneva: World Health Organization.

Table 6 Scheme for iron supplementation of preschool and school-age children

Target group	*Preschool children (24–59 months of age)*	*School-age children (5–12 years of age)*
Composition of the supplement	25 mg of elemental iron[a]	45 mg of elemental iron[a]
Special conditions	In malaria and hookworm endemic countries, additional pharmacological treatment is recommended at least annually	
Form of the supplement	Drops/syrup	Tablets/capsules
Frequency	Once weekly	
Duration and time interval between supplementation periods	3 months of supplementation followed by 3 months without supplement; after this period, reinstate supplementation	
Scenario	When the prevalence of anemia in preschool and school-age children is 20% or higher	

[a]25 mg of elemental iron equivalent to 75 mg of ferrous fumarate, 125 mg of ferrous sulfate heptahydrate, or 210 mg of ferrous gluconate.

supplementation is recommended, which should focus on vulnerable groups such as children ages 6–24 months and pregnant women. These programs must be accompanied by educational messages that will provide information about the foods that should be preferred for their iron content. Also, exclusive breastfeeding should be supported for 6 months, continuing with complementary feeding (without neglecting breastfeeding). The infant should be provided with iron-rich and -fortified foods as much as possible, especially during the first 2 years of life. It is noteworthy that some breast milk substitutes, especially cow's milk, can cause gastrointestinal bleeding in infants, possibly causing iron-deficiency anemia. It is worth mentioning that iron supplementation in malaria-endemic areas should be administered together with measures for disease prevention, diagnosis, and treatment.

Conclusions

Iron-deficiency anemia affects a large number of women of childbearing age and children <5 years of age. Periodic monitoring of hemoglobin level is recommended in these age groups. If the population has a high prevalence of anemia (>50%), universal supplementation is essential. When the prevalence is lower, supplementation is recommended for specific groups. Iron compounds used for the treatment of anemia must be well selected, with a preference for water-soluble compounds, such as ferrous sulfate, or compounds soluble in weak acids, such as ferrous fumarate. Compounds with bound iron (such as bisglycinate or Fe-EDTA) represent other options. It is advisable to recommend eating foods with highly bioavailable iron such as animal tissues, mainly liver. Other foods of plant origin should be eaten along with absorption facilitators, such as vitamin C and other organic acids.

Anemia: Prevention and Dietary Strategies

Introduction

Anemia is a widespread public health issue affecting people in both developing and developed countries. Anemia due to iron deficiency has been ranked by the World Health Organization in 2002 as one of the leading factors affecting the global burden of disease. Nearly one-quarter of the world's population is affected by anemia, with over one and a half billion people affected worldwide.

People living in developing countries are at increased risk of developing anemia. Populations most vulnerable to anemia include infants, children, adolescents, women of reproductive age, and pregnant women. It has been estimated that 47.4% of preschool children worldwide, 41.8% of pregnant women, and 30.2% of nonpregnant women have anemia.

Anemia (a low concentration of circulating red blood cells resulting in a reduced capacity to transport oxygen around the body) is caused by a number of factors. These may occur in isolation or simultaneously. Anemia may be caused by genetic factors (e.g., hemoglobinopathies), infections (e.g., malaria, tuberculosis, human immune deficiency virus, and intestinal helminths), blood loss (e.g., menstruation), and chronic conditions (e.g., cancer). Micronutrient deficiencies including vitamin A, vitamin B12, folate, and copper also increase the risk of anemia, but the level at which they contribute to anemia risk is not clear.

Iron deficiency is estimated to contribute to ~50% of anemia cases globally. Between two and five times the amount of individuals who have iron-deficiency anemia are affected by nonanemic iron deficiency. An individual's iron status falls on a continuum from replete iron stores to iron-deficiency anemia. Iron-deficiency anemia is usually preceded by the depletion of iron stores (reflected by a decrease in serum ferritin concentration). The depletion of iron stores may progress to iron deficiency (reflected by further reductions in serum ferritin (a reduction in iron stores); decreases in serum iron and increases in total iron-binding capacity, which results in a fall in transferrin saturation; and increases in soluble transferrin receptor and zinc protoporphyrin concentrations). In the final stage (iron-deficiency anemia), oxygen supply to the tissues is impaired and hemoglobin concentrations fall. Hemoglobin concentrations are often used as a proxy for iron-deficiency anemia, even though not all individuals with anemia are iron-deficient.

Iron-deficiency anemia can result in irreversible cognitive impairment in infants and, in children, reduced performance at school. In pregnant women, severe iron-deficiency anemia is associated with increased maternal and child mortality. Iron-deficiency anemia increases the risk of preterm delivery, low-birth-weight infants, and poor iron status of the mother, which contributes to a reduction in iron status of the infant. Iron-deficiency anemia is associated with decreased work capacity and has major social and economic implications.

Several strategies are required in the prevention and treatment of anemia, mainly due to anemia's multifactorial nature. These strategies will depend on the population group at risk, including stage of life, local conditions, and the etiology of anemia within the specific population. For example, strategies to prevent and treat anemia are likely to differ between developed and developing countries. Strategies to prevent anemia have focussed on infection control, improvement of nutritional status, and increasing dietary iron intake and bioavailability through dietary education, food fortification, and iron supplementation.

Dietary Factors and Anemia

Both dietary and nondietary factors contribute to iron deficiency and, ultimately, iron-deficiency anemia. Nondietary factors contributing to iron deficiency include genetics, physiological factors that increase iron requirements (e.g., pregnancy and growth), blood loss (e.g., menstruation), parity, and the inflammation associated with obesity, which upregulates hepcidin (a peptide hormone produced in the liver that inhibits iron absorption). Approximately half the variation in iron absorption is explained by hepcidin and other genetic or physiological factors, while an individual's iron status (increased iron absorption in states of iron deficiency) and dietary factors account for the remaining variation.

Dietary Factors Affecting Iron Absorption

Iron absorption involves the entry, movement through, and release of iron from the intestinal cell to the circulation. There are two main types of iron in the diet, absorbed through different pathways in the small intestine. Heme iron derived from hemoglobin and myoglobin is found in meat, fish, and poultry, and while heme iron only contributes ~10–15% of dietary iron intake, ~15–35% of heme iron is absorbed. Relatively few dietary factors impact on heme iron absorption. Meat and soy protein have been shown to enhance heme iron absorption, while calcium inhibits it. Heme iron is converted to nonheme iron if meat is cooked for a long period of time at too high a temperature.

The majority of dietary iron is from nonheme iron found not only in meat, fish, and poultry but also in cereals, pulses, legumes, nuts, seeds, eggs, and some vegetables. Only 2–20% of nonheme iron is absorbed by the body, and absorption of nonheme iron is affected by a number of factors. It is also likely that dietary iron is taken into the intestinal cells as ferritin, the iron storage molecule of animal and plant cells. Once in the intestinal cell, heme iron and nonheme iron enter a common pool and are treated in the same manner.

Dietary factors enhancing nonheme iron absorption act by converting the insoluble ferric form of iron (Fe^{3+}) to the more

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00030-1

soluble ferrous form (Fe^{2+}) or by maintaining the iron released from food during digestion in a soluble form prior to entering the intestinal cell. Vitamin C is a strong enhancer of nonheme iron absorption, as is an unidentified factor in meat, commonly known as the meat–fish–poultry factor. Other organic acids (e.g., citric acid), alcohol, and fermented foods also enhance nonheme iron absorption. In some, but not all studies, vitamin A and carotenoids have been shown to enhance nonheme iron absorption. Nonheme iron absorption is inhibited by phytic acid (found in whole grain breads, cereals, legumes, nuts, and seeds), polyphenols (found in tea, coffee, fruit, vegetables, some cereals and legumes, and red wine), and some proteins (e.g., soy protein). These bind nonheme iron to form insoluble complexes inhibiting entry into the intestinal cell. Calcium inhibits the absorption of both heme and nonheme iron. Supplemental doses (rather than the amounts found in food) of organic elements such as zinc, manganese, and copper also compete with nonheme iron for transport into the intestinal cell. The effects of enhancers and inhibitors on iron absorption are strongest when consumed with meals containing iron. Studies conducted over several days or weeks have shown that the effects of these individual dietary factors on iron absorption may be reduced when consumed as part of a whole diet rather than being consumed as part of a single meal. Vitamin C, meat, and phytic acid appear to have the strongest influence on nonheme iron absorption when consumed as a meal containing multiple enhancers and inhibitors of iron absorption.

Dietary Factors Affecting Iron Status

Despite the number of dietary factors affecting iron absorption, it has been difficult to determine whether these factors translate to an actual effect on iron status (usually measured using serum ferritin concentrations). A large number of cross-sectional studies (observational studies analyzing population data at one time point) have shown meat intake to be associated with an increased iron status. The serum ferritin concentrations of vegetarians tend to be lower than in nonvegetarians, but still within the normal range, and vegetarians tend to have similar rates of anemia compared with nonvegetarians. Some, but not all, studies have observed an inverse relationship between calcium and dairy product intake and iron status. Studies have found either a positive association or no association between alcohol intake and iron status. Tea intake appears to only affect iron status in individuals with marginal iron status. Most cross-sectional studies have observed no relationship between iron status and intakes of iron, vitamin C, fruit and vegetables, fiber, or phytate. These studies have however had a number of limitations, including inadequate assessments of dietary intake and the use of food composition databases, which contain limited data, especially for phytic acid and polyphenol contents, varying cutoff points to determine iron deficiency and not taking into account confounders that may affect iron status (e.g., many studies have not measured markers of inflammation, also associated with increased serum ferritin concentrations). Furthermore, cross-sectional studies are unable to identify cause and effect and have tended not to take into account the timing of food consumption or the interaction or synergistic effects enhancers and inhibitors of nonheme iron absorption have on one another.

Recent cross-sectional studies have attempted to address this, by investigating associations between combinations of foods consumed and a population's iron status. A study in China found a 'healthy' dietary pattern (consisting of whole grains, fruits, and vegetables) to be inversely associated with anemia, while 'sweet tooth' (drinks and cakes) and 'traditional' (rice, vegetable, and wheat flour) dietary patterns were positively associated with anemia. In Norway, high serum ferritin concentrations were associated with a 'reindeer meat' (reindeer meat, reindeer products, moose meat, cured/salted fish, and boiled coffee) dietary pattern. In New Zealand, the likelihood of suboptimal iron status was lower in premenopausal women who followed a 'meat and vegetable' (beef, chicken, broccoli, capsicum, and lettuce) dietary pattern and increased in premenopausal women who followed a 'milk and yogurt' (milk added to food, milk as a drink, and yogurt) dietary pattern. The few studies that have investigated associations between iron status and timing of food and beverage consumption have had mixed results.

Only a few prospective studies (involving repeated observations in the same individuals over time) have investigated associations between dietary factors and iron status. Results have been mixed, but the majority have observed no associations between dietary intake and serum ferritin concentrations. The majority of randomized controlled trials (gold standard research study design in which people are randomly assigned to one of two or more treatments) have not observed an effect of dietary enhancers and inhibitors on iron status. However, these studies have largely been undertaken in iron-replete Western populations, who are less likely to absorb iron. Recent studies of more than 16 weeks' duration undertaken in iron-depleted populations have found meat intake to maintain iron status and vitamin C to increase iron status when consumed with meals that contain iron. The most effective dietary strategies for improving iron status appear to be those that use a combination of dietary strategies to improve iron status, for example, increasing the intake of iron in the diet (through iron-fortified foods and the use of cast-iron cookware), increasing the intake of enhancers of iron absorption (e.g., meat and vitamin C), decreasing the intake of dietary inhibitors of iron absorption (e.g., tea and coffee and phytic acid), and optimizing the timing of foods (e.g., consuming iron-containing foods at mealtimes alongside iron absorption enhancers and inhibitors of iron absorption in between meals). However, these changes are not usually enough to move an individual from an iron-deplete state to an iron-replete state. Other strategies to improve the iron bioavailability of foods include food processing methods such as the fermentation and germination of foods such as cereals and legumes to reduce their phytate content. For individuals with anemia, dietary strategies should be used alongside iron supplementation. Dietary strategies are useful in the treatment and prevention of iron deficiency (prior to iron deficiency developing). Other approaches for reducing iron-deficiency anemia include large-scale educational programs and promotional campaigns focussing on improving the intake and bioavailability of iron in the diet. Educational programs targeted at health workers may also be effective. For populations in developing

countries, dietary changes may however be less feasible due to limited dietary diversity and poor economic circumstances.

Recommended Iron Intakes for Different Population Groups

It is generally recognized that dietary contributors to iron-deficiency anemia include diets of limited diversity, with low dietary iron and poor iron bioavailability. These diets contain low levels of foods that enhance iron absorption (e.g., meat and fruit and vegetables high in vitamin C) and high amounts of foods that inhibit iron absorption (e.g., staple foods such as cereals that are high in phytic acid) and tend to be consumed in developing countries. People living in developed countries tend to consume diets with greater dietary diversity and higher iron bioavailability. These diets contain generous amounts of meat and foods that enhance iron absorption and low levels of foods that inhibit iron absorption.

Recommended intakes for iron have been established in several countries. The recommended intakes for iron across different life stages are displayed in Table 1. These are presented as recommended dietary allowances, recommended dietary intakes, or reference nutrient intakes (depending on country/-population), which meet the needs of 97.5% of individuals in a particular stage of life. The variation in the iron bioavailability across diets and varying levels of iron status across populations (i.e., iron-deficient individuals absorb more iron) make it difficult to estimate individual iron requirements, and this in part causes recommendations for iron intake to vary between countries. For example, recommendations for iron intake by the Food and Agriculture Organization of the United Nations and World Health Organization are based on lower levels of iron bioavailability in the diet and are therefore somewhat higher than recommendations from developed countries such as the United Kingdom, the United States, and Canada.

The iron requirements for adolescent and premenopausal females are higher than those in children and males of a similar age to account for iron losses during menstruation. Physiological requirements for iron increase during pregnancy and iron requirements increase at 6 months of age due to rapid growth and depletion of iron stores. Therefore, infants require an additional source of iron, and complementary foods are recommended by the World Health Organization from 6 months of age. The iron content of breast milk is highly bioavailable compared with the iron in infant formula. The early introduction of other fluids such as water, tea, and fruit juice may also displace breast milk in the diet. The iron content of cow's milk is low and poorly bioavailable, and its early introduction has been identified as a risk factor for the development

of iron-deficiency anemia. Severe maternal iron-deficiency anemia may adversely affect the iron content of breast milk, and therefore, it is advantageous to both mother and infant that maternal iron deficiency is treated.

Iron Supplementation: Prevention and Treatment of Iron-Deficiency Anemia

In many countries, the amount of iron absorbed from the diet is not adequate to maintain iron stores. The increased iron requirements during pregnancy and in infancy mean that individual iron requirements are difficult to achieve through diet alone. Iron supplementation should therefore be considered for pregnant women and infants aged 6–24 months, due to their increased risk of developing iron-deficiency anemia and widespread public health benefits.

Iron supplementation programs during pregnancy operate in both developed and developing countries. In some countries, iron supplementation in pregnancy is only recommended for women with clinically diagnosed iron-deficiency anemia. However, in countries where the prevalence of anemia is high, diets are low in bioavailable iron, and there is no widespread fortification of foods, iron supplementation is the most practical and cost-effective way to assist women of child-bearing age to enter pregnancy with adequate iron stores. In these countries, iron supplementation should continue after the infant's delivery to ensure that adequate iron stores are achieved.

In populations where iron-fortified complementary foods for infants are not readily available, infants may benefit from iron supplementation. Iron supplementation may also benefit children, adolescents, and women of reproductive age particularly in countries where the prevalence of anemia is high. However, untargeted iron supplementation of children living in countries where malaria is endemic may be problematic, with one study observing an increased risk of severe illness and death in preschool children consuming iron and folic acid supplements. Several studies have investigated the efficacy of iron supplementation once or twice per week, as opposed to daily iron supplementation, and results in school-age children, adolescents, and nonpregnant women appear promising. Limitations of iron supplementation programs include the logistics of delivering iron supplements to the intended population and individual lack of compliance to taking iron supplements.

Where iron-deficiency anemia has already developed, dietary treatment alone is insufficient to improve iron status. The quickest and most effective way to treat iron-deficiency anemia is through iron supplementation. In populations where severe anemia is common, its early detection and treatment are essential to prevent morbidity and mortality. Heath workers need to be trained to recognize and treat (or appropriately refer) individuals presenting with anemia. As the causes of anemia are multifactorial in nature, an individual should be followed up after commencing iron supplementation to ensure the treatment is working effectively.

Fortification of Food with Iron

Fortification of food with iron involves the addition of iron to a food, in order to prevent or treat iron deficiency. Fortifying food with iron can be a cost-effective, long-term approach to combating iron deficiency in populations with a high prevalence of dietary iron deficiency and is the main approach used to improve the iron supply in the diet. Iron fortification has the advantage of not being dependent on individual motivation and compliance. However, the risks of iron overload (e.g., in people with hemochromatosis) need to be considered.

The reasons for fortification of food with iron vary. Market-driven fortification is common in developed countries and includes initiatives used by the food industry to increase sales such as adding iron to breakfast cereals. Targeted fortification is aimed at meeting the needs of specific groups (e.g., infant formulas and complementary foods) and has been shown to be effective in preventing iron-deficiency anemia in infants in Latin America and the United States. Mass fortification is usually mandatory and involves the addition of iron to foods commonly consumed by the general population. Depending on the choice of food, mandatory fortification may enable all sectors of the population to be reached. Foods that have been fortified with iron include wheat flour, cereals, milk and milk products, and condiments such as sugar, salt, fish sauce, soy sauce, and curry powder. Iron is often added to foods such as flour to replace iron lost during the milling process.

Iron compounds used to fortify foods are affected by the same factors that affect iron absorption in food (e.g., an individual's iron status, other dietary factors, and the characteristics of the iron fortificant itself). The development of an iron-fortified food involves the selection of an iron compound that is adequately absorbed but does not change the taste and appearance of the food to which it is added. The iron chosen must also be able to overcome the inhibitory effects of food components such as phytic acid on iron absorption. Water-soluble iron compounds such as ferrous sulfate are highly bioavailable and therefore desirable to use as food fortificants. However, they often lead to sensory changes (e.g., taste and color changes and rancidity), making them unsuitable for use in many foods. Ferrous sulfate is often used to fortify foods that are stored for short periods of time (e.g., infant formulas). Fortificants that are water-insoluble but soluble in acids (e.g., ferrous fumarate) tend to be well absorbed. Iron fortificants that are water-insoluble and poorly soluble in dilute acid (e.g., elemental iron powders and ferric pyrophosphate) have the lowest and most variable bioavailability. Despite this, elemental iron compounds are commonly used to fortify food products such as breakfast cereal and wheat flour, as they are relatively inexpensive and do not cause sensory changes, increasing shelf life and consumer acceptability.

Early reports suggested a lack of evidence regarding the efficacy of iron fortification of staple foods such as flour in improving the iron status of populations. This was attributed to the use of less bioavailable elemental iron powders, inadequate intakes of iron-fortified foods, and insufficient levels of iron fortificants in food. However, in a recent systematic review of randomized controlled trials, consumption of iron-fortified foods was found to significantly increase serum ferritin and hemoglobin concentrations and reduce the risk of iron deficiency and iron-deficiency anemia. More recently, selective breeding and genetic engineering have been used to increase the iron content of staple foods. More work is needed to ensure the bioavailability of this iron and that the iron content is increased to nutritionally beneficial levels.

Conclusion

Traditionally, one approach (e.g., iron supplementation, dietary education, and fortification of food) has been recommended as the main avenue to pursue in the development of iron nutrition programs. However, it is now recognized that a multitude of integrated strategies are necessary in order to effectively control iron deficiency (and anemia) in populations. The absorption of nonheme iron (the predominant form of iron in the diet) is affected by several dietary factors. Clear evidence is lacking regarding the most effective strategy for improving the iron status of populations. Intervention strategies include the widespread fortification of staple foods (and complementary foods) with iron, wider use of oral iron supplementation, education regarding strategies to improve iron intake and bioavailability in the diet, and the improvement of complementary feeding in infants. These strategies should complement other public health programs, such as infection control, deworming and other nutrition programs, and programs focussed on maternal and child health such as family planning and breastfeeding initiatives. Governments need to prioritize and commit to sustainable, long-term programs to prevent iron-deficiency anemia in vulnerable populations, particularly in countries with limited dietary diversity. All agencies and stakeholders should be involved including government agencies, the food industry, and the health sector. The prevalence of anemia and effectiveness of programs implemented to prevent anemia should be monitored using ongoing and reliable surveillance systems.

Tips to Increase Iron Absorption from Food

- Include meat, fish, or poultry in meals where possible.
- For vegetarians or in populations with limited access to meat, fish, and poultry, include foods rich in nonheme iron such as cereals, pulses, legumes, nuts, seeds, eggs, vegetables, and iron-fortified foods.
- Include vitamin C-rich food or drinks alongside meals containing nonheme iron.
- Avoid drinking tea and coffee with meals containing nonheme iron. Drink between these meals instead.
- Consume milk and milk products in between meals, rather than with meals containing nonheme iron.
- Limit the addition of foods high in phytate to main meals (e.g., the addition of extra bran to breakfast cereals).
- Infants should be exclusively breastfed for approximately six months. At 6 months of age, include complementary foods high in iron or fortified with iron where possible. Cow's milk as a drink should be avoided until at least 1 year of age.
- For individuals with iron-deficiency anemia, iron supplementation is required. Dietary treatment supplementation alone is not sufficient to treat iron-deficiency anemia, but should be used alongside iron supplementation.

Annonaceous Fruits

P Padmanabhan and G Paliyath, University of Guelph, Guelph, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The family Annonaceae is composed of more than 119 genera with more than 2000 species. It is the largest family in Magnoliales. Only four genera (*Annona*, *Asimina*, *Rollinia*, and *Uvaria*) produce edible fruit. The genus *Annona* is composed of about 120 species and is the most important source of edible fruit in Annonaceae. *Annona cherimola* L., *Annona muricata* L., *Annona squamosa* L., *Annona reticulata* L., *Asimina triloba* L., and the interspecific hybrid atemoya (*A. cherimola* x *A. squamosa* Mabb.) are some of the most important species of this genus.

Sources, Production, and Fruit Morphology

Annona cherimola Mill

Annona cherimola or cherimoya is believed to have originated in the highland Andes valley between Peru and Ecuador and is considered as the best of the Annonaceae fruits. *Annona cherimola* is known as cherimoya (Spanish), cherimolier (French), anona (Mexico), and noina ostrelia (Thailand). This species is commercially grown in Spain, Bolivia, Chile, Peru, and New Zealand. Cherimoya is cultivated mainly in the Mediterranean, and Spain is the world's leading producer. It is a small, erect, spreading deciduous tree (NRC, 1989). Cherimoya is more tolerant to low temperatures than the soursop. Cherimoya fruit is normally conical, oval, or heart-shaped and the skin may be smooth with fingerprint-like markings in some varieties or covered with conical or rounded protuberances. Five botanical forms of cherimoya are seen based on the fruit shape and markings on the skin: finger-printed, smooth-skinned (cherimoya lisa), tuberculate (the most common type with heart-shaped fruit and wartlike tubercles), mammilate, and umbonate (the barbed or the spiny cherimoya). Its fruit has a thick green peel and creamy white flesh with custard-like consistency. Cherimoya fruit is fleshy and sweet and the pulp is white in color. The low-acid flesh has a delicate, rich, aromatic flavor that resembles that of pineapple and banana. The fruit has numerous black seeds. Fully mature fruit is harvested while still firm, and on ripening, the fruit's skin color changes from grayish green to yellow-green.

Annona muricata L.

Annona muricata, commonly known as graviola or soursop or guyabano, is another tropical fruit tree in the Annonaceae family. This plant probably originated in the Antilles in the Caribbean. Soursop is cultivated in many countries such as Angola, Brazil, Colombia, Costa Rica, Cuba, Jamaica, Mexico, Panama, Peru, Puerto Rico, Venezuela, and SE Asia. Mexico is the main soursop producer in the Americas. Soursop is a small perennial branched, quick-growing tree. Soursop thrives well in the humid tropical and subtropical lowlands with warm winters. Trees are sensitive to low temperature below 5 °C and to frost. Soursop has the largest fruit in the genus, weighing from 0.9 to 10 kg with an average weight of 4 kg. Soursop fruits are normally ovate, heart-shaped, or conical. The fruit is prickly and has a sour and sweet flavor. Unripe fruit is dark green that turns to light green when ripe. Soursop fruit is derived from the fusion of many fruitlets. The fruit pulp consists of white fibrous juicy segments. Numerous black or dark brown seeds are embedded in a firm fleshy, acid-sweet, whitish pulp. It has more acidic flavor than cherimoya and resembles a mixture of pineapple and mango. The aroma volatiles of soursop consist of mainly esters (80%). Fruit is harvested when it is fully mature, firm, yellow-green, and with spines apart.

Annona squamosa L.

Annona squamosa is the most widely grown *Annona* spp., and this small tropical tree originated in the New World tropics, probably in the Caribbean region. This plant is also known as sugar apple or sweetsop and has many other regional names such as custard apple (India), anon (Portuguese), and noi-na (Thailand). Sugar apple is a favorite fruit in Cuba and is also common in West Indies. Sweetsop is also widely cultivated in Taiwan. It is still grown as a backyard tree and the Philippines is considered as one of the largest producer in the world. Sweetsop tree is smaller than the cherimoya and is semi-deciduous in growth habit. It grows 3–8 m in height with a short trunk and irregularly spreading branches. Owing to small fruit size, poor shelf life, and fruit cracking at maturity, this fruit has not shown much potential for large-scale commercial cultivation. Sweetsop is a round, heart-shaped, ovate, or conical fruit weighing about 120–330 g. Fruit are greenish yellow with many outer round protuberances and covered with a white powdery bloom. The flesh is white with numerous black seeds and has a pleasant sweet–sour flavor. Fruit has high caloric value and a high sugar content of 58% (dry mass). The majority of cultivars are grown in India.

Annona reticulata L.

This plant, also called custard apple, bullock's heart, or netted custard apple, is used as a common medicinal plant in the Caribbean. It is a native of the West Indies and cultivated in the Bahamas and occasionally in Bermuda and southern Florida. *A. reticulata* is a warm tropical species, but can survive in subtropical conditions. It prefers humid atmosphere, but is not cold-hardy or drought-tolerant. This plant is a small tree often growing 3–10 m tall with an irregular canopy and widely branched near the base. Fruit are commonly heart-shaped but may be conical, ovoid, or irregular in form and weigh from 0.1 to 1.0 kg. The flesh is white and sweet with several dark coffee-colored seeds. Fruit are more or less smooth with a reddish-yellow fruit skin color and the pulp is white, granular, and aromatic. Numerous dark brown glossy seeds are present in the pulp.

Atemoya

Atemoya is a hybrid between *A. squamosa* and *A. cherimola* Mabb. (sugar apple and cherimoya) in the *Annona* family. The crosses were made by P. J. Webster in 1907 for the USDA in Florida. Natural crossing also occurred in the field in Australia in 1850 and in Palestine in 1930. This hybrid is in cultivation in Australia where it is called custard apple. It is also grown in Spain, Bolivia, Chile, Peru, Israel, Florida, and Hawaii. Atemoya is a small tree with a short trunk and low drooping branches growing to a height of 8–10 m. Atemoya thrives best in warm tropical to subtropical areas with 70–80% relative humidity and with adequate rainfall. Atemoya is frost-sensitive and destroyed by low temperatures. Trees are semideciduous and remain dormant in late winter and early spring. Most atemoya hybrids resemble cherimoya in tree vigor and habit. Atemoya fruit is a fleshy syncarp formed by the fusion of carpels and the receptacles. The fruit is pale-bluish green to pea green, heart-shaped, or conical weighing 2–2.5 kg. The fruit shape is highly variable and the fruit surface is covered with prominent angular areoles, which are either smooth or pointed. The fruit flesh is white with fewer seeds and not conspicuously divided into segments. The pulp is easily separable from the seeds. The seeds are dark brown to black and are smooth.

Asimina triloba

Asimina triloba (L.) Dunal, or pawpaw, is the only temperate plant species belonging to tropical Annonaceae. *Asimina* comprises nine species, most of which are native to southeastern regions of Florida and Georgia. The North American pawpaw, also known as the Kentucky or Hoosier or poor man's banana, is the largest fruit native to North America. Pawpaws grow wild in the forests of 25 states in the eastern United States from northern Florida to southern Ontario (Canada) and as far west as eastern Nebraska. At present, pawpaw is gaining interest as a gourmet food. Commercial cultivation of pawpaw is limited to small private orchards usually less than 1 ha in size. Currently, most pawpaw fruit for sale are collected from the wild. In the United States, pawpaw fruit are sold at the farmer's market. Pawpaw fruit have both fresh market and processing potentials. Pawpaw is a small deciduous tree or shrub attaining a height of 5–10 m. Pawpaw fruit is a berry. Fruit are oblong with green skin and occur singly or in clusters. The fruit are typically 3–15 cm long and weigh from 100 to 1000 g. Two rows of seeds are seen in the fruit that are brown-colored and bean-shaped. Ripe fruits have a strong and unique aroma and characteristic flavor that resemble a mixture of banana, mango, and pineapple. Skin and seeds of the fruit are not eaten. The pawpaw fruit is highly nutritious and is comparable to banana in dietary fiber and overall nutrient content. Fully ripe pawpaw fruit is very soft, so it should be handled with extreme care as they are easily susceptible to bruises and other physical damages. The seed endosperm contains alkaloids that impair digestion. Pawpaw allergies have been reported in some individuals.

Patterns of Consumption

Most annonaceous fruits are primarily dessert fruit and are consumed fresh when fully ripe. The fruit pulp can also be frozen and eaten like ice creams. Ripe fruits are used for making ice creams, milk shakes, jellies, or sorbets. Fruit pulp can be frozen and can also be processed into yogurt, juice, nectars, and wine. Among the various annonaceous fruits, soursop has the greatest processing potential because of its high sugar content, excellent flavor, and high recovery from the large fruit. Pulp recovery ranges from 62% to 85.5% of the fruit. Viscous soursop pulp is diluted and the pH is adjusted to 3.7 by the addition of citric acid. Sugar is also added to the pulp to create a desirable balance between acidity, sweetness, and flavor. Soursops are considered as too acid for eating fresh, but it is good for preparing refreshing drinks. Soursop is also made into strained juice and also preserved as juice blends, nectars, canned juice, jam, or jelly. In the Philippines, soft soursop fruit is used as a vegetable cooked with coconut milk. Two types of soursop were distinguished in El Salvador, the sweet variety that is eaten raw (guanaba azucaron) and the very sour (guanaba acida) used for the preparation of drinks. Immature soursop fruits are used as vegetables. In Brazil, seeds are roasted or fried. In Indonesia, soursop fruits are added to soups. An alcoholic drink called champola is prepared from processed pulp. A method for canning soursop juice was developed by blending with sugarcane juice or papaya juice. The cherimoya fruit is chilled often with salt and lemon. The fruit is also mixed with wine, milk, and yogurt and also processed into ice cream and sherbet and baked into cookies and pastries. Chilling of annonaceous fruits improves their flavor.

Postharvest Quality and Shelf Life

Annonaceous fruits are climacteric with a rise in ethylene production during ripening. Most of them have a short postharvest life. Ripe fruits are very soft and are susceptible to injury and bruises during handling. *Annona* fruits are very delicate and extreme care should be taken while handling and transportation. Annonaceous fruits are harvested while still firm and are ripened at room temperature. Immature fruits do not develop the full flavor and aroma off the tree. Optimum handling temperature for *Annona* fruits is suggested to be 8–12 °C and the fruits are sensitive to temperatures below 8–12 °C resulting in chilling injury causing mealiness, less flavor, darkening, and hardening of the skin.

Nutritional Composition and Health Effects

The pulp of annonaceous fruit is flavorful and has a reasonable content of vitamins and minerals. Cherimoya, soursop, and sugar apple are the most widely consumed fruits. The compositions of nutrients in raw annonaceous fruits (100 g edible portion) are presented in Table 1. In general, annonaceous fruits are high in sugars. Cherimoya fruit is a rich source of antioxidants such as vitamins A and C. About 60% of cherimoya fruit is edible. The sugars constitute a mixture of fructose, glucose, and sucrose. Pulp carbohydrate content of cherimoyas is generally high, but low in acidity. Furthermore, it is a good source of thiamine, riboflavin, and niacin. Fiber content is represented by cellulose, hemicellulose, lignin, and pectic substances. Cherimoya fruit is particularly high in several essential minerals such as potassium, copper, manganese,

and magnesium. Edible portion of cherimoya fruit is rich in numerous health-promoting phytochemicals. The pulp of soursop is high in carbohydrates and sugars. It is also a good source of vitamin C, vitamin B_1, vitamin B_2, and potassium. The edible portion corresponds to about 67.5% of the total fruit weight. Soursop fruit pulp is a potential source of dietary fiber and is the only annonaceous fruit with tannin in pulp. The sugars are represented mainly by fructose, glucose, and sucrose. The fruit also contains vitamins A and B_5. The most predominant acid is citric acid followed by low content of malic and isocitric acid. Custard apple pulp is creamy yellow and sweet with low acidity. The edible portion of the fruit is about 45%. Sugar apple flesh is slightly granular, creamy yellow, or white and is flavorful with low acidity. It is the sweetest of the *Annona* and 28–37% of the total fruit weight is edible. The fruit flesh is high in carbohydrates and sugars and also contains vitamins C, B_1, and B_2; potassium; and dietary fiber. Vitamin A content is low. Sugar apple has vitamin C slightly higher than in grapefruit. Fructose, glucose, sucrose, and oligosaccharides form the major carbohydrates of the fruit pulp. The amount of sugar is quite high (58% of dry mass). The fruit has low triglyceride content. A diterpenoid compound, kaur-16-en-18-oic acid, was also identified in the lipid fraction. Atemoya fruit contain significant amounts of vitamin C, thiamine, potassium, magnesium, and dietary fiber. The fruit also has citric and malic acids. Fructose and glucose forms the main sugar components (80–90%). Pawpaw fruit has high nutritional value and is rich in many nutraceutical compounds. Pawpaw and banana are similar in dietary fiber content and in overall nutritional composition. In particular, pawpaw fruit contains threefold more magnesium and 17-fold more manganese than banana.

Acetogenins and Their Biological Effects

Annonaceous plants contain acetogenins in parts such as the leaf, bark, fruit, and root. Annonaceous acetogenins are a unique class of C35 or C37 secondary metabolites derived from the polyketide pathway. Acetogenins are gaining much attention recently due to their diversity of biological activities and are one of the most rapidly growing classes of new natural products. Acetogenins are fatty acid derivatives with tetrahydrofuran rings and a methylated γ-lactone having various hydroxyl, acetoxyl, and/or ketoxyl groups along the hydrocarbon chains. Numerous studies on acetogenins indicate that these compounds are powerful cytotoxins and demonstrated *in vivo* antitumor, pesticidal, antipiscicidal, antihelminthic, antiviral, antimalarial, and antimicrobial properties, suggesting many potentially useful applications. The isolation of

uvaricin from the roots of *Uvaria accuminata* by Joland and his coworkers in 1982 initiated the research on acetogenins. Since then, more than 400 acetogenin compounds were identified and studied from various plants. The various biological activities of acetogenins are summarized here.

Anticancer Activity

Presently, acetogenin compounds are attracting much research attention worldwide due to their potent cytotoxic activities, which is tested *in vitro* against a large number of tumor cell lines. Annonaceous acetogenins are known as powerful inhibitors of complex I (NADH/ubiquinone oxidoreductase) in mammalian and insect mitochondrial electron transport systems. They also inhibit the NADH oxidase of the plasma membranes of cancer cells. Both these mechanism of actions deplete the ATP supply of the cells, which induces apoptosis (programmed cell death). Cancer cells have higher ATP demand than the normal cells and are better targets for the cytotoxic action of acetogenins. Acetogenins also show potent cytotoxic activity against multidrug-resistant tumors and insecticide-resistant pests.

Numerous research reports on the cytotoxic effects of acetogenins from various annonaceous plants towards different human cancer cell lines are available. Only a few relevant studies are mentioned here. Various parts of soursop tree contain an array of acetogenins that are responsible for its several different types of biological and medicinal activities. One of the acetogenin, cis-annonacin isolated from the seeds of soursop, showed very high cytotoxicity towards colon adenocarcinoma cells with a potency of 10 000 times that of Adriamycin, a drug used to treat cancer. A number of acetogenins were identified and isolated from the seeds of ripe soursop including annonacin, isoannonacin, goniothalamicin, and gigatetrocin. These acetogenins showed cytotoxicity against A-549 lung carcinoma, MCF-7 breast carcinoma, and HT-29 colon adenocarcinoma cell lines. In *in vitro* studies, solamin, an acetogenin from soursop leaves, showed cytotoxic action against KB and VERO cell lines. Murisolin (acetogenin isolated from seed of soursop) showed 105 to 106 times more potency than Adriamycin in their cytotoxic activity against human tumor cell lines.

A. squamosa are abundant in acetogenins especially in the bark and seeds. Squamotacin, the acetogenin from the bark of sugar apple, has been reported to possess extremely high cytotoxicity against human prostate tumor cell line (PC-3). Two acetogenins from seeds, squadiolins A and B, showed high cytotoxicity against human hepatocellular carcinoma (HepG2) and human breast cancer (MDA-MB-23) cells. The acetogenins contained in the bark and leaf of *A. reticulata* have been shown to have very potent anticancer properties. Two acetogenins called squamocin and annonacin, isolated from the seeds, showed strong cytotoxic activities against a number of cancer cell lines tested and showed great potential as anticancer compounds. Squamocin also arrested the T24 bladder cancer cells at the G1 phase and also induced the expression of Bax and Bad pro-apoptotic genes and triggered cell apoptosis. Various acetogenins such as annonacin, annonisin, and bullatacin were identified from the seeds of atemoya. Bullatacin was shown to inhibit proliferation of human hepatocellular carcinoma . Pawpaw contains acetogenins in its unripe fruit, seeds, roots, twigs, and bark tissues that exhibit antitumor and pesticidal properties. This plant species contains annonaceous acetogenins. Three acetogenins, namely, asimicin, bullatacin, and bullatalicin, were identified in the ripe pawpaw fruit pulp by HPLC-MS analysis.

Pesticidal and Insecticidal Effects

Acetogenins isolated from fruit pericarp of *A. squamosa* showed antileishmanial activity and were inhibitory to *Leishmania in vitro*. Acetogenins also showed pesticidal properties. Extracts of *A. muricata* and *A. cherimola* seeds showed potent antiparasitic activity against *Entamoeba histolytica*, *Nocardia brasiliensis*, and *Artemia salina*. Also, acetogenins such as annonacin, isoannonacin, and goniothalamicin isolated from the leaves showed strong antimolluscicidal activity. Apart from this, the leaves of *A. muricata* demonstrated antimalarial and antiprotozoal activities *in vitro*. A number of acetogenin-based commercial products were developed including a shampoo for treating head lice infestation, pesticidal sprays, and an ointment for the treatment of oral herpes (HSV-1) and other skin ailments. Additionally, acetogenins from Annonaceae and pawpaw showed very high insecticidal activity against a number of insects. They are particularly effective against chewing insects. Studies demonstrated that acetogenin compounds are toxic to pests including cockroaches, Colorado potato beetle, blowfly larvae, mosquito larvae, spider mites, European corn borers, melon or cotton aphids, and nematodes.

Other Medicinal/Therapeutic Properties

The stem extract of *A. muricata* showed antiviral activity against herpes simplex virus. Several kaurane compounds were isolated from *A. squamosa* fruit and some of them showed significant activity against HIV replication in H9 lymphocyte cells. Some animal studies showed the hyperglycemic activities of methanolic extracts of *A. muricata*. *Annona squamosa* is used by ethnic groups in India for the management of diabetes and its complications. Studies showed that the hot leaf extract of this plant possess hypoglycemic and antidiabetic activities. Studies conducted in animal systems demonstrated that administration of *A. squamosa* leaf extract improved the lipid profile of the treated group than the control. Studies reported that *A. squamosa* fruit pulp could reduce the total cholesterol level by 45–46% in normal and 32% in diabetic animals. Some reports are available that show the potential antithyroid activity of seed extracts of *A. squamosa* in reducing hyperthyroidism in lab animals. Eleven ent-kauranes isolated from the stem bark of *A. squamosa* showed immunomodulatory activities in leukocytes.

Adverse Effects

Chronic consumption of annonaceous fruits has also been linked to an increased risk of developing atypical Parkinsonism.

Prevalence of an atypical form of Parkinsonism among the natives of Guadeloupe in the West Indies and in New Caledonia in the Pacific was reported. Patients with severe progression of the disease often consumed the fruits and tea of leaves of the Annonaceae family (*A. muricata*, *A. reticulata*, and *A. squamosa*) particularly *A. muricata*. At first atypical form of Parkinsonism was attributed to the benzylisoquinoline alkaloids present in Annonaceae, but later, acetogenins became the suspected potential neurotoxins. Recent studies have suggested a possible link between the long-term frequent intake of Annonaceae fruit and tea by the people of Guadeloupe, New Caledonia, and the Caribbean region and the development of high rate of atypical Parkinsonism in their later life. The fruit and other parts of *A. muricata* are abundant in annonacin, an acetogenin that has been shown to be toxic *in vitro* and *in vivo* to dopaminergic neurons. A number of animal studies reported the annonacin-induced degeneration of the basal ganglia and brain stem. Scientific studies are needed to determine the risks of neurotoxicity and neurodegeneration associated with the consumption of soursop, pawpaw, and other related annonaceous plant derivatives.

Traditional Medicinal Uses

Various parts of Annonaceae plants have been used traditionally in many parts of the world for treating various ailments and complaints ranging from high blood pressure and cancer.

Annona muricata is popularly used in traditional Indian medicine for the treatment of kidney troubles, fever, and ulcers and possesses antispasmodic, antidysenteric, and parasiticidal activities. In Ayurvedic medicine, this plant is used as a tonic, as an abortifacient, as a febrifuge, for scorpion stings, for controlling high blood pressure, and as a respiratory stimulant. In Trinidad and Tobago, the leaves are used to treat hypertension. In Brazil, a tea made from the leaf is used to treat arthritis pain, rheumatism, and neuralgia. In Jamaica, Haiti, and West Indies, the fruit and/or fruit juice is used for treating fevers, parasites, and diarrhea and as a lactagogue. The bark or leaf of this plant is used as an antispasmodic and as a sedative, to control coughs and spasmodic bowel pain and help ease difficult child birth, and against asthma, hypertension, and parasites. Pulverized seeds and seed oil are found to be effective for head lice infection. Seeds, bark, root, and unripe fruit have strong astringent properties.

Crushed leaves of *A. squamosa* are inhaled for dizziness. In the Philippines, insect bites are treated by the application of juice from *A. squamosa* unripe fruit. Crushed seeds of *A. squamosa* are used as an abortifacient. Poultice of mashed leaf of *A. muricata*, *A. squamosa*, and *A. reticulata* has been used externally as compresses for swollen feat and also used to treat skin ailments such as eczema, boils, abscesses, and ulcers. Unripe fruits of *A. muricata*, *A. squamosa*, and *A. reticulata* are rich in tannins, have astringent property, and used for treating dysentery and diarrhea. Root bark of *A. reticulata* is used to relieve toothaches. Powdered seeds and seed oil from *A. muricata*, *A. squamosa*, and *A. reticulata* have insecticidal property and are effective for treating head lice. *A. reticulata*, *A. squamosa*, and *A. muricata* leaves are used internally against worms.

Antibiotics and Drugs: Drug–Nutrient Interactions

KM Gura, Boston Children's Hospital, Boston, MA, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The composition of patients' diet and their overall nutritional state can markedly impact both pharmacokinetic (i.e., what the body does to the drug such as absorption, distribution, metabolism, and elimination) and pharmacodynamic (i.e., what the drug does to the body such as affinities to receptors or tissues) drug properties. Many nutritional components can affect biotransformation and disposition of drugs, by impacting blood flow, gastrointestinal (GI) motility, and enzymatic activity. These effects are variable and patient-specific, and confounded by numerous other factors, and often unpredictable. In times of increased energy demands (i.e., during growth, pregnancy, and lactation), there is an increased risk for drug-induced nutrient deficiencies. Not considering these factors can result in a serious consequence such as antibiotic treatment failure that can occur when the absorption of an orally administered antibiotic is taken with food. Similarly, toxicities can occur if a nutrient inhibits the enzymes in the gut that detoxify a medication. The practitioner must consider the potential for interactions that may occur between nutritional status, disease state, and drug action and even patient age when developing a therapeutic plan. This article will review how drug therapy can impact a patient's nutritional state and how nutrition can impact drug response, with a particular emphasis on anti-infective agents.

Factors That Impact Drug Pharmacokinetics

Differences in body composition are an important consideration when determining the pharmacokinetic properties of a given drug. Both nutrients and drugs are delivered via the GI tract and go through an absorption phase before reaching the systemic circulation and the sites of action. Once absorbed, these compounds enter the portal vein from the GI lumen and via a series of complex processes eventually leading to the systemic circulation. Properties such as dissolution of the solid dosage form, the passage of the chyme along the GI tract, passive diffusion, active transport, presystemic metabolism, and the presence of GI disease may further affect the pharmacokinetics of the drug.

Influence of Medications on Nutrient Status

Nutrient Transport and Absorption

Drugs can impact the uptake of nutrients. For example, fluoroquinolones can inhibit L-carnitine transport, which may account for the toxicity of this drug class to the fetus. There are several factors that can interfere with nutrient absorption. The direct systemic effect of a drug on one nutrient may have secondary effects on another nutrient. For example, neomycin and para-aminosalicylic acid may damage intestinal mucosa and destroy intestinal villi and microvilli, resulting in an inhibition of brush border enzymes and intestinal transport systems. Similarly, isoniazid can inhibit the hydroxylation of vitamin D in the liver and kidney, resulting in a functional deficiency of vitamin D and secondary impaired calcium absorption.

Nutrient Metabolism

Medications may affect nutrient metabolism via several mechanisms. They may promote the catabolism of the nutrient or inhibit the essential intermediary metabolism of a nutrient, usually a vitamin. This is often an unwanted side effect, as in the case of pyridoxine antagonism seen with isoniazid use. Isoniazid therapy can result in pyridoxine deficiency by inhibiting pyridoxal kinase. Isoniazid depletes pyridoxine stores and subsequently the neurotransmitter gamma-aminobutyric acid, resulting in seizures. In the event of an isoniazid overdose, administration of pyridoxine can eliminate the resulting seizures and metabolic acidosis.

Many medications induce drug-metabolizing enzymes leading to enhanced enzymatic activity, with a subsequent increased demand for their vitamin cofactors. For example, patients treated with cephalosporin antibiotics may develop hemorrhagic states secondary to drug-induced vitamin K deficiency. Cephalosporins block vitamin K reductase, which is necessary for vitamin K activation. Cephalosporins may also block carboxylation of vitamin K-dependent peptides to yield Gla residues that are required for calcium binding in the conversion of vitamin K-dependent proenzymes to their active state, which are necessary in the coagulation cascade.

Drug-Associated Fluid and Electrolyte Disturbances

Several commonly used anti-infective agents can alter electrolyte balance. Amphotericin B and the antipseudomonal penicillins both can cause renal wasting of potassium, resulting in hypokalemia. Conversely, trimethoprim can cause hyperkalemia due to its weak diuretic properties coupled with potassium-sparing activity.

The impact of a drug on phosphorus balance is important in patients receiving nutritional support as the synthesis of new cells increases phosphorus requirements. Patients already at risk for refeeding syndrome are especially prone to the effects of drugs known to decrease available phosphorus stores. Medications such as sucralfate can decrease the absorption of phosphorus from the Gl tract by binding to dietary phosphate. On the other hand, patients with renal dysfunction are at risk for development of hyperphosphatemia due to the inherent phosphate content present in clindamycin phosphate injection or that contained in the phospholipid emulsifiers in intravenous fat emulsions. Hypomagnesemia as a result of renal wasting can occur in patients treated with amphotericin B, aminoglycosides,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00239-7

loop diuretics, thiazide diuretics, cisplatin, or cyclosporine. Renal wasting of magnesium can also occur in patients receiving prolonged courses of high doses of aminoglycosides. Aminoglycosides inhibit the proximal tubular transport of magnesium in the kidney, predisposing patients with already low magnesium intake to hypomagnesemia. If left untreated, magnesium deficiency can induce a transient hypoparathyroidism by reducing the secretion of parathyroid hormone (PTH) and a blunted PTH response. This leads to an inhibition of the hypocalcemic feedback loop. Management of hypomagnemia-induced hypocalcemia involves correcting the hypomagnesemia first and then replacing ongoing magnesium losses. In some cases, calcium supplementation may even be unnecessary.

Glucose

Patients with diabetes mellitus or those with insulin resistance (e.g., severe infections, catabolic stress) are susceptible to the effects of drugs known to influence glucose metabolism. Protease inhibitors have long been recognized as a cause of hyperglycemia. Conversely, hypoglycemia is the most common metabolic derangement linked to pentamidine therapy. The mechanism responsible involves a direct cytolytic effect on pancreatic beta cells, resulting in insulin release and hypoglycemia and a subsequent insulin deficiency due to a loss of beta cell function. Over time, however, pentamidine-induced pancreatic beta cell damage may result in insulin deficiency and lead to hyperglycemia, although this is considerably less frequent than hypoglycemia. Other anti-infectives that alter glucose metabolism are listed in Table 1.

Table 1 Anti-infectives that impact glucose metabolism/response

Drug	*Response*
Amprenavir	Hyperglycemia
Chloroquine	Hypoglycemia
Ciprofloxacin	Hyper/hypoglycemia
Clofazimine	Hyperglycemia
Darunavir	Hyperglycemia
Didanosine	Hyperglycemia
Dolutegravir	Hyperglycemia
Emtricitabine	Hyperglycemia
Ethionamide	Hypoglycemia
Ertapenem	Hyperglycemia
Etravirine	Hyperglycemia
Fosamprenavir	Hyperglycemia
Gemifloxacin	Hyper/hypoglycemia
Indinavir	Hyperglycemia
Lamivudine	Hyperglycemia
Micafungin	Hyper/hypoglycemia
Moxifloxacin	Hyper/hypoglycemia
Nelfinavir	Hyperglycemia
Norfloxacin	Hyper/hypoglycemia
Pentamidine	Hyper/hypoglycemia
Posaconazole	Hyperglycemia
Quinine	Hypoglycemia
Ritonavir	Hyperglycemia
Saquinavir	Hyperglycemia
Valganciclovir	Hyperglycemia
Zalcitabine	Hyperglycemia

Fat

Drug-induced lipoprotein abnormalities should be considered in individuals in whom no other causes of dyslipidemia exist (Table 2). When a drug is used for a short duration, prescribers need to be aware of the effects on the patient's baseline lipoprotein profile versus the chance that an underlying dyslipidemia has been exacerbated. Chronically used medications that cause dyslipidemia may be more problematic as they may predispose the patient to atherosclerosis.

In addition to causing hyperglycemia, protease inhibitors interfere with proteins involved in fat metabolism (i.e., cytoplasmic retinoic acid-binding protein type 1). Protease inhibitor binding to low-density lipoprotein receptor-related proteins (LRPs) impairs hepatic chylomicron uptake and triglyceride clearance via the endothelial LRP–lipoprotein lipase complex. The resulting hyperlipidemia contributes to insulin resistance and central fat deposition. Moreover, by disrupting steroid hormone production, protease inhibitors may predispose patients to lipodystrophy.

GI Complications

Many drugs can negatively impact the function of the GI tract. Most are minor and self-limiting. Others, however, can be significant, causing severe GI illness (e.g., colitis and esophagitis) that can adversely affect the tolerance to an oral or tube-fed diet. Drug-induced esophagitis (i.e., 'pill esophagitis') can

occur with such antibiotics as doxycycline and tetracycline. Typically, this complication occurs in patients with left atrial enlargement or cardiomegaly as the heart impinges on the esophagus, thus increasing the transit time of the medication in the esophagus, or in adolescents who drink inadequate amounts of fluid with their medications. Switching to the liquid formulation of the medication or administering the problematic drug with plenty of water can often alleviate the situation.

Changes in Appetite

Drug-induced nutritional deficiencies may result when a medication causes appetite suppression leading to decreased food intake. In many cases, the signs and symptoms of nutrient deficiencies are nonspecific and mimic those of other disease states. Drugs that affect appetite (Table 3) may do so by either a central or a peripheral effect, including anorexia, inducing drowsiness, or triggering an adverse response when food is ingested. The primary effect usually focuses on appetite suppression, a centrally acting mechanism that includes the catecholaminergic, dopaminergic, serotonergic, and endorphin modulators, which may lead to appetite suppression. Peripherally acting mechanisms that can indirectly suppress appetite include bulking agents and those drugs that inhibit gastric emptying. A secondary response may also result when a drug induces a negative reaction to food that leads to a loss in appetite. The emetic center, located within the brain stem, is easily stimulated by the action of numerous medications. These include drugs that cause nausea and vomiting, a loss of taste, or stomatitis. Altered taste perceptions can also lead to a decrease in nutrient intake. Drugs such as metronidazole and clarithromycin have been linked with causing taste perversions. Taste is regulated by chemosensory nerves that respond to stimulation chemicals by direct receptor binding, opening ion channels, or via a secondary messenger channels using nucleotides or phosphorylated inositol. Drugs that disrupt these cellular processes can trigger a loss or distortion in taste. Likewise, xerostomia due to decreased saliva production can alter ion concentrations between saliva and plasma that results in diminished taste sensation. Another way in which drugs can cause anorexia is through nutrient depletion. Medications known to deplete folate, such as phenytoin, sulfasalazine, and trimethoprim, can result in weight loss and anorexia.

Basic Principles of Nutrient–Drug Interactions

By definition, a nutrient–drug interaction is one that is the result of a physical, chemical, pathological, or physiological relationship between a medication and a nutrient. Such interactions are clinically relevant if they impact the therapeutic response of a drug either by decreasing bioavailability (and thereby increasing the risk of treatment failure) or by increasing bioavailability (and thus increasing the risk of toxicity) of the drug.

There are four basic classifications of drug–nutrient interactions that are based on their nature and mechanism:

1. Type I *ex vivo* bioinactivations – These occur between the medication and the nutrient, via biochemical or physical reactions, usually in the delivery device. These interactions are most commonly seen with drugs and nutrients administered intravenously or via feeding tubes. Examples include complexation, hydrolysis, neutralization, oxidation, and precipitation.
2. Type II – These interactions are characterized by a modification of the bioavailability of the medication and effect absorption. The function of the enzymes or transport systems that are responsible for drug biotransformation may be altered.
3. Type III – The systemic disposition of the drug is involved in this form of interaction and occurs after the drug or nutrient has been absorbed from the GI tract into the systemic circulation. This interaction leads to changes in

tissue distribution, transport, or penetration to a specific organ or tissue.
4. Type IV – The elimination or clearance of the drug or nutrient is impacted in this form of interaction. It may modify either the enterohepatic or the renal elimination process.

Relationship of Meal Timing and Drug Absorption

The concurrent of food and oral drug absorption is an example of a type II interaction. The rate and extent of drug absorption can both be altered (Table 4). In many cases, food will stimulate both gastric and intestinal secretions, thus aiding drug dissolution and improving in its absorption. High-fat meals can improve the intestinal uptake of highly lipophilic drugs due to the release of bile salts triggered by dietary fat. Moreover, cholecystokinin release can be stimulated by dietary fat that decreases gastric motility, thereby increasing the contact time between a drug and the intestine that can potentially increase drug absorption.

In some cases, this interaction is used for therapeutic benefit. For example, the antibiotics cefuroxime and erythromycin ethylsuccinate should both be taken with food to maximize their absorption. Conversely, food composition may hinder drug absorption by binding. In such instances, the drug should be administered on an empty stomach (i.e., 1 h before or 2 h after a meal) to allow for maximal absorption. These include protease inhibitors such as indinavir and antibiotics such as ampicillin, ciprofloxacin, and doxycycline. In some instances, the dosage form of the antibiotic will determine if such meal timing is necessary. For example, the azalide antibiotic, azithromycin, if administered in the capsule form with food, exhibits a negative effect in which the bioavailability of the azithromycin is reduced in comparison to its tablet form. This phenomenon is because the capsule form of azithromycin disintegrates more slowly than the tablet in the fed stomach, resulting in more contact time with gastric acid, thus allowing significantly more descladinose azithromycin, an acid degradation product, to form.

Table 4 Examples of anti-infectives whose absorption is altered by food

Drug absorption enhanced by food	*Drug absorption reduced/delayed by food*
Albendazole	Ampicillin
Atazanavir	Azithromycin
Atovaquone	Cefaclor
Cefuroxime	Cefixime
Clarithromycin	Cephalexin
Clofazimine	Ciprofloxacin
Darunavir	Dapsone
Efavirenz	Didanosine
Etravirine	Doxycycline
Erythromycin estolate	Dirithromycin
Erythromycin ethylsuccinate	Erythromycin stearate
Ganciclovir	Famciclovir
Griseofulvin	Indinavir
Hydroxychloroquine	Isoniazid
Itraconazole	Metronidazole
Ivermectin	Nafcillin
Ketoconazole	Nalidixic acid

Drug and Nutrient Transport Systems

Oral drug absorption across the GI tract is highly dependent on its lipophilic properties and its affinity for membrane transporters. Most drugs are absorbed in the small intestine where transport proteins present in the enterocytes facilitate in drug absorption. These transport proteins aid in absorption by increasing the intraluminal uptake of compounds. These transporters also efflux molecules already absorbed in the cytoplasm of the enterocyte back into the intestinal lumen, thus decreasing the bioavailability of some compounds. It is thought to be an intrinsic protective mechanism by the host to minimize xenobiotic exposure. P-glycoprotein (P-gp) is an example of this type of efflux system. P-gp is part of adenosine triphosphate (ATP)-binding cassette (ABC) family of transporters that is an efflux protein widely distributed a variety of tissues, including the blood–brain barrier, intestinal epithelium, liver, and renal tubule. Hepatic transporters are membrane proteins that facilitate nutrient and drug transport into the cell via uptake transporters or pump out toxic entities via canalicular transporters.

Certain foods contain phytochemicals that have the potential to alter drug absorption. Fruits and vegetables are particularly rich in them. Recent studies suggest that phytochemicals can serve as substrates and modulators of specific members of the superfamily of ABC-transporting proteins (i.e., P-gp, MRP1, MRP2, and BCRP). The two most important limiting factors in regulating the oral bioavailability of drugs are CYP3A4 and P-gp. CYP3A4 is thought to be responsible for the metabolism of more than 50% of all medications. Another is the isothiocyanates, a class of chemotherapeutic agents derived from cruciferous vegetables (i.e., broccoli and cabbage) that influence the pharmacokinetics of substrates of these transporters and interact with ABC efflux transporters.

The Relationship between Malnutrition and Pharmacokinetic Parameters

The pharmacological effect of a medication can be modified by an individual's nutritional state. Obesity and undernutrition can alter a medication's pharmacokinetic and pharmacological properties by causing structural alterations in organs that

directly impact drug disposition. Malnutrition can affect the absorption, distribution, metabolism, and elimination of a drug that can ultimately alter its therapeutic or toxic response. Patient-specific variations in the pharmacokinetic responses can further complicate interpreting the true impact of altered nutritional status on drug disposition. This variation can be threefold to over 20-fold, depending on genetic (e.g., genetic polymorphism) and environmental factors and underlying disease. The pathological changes that occur vary with degree of malnutrition, suggesting that the severity of malnutrition can govern the body's response to a particular drug. Even short-term malnutrition can potentially have a negative impact on drug absorption and metabolism, a risk that increases significantly in patients who go without food more than 5 days as a consequence of impaired mucosal integrity. The integrity of the intestinal mucosa is dependent on a continuous intake of adequate nutrition. The turnover of enterocytes in the small intestine takes 2–3 days, while in the colonocyte of the large intestine, it is 3–5 days. Protein–energy malnutrition (PEM) may result in physiological alterations in the absorptive capacity of the GI tract, body fluid status, cardiac output, glomerular filtration rate (GFR), and plasma protein concentrations. Hormonal and metabolic changes may also occur. Malnutrition-associated tissue receptor alterations may alter therapeutic drug levels. Taken together, malnourished patients are at greater risk of developing toxicities due to a drug or its metabolite, with a subsequent risk of morbidity or mortality, making therapeutic drug monitoring and dosage adjustments crucial. Drugs with narrow therapeutic indexes or narrow dose–response curves (i.e., aminoglycosides) are particularly susceptible with even small changes in absorption, resulting in significant changes in blood levels.

Little is known about the handling of drugs in malnourished patients even though the combination of infection and malnutrition is common in many parts of the world. The high morbidity of mortality associated with malnutrition could be due in part by adverse drug reactions.

The risk of antimicrobial resistance may be enhanced in the presence of starvation. Starvation produces stress in the pathogen's host environment that can produce a multitude of adaptive responses that not only protect bacteria from the offending stress but also may change the cell that can impact innate antimicrobial susceptibility. Bacterial susceptibility to a number of antimicrobials may be influenced when the host is malnourished or experiencing a nutrient deficiency. For example, antibiotics tend to kill rapidly replicating bacteria, and in states of starvation or nutrient deficiency, reduced growth and metabolic activity may trigger antimicrobial resistance. One case of nutritional stress is PEM that results in a depletion of amino acid that activates the stringent response. Other nutritional stresses (e.g., iron deficiency, hypophosphatemia, and fatty acids deficiencies) can activate the stringent response-mediated increase in ppGpp influencing bacterial cell physiology and subsequent antimicrobial susceptibility. In times of amino acid deprivation, diminished penicillin susceptibility in *Escherichia coli* relA mutants unable to synthesize ppGpp can occur that are more susceptible to penicillin-dependent lysis. Presumably, plsB is a ppGpp target and ppGpp-dependent inhibition of phospholipid biosynthesis interferes with membrane-associated steps in peptidoglycan biosynthesis, thereby promoting penicillin resistance. Inhibition of cell wall synthesis by ppGpp has been described in other bacteria (i.e., *Streptomyces coelicolor*, *Bacillus subtilis*, and *M. tuberculosis*) where it is also linked to reduced β-lactam susceptibility. Resistance to other antimicrobials is also linked to ppGpp. *E. coli* mutants deficient in ppGpp production are more susceptible to trimethoprim and gentamicin. Conversely, increased ppGpp accumulation in mutant *E. coli* is linked to improved resistance and increased survivability in the presence of fluoroquinolones. Antimicrobials (i.e., mupirocin, vancomycin, and penicillin) have been reported to stimulate ppGpp accumulation, but this has not been associated with any increases in antimicrobial resistance except in the case of *Enterococcus faecalis*, where a mutant strain unable to synthesize ppGpp displayed an increased susceptibility to vancomycin. Similarly, recent evidence illustrates that both ppGpp and the stringent response are linked to resistance to several antimicrobials in nutrient-starved biofilm cells of *P. aeruginosa*. Nutrient-limited planktonic and biofilm cells that are defective in the genes for ppGpp production were shown to be less resistant to antimicrobials than their wild-type counterparts, with ppGpp-deficient biofilm cells presenting with increased susceptibility to several classes of antimicrobials, including aminoglycosides, β-lactams, cationic antimicrobial peptides, and fluoroquinolones. The mechanism of cell lysis is linked to the production of hydroxyl radicals. The stringent response promotes antimicrobial resistance by increasing antioxidant defenses and by limiting 4-hydroxy-2-alkylquinolines synthesis, which serve to enhance the oxidative killing of cells upon contact with an antimicrobial. These findings suggest that starved, nongrowing cells may be at greater risk from oxidative stress/killing, and to avoid it, they adapt, thereby providing protection from the oxidative killing by bactericidal antimicrobials.

Other forms of nutrient starvation can similarly impact the type and severity of antimicrobial resistance. One study of the effects of nutrient deprivation on antibiotic resistance involving *E. coli* demonstrated that phosphate starvation stimulated a transient increase in ofloxacin resistance, while amino acid starvation was associated with transient resistance to both ofloxacin and ampicillin; furthermore, the combination of amino acid and glucose starvation can lead to ampicillin and ofloxacin resistance. Likewise, decreased magnesium intake can also impact antimicrobial susceptibility in a variety of bacteria. For example, in the case of *P. aeruginosa*, there are several reports of PhoQ and pmrB mutations responsible for PXB and colistin resistance. Similarly, in *Salmonella*, the response to magnesium deficiency is mediated by the PhoPQ two-component system, where PhoQ, a sensor kinase, senses the nutrient limitation and activates the PhoP response regulator to upregulate a variety of target genes that ultimately promote adaptation to this nutrient stress.

Impact of Nutritional Status on Pharmacokinetic Properties

Absorption

The limited evidence on the impact of malnutrition on drug absorption is variable. In one case, it was shown that tetracycline absorption was significantly reduced in subjects with

malnutrition and pellagra but not in patients with vitamin B complex deficiency or in those with severe anemia. This contrasts with reports that showed the absorption rate of acetaminophen disposition in children with PEM was not altered in malnutrition.

Distribution

Drugs can distribute into various body compartments such as the extravascular space, intracellular fluids, adipose, and lean body tissue. Shifts in body composition, particularly the presence of edema, can impact the plasma clearance of a drug by changing its volume of distribution (Vd). Once in the systemic circulation, many drugs become bound to plasma proteins, such as albumin, globulins, and lipoproteins. These binding proteins play an important role in the delivery of a medication to its target organ. In the bloodstream, free drug (i.e., not bound to plasma proteins) is able to exert their pharmacological response. The degree of drug–protein binding is contingent on the drug's physicochemical properties and the concentration of plasma binding proteins. In malnutrition, albumin and lipoprotein synthesis is reduced, while globulin and a1-acid glycoprotein synthesis is increased. Medications that are extensively bound to a1-acid glycoprotein (i.e., propranolol) have a decreased percentage of unbound drug in malnourished subjects, resulting in less available active drug to exert a therapeutic response. Other drugs, for example, metronidazole, have no significant change in their volume of distribution (Vd) between malnourished and well-fed states. In the case of parenteral penicillin, the rate of absorption from the muscle mass to the systemic circulation is unchanged in malnourished versus eutrophic individuals as evidenced by no significant differences in the maximum concentration (C_{max}) when the antibiotic was administered intramuscularly. Conversely, in patients with marasmus and kwashiorkor, there was a trend toward a lower Vd for penicillin, suggesting that if the typical dosing strategies are used, the risk of overdose could be a concern.

Metabolism

In chronic starvation, the body adapts or alters various processes to keep or maintain enzyme functions. In fact, enzyme activity may even increase in states of chronic starvation. In the starved state, the conjugation and biotransformation of aromatic compounds are decreased, whereas oxidation remains dominant. Since many hormones serve as substrates for drug-metabolizing enzymes, endocrine tissue is typically affected in semistarvation. For example, in malnourished females, elevations in free cortisol can occur that may enhance the metabolism of contraceptive steroids, thus increasing the risk of contraceptive failure.

Clearance

Hepatic drug clearance may be influenced by an individual's nutritional state. PEM may result in decreased cardiac function with a subsequent reduction in renal and hepatic perfusion. Three independent factors can influence the hepatic clearance: hepatic blood flow, the amount of free drug in the blood, and hepatic clearance of the unbound drug. Drugs with high extraction ratios may experience reduced clearance due to diminished hepatic blood flow. Alterations in presystemic metabolism can occur. Enhanced drug clearance and lower serum drug concentrations can occur in states of hypoalbuminemia due to increased amounts of free drug becoming available for metabolism.

Renal elimination of a drug is closely linked with kidney function. Glomerular filtration, active tubular secretion, and passive tubular excretion are all involved in renal elimination. Nutritional status can impact those medications or their metabolites that are primarily renally filtered and excreted. Increased protein intake can increase the GFR, renal blood flow, and renal tubular function. Conversely, PEM is associated with decreased GFR and renal blood flow. Reduced renal perfusion results in less drug being available to undergo filtration by the tubules. Nevertheless, as plasma protein binding is similarly reduced, more free drug becomes available for renal excretion, thus further reducing plasma drug concentrations. Examples of medications that undergo decreased renal elimination in severely malnourished patients include tetracyclines, aminoglycosides, cefoxitin, and penicillins.

The systemic clearance of a medication can occur when an undernourished patient is refed, requiring that dosage adjustments be performed so as to maintain a therapeutic response. The protein component of enteral or parenteral nutrition (PN) appears to be the major macronutrient that improves the systemic clearance of susceptible drugs in patients transitioned from the 'unfed' to the 'fed' state. For example, the daily maintenance dose of metronidazole for pediatric patients with severe malnutrition should be 60% less of the usual pediatric dose to achieve and maintain adequate therapeutic plasma levels of the drug.

Impact of Kwashiorkor on Pharmacokinetics

The edema that occurs in kwashiorkor is due to increases in total body water, extracellular fluid volume, and plasma volume, with a decrease in intracellular water. Low protein intake results in a negative nitrogen balance that leads to decreased drug metabolism, while adequate intake of total calories but with less than optimal protein intake does not significantly impact drug metabolism.

Drug Therapy in Marasmus

Marasmus, unlike kwashiorkor, is associated with an adaptation to insufficient energy intake. There are decreased total body water and intracellular water, with increased plasma volume and extracellular fluid. In malnourished patients, an increased Vd in gentamicin is observed in comparison with well-nourished patients due to its extensive distribution into the extracellular fluid. In patients treated with metronidazole however, no difference in Vd was noted between malnourished and nutritionally rehabilitated individuals due to its large Vd. One pharmacokinetic study focussing on the role of PEM in quinine metabolism showed that the metabolism of quinine is increased in individuals with PEM, suggesting that the dosing interval should be reduced in order to obtain the same therapeutic quinine concentrations compared those seen in well-nourished patients.

Thus, normal or increased drug metabolism can occur in cases of mild to moderate malnutrition, while decreased metabolism occurs in severe malnutrition. Given the unique needs of ill children with severe acute malnutrition, special guidelines have been developed for the use of antimicrobial agents.

Obesity

Obesity (BMI >95th percentile for age and sex) is linked with physiological changes that can impact the pharmacokinetic parameters of many drugs, but for most medications, dosage recommendations fail to take into account these alterations in body composition in which there are both an increased proportion and absolute amount of adipose tissue and an increase in lean body mass, blood volume, cardiac output, and organ size. In the obese patient, increases in both CYP2E1 activity and phase II conjugation activity have been observed, although there is no difference in albumin binding of drugs. This increase in CYP2E1 activity appears to be downregulated with weight loss. Increased abdominal fat can also impact gastric emptying, which becomes altered by increased intra-abdominal pressure due to excess adipose tissue. Evidence to date suggests that drug absorption is unchanged in obese individuals. As expected, obese patients who have undergone bariatric surgery such as gastric bypass may experience alterations in drug absorption that may affect a drug's therapeutic response. Drug malabsorption is more likely to occur with the primary procedures such as jejunoileal bypass and pancreatobiliary diversion. Other surgical procedures for weight loss, such as the Roux-en-Y gastric bypass, a primary restrictive procedure with mild malabsorptive component, have similar changes in drug absorption and bioavailability that require standard drug doses and administration guidelines to be adjusted. Similarly, little is known on the impact of other procedures, such as gastric banding, on drug pharmacokinetics.

The lipophilicity of a drug determines the extent to which obesity affects the Vd and ultimately whether dosing should be based on actual or adjusted body weight. In severely obese patients, modest increases in Vd have been observed with aminoglycosides and vancomycin. This suggests that dosing of these agents should be done using an adjusted body weight rather than actual body weight to avoid toxicity. Nevertheless, the most accurate approach to adjust for the excess body mass remains unknown and may vary, depending on the characteristics of the individual compounds. Therapeutic drug monitoring is essential to optimize therapy.

The free fraction of basic drugs may be decreased with obesity although the protein binding of acidic drugs appears to be unchanged. Similarly, changes in hepatic drug clearance are variable. In obese subjects, phase I reactions and phase I acetylation appear to be unaffected, but the phase II glucuronidation and sulfation pathways are intensified. Systemic clearance of highly extracted drugs such as aminoglycosides may also be impacted by obesity.

Aminoglycosides are distributed within the extracellular fluid compartment. Early dosage recommendations were based on ideal body weight based on the premise that the drug distributed only into lean body mass. It has since been shown that when the Vd is corrected for total body weight, it is considerably smaller in comparison to normal-weight subjects. The distribution of aminoglycosides into excess body weight is estimated to be about 40% of that distributed into ideal body mass. It is suggested that in obese individuals, initial doses of aminoglycosides be calculated by adding 40% of the excess weight to the patient's ideal body weight, with any further dosage adjustments determined by serum drug concentrations and clinical status. Less is known about other antimicrobials in obesity and dosage adjustments should be done on a case by case basis, depending on initial response.

Effect of Dietary Manipulation on Pharmacokinetics

Modifying the intake of specific foods may impact a drug's therapeutic response (Table 5). Individuals at specific risk to an adverse event due to a drug–nutrient interaction include those with a chronic condition necessitating the need for multiple medications, those requiring specialized nutritional support, or those with some evidence of malnutrition.

Several dietary factors can change the rate and extent of drug absorption. These alternations in response may be the result of the effects on gastric pH, gastric emptying time, intestinal motility, and mesenteric and hepatic portal blood flow or biliary flow or the activities of the enzymes and transport proteins in the gut. The absorption of susceptible agents can be altered by direct physicochemical interactions with dietary components. Solubilization of a drug in dietary fat, binding with metal ions, and adsorption to insoluble dietary components are examples of such interactions.

The activity and expression of hepatic drug-metabolizing enzymes may be altered by dietary modifications. This can lead to changes in the systemic elimination kinetics of drugs metabolized by these enzymes, although the impact of these changes is typically minimal. The rate of drug metabolism can be enhanced by the medications themselves or via a variety of dietary factors, such as inclusion of charcoal-broiled meats or cruciferous vegetables in the diet or protein supplementation. Large intakes of polycyclic aromatic hydrocarbons contained in charcoal-broiled beef are responsible for hepatic enzyme induction. Conversely, levels of drug-metabolizing enzymes can be reduced by high-carbohydrate, low-protein diets and various vitamin and mineral deficiencies, consequently altering the rate of drug metabolism such that the serum drug concentrations decline much more slowly, leading to increased drug potency.

When orally administered drugs are taken with meals, the rate rather than the extent of absorption is more significantly altered. Food affects drug absorption by improving gastric blood flow in conjunction with delayed gastric emptying or by changing its dissolution. The absolute systemic availability of a medication can be increased and decreased, or the presence of food may have no effect on its availability. Simultaneous ingestion with food reduces the absorption of medications such as ampicillin, penicillin, and isoniazid. In some instances, food may enhance the absorption of other drugs, such as griseofulvin. Table 4 lists medications whose absorption is altered by food. In most instances, altering the rate of absorption of a medication alone without changing the total amount absorbed is not expected to impact its efficacy.

Table 5 Effect of nutrients on therapeutic drug response

Nutrient	*Impact on metabolism Decreased or Increased (↓ or ↑)*	*Proposed mechanism*
Macronutrients		
Protein	Deficiency: ↓ rate of metabolism Excess: ↑ rate of metabolism	↓ Protein synthesis ↓ Synthesis of other elements (i.e., hormones) involved in enzyme induction
Carbohydrates	Excess: ↓	May be due to ↓ protein or inhibition of CYP 450 via ↓ in supporting enzyme components
Fats	High intake of saturated fatty acids: ↓ High intake of polyunsaturated fatty acids: ↑ activity and induction of CYP enzymes Deficiency: ↓ Excess: ↑	Decreased CYP activity may be due to requirement of PUFAs in the B-position of phosphatidylcholine (lecithin), which is an essential component of the CYP system
Micronutrients		
Iron	Excess: ↑ microsomal lipid peroxidation Deficiency: ↑↓	↑ Lipid peroxidation may lead to damage to the integrity of the system
Pyridoxine	Deficiency: ↓	Impaired protein synthesis ↓ synthesis of heme
Riboflavin	Deficiency ↑↓ depending on severity	↓ Reductase activity but ↑ CYP450 activity such that drug metabolism may be altered (↑↓)
Thiamine	Excess: ↓ (both reductase and CYP 450) Deficiency: ↑ CYP450 activity	Excess may be due to decreased substrate binding ↑ Activity of specific CYP450 isoenzymes and perhaps other enzymes in deficiency (mechanism unknown)
Ascorbic acid	Deficiency: ↓ Excess: ↑ CYP 450 activity	Alterations in CYP450 and CYP 450 reductase via changes in expression of specific CYP isoenzymes depending on excess or deficiency state
Vitamin E	Deficiency: ↓	May be due to a reduction in antioxidative mechanisms (e.g., protection of the lecithin component; thus, the activities of CYP450 and reductase are unaffected)

Adapted from Raiten, D. J. (2011). Nutrition and pharmacology: general principles and implications for HIV. *American Journal of Clinical Nutrition* 94(6), 1697S–1702S. Epub 2011 November 16.

Meal composition will also alter splanchnic blood flow. A liquid glucose meal can slightly reduce blood flow, whereas a high-protein liquid meal can double it. The importance of this effect on splanchnic flow is significant for those drugs with high hepatic extraction. Continued meal intake, especially with foods with high fat content, will also slow the rate gastric emptying, which may subsequently cause a delay in drug absorption from the GI tract. The type of meal may impact gastric emptying due to the physicochemical properties of the drug. Highly viscous solutions, those rich in fat, or simply hot meals have the most significant impact on decreasing gut motility. Food has been shown to enhance the presystemic clearance of lipophilic basic drugs (e.g., amitriptyline and propranolol) but rarely alter the clearance of lipophilic acids drugs (e.g., salicylic acid and penicillin). On the other hand, food may decrease the presystemic clearance of some lipophilic basic drugs via transient, complex effects on splanchnic–hepatic blood flow. Furthermore, repeated intake of specific food contaminants (e.g., aromatic hydrocarbons) and nutrients (e.g., protein) can enhance presystemic drug clearance via enzyme induction.

Role of Specific Nutrients in Pharmacokinetics

Until recently, the perception that dietary substances could significantly alter drug response by disturbing intestinal transporter and metabolizing enzymes was viewed as immaterial. This was believed to be due to the misconception that drug absorption was a passive process and the intestine had no significant role in drug elimination. With the subsequent reports of the interaction between grapefruit juice and several medications, this commonly held belief has changed, and the importance of the diet on drug performance has been reassessed.

Carbohydrates

There evidence on the importance of carbohydrates on drug metabolism is conflicting. It is known that diets rich in carbohydrates may induce the expression of several glycolytic and lipogenic hepatic enzymes. Some suggest, however, that carbohydrates have little impact on drug metabolism. In animal models, dietary carbohydrates and fat have been shown to significantly influence hepatic drug-metabolizing enzymes. These changes may occur due to an alteration in the phospholipid composition of endoplasmic reticulum or by limiting the supply of cofactor(s) necessary for optimal functioning of CYP and UGT.

Protein

After ingesting a high-protein meal, medications that undergo extensive first-pass effect may have enhanced bioavailability due to increased hepatic blood flow. High-extraction drugs can rapidly pass through the liver, allowing higher drug concentrations in the systemic circulation. Reductions in dietary protein decrease creatinine clearance and renal plasma flow. In situations where there is low protein intake, care is needed to avoid toxicity secondary to delayed drug clearance. Specific dietary proteins may also impact medication response. A classic example is the interaction between the monoamine oxidase inhibitors (MAOIs) and the amino acid tyramine that is present

in aged cheeses, pickled/smoked meats, fermented foods, and red wines. Tyramine is an indirect sympathomimetic amine that releases norepinephrine from the adrenergic neurons, resulting in a significant hypertensive response. Normally, tyramine is metabolized by the enzyme monoamine oxidase before any significant pressor response occurs. When the enzyme becomes blocked, however, severe and potentially fatal increases in blood pressure can ensue when tyramine-rich foods are ingested. Although MAOIs are not used routinely as antidepressants, other drugs, such as isoniazid and linezolid, also possess MAOI properties, and patients should avoid ingesting large amounts of tyramine while being treated with them.

The renal tubular transport of certain compounds by dietary can also be affected by dietary protein. Dietary proteins bind to a drug that accentuates changes in bioavailability after a protein meal. For example, ciprofloxacin, when taken with milk or other dairy product, not only undergoes complexation with calcium but also adsorbs to the surface of proteins, which decreases the absorbable amount of ciprofloxacin and may increase the risk of treatment failure or resistance. It is thought that the casein component present in milk has a more pronounced effect on the amount of absorbable ciprofloxacin.

Dietary Fat

Lipids are an essential part of cell membrane structure and are involved in many of its normal enzymatic activities. Essential fatty acid deficiency or low-fat diets decrease the activity of the enzyme systems responsible for nutrient metabolism. After consumption of a high-fat meal, plasma free fatty acid levels rise, increasing the potential to become bound to plasma albumin and consequently displacing albumin bound drugs, making the risk for toxicity greater. Dietary fats along with food-stimulated secretions (e.g., bile salts) may aid in the solubilization and dispersion of lipophilic compounds. This leads to a reduction in the extent of first-pass metabolism due to improved splanchnic blood flow. High-fat diets are linked with the induction of CYP2E1. The extent this enzyme is upregulated is governed by the type of fat. Polyunsaturated fats (PUFAs) such as soybean and fish oils appear to have the greatest influence in comparison to lard or olive oils. This can result in enhanced peroxidation of the PUFA substrates and aid in free radical production. The fat content of a meal can also influence the rate of gastric emptying. Fat delays gastric emptying to a greater extent than either protein or carbohydrate.

The effect of dietary fat on drug absorption depends upon the area of the drug absorption, either portal or lymphatic. For drugs absorbed via the lymphatic system, dietary fat improves the absorption of the dissolved medications, while poorly bioavailable lipophilic drugs absorbed by the portal route (thus bypassing the lymphatic system) have their absorption enhanced by better drug dissolution. Conversely, lipophilic medications having good bioavailability will less likely to be altered by a high-fat meal. The absorption of hydrophilic medications does not appear to be influenced by fatty meals.

Fruits and Vegetables

Diets rich in fruits and vegetables may also impact drug response. Many plants contain flavonoids, isothiocyanates, and allyl sulfides that are potent modulators of the cytochrome monooxygenase system. Fruits and vegetables serve as sources of trace minerals that are contained in metalloenzymes, including several antioxidants that can influence a variety of enzymatic pathways. Cruciferous vegetables, citrus juices, spices, dietary supplements, and herbs contain phytochemicals that modulate of a variety of metabolic pathways. There are five major families of phytochemicals: alkaloids, carotenoids, nitrogen compounds, phenolics, and sulfur compounds. Typically, induction of these enzyme systems is rapid and plateaus within 5 days of continued daily ingestion of the food possessing the enzyme-inducing capacity.

Minerals

Mineral deficiencies (i.e., iodine, magnesium, potassium, and zinc) have been linked with a decrease in drug oxidation and drug clearance. Although not well understood, low dietary iron intake has been associated with an increase in some CYP activities and a decrease in other degradative functions. Foods fortified with calcium or other multivalent minerals present a new challenge. For example, any drug carrying a warning to avoid milk, dairy products, or nutritional supplements can be affected by calcium-fortified orange juice. Antibiotics are the most susceptible drug class to undergo chelation and adsorption by fortified cereals, calcium-fortified orange juice, or protein supplements. Patients need to be counseled that consuming fortified foods with susceptible antibiotics may decrease their therapeutic response, thereby increasing the risk of treatment failure.

Other Dietary Restrictions

In addition to caloric restriction, restriction of other dietary components can also influence drug response. For example, patients receiving aminoglycosides, amphotericin B, cisplatin, or radiocontrast media in conjunction with a low-sodium diet have an increased risk for hemodynamic, nephrotoxic, and ischemic acute renal failure.

Effect of Beverage Type on Drug Bioavailability

Any drinkable liquid other than plain water is commonly referred to as a 'beverage.' They are classified as alcoholic, caffeinated, fruit/vegetables juices, milk-based, or mineral waters. Depending upon the type of fluid ingested, drug absorption may be impacted. When a medication is mixed with fruit juice or other beverages to mask their taste, its absorption may be altered due to changes in gastric pH, which in turn can affect dissolution of solid dosage forms and formulations with a pH-sensitive coating. Dairy products decrease the absorption of tetracyclines and reduce their bioavailability due to the formation of insoluble chelates between the drug and the calcium present in the beverage. Soft drinks may decrease drug absorption for a number of reasons. These carbonated drinks contain phosphoric acid and that can slow gastric emptying and the tendency to serve them chilled may further reduce the rate of intestinal blood flow. Additionally, carbonation may increase mixing and possibly motility. Acidic beverages improve dissolution of tablets and capsules and thus can improve and stabilize oral bioavailability. If a drug is one

Table 6 Examples of anti-infective-nutrient interactions

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Antibiotics			
General	Gut microflora decreases vitamin K synthesis; antibiotic depletion of gut microflora can also lead to dysbiosis that can alter the digestion and absorption of nutrients	N/V/D Lactase deficiency	
Aminoglycosides	↑ Urinary excretion of potassium and magnesium May also ↓ sodium and calcium	↓ Appetite N/V Increased salivation	
Amoxicillin Amoxicillin/clavulanic acid		N/V/D Incidence of diarrhea higher with amoxicillin/clavulanic acid versus amoxicillin alone	Take with food to reduce GI upset
Cephalosporins	Possible nephrotoxicity with vitamin K deficiency	V/D GI mucosa damage	
Chloramphenicol	Decreased protein synthesis; increased need for cyanocobalamin, pyridoxine, riboflavin	V/D Stomatitis Enterocolitis Glossitis	Take on an empty stomach
Clindamycin		N/V/D Esophagitis Pseudomembranous colitis	Take with a full glass of water to avoid esophageal irritation
Fluoroquinolones Ciprofloxacin Gemifloxacin Levofloxacin Norfloxacin	Ciprofloxacin: food decreases rate, but not extent, of absorption. Enteral feedings may decrease plasma concentrations of ciprofloxacin probably by >30% inhibition of absorption Ciprofloxacin should not be administered with enteral feedings. The feeding should be discontinued for 1–2 h prior to and after ciprofloxacin administration. Nasogastric administration produces a greater loss of ciprofloxacin bioavailability than does nasoduodenal administration Gemifloxacin: may take tablets with or without food, milk, or calcium supplements Moxifloxacin: may be taken without regard to meals Norfloxacin: best taken on an empty stomach with water (1 h before or 2 h after meals, milk, or other dairy products) Ofloxacin: average peak serum concentrations may be ↓ if taken with food	N/V/D Abdominal pain ↑ Serum transaminases ↑ Gamma-glutamyl transferase	May administer with food to minimize GI upset Avoid or take ciprofloxacin 2 h before or 6 h after antacids, dairy products, or calcium-fortified juices alone or in a meal containing >800 mg calcium, oral multivitamins, or mineral supplements containing divalent and/or trivalent cations Ensure adequate hydration during therapy Gemifloxacin: should be taken 3 h before or 2 h after supplements (including multivitamins) containing iron, zinc, or magnesium Moxifloxacin: may be taken without regard to meals. Take 4 h before or 8 h after multiple vitamins, antacids, or other products containing iron, zinc, magnesium, or aluminum Norfloxacin: hold antacids, sucralfate, or multivitamins/supplements containing iron, zinc, magnesium, or aluminum for 2 h after giving dose; do not administer together. Best taken on an empty stomach with water Ofloxacin: do not take within 2 h of food or any antacids, which contain zinc, magnesium, or aluminum
Linezolid	Concurrent use with foods or beverages containing large quantities of tyramine may result in a significant hypertensive response	N/D Dyspepsia Oral moniliasis Tongue discoloration Localized abdominal pain Constipation Pseudomembranous colitis	Patients receiving linezolid and tyramine-containing foods or beverages should be monitored for significant blood pressure increases. Avoid foods containing large amounts of tyramine (<100 mg per meal) including aged cheese, sour cream, red wine

(*Continued*)

Table 6 (Continued)

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Macrolides Azithromycin Clarithromycin Erythromycin Lincomycin	Rate and extent of GI absorption may be altered depending upon the formulation Azithromycin: food does not affect bioavailability of the tablet formulation, immediate release oral suspension, or the 1 g suspension regimen; however, extended release suspension ↑ absorption when given with a high-fat meal Clarithromycin: food delays rate, but not extent of absorption; extended release, food ↑ clarithromycin AUC by ~30% relative to fasting conditions Erythromycin: serum levels may be altered if taken with food (formulation-dependent)	Abdominal pain Cramping N/V/D Stomatitis Dyspepsia	Do not crush enteric coated or delayed release products Azithromycin: immediate release suspension and tablet may be taken without regard to food; extended release suspension should be taken on an empty stomach (at least 1 h before or 2 h following a meal) Clarithromycin: immediate release tablets and oral suspension may be given with or without meals and may be taken with milk. Extended release tablets should be taken with food Erythromycin: avoid milk and acidic beverages 1 h before or after a dose; administer after food to decrease GI discomfort
Metronidazole	Food decreases peak drug concentration	N/V/D Metallic taste Xerostomia Furry tongue	Disulfiram reaction with alcohol
Neomycin	↓ Absorption of fat, MCT, vitamins A,D,K, B12, sodium, glucose, lactose, sucrose, xylose; may also deplete beta-carotene, calcium, iron, magnesium, potassium	N/V/D Colitis Cadidiasis Inactivation of bile salts GI mucosal damage ↓ activity of disaccharidases Lipase inhibition	
Penicillins	↑ Urinary potassium excretion May inactivate B6 Food ↓ drug absorption	Decreased appetite diarrhea	Administer with water on an empty stomach (1 h before or 2 h after meals); may take with food to ↓ GI upset
Quinolones	Dairy foods, mineral supplements, calcium-fortified juices ↓ drug concentrations; may ↑ caffeine concentrations	N/V/D GI bleeding Abdominal pain Anorexia Pseudomembranous colitis Dyspepsia	Administer 2 h after meals, may take with food to ↓ GI upset
Sulfonamides	↓ Synthesis of folic acid, B vitamins, vitamin K; ↓ iron absorption; ↑ urinary excretion of vitamin C; presence of food delays but does not ↓ absorption	↓ Appetite N/V Stomatitis Pseudomembranous colitis Abdominal pain	Avoid large amounts of vitamin C or acidifying agents (cranberry juice) to prevent crystalluria
Tetracyclines	Chelate divalent ions; ↓ absorption of calcium, iron, zinc, magnesium, amino acids; ↑ urinary excretion of vitamin C; absorption of tetracycline Hydrochloride ↓ by 50% when taken with milk/dairy products	N/V/D Anorexia Stomatitis Glossitis Pseudomembranous colitis Esophagitis Candidiasis	Take on empty stomach 1 h before/2 h after dose; avoid milk/dairy products, polyvalent ions with 2–3 h of dose Doxycycline and minocycline may be given without regard to meals but best to avoid concurrent administration with milk/dairy products
Trimethoprim	↓ Folate concentrations	N/V Epigastric distress	Leucovorin may be given until normal hematopoiesis is restored
Antifungals			
Amphotericin B	Possible nephrotoxicity with ↑ urinary excretion of potassium and magnesium	↓ Appetite N/V Steatorrhea/diarrhea with oral formulation	Monitor potassium, magnesium/supplement as needed

(*Continued*)

Table 6 (Continued)

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Caspofungin		N/V/D Abdominal pain Anorexia Mucosal inflammation	
Fluconazole	Food delays time of peak absorption but has no effect on total amount of drug absorbed	N/V/D Abdominal pain	
Flucytosine	Food ↓ rate but not extent of absorption; magnesium or aluminum salts delay rate of absorption	N/V/D Enterocolitis	May take with food
Griseofulvin	High-fat foods ↑ absorption rate	N/V/D Oral thrush	Give with fatty meals to ↑ absorption as well as avoid GI upset
Itraconazole	Food ↑ absorption of capsule formulation; hypochlorhydria may ↓ Absorption Grapefruit juice ↓ AUC by 30% Absorption ↑ when taken with a cola beverage	N/V/D Abdominal pain Anorexia	Take capsules with food Take oral solution on an empty stomach
Ketoconazole	Food ↑ rate and extent of absorption Administration with an acidic beverage (cola and citrus juice) enhances absorption	N/V/D Abdominal discomfort GI bleeding	Take with food to ↓ GI upset
Micafungin		N/V/D Mucosal inflammation Constipation Anorexia/dyspepsia	
Posaconazole	Adequate posaconazole absorption from GI tract and subsequent plasma concentrations are dependent on food for efficacy	N/V/D Anorexia Abdominal pain Constipation Dyspepsia	Must be administered during or within 20 min of a full meal or oral liquid nutritional supplement or may be given with an acidic carbonated beverage
Voriconazole	High-fat meals ↓ extent of absorption	N/V Anorexia Constipation Abdominal pain	Take 1 h before or 1 h after meals
Anthelmintics			
Albendazole	Bioavailability increased when taken with a fatty meal	N/V Abdominal pain	
Ivermectin	Bioavailability ↑ 2.5-fold when administered following a high-fat meal	N/D	Take on an empty stomach with water
Mebendazole	Food ↑ drug absorption	N/V/D Abdominal pain	Administer with food
Antimalarials			
Artemether and lumefantrine		N/V Abdominal pain Anorexia	Administer with a full meal for best absorption. Patients should be encouraged to take with a meal as soon as food can be tolerated. Patients who remain averse to food during treatment should be closely monitored as the risk of recrudescence increases
Chloroquine phosphate		N/V/D Anorexia Stomatitis Weight loss	Take with food to ↓ GI upset Bitter taste may be masked by mixing with chocolate syrup
Hydroxychloroquine	Food ↑ bioavailability	N/V/D Anorexia Abdominal cramps	Take with food to ↓ GI upset
Primaquine phosphate		N/V Abdominal cramps anorexia	Take with food to ↓ GI upset Drug has bitter taste

(*Continued*)

Table 6 (Continued)

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Pyrimethamine	↓ Serum folate concentrations	Anorexia Abdominal cramps V/D Atrophic glossitis	Take with meals to ↓ GI upset Leucovorin may be given until normal hematopoiesis is restored
Sulfadoxine Pyrimethamine	↓ Serum folate concentrations	Anorexia Gastritis Glossitis V/D	Take with meals; leucovorin may be given until normal hematopoiesis is restored
Antiprotozoals			
Atovaquone	Food ↑ bioavailability	N/V/D Abdominal pain Constipation Anorexia	Patients who cannot take with meals or have chronic diarrhea or GI problems at risk for drug malabsorption and treatment failure
Nitazoxanide	Food ↑ AUC	N/V/D Abdominal pain	Administer with food
Antiretrovirals			
Protease inhibitors			
Amprenavir	High-fat meals may ↓ AUC; product contains vitamin E to improve bioavailability; may increase risk of bleeding if Vitamin K deficient or on concomitant anticoagulant therapy	N/V/D Taste disorders	Fat redistribution and accumulation have been reported
Atazanavir	Bioavailability ↑ when taken with food	N/V/D	Administer with food; may cause redistribution of fat (e.g., buffalo hump, peripheral wasting with increased abdominal girth, and cushingoid appearance)
Darunavir	Absorption increased with food Take with meals	N/V/D Pancreatitis Abdominal pain ↓ Appetite ↑ Serum lipase ↑ ALT ↑ AST Abdominal distention Dyspepsia	Coadministration with ritonavir and food is required (bioavailability is increased) May cause redistribution of fat (e.g., buffalo hump, peripheral wasting with increased abdominal girth, and cushingoid appearance)
Fosamprenavir	Tablets may be taken with or without food. Adults should take oral suspension without food; however, children should take oral suspension with food	N/V/D Abdominal pain May cause transaminase elevations, hepatitis, and/or exacerbate preexisting hepatic dysfunction	Take tablets with food if taken with ritonavir. May be administered without regard to food if not taken with ritonavir Adults should take oral suspension *without* food; however, children should take oral suspension *with* food May cause redistribution of fat (e.g., buffalo hump and peripheral wasting with increased abdominal girth)
Indinavir	↓ Absorption when given with high amounts of protein or fatty foods; grapefruit juice ↓ AUC by 26%	N/V/D Abdominal pain Metallic taste	Ensure adequate hydration; take on empty stomach; if GI upset a problem, take with light meals or other liquids
Lopinavir Ritonavir	Solution should be taken with food Tablet may be taken with or without food	N/V/D Abdominal pain Altered taste Weight loss	Solution: administer with food; if using didanosine, take didanosine 1 h before or 2 h after lopinavir/ritonavir Tablet: may be taken with or without food. Swallow whole, do not break, crush, or chew. May be taken with didanosine when taken without food
Nelfinavir	Food ↑ absorption	N/V/D Abdominal pain anorexia Dyspepsia Epigastric pain Mouth ulceration GI bleeding Pancreatitis	Do not administer with acidic foods or juices (results in bitter taste)

(*Continued*)

Table 6 (Continued)

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Ritonavir	Food ↑ absorption May cause avitaminosis	N/V/D Taste perversion Abdominal pain Pancreatitis	Administer with food to ↑ Absorption; liquid formulations taste unpleasant, reserve use for tube-fed patients, or mix with chocolate milk or nutritional supplement
Saquinavir	High-fat meals maximize bioavailability Grapefruit juice ↑ saquinavir levels	N/V/D Abdominal discomfort Stomatitis	Take within 2 h of a full meal; high-calorie/high-fat meals ↑ AUC and C_{max} more than low-cal/low-fat meals
Tipranavir	Coadministration with ritonavir is required Administer with ritonavir capsules or solution without regard to meals; administer with ritonavir tablets with meals	N/V/D Abdominal pain Weight loss Dehydration Taste perversion	May cause redistribution of fat (e.g., buffalo hump, peripheral wasting with increased abdominal girth, and cushingoid appearance) May cause facial wasting Capsule contains dehydrated ethanol. Oral solution formulation contains vitamin E; additional vitamin E supplements should be avoided
Nucleoside analog reverse transcriptase inhibitor (NRTI)			
Abacavir	Food does not affect AUC	N/V/D Anorexia Pancreatitis	Fat redistribution and accumulation have been reported
Didanosine	May alter GI absorption of various nutrients due to prolonged GI transient time Food may ↓ oral bioavailability by 50%	N/V Constipation Xerostomia Dry throat Dysphagia	Buffered powder for oral solution is inactivated in acidic juices/fluids
Emtricitabine	May be administered with or without food	N/V/D Abdominal discomfort Gastroenteritis	May cause redistribution of fat
Lamivudine	Food may ↓ rate of absorption and peak serum concentrations, but does not significantly change the AUC	N/V/D Feeding problems Abdominal discomfort Pancreatitis Anorexia Stomatitis	May cause fat redistribution and accumulation
Stavudine	Food ↓ peak serum concentrations by 45%, bioavailability not changed	N/V/D Abdominal pain Anorexia Pancreatitis	Take without regard to food
Tenofovir disoproxil	High-fat meals ↑ oral bioavailability	N/V/D Flatulence Anorexia Pancreatitis	Administer with meals to improve absorption
Zalcitabine	Food ↓ rate and extent of absorption; AUC ↓ by 14%	N/V/D Oral/esophageal ulcers Dysphagia Anorexia Abdominal pain Constipation Pancreatitis Weight loss Anemia	Take on empty stomach
Zidovudine	Folate/B12 deficiency ↑ zidovudine-associated myelosuppression; rate of absorption and peak serum concentration may ↓ when taken with food	N/V/D Anorexia	May take with food; take capsules while in upright position to ↓ risk of esophageal ulceration; syrup is strawberry-flavored

(*Continued*)

Table 6 (Continued)

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Nonnucleoside reverse transcriptase inhibitor (NNRTI)			
Delavirdine	Patients with achlorhydria should take the drug with an acidic beverage	N/V/D Abdominal pain	May be taken without regard to meals Patients with achlorhydria should take the drug with an acidic beverage 200 mg tablets should be taken intact May cause fat redistribution and accumulation
Efavirenz	High-fat/high-calorie meals ↑ AUC and peak concentration and may ↑ adverse effects	N/V/D Abdominal pain	Take with water on an empty stomach preferred, tastes peppery (grape jelly may be used to improve taste) Tablets should not be broken. Some clinicians recommend opening capsules and adding to liquid or food for patients that cannot swallow capsules; however, no pharmacokinetic data are available and this is not recommended
Etravirine	Food ↑ absorption by ∼50%	N/D	Central redistribution of body fat Take after meals. May disperse tablets in glass of water; stir well prior to drinking and rinse glass several times to ensure administration of complete dose
Nevirapine	Can be given without regard to food	N/V/D Abdominal pain	Central redistribution of body fat Extended release tablets must be swallowed whole and not crushed, chewed, or divided
Rilpivirine	Administer with a normal- to high-calorie meal. Absorption ↑ by ∼40% when taken with a normal to high-calorie meal. Administration with a protein supplement drink alone does not ↑ absorption	Abdominal discomfort/pain Appetite ↓ N/V/D	May cause redistribution of fat
Entry inhibitor (fusion inhibitors)			
Enfuvirtide		D/N Weight loss Abdominal pain Appetite ↓ Pancreatitis Anorexia Xerostomia	
Maraviroc	Absorption ↓ with ingestion of a high-fat meal; however, can be given with or without food	Abdominal pain Altered appetite Constipation	
Integrase inhibitor			
Raltegravir	May be administered without regard to meals; however, clinically insignificant variability in absorption exists depending on meal type	N/D	May be taken without regard to meals. Some products may contain phenylalanine
Dolutegravir	May be administered without regard to meals Food increases the extent of absorption and slowed the rate of absorption Low-, moderate-, and high-fat meals increased dolutegravir AUC by 33%, 41%, and 66%, respectively; increased C_{max} by 46%, 52%, and 67%, respectively; and prolonged T_{max} to 3, 4, and 5 h from 2 h under fasted conditions, respectively	N/D Abdominal pain ↑ Liver function Tests Hyperglycemia	May be taken with or without food. Take 2 h before or 6 h after cation-containing antacids or laxatives, oral supplements containing iron or calcium, or buffered medications Alternatively, dolutegravir and supplements containing calcium or iron can be taken together with food Zinc salts may decrease the serum concentration of dolutegravir May cause redistribution of fat (e.g., buffalo hump, peripheral wasting with increased abdominal girth, and cushingoid appearance) Increased liver function Tests

(*Continued*)

Table 6 (Continued)

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Elvitegravir/cobicistat, emtricitabine/tenofovir		N/D ↑ AST	Administer with food Consider calcium and vitamin D supplementation in patients with history of bone fracture or osteopenia May cause redistribution of fat (e.g., buffalo hump, peripheral wasting with increased abdominal girth, and cushingoid appearance) May cause osteomalacia with proximal renal tubulopathy
Antitubercular agents			
Cycloserine	B6 antagonist; ↓ absorption of calcium, magnesium, vitamin B12; decreased folate utilization and vitamin K synthesis; may ↑ B12 and folate requirements		Some neurotoxic effects may be prevented or lessened by pyridoxine supplementation. May administer without regard to meals
Ethambutol	May ↓ copper and zinc	N/V Abdominal pain Anorexia	Take with food to ↓ GI upset
Ethionamide	Neurotoxic effects may be prevented or relieved by the coadministration of pyridoxine	N/V/D Abdominal pain Anorexia Excessive salivation Metallic taste Stomatitis Weight loss	May be taken with or without meals
Rifabutin	High-fat meal may ↓ the rate but not extent of drug absorption	N/V/D Anorexia Dyspepsia Abdominal pain Dysgeusia Flatulence	Take with food to ↓ GI upset
Rifampin	Food may ↓ or delay amount of drug absorbed	N/V/D Anorexia Stomatitis	Take on empty stomach
Antivirals			
Acyclovir	Food does not appear to impact absorption	N/V/D	May administer with food
Amantadine		N/V/D Xerostomia Anorexia Constipation	
Cidofovir		N/V/D Anorexia	
Famciclovir	Rate of absorption and/or conversion to penciclovir and peak concentration is ↓ with food, bioavailability not affected	N/V/D Constipation Anorexia Abdominal pain	May take with food to ↓ GI upset
Ganciclovir	High-fat meal ↑ AUC	N/V/D Pancreatitis	Administer with food; do not open capsules or crush tablets
Oseltamivir	May be administered without regard to meals; take with food to improve tolerance	N/V/D Pseudomembranous colitis	Administer with food to ↓ GI upset Capsules may be opened and mixed with sweetened liquid (e.g., chocolate syrup)
Valacyclovir	May administer with or without food	N/V/D Abdominal pain	May be taken with or without food. Administer with food to ↓ GI upset
Valganciclovir	Coadministration with a high-fat meal ↑ AUC by 30%	N/V/D Abdominal pain Constipation Dyspepsia ↓ Appetite	Take with food

(*Continued*)

Table 6 (Continued)

	Nutritional considerations	*Possible gastrointestinal side effects*	*Comments/recommendations*
Miscellaneous anti-infective agents			
Clofazimine	Food ↑ extent of absorption	N/V/D Abdominal pain Constipation Bowel obstruction GI bleeding Dysgeusia	Administer with meals/milk to maximize absorption
Furazolidone	Large doses or prolonged therapy ↑ risk of hypertensive effects if taken with tyramine-containing foods	N/V/D	Avoid tyramine-containing foods
Methenamine	Foods/diets that alkalinize urine pH >5.5 ↓ activity of methenamine; cranberry juice can be used to acidify urine and ↑ activity of methenamine	N/V/D Abdominal cramping anorexia Stomatitis	Administer with food
Nalidixic Acid	Food delays absorption	N/V/D Abdominal pain	
Nitrofurantoin	Food ↑ total amount absorbed Cranberry juice or other urine acidifiers enhance drug action	N/V Anorexia Pancreatitis	Administer with food or milk
Pentamidine		N/V/D Metallic taste Pancreatitis Anorexia Dyspepsia Xerostomia	

Adapted from Gura, K. M. (2013). Drug-nutrient interactions. In: Sonneville, K. and Duggan, C. (eds.) Manual of pediatric nutrition (5th edn.). Shelton, CT: People's Medical Publishing House.

that is poorly soluble at higher pH, dissolution of the tablet or capsule form in an acidic beverage can improve and stabilize its oral bioavailability. For example, the acidic pH of cola beverages can be used therapeutically to optimize the clinical responses of orally administered ketoconazole and itraconazole in patients with gastric hypochlorhydria, such as those patients with AIDS gastropathy.

Parenteral Nutrition

Mucosal atrophy due to lack of oral nutrient intake during PN can also lead to a reduction in gastric biliary, pancreatic, and intestinal secretions. As a result of the progressive decline in intestinal function due to impaired motility and depressed enzyme activity, bacterial overgrowth can occur. This may alter both the rate and the extent of absorption of various drugs as well as specific nutrients such as chloramphenicol, chloroquine, tetracycline, and rifampin and nutrients including fat, iron, peptides, and vitamins A and B12.

Examples of Drug–Nutrient Interactions in Specific Infectious Disease States

Human Immunodeficiency Virus

Patients infected by human immunodeficiency virus (HIV) are likely to develop nutritional deficiencies secondary to drug–nutrient interactions. The relationship between nutrition and antiretroviral therapies (ARTs) has been an important factor in the effectiveness of these agents in the prevention and treatment of HIV and its complications. It was noted that certain foods such as garlic and African potato altered the bioavailability of ARTs and that complementary and alternative 'traditional' medicines also impacted the efficacy of ARTs and patient compliance. Table 6 lists the common drug–nutrient interactions seen with ARTs.

Nutrient utilization can be affected by ARTs. Protease inhibitors, such as ritonavir and nelfinavir, can disrupt lipid metabolism, resulting in hypertriglyceridemia and hypercholesterolemia. In other cases, protease inhibitors have been linked with alterations in carbohydrate metabolism, leading to insulin resistance. Interestingly, kwashiorkor can be precipitated with the initiation of ARTs in HIV-infected children with preexisting marasmus. There are several potential mechanisms. First, it is thought that some immune competence is necessary to develop the edema seen with kwashiorkor. Second, the immune reconstitution inflammatory syndrome may occur after ART is initiated. Third, the edema that ensues may be the result of the refeeding syndrome caused by ART-associated appetite stimulation. It may also be simply a manifestation of ART toxicity in severely malnourished children. Regardless, current guidelines recommend initial therapeutic feedings for HIV-infected children with severe malnutrition, followed by 50–100% increased energy intake for the first 6–10 weeks of ART.

Macronutrients can also impact the bioavailability of many ARTs. Dietary fat can alter the absorption of the antiviral agent

zidovudine. When orally administered with a high-fat meal, its absorption is reduced in comparison when the drug is taken on an empty stomach. It is recommended that zidovudine be taken in the fasted state to achieve peak serum concentrations and minimize the risk of treatment failure.

Tuberculosis

Tuberculosis (TB) is one of the leading causes of death due to infection. Strict patient compliance to medication regimens and minimizing any drug–nutrient, drug–food interactions are necessary. Failure to do so can result in disease relapse, treatment failure, and the development of drug-resistant TB. GI side effects that accompany these multidrug regimens in the initial weeks of therapy (e.g., anorexia, nausea, vomiting, and abdominal pain) are a frequent cause for noncompliance. It is recommended that these medications best be taken with meals if GI intolerance persists. This practice is not without concern, however. The bioavailability of both rifampin and isoniazid is decreased when taken with food and may lead to treatment failure. High-fat meals can reduce the C_{max} and area under the curve (AUC) of isoniazid 69% and 43%, respectively. Similarly, the absorption of rifampin is reduced when taken with food, with the mean C_{max} and AUC reduced to 29% and 16%, respectively. Ethambutol, ethionamide, and pyrazinamide are less likely to be impacted by the presence of food. The time for absorption of second-line antitubercular agent cycloserine/terizidone can be delayed by 3.5 times along with a 35% reduction in maximum blood concentrations when taken with food. Conversely, food can enhance the absorption of clofazimine and para-aminosalicylic acid.

Isoniazid, in addition to having food alter its bioavailability, can also interact with foods that have high histamine and/or tyramine content (i.e., scombroid fish, cheeses, or red wine). Isoniazid indirectly inhibits the metabolism of tyramine and histamine and may predispose patients to tyramine intoxication (e.g., hypertension) or histamine poisoning (e.g., headache, palpitations, and sweating).

Conclusion

The pharmacokinetic and pharmacodynamic responses a patient may experience to a medication vary widely based on age, gender, culture, genetic makeups, and economic status. Those responses that are influenced by a component of individuals' diet or their underlying nutritional state will add an additional layer of complexity. Even within the same individual, seasonal variations will occur that impact dietary habits and ultimately drug-related effects. Although each factor may be minor alone, a much greater synergistic effect could result when combined with other dietary, environmental, or genetic factors. By limiting medication use to as short a period of time as necessary and by periodically reassessing the pharmaceutical care plan, one can potentially reduce the risk of such complications.

Antibiotics and Drugs: Residue Determination

A Gentili, L Mainero Rocca, F Caretti, and S Bellante, 'Sapienza' University of Rome, Rome, Italy

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Animal husbandry on a large scale has stimulated the production of drugs designed to treat diseases and to prevent their spread among animals confined in a restricted area. Only in the United States, the demand for animal health products is expected to rise 3.5% annually to almost 13 billion dollars in 2016. Antibacterials cover the larger segment of this market, but a considerable sector is also related to the volume of parasiticides consumed in the modern farming practices. Detailed data from the Department for Environment, Food and Rural Affairs of the United Kingdom indicate that the five categories of veterinary products most sold in this country in 2009 were antimicrobials (402 tons) and coccidiostats (234 tons), followed by antifungals (8 tons) and antiprotozoals (3 tons), while no sale figure is available for anti-inflammatory drugs.

Most used veterinary medicines are listed in Table 1 together with generalities, treatment details, and physicochemical properties. Besides their therapeutic, metaphylactic, and prophylactic purposes, veterinary drugs are used to control reproduction, to relieve stress, and to promote growth. Animals may be treated individually, but it is often more efficient to treat entire groups, especially in the case of poultry and fish, by medicating feed or water. The occurrence of unwanted residues in foodstuffs can be caused by either an illegal use of banned substances (group A compounds) or an inadequate withdrawal time of the authorized ones (group B compounds). The risk these chemicals pose for the public health is related to the adverse effects of the parent drug and its metabolites, which can induce subacute reactions and chronic symptoms like immunodepression, teratogenicity, mutagenicity, and carcinogenicity. Nevertheless, the antibiotic resistance is the problem of major concern because some pathogenic bacteria have become resistant to several antibiotics currently used in human medicine. This phenomenon has been associated with the selection of resistant forms in intestines of animals continuously treated with subtherapeutic doses of antibacterials. In order to reduce the consumption of antibiotics in animals by 30–50%, the EU has banned their use as growth promoters since 2006, whereas the United States and other countries have kept unchanged this kind of employment.

The regulatory agencies of many countries have introduced restrictive food-control measures to ensure a high level of safety for consumers. In this regard, the European Union (EU) has pursued a very severe policy, and among the actions taken to minimize the occurrence of drug residues in foodstuffs are the strict regulation on the use of veterinary drugs (Council Regulation 2377/90/EEC), the establishment of maximum residue limits for the allowed substances (Council Regulation 2377/90/EEC; Commission Regulation (EU) No. 37/2010), and the ban of hormones and other performance enhancers (Council Regulation 2377/90/EEC; Commission Regulation (EU) No. 37/2010; Directive 96/23/EC; Directive 96/22/EC). At the same time, the EU has encouraged the development of novel and efficient analytic methods that meet the criteria described in the Commission Decision 2002/657/EC and its implementation. This grade of flexibility is advantageous because it allows the ready adaptation to the latest technological advances and readiness to face new emergencies.

At the present moment, the control of residues is based on screening and subsequent confirmation of those suspected noncompliant samples. The screening methods, involving both immunologic and chromatographic techniques, can quickly detect an analyte or a class of analytes with high sensitivity and specificity. Some false-positives are acceptable since they will be submitted for confirmatory analysis, but the number of false-negatives must be as low as possible because samples considered compliant will not be reanalyzed. Unlike the immunologic techniques, the chromatographic techniques can perform quantitative multiresidue determinations. In particular, liquid chromatography (LC) is more suitable than gas chromatography (GC) since it can analyze veterinary drugs directly, due to their polar and nonvolatile nature. For this reason, LC has become the technique of choice for multiclass analysis, especially when coupled to mass spectrometry (MS). GC/LC-MS techniques are also indispensable to perform confirmation analyses when following the identification criteria stated in the Commission Decision 2002/657/EC.

This article illustrates the most recent advances and trends in the residue analysis of veterinary drugs in food, giving particular emphasis on the multiclass determinations. In fact, the growing interest for these methods is motivated by the incidental occurrence of residues in foodstuffs as multicomponent mixtures exhibiting synergistic effects potentially more toxic than those of the individual compounds. Table 2 shows some remarkable examples of multiclass methods published in the past 3 years, displaying a concise summary of procedures for extracting, screening, and confirming veterinary drugs, while generalities, analytic problems, and other interesting examples of multiresidue methods are illustrated in the subsequent paragraphs.

Sample Preparation

Problems Related to the Food Matrix and Physicochemical Properties of Veterinary Drugs

The scientific literature is rich with papers dealing with the analysis of veterinary drugs in milk and dairy products, tissues, eggs, honey, seafood, and, to a less extension, fruit and vegetables; in fact, it is less known that antibacterials are also used in agriculture. The proposed methods range from single-analyte methods to single-class or multiclass multiresidue methods; in every case, the sample preparation is a key step depending on the kind of food, the physicochemical properties of the interest drugs, and the number of compounds to be extracted.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00034-9

Table 1 Physicochemical properties, action mechanism, and priority uses of veterinary drugs

Pharmaceutical class	*Action*	*Uses*	*Classes (subclasses)*	*Physicochemical properties*
Antibiotics	Technically, antibiotic is a natural substance produced by bacteria or fungi that can kill or inhibit the growth of other bacteria. However, the terms antibacterial, antimicrobial, and antibiotic are often used interchangeably to represent natural, semisynthetic and synthetic anti-infectives	Therapy, metaphylaxis, auxinic use	β-Lactams (penicillins and cephalosporins) Tetracyclines Macrolides Aminoglycosides Amphenicols Sulfonamides Quinolones Nitrofurans Nitroimidazoles Polyether ionophores	300–800 mol wt range From very simple to extremely complex structures with basic and/or acid functionalities Under different pH conditions, antibiotics can be neutral, cationic, anionic, or zwitterionic Solubility and stability can be affected by the solution pH: for example, polyether ionophores and macrolides are unstable in acidic media, while β-lactams degrade in aqueous acids and bases
Anthelmintics	Anthelmintics are parasiticides, also known as endectocides, used to control nematodes and arthropods affecting livestock. Since they expel or destroy gastrointestinal worms, their more common name is dewormers	Therapy, prophylaxis of cattle, sheep, and swine	Benzimidazoles Nicotinic agonists (imidazothiazoles and tetrahydropyrimidines) Macrocyclic lactones (avermectins and milbemycins) Aminoacetonitrile derivatives	80–900 mol wt range Depending on the structure, they can be soluble in water (cambendazole and thiabendazole), alcohols (levamisole and mebendazole), and nonpolar solvents (dichlorvos) Dissimilar physicochemical properties can be recognized in the same chemical class: for example, benzimidazoles belong to a large family varying in lipophilicity and acid–base behavior
Antifungals	Antifungals are used orally or topically to treat fungal or yeast infections. They can be grouped into three classes based on their site of action: azoles, which inhibit the synthesis of ergosterol (the main fungal sterol); polyenes, which interact with fungal membrane sterols physicochemically; and 5-fluorocytosine, which inhibits macromolecular synthesis	Therapy	Azoles Polyene macrolides Flucytosine	Azoles are poorly soluble in water but can be dissolved in organic solvents. An exception is fluconazole. Imidazoles are weak dibasic agents Polyenes are poorly soluble in water and the common organic solvents. They are soluble in highly polar solvents (DMF and DMSO). They are quite unstable in aqueous, acidic, or alkaline media
Coccidiostats	Coccidiostats are used in the treatment of coccidiosis, an infectious disease caused by parasitic microbial organisms (protozoa), collectively known as coccidian	Therapy, prophylaxis of intensively reared species (poultry, pigs, cattle, and sheep)	Chemical coccidiostats; ionophores	140–940 mol wt range Their chemical structure and polarity vary greatly, particularly in the group of chemical coccidiostats
Tranquilizers	Tranquilizers are administered to sedate animals	Stress reduction during the transportation of food-producing animals (pigs)	Phenothiazine derivatives Propanediol derivates	The solubility of phenothiazine derivatives depends on the type of substituents The unsubstituted phenothiazine exhibits thermal stability only up to 100 °C The pK_a values are ~9.2–9.4
Anti-inflammatories	Anti-inflammatory drugs are used to relieve pain and inflammation, to lower fever, and to treat allergy (corticosteroids)	Management of musculoskeletal disorders and acute respiratory distress syndrome in cattle	Nonsteroidal anti-inflammatory drugs (three classes – carboxylic acids, enolic acids, and anilides and related subclasses) Corticosteroids	Most of NSAIDs are acid compounds (pK_a ~3–5), while anilides are neutral compounds with the exception of nimesulide. Their lipophilicity is related to the nature of their aryl groups and substituents Glucocorticoids are thermolabile: in particular, triamcinolone can isomerize during mild heat treatments (40–50 °C)

Table 2 Selected multiclass methods for analyzing veterinary drug residues in foods

Screening methods

Class	*Matrix*	*Technique/type of assay*	*Remarks*	*Extraction procedure*	*Recovery (%)*	*Method limits*	*Reference*
β-Lactams, tetracyclines, sulfonamides, and quinolones Total of 26 analytes	Milk	Microbiological bioassay in microtiter plates (*Geobacillus stearothermophilus*, *Bacillus cereus*, and *Bacillus subtilis*)	Dichotomous colorimetric responses in short time (6 h); semiquantitative	No sample treatment	Not reported	LOD: 4–3240 μg l^{-1}	Nagel et al.
Tetracyclines, macrolides, sulfonamides, aminoglycosides, quinolones, β-lactams Total of 28 analytes	Honey	Microbiological kits (*Bacillus stearothermophilus*)	Validation of two microbiological kits (Eclipse 50® and Premi®Test) according to the Commission Decision 2002/657/EC	SE with CH_3CN: CH_3COCH_3 (70:30, v/v)	Not reported	Eclipse 50® CCβ: 40–1500 μg kg^{-1} and 5% false-positive results Premi®Test CCβ: 5–25 μg kg^{-1} but 14% false-positive results	Gaudin et al.
Fluoroquinolones and sulfonamides Total of 35 analytes	Milk	Dual-colorimetric ELISA (two different enzymes) (*alkaline phosphatase* and *horseradish peroxidase*)	–	Samples defatted by centrifugation and added to $Na_2[Fe(CN)_5NO]\cdot 2H_2O$ and $ZnSO_4$. Supernatant diluted with phosphate-buffered saline	67–105	LOD: 2.4–5.8 μg l^{-1}	Jiang et al.
Fluoroquinolones, sulfonamides, and phenicols	Milk	Six channels SPR biosensor	–	Samples diluted with water	Not reported	LOD: 1.7–2.1 μg l^{-1}	Fernandez et al.
Antibiotics and veterinary drugs Total of 29 analytes	Milk and infant formulas	Comparison of three screening methods: (a) UHPLC-ESI(+)-Orbitrap (b) UHPLC-ESI(+)-QqTOF (c) UHPLC-ESI(+)-QqQ	Two columns for the three methods: (a) Hypersil GOLD aQ C18 (100 × 2.1 mm, 1.7 μm). Total run time: 4 min (b) and (c) ACQUITY UPLC BEH C18 (100 × 2.1 mm, 1.7 μm). Total run time: 3 min Mobile phases: H_2O 0.05% formic acid and CH_3OH. Gradient elution Flow rate: 0.3 ml min^{-1} at 30 °C	Buffered QuEChERS extraction with CH_3CN 1% CH_3COOH and H_2O 0.1 M Na_2EDTA	Not reported	CCα: 4.1–213.3 μg kg^{-1} CCβ: 8.1–226.6 μg kg^{-1}	Romero-González et al.

Macrolides, sulfonamides, quinolones, avermectins, benzimidazoles, imidazothiazoles, and tetracyclines Total 21 analytes	Milk	UHPLC-ESI(+)-QqQ Two screening methods operating in NLS or PIS mode. Confirmation of nonnegative samples with two MRM transitions	ACQUITY UPLC BEH C18 (100 × 2.1 mm, 1.7 μm). Column temperature: 30 °C Mobile phases: CH_3OH and H_2O 0.05% formic acid. Gradient elution Flow rate: 0.3 ml min^{-1}. Total run time: 3 min for screening methods and 8.5 min for the confirmation method	QuEChERS extraction with CH_3CN 0.1% CH_3COOH and H_2O 0.1 M Na_2EDTA	63–122	Screening methods: CCβ: 0.8–97 μg kg^{-1} Confirmation method: LOQ: 0.3–10 μg kg^{-1}	Martínez Vidal et al.
Sulfonamides, tetracyclines, β-lactams, macrolides, NSAID metabolite, and benzimidazole Total of 25 analytes	Milk	HPLC-ESI(+/−)-QqTOF Nontarget screening method	YMC ODS-AQ (2 × 100 mm, 3 μm). Column temperature: 35 °C Mobile phases: CH_3CN and H_2O 0.1% formic acid. Gradient elution Flow rate: 0.25 ml min^{-1} Total run time: 16.5 min	SE with CH_3CN. Cleanup with a 3000 Da molecular weight cutoff centrifuge filter	42–154	Not reported	Turnipseed et al.
Aminoglycosides, amphenicols, β-lactams, quinolones, tetracyclines, macrolides, NSAIDs, sulfonamides Total of 38 analytes	Veal muscle	HPLC-ESI(+/−)-QqQ	Two different columns: (A) Waters Atlantis dC18 Guard (20 × 3.9 mm, 3 μm) (B) ZIC-HILIC (50 × 2.1 mm, 5 μm, 200 Å) Mobile phases: H_2O 0.1% formic acid and CH_3CN. Gradient elution Flow rate: 1.0 ml min^{-1}. Column (A). Autosampler temperature: 4 °C Two separate injections: one with positive ionization and one with negative ionization Total run time: 15 min (column B) and 16.5 (column A) min	Two consecutive extractions: with CH_3CN:H_2O (86:14, v/v), followed by heating, cooling, and addition of formic acid and with H_2O. Extract defatted with hexane	45–106	MDL: 1–41 ng g^{-1}	Martos et al.

Screening methods

Class	*Matrix*	*Technique/type of assay*	*Remarks*	*Extraction procedure*	*Recovery (%)*	*Method limits*	*Reference*
Antibiotics and veterinary drugs (anthelmintics, β-lactam antibiotics, fluoroquinolones, flukicides, macrolides, nitroimidazoles, NSAIDs, thyreostats, tranquilizers, and others) Total of 113 analytes (quantified 87)	Bovine muscle	UHPLC-ESI(+/−)-QqQ	ACQUITY UPLC HSS T3 column (100 × 2.1 mm, 1.8 μm). Column temperature: 40 °C Mobile phases: 5:95 (v/v) CH_3CN:H_2O and CH_3CN (both 0.1% formic acid). Gradient elution Flow rate: 0.5 ml min^{-1} Total run time: 13 min	SE with CH_3CN:H_2O; dispersive SPE with 500 mg of end-capped C18 sorbent	70–120	Not reported	Geis-Asteggiante et al.
Veterinary drugs (tetracyclines, ionophores, coccidiostats, penicillins, cephalosporins, fluoroquinolones, sulfonamides, and mycotoxins) Total of 15 drugs	Hen eggs	HPLC-ESI(+)-QqQ	ACE C18 column (150 × 2.1 mm, 3 μm, 100 Å). Column temperature: 40 °C Mobile phases: H_2O 0.1% HCOOH and CH_3CN 0.1% HCOOH. Gradient elution Flow rate: 200 ml min^{-1} Total run time: 35 min	QuEChERS extraction with CH_3OH:H_2O:CH_3COOH 80:20:1 (v/v/v) and the addition of 0.125 g ml^{-1} CH_3COONa and 0.5 g ml^{-1} Na_2SO_4 anhydrous	>62	MDL: 0.9–27.1 μg kg^{-1} MQL: 1.3–28.7 μg kg^{-1} CCα: 11.9–246 μg kg^{-1} CCβ: 14.0–283 μg kg^{-1}	Capriotti et al.
Pesticides, antibiotics, and veterinary drugs (macrolides, quinolones, tetracyclines, sulfonamides, avermectins, nitroimidazoles, coccidiostats, penicillins, amphenicols, tranquilizers, corticoids, ionophores, NSAIDs, and others) More than 350 analytes	Honey	UHPLC-ESI(+/−)-Orbitrap MS	Hypersil GOLD aQ C18 column (100 × 2.1 mm, 1.7 μm). Column temperature: 30 °C Mobile phases: H_2O and CH_3OH (both 0.1% (v/v) formic acid and $HCOONH_4$ 4 mM). Gradient elution Flow rate: 0.3 ml min^{-1}. Total run time: 14 min	SE with 7.5 ml of CH_3CN containing 1% of formic acid (v/v)	60–120	Not reported	Gómez-Pérez et al.

Sulfonamides, quinolones, macrolides, tetracyclines, penicillins, imidazothiazoles, avermectins, and benzimidazoles Total of 40 analytes	Honey	UHPLC-ESI(+)-Orbitrap MS Posttarget screening approach and confirmation by fragmenting in the higher-energy collision-induced dissociation cell	Hypersil GOLD aQ C18 column (100 × 2.1 mm, 1.7 μm). Column temperature: 35 °C Mobile phases: H_2O and CH_3OH both 4 mM $HCOONH_4$ acidified with 0.1% formic acid. Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 10 min	Extraction with aqueous solution of Na_2EDTA (0.1 M). Turbulent flow chromatography (TFC) with a Cyclone P (50 × 0.5 mm, 60 μm; 60 Å). TFC solvents: (A) H_2O 0.05% formic acid (v/v) (B) CH_3OH:CH_3CN (1:1, v/v) with Na_2EDTA, 0.1% (C) H_2O 10 mM CH_3COONH_4 (D) CH_3CN: CH_3COCH_3:2-propanol (4:3:3, v/v/v)	68–121	LOI: 0.1–50 μg kg^{-1}	Aguilera-Luiz et al.
Sulfonamides and tetracyclines Total of 22 analytes	Fish, poultry, and porcine meat	UHPLC-ESI(+)-QqQ Two runs: one operating in precursor ion scan and one in data-dependent scan modes	Zorbax Eclipse Plus C18 (50 × 2.1 mm, 1.8 μm) Mobile phases: H_2O and CH_3CN (both 0.1% formic acid). Gradient elution Flow rate: 0.1 ml min^{-1} Total run time: 21 min	SE with CH_3OH:CH_3CN (50:50, v/v) 0.05% formic acid	30–100	CCα: 3.99–25.1 μg kg^{-1} CCβ: 6.80–37.1 μg kg^{-1}	Dasenaki and Thomaidis
Trimethoprim, sulfamethoxazole, chloramphenicol, quinolones, and fluoroquinolones Total of 8 analytes	Aquacultured species	HPLC-ESI(+/−)-QTOF Posttarget and nontarget screening methods followed by confirmation for detected analytes	YMC ODS-AQ (2 × 100 mm, 3 μm). Column temperature: 35 °C Mobile phases: CH_3CN and H_2O 0.1% formic acid. Gradient elution Flow rate: 0.25 ml min^{-1} Total run time: 18.5 min	SE with diluted acetic acid, CH_3CN, and NaCl	80–130	Not reported	Turnipseed et al.
Tetracyclines, sulfonamides, penicillins, quinolones, macrolides, and benzimidazoles Total of 34 analytes	Porcine muscle	HPLC-ESI(+)-QqQ	Zorbax Eclipse XDB C18 column (150 × 4.6 mm, 5 μm). Column temperature: 30 °C Mobile phases: H_2O: CH_3CN (95:5 v/v) and H_2O:CH_3CN (5:95 v/v) (both 0.1% formic acid). Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 18 min	SE with fast partition at very low temperature. Extraction with CH_3CN, centrifugation, and 15 s in liquid nitrogen	Not reported	CCβ:12.5–150 μg kg^{-1}	Lopes et al.

(*Continued*)

Table 2 (Continued)

Screening methods

Class	*Matrix*	*Technique/type of assay*	*Remarks*	*Extraction procedure*	*Recovery (%)*	*Method limits*	*Reference*
Antibiotics, pesticides, and mycotoxins Total of 82 analytes	Fish feed and fish fillets	UHPLC-ESI(+)-QqTOF for screening and UHPLC-ESI(+)-QqQ for confirmation of positive samples	ACQUITY UPLC BEH C18 column (100 × 2.1 mm, 1.7 μm) Mobile phases: H_2O and CH_3OH (both 0.01% HCOOH and 0.1 mM NH_4Ac). Gradient elution Flow rate: 0.3 ml min^{-1} at 60 °C Total run time: 18 min	SE with CH_3CN:H_2O 80:20 v/v 0.1% formic acid	Not reported	LOI: 20–100 μg kg^{-1}	Nacher-Mestre et al.
Tetracyclines, quinolones, and sulfonamides Total of 21 analytes	Cattle and poultry meat	HPLC-ESI(+)-QqQ	Symmetry C18 (75 × 4.6 mm, 3.5 μm). Column temperature: 20 °C Mobile phases: H_2O and CH_3CN (both 0.1% formic acid). Gradient elution Flow rate: 0.4 ml min^{-1} Total run time: 17 min	MSPD with EDTA-treated sand; extraction with CH_3CN 0.1% formic acid	19–29	CCβ: 25–50 μg kg^{-1}	Bittencourt et al.
Sulfonamides, tetracyclines, macrolides, quinolones, and chloramphenicols Total of 33 analytes	Bovine, caprine, and ovine milk	UHPLC-ESI(+/−)-QqQ	ACQUITY UPLC HSS T3 column (100 × 2.1 mm, 1.8 μm) Mobile phases: H_2O and CH_3CN (both 0.1% formic acid). Gradient elution Flow rate: 0.45 ml min^{-1} at 40 °C Total run time: 12 min	SE with CH_3CN	Not reported	CCβ: 0.1–100 μg kg^{-1}	Freitas et al.
Penicillins, cephalosporins, sulfonamides, macrolides, tetracyclines, aminoglycosides, and quinolones Total of 63 analytes	Bovine meat	UHPLC-ESI(+)-LTQ-Orbitrap	Purospher STAR RP-18e (125 × 3 mm, 5 μm) Mobile phases: H_2O 1 mM HFBA and 0.5% formic acid and CH_3OH:CH_3CN (50:50, v/v) 0.5% formic acid. Gradient elution Flow rate: 0.5 ml min^{-1} at 25 °C Total run time: 15 min	Two protocols: SE with CH_3CN and SE with H_2O:CH_3CN 5% TCA followed by SPE on C18 cartridge	Not reported	LOD: 1–308 μg kg^{-1} CCβ: 25–1000 μg kg^{-1}	Hurtaud-Pessel et al.

Confirmatory methods

Class	*Matrix*	*Technique*	*Chromatographic conditions*	*Extraction*	*Recovery (%)*	*Method limits*	*Reference*
Macrolides, β-lactams, lincosamide, fluoroquinolones, and anthelmintics Total of 23 analytes	Milk	UPLC-ESI (+)-QqQ	HSS T3 (10 × 2.1 mm, 1.8 μm) Mobile phases: H_2O and CH_3CN (both 0.05% formic acid). Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 20 min	SE with CH_3CN	51.5–139.0	Not reported	Tang et al.
Penicillins and amphenicols Total of 8 analytes	Milk	HPLC-DAD	Kinetex XB-C18 (150 × 4.6 mm, 2.6 μm) Mobile phases: H_2O (0.05 M CH_3COONH_4) and CH_3CN. Gradient elution Flow rate: 0.9 ml min^{-1} Total run time: 17 min	MSPD procedure using a mixture of sorbents (Strata-X by Phenomenex plus QuEChERS by Agilent Technologies). Elution with 1 ml CH_3OH and 1 ml CH_3CN	84–102	CCα: 35.2–56.3 μg kg^{-1} CCβ: 39.9–61.9 μg kg^{-1}	Karageorgou and Samanidou
Macrolides, sulfonamides, and anthelmintics Total of 17 analytes	Cheese	UPLC-ESI(+)-QqQ	ACQUITY UPLC BEH C18 column (100 × 2.1 mm, 1.7 μm). Column temperature: 30 °C Mobile phases: CH_3OH and H_2O 0.01% (v/v) formic acid. Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 8.5 min	QuEChERS procedure with 10 ml of CH_3CN 1% acetic acid, 10 ml of a solution of 0.1 M Na_2EDTA, 4 g of $MgSO_4$ anhydrous, and 1 g of sodium acetate	70–112.7	CCα: 2.3–11.3 μg kg^{-1} CCβ: 4.2–14.3 μg kg^{-1}	Gómez-Pérez et al.
Coccidiostats, antimicrobial agents, corticosteroids, and antifungal agents Total of 18 analytes	Milk	HPLC-ESI (+)-QqQ	Synergi Polar-RP (50 × 2.00 mm, 2.5 μm, 100 Å) Mobile phases: H_2O and CH_3CN (both 0.1% formic acid). Gradient elution Flow rate: 0.2 ml min^{-1} Total run time: 36 min	SE with CH_3CN; SPE with Strata-X cartridge, elution with CH_3OH	65–119	CCα: 0.1–18.7 ng ml^{-1} CCβ: 0.2–31.8 ng ml^{-1}	Nebot et al.
Antibiotics and benzimidazoles Total of 29 analytes	Milk-based infant formulas and meat-based baby food	UPLC-ESI(+)-QqQ	ACQUITY UPLC BEH C18 column (100 × 2.1 mm, 1.7 μm). Column temperature: 30 °C Mobile phases: CH_3OH and 0.05% (v/v) formic acid in H_2O. Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 9.5 min	Two procedures: (A) 'Dilute and shoot': diluting samples with H_2O and extracting with CH_3CN (1% formic acid, v/v); filtration, injection (B) QuEChERS: extracting with 1% (v/v) acetic acid in CH_3CN, anhydrous $MgSO_4$, and sodium acetate; filtration, injection	(B) 70–120	(B) CCα: 0.5–16.2 μg kg^{-1} CCβ: 1.2–22.4 μg kg^{-1}	Aguilera-Luiz et al.
Veterinary drugs (agonists, benzimidazoles, β-lactams, lincosamides, nitroimidazoles, quinolones, quinoxalines, sedatives sulfonamides, tetracyclines, and thyreostats) and other contaminants Total of 255 analytes	Raw milk	UHPLC-ESI(+)-QqQ and UHPLC-ESI(−)-QqQ	ACQUITY HSS T3 column (100 × 2.1 mm, 1.8 μm). Column temperature: 40 °C Two different chromatographic runs: one for ESI + and the other for ESI −. Mobile phases: (positive) H_2O containing 0.5 mM CH_3COONH_4 and CH_3OH (both 0.1% (v/v) formic acid); (negative) H_2O containing 2.5 mM CH_3COONH_4 and CH_3OH Flow rate: 0.4 ml min^{-1}. Time of each run: 12 min	SE with CH_3CH_2OH:CH_3CN (1:5, v/v) containing EDTA	63–141	LOD: 0.05–10 μg kg^{-1}	Zhan et al.

(*Continued*)

Confirmatory methods

Class	*Matrix*	*Technique*	*Chromatographic conditions*	*Extraction*	*Recovery (%)*	*Method limits*	*Reference*
Aminoglycosides and macrolides Total of 6 analytes	Meat	HPLC-ESI (+)-QqQ	Luna C18 (250 × 4.6 mm, 5 μm) Mobile phases: H_2O and CH_3OH (both 1 mM heptafluorobutyric acid). Gradient elution Flow rate: 0.5 ml min^{-1} Total run time: 35 min	PLE using EDTA-treated sand as dispersive medium; extraction with CH_3OH at 80 °C and 1500 psi for 10 min in two cycles	70–96	CCα: 85–510 μg kg^{-1} CCβ: 98–514 μg kg^{-1}	Berrada et al.
β-Lactams and tetracyclines Total of 11 analytes	Bovine muscle	UPLC-ESI (+)-QqQ	ACQUITY UPLC BEH C18 column (50 × 2.1 mm, 1.7 μm) Mobile phases: water with 0.1% formic acid and methanol. Gradient elution Flow rate: 0.60 ml min^{-1} Total run time: 11 min	SE with H_2O and CH_3CN; dispersive SPE with C18	90–110	CCα: 30.9–371.7 μg kg^{-1} CCβ: 36.8–443.4 μg kg^{-1}	Rezende et al.
Quinolones, sulfonamides, macrolides, anthelmintics, avermectins, diamino derivatives, benzathine Total of 22 analytes	Chicken muscle	UPLC-ESI (+)-QqQ	ACQUITY UPLC BEH C18 column (100 × 2.1 mm, 1.7 μm). Column temperature: 30 °C Mobile phases: CH_3CN and H_2O (both 0.1% (v/v) formic acid). Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 8.5 min	QuEChERS procedure: SE with 5.0 ml of H_2O and 10.0 ml of 1% acetic acid in a solution of CH_3CN: H_2O (80:20, v/v); addition of sodium citrate dibasic sesquihydrate, sodium citrate dehydrate, anhydrous $MgSO_4$; dispersive SPE with PSA	70–120	CCα: 17.0–411.8 μg kg^{-1} CCβ: 24.1–423.6 μg kg^{-1}	Pereira Lopes et al.
Sulfanilamide, nitroimidazoles, quinolones, macrolide antibiotics, lincosamides, and praziquantel Total of 54 analytes	Pork meat	HPLC-ESI (+)-QqQ	Zorbax Eclipse XDB C8 column (150 × 4.6 mm id, 5 μm). Column temperature: 30 °C Mobile phases: CH_3CN, CH_3OH, and H_2O (0.15% (v/v) formic acid). Gradient elution Flow rate: 0.8 ml min^{-1} Total run time: 23 min	SE with CH_3CN. SPE with Supelclean LC-18 cartridges, elution with CH_3OH	20.9–121	Not reported	Xie et al.
Aminoglycosides, β-lactams, lincosamides, macrolides, quinolones, sulfonamides, tetracycline Total of 24 analytes	Chicken muscle	UPLC-ESI (+)-QqQ	ZIC-HILIC (100 × 2.1 mm, 3.5 μm). Column temperature: 40 °C Mobile phases: 50 mM $HCOONH_4$ in H_2O at pH 2.5 and CH_3CN. Gradient elution Flow rate: 0.2 ml min^{-1} Total run time: 10 min	SE with aqueous solution – CH_3CN (1:1, v/v) 2% TCA	53–99	CCα: 58–510 μg kg^{-1} CCβ: 65–525 μg kg^{-1}	Chiaochan et al.

Aminoglycosides, macrolides, lincosamides, sulfonamides, tetracyclines, quinolones, and trimethoprim Total of 36 antibiotics	Chicken muscle	HPLC-ESI (+)-QqQ	BetaSil Phenyl/Hexyl (50 × 2.1 mm, 3 μm) Mobile phases: 1 mM HFBA + 0.5% formic acid and 0.5% formic acid in ACN/methanol (1:1, v/v) Flow rate: not specified Total run time (online cleanup + chromatographic separation): 19 min	SE with CH_3CN:2% TCA (45:55, v/v). Centrifugation, filtration, injection onto TFC-HPLC system TFC column: Cyclone P (50 × 0.5 mm, 60 μm; 60 Å) TFC solvents: same as analytic column Flow rate: 1.5 ml min^{-1}	80–120	CCα: 1.7–602.2 μg kg^{-1} CCβ: 2.2–704.4 μg kg^{-1}	Bousova et al.
Sulfonamides, diaminopyridine derivates, quinolones, tetracyclines, macrolides, penicillins, lincosamides Total of 41 analytes	Hen eggs	UPLC-ESI (+)-QqQ	Mobile phases: H_2O 0.02% formic acid and 1 mmol l^{-1} oxalic acid and CH_3CN 0.1% formic acid. Gradient elution Flow rate: 0.3 ml min^{-1} at 40 °C Autosampler temperature: 15 °C Total run time: 13 min	Static PLE extraction with CH_3CN: 0.01 mol l^{-1} succinic acid buffer pH 6.0, 1:1 (v/v) at 70 °C 1500 psi	47–320%	CCα: 0.3–232.3 μg kg^{-1} CCβ: 0.9–264.6 μg kg^{-1}	Jiménez et al.
Polyether ionophores, macrolides, lincosamide Total of 10 analytes	Eggs	LC-ESI(+)-QqQ 3 MRM transitions for each analyte	ACE C_{18} column (50 × 2.1 mm, 3 μm, 100 Å) Mobile phases: H_2O, CH_3CN, and CH_3OH (all with 0.1% formic acid). Gradient elution Flow rate: 0.3 ml min^{-1} at 35 °C Total run time: 18 min	SE with 4 ml of CH_3CN; evaporation to dryness of an aliquot of 250 μl of the supernatant, dilution to 1 ml with 5 mmol l^{-1} CH_3COONa: MeOH (70:30, v/v); filtration, injection	78.5–168.1	CCα: 0.87–229.7 μg kg^{-1} CCβ: 1.74–262.7 μg kg^{-1}	Ferraz Spisso et al.
Tetracyclines, macrolides, quinolones, sulfonamides, anthelmintics Total of 25 analytes	Eggs	UPLC-ESI (+)-QqQ	ACQUITY UPLC BEH C18 column (100 × 2.1 mm, 1.7 μm^{-1}). Column temperature: 30 °C Mobile phases: CH_3OH and H_2O 0.05% formic acid. Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 9.5 min	Comparison between several extraction procedures: (1) SE with CH_3CN: 0.5 M citric acid (pH 4): 0.1 M Na_2EDTA (10:1:0.5, v/v/v) and SPE with Oasis HLB cartridge (2) QuEChERS procedure with CH_3CN 1% acetic acid and H_2O 0.1 M Na_2EDTA followed by the addition of $MgSO_4$ and CH_3COONa_2 (3) MSPD with Florisil. Elution with CH_3OH, CH_3CN, and 0.04% (v/v) of 35% NH_3 solution in CH_3OH (4) SPE with Oasis HLB washing with hexane and elution with CH_3OH, CH_3CN, and 0.04% (v/v) 35% NH_3 in CH_3OH	(1) 71–97 (2) 11–96 (not all analytes extracted) (3) 2–90 (not all analytes extracted) (4) 3–131 (not all analytes extracted)	For solvent extraction: LOQ: 0.1–5.0 μg kg^{-1} CCα: 2.1–220.8 μg kg^{-1} CCβ: 4.7–241.6 μg kg^{-1}	Garrido Frenich et al.
Macrolides, lincosamides, quinolones, tetracyclines, pleuromutilins, and diaminopyrimidine derivatives Total of 37 analytes	Honey	HPLC-ESI(+)-QqQ	AQUA C18 (150 × 2.1 mm, 3 μm). Column temperature: 30 °C Mobile phases: CH_3CN and H_2O (both 0.2% (v/v) formic acid). Gradient elution Flow rate: 0.3 ml min^{-1} Total run time: 25 min	Extraction with buffer solution. SPE with Oasis HLB cartridge, elution with CH_3OH	92–106	CCα: 7.5–12.9 μg kg^{-1} CCβ: 9.4–19.9 μg kg^{-1}	Bohm et al.

Single-analyte analyses are optimized for achieving the maximum recovery of the target compound in a specific matrix. In order to realize a quantitative extraction, a problem that has to be often overcome is the tight interaction of some drugs with proteins or other components of the matrix. For example, nitrofurans are rapidly converted into peptide-bound metabolites that persist for a long time in animal tissues; the sample homogenization in the presence of diluted hydrochloric acid is a common solution applied for their release. A strong noncovalent interaction is also established by nonsteroidal anti-inflammatory drugs (NSAIDs) with proteins of milk and tissues. Since the value of the drug–protein association constant increases with decreasing pH, acid deproteinization is less effective than that obtained with an organic solvent. As a matter of fact, the addition of neutral water-miscible organic solvents (acetonitrile, acetone, and ethyl acetate) to bovine milk and minced meat samples is advantageous because, decreasing the medium dielectric constant, protein molecules aggregate and precipitate, while pK_a value of NSAIDs rises steeply. Glucuronidation of NSAIDs and glucocorticoids is another problem to be faced to increase extractive yields from milk and meat; for example, carprofen and carprofen glucuronide are the marker residues in bovine muscle tissue. Usually, chemical hydrolysis with hydrochloric acid or enzymatic digestion with β-glucuronidase is a deconjugation step performed prior to a solid-phase extraction (SPE) cleanup. Enzymatic hydrolysis is also sometimes chosen to deconjugate glucuronate residues of corticosteroids potentially occurring in milk and in the liver from various animal species, while the linkage of sulfonamides to the sugars of honey is commonly solved with a step of acid hydrolysis, useful to break the *N*-glycoside linkage. The occurrence of multivalent cations in food causes the formation of strong complexes with tetracyclines, which are strongly retained in tissues. For these same reasons, tetracyclines can establish specific interactions with silanol groups of silica-based adsorbents, complicating their analysis; in order to avoid analyte losses during sample preparation and tailed peaks during LC, chelating agents like EDTA salts have been used during the sample treatment. β-Lactams are difficult to treat for other reasons: they are degraded by endogenous muscle enzymes and are unstable to heat and in alcohols. Quinolones, amphoteric and zwitterionic compounds, are poorly soluble in water and can penetrate tissues between pH 6 and pH 8. Because of these proprieties, their extraction has been often performed using an acidified organic extractant. Extraction of antibacterials, coccidiostats, and anthelmintics from eggs can be very problematic due to the high lipid and protein content, the linkage to lipoproteins, and the formation of emulsions and foams with organic solvents. In these cases, acetonitrile is considered the best extractant because it precipitates proteins and denatures enzymes that could degrade drugs during the sample treatment.

Single-Class and Multiclass Multiresidue Methods

In contrast with the single-analyte methods, single-class multiresidue methods are designed to monitor the maximum number of analytes within a particular class with an acceptable recovery. Multiclass methods have the similar but more difficult goal of maximizing the number of analytes belonging to more than one pharmaceutical class. The chemical heterogeneity of drugs, their different physicochemical properties, and their occurrence at trace level in complex matrices make very difficult to find common extraction conditions. For this reason, multianalyte protocols include generic and nonselective sample-preparation procedures that have the advantage of reducing time, cost, and complexity of the pretreatment and achieving high sample throughput. Basically, the most suitable techniques for this purpose are solvent extraction (SE), SPE, and the QuEChERS methodology.

SE without further purification is a commonly adopted solution for multiresidue analyses: the solvent is selected to obtain the maximum yield of the target drugs and, at the same time, the minimum extraction on interfering compounds from the matrix. The procedures are easy, fast, cheap, and especially suitable for the simultaneous analysis of families of veterinary drugs; Table 2 illustrates 14 examples of such methods that have succeeded in isolating a huge number of compounds (up to 255) often identified via LC-MS. Nevertheless, the coextraction of interferences is responsible for high quantitation limits, low sensitivity, poor selectivity, and stress on analytic systems (chromatographic column and/or MS). The so-called 'dilute and shoot' approach, used in the strict sense of the term only for matrices such as urine and plasma, has been sometimes applied to food matrices before/after a SE step; for example, the dilution of the final extract and a reduced injection volume into the LC-MS/MS system allow controlling matrix effect and improving method performances. Interesting variants of SE, developed in the recent years to decrease organic solvent usage, succeed in isolating only a limited number of veterinary drugs. For example, ion-paired SE can be applied to extract penicillin antibiotics using tetrabutylammonium bromide as ion-pairing agent at pH 8 (fully deprotonation of the analytes) and a binary water–acetonitrile mixture as extractant; the addition of $(NH_4)_2SO_4$ between 16 and 43 wt% decreases the acetonitrile solubility in aqueous solution, inducing phase separation and quantitative recoveries. Supramolecular solvent-based extraction is another recent proposal that uses reverse micelles of decanoic (DeA) acid; this nanostructured liquid is produced by mixing DeA, tetrahydrofuran, and a hydrochloric acid aqueous solution in proper ratios at pH 4 (i.e., at pH values lower than the DeA pK_a) and is able to establish strong hydrogen bonds with sulfonamides, guarantying high yields. Dispersive liquid–liquid microextraction (DLLME) utilizes a mixture of a high-density solvent (extractant) and water-miscible polar solvent (disperser); if applied to extract veterinary drugs (e.g., NSAIDs), acetonitrile is usually chosen as disperser and chloroform as extractant. The rapid addition of the two solvents into an aqueous medium containing the sample generates fine droplets of the extractant and, therefore, a large contact surface with analytes. After centrifugation, the droplets settle at the bottom of the centrifuge tube, facilitating the recovery. The main disadvantage of the DLLME is related to the toxicity of chlorinated solvents, while simplicity, rapidity, low cost, and high enrichment factor are the main advantages.

Conventional SPE, used singly or in combination with other extractive techniques, is still the most common approach applied for the isolation of a large number of pharmacological

molecules from solid or liquid foods. Nevertheless, due to its intrinsic characteristics of selectivity, this technique is less suitable than SE for extended multiclass methods (see examples in Table 2), and the number of extracted veterinary drugs is around 50 at the most. According to the properties of the analytes and the sample composition, the most tested phases are

- classical reversed phases (C_4, C_8, C_{18}, phenyl, and polymeric sorbents),
- ion exchangers,
- mixed-mode cation-exchange sorbents,
- normal phases (alumina, silica, and amine-bounded silica).

In general, a preliminary deproteinization/extraction step with an organic solvent comes first the cleanup on SPE cartridges for protein-rich foods, while a defatting step with hexane can be performed for fatty foods before or during SPE. Another simple solution to remove lipids is the low-temperature centrifugation of an organic extract prior and after SPE. In analyzing honey, the high content of sugar, wax, and dyes has to be removed because it is responsible for severe signal suppression during LC-MS analysis. Moreover, sugars are a real problem for the analysis of sulfonamides and ronidazole (a nitroimidazole) since they combine in a complex with these antibacterials. SPE has proved to be very effective in removing all these interfering compounds and it has been sometimes used directly after a simple dilution of honey with water. Hitherto, most published analytic methods have involved off-line SPE, but lately, online SPE coupled to LC-MS has been proposed for the multiresidue determination of antibacterials in different kinds of foods (fish, milk, meat, and eggs): Using an automatized device (an example is the Symbiosis™ Pico online SPE system, Emmen, the Netherlands), the analytes are eluted from the cartridge to the chromatographic column in backflush mode, after the 'sample loading' and 'sample cleanup' steps, while a new cartridge is ready for another extraction.

In recent years, other modes to perform SPE have been designed to improve performances of this extractive technique. For example, the membrane-protected micro-SPE uses a porous polypropylene membrane, folded into a small envelope, that contains a small amount of polymeric sorbent. This membrane avoids the sorbent blockage during the manipulation of particularly 'dirty' samples. Another variant of SPE is the dispersive SPE (dSPE). This technique, based on the uniform dispersion of the sorbent in the sample solution/suspension, is applied for single-class and multiclass determinations, being successful in isolating more than 100 veterinary drugs (two examples in Table 2). Its remarkable development is the magnetic SPE (MSPE) that uses functionalized magnetic materials (FMMs) with high adsorption ability and superparamagnetism. In the food safety field, the most used FMMs are iron oxide microparticles or nanoparticles embedded with phenyl silica sorbent or silica coated with MAA-co-EGDMA (i.e., methacrylic acid-co-ethylene glycol dimethacrylate). In a typical experiment, these materials are first dispersed in a sample solution, incubated for an appropriate time to favor the analyte adsorption, and then isolated from the solution with a magnetic lure (no centrifugation or filtration steps). Compared with conventional SPE, both dSPE and MSPE take less time, require less labor, use lower amounts of solvent and sorbent, and avoid the cartridge blockage, channeling effects and breakthrough phenomena.

QuEChERS (quick, easy, cheap, effective, rugged, and safe) is an extractive methodology that has become popular for the multiresidue analysis of veterinary drugs in food products. Figure 1 schematically illustrates a typical experiment. Practically, the homogenized sample is placed in a centrifuge tube along with a high salt content (anhydrous $MgSO_4$ plus CH_3COONa or NaCl) and an organic solvent (usually acidic acetonitrile in the presence or absence of EDTA); afterward, the tube is capped, shaken vigorously, and centrifuged. In this way, the analytes are partitioned from the sample to the organic phase via salting out. An important parameter is the salt dosage: if it is too low, the phase separation is incomplete; if it is too high, the organic extractant is less efficient due to possible adsorption phenomena of analytes to the drying agent. This stage is sometimes followed by another one based on dSPE: a portion of the organic extract from the previous step is transferred to a tube containing a combination of $MgSO_4$ and different sorbents for cleaning up unwanted sample components. Silica-based sorbents functionalized with primary/secondary amino (PSA) or C_{18} groups are the most used, alone or in combination: PSA is efficient in the removal of organic acids, whereas C_{18} retains fats and hydrophobic compounds. The coined acronym explains perfectly all the advantages of this approach, which allows preparing many samples in a few minutes and extracting a large number of structurally different compounds with good efficiencies. Table 2 illustrates eight of such examples that applied QuEChERS-like strategies prior to screening and confirmatory analyses.

In the last 3 years, other techniques that have been used for an extensive multiresidual extraction of veterinary drugs are turbulent flow chromatography (TFC), matrix solid-phase dispersion (MSPD), and pressurized liquid extraction (PLE). Table 2 shows examples for all three techniques. TFC is a size exclusion-based technique, which allows injecting a liquid sample onto a column (0.5 or 1.0 mm of internal diameter) packed with large porous particles (30–60 μm diameter; 60 Å pore size) at flow rates of mobile phase higher than 1 ml min^{-1} to obtain a turbulent flow. Under these conditions, the small molecules of analytes diffuse into the particle pores of the stationary phase, whereas high-molecular-weight compounds from matrix (polysaccharides, proteins, and lipids) are quickly flowed to the waste. After this retention on the TFC column, the analytes are eluted toward the analytic column for the chromatographic separation. The main drawbacks of this technique are the low concentration capacity and the high solvent consumption, whereas its major advantage is the speed of the analysis, maintaining acceptable levels of recovery for a good number of veterinary drugs (up to 40) after a reduced sample manipulation (Table 2). In the case of solid or semisolid samples, such as tissues and eggs, the use of a PLE, a solid–liquid extraction that uses MSPD for the sample preparation and solvents at high temperature and pressure, is quite common. Automation, low solvent consumption, and short extraction times make it a feasible technique for high-throughput multiresidue extractions.

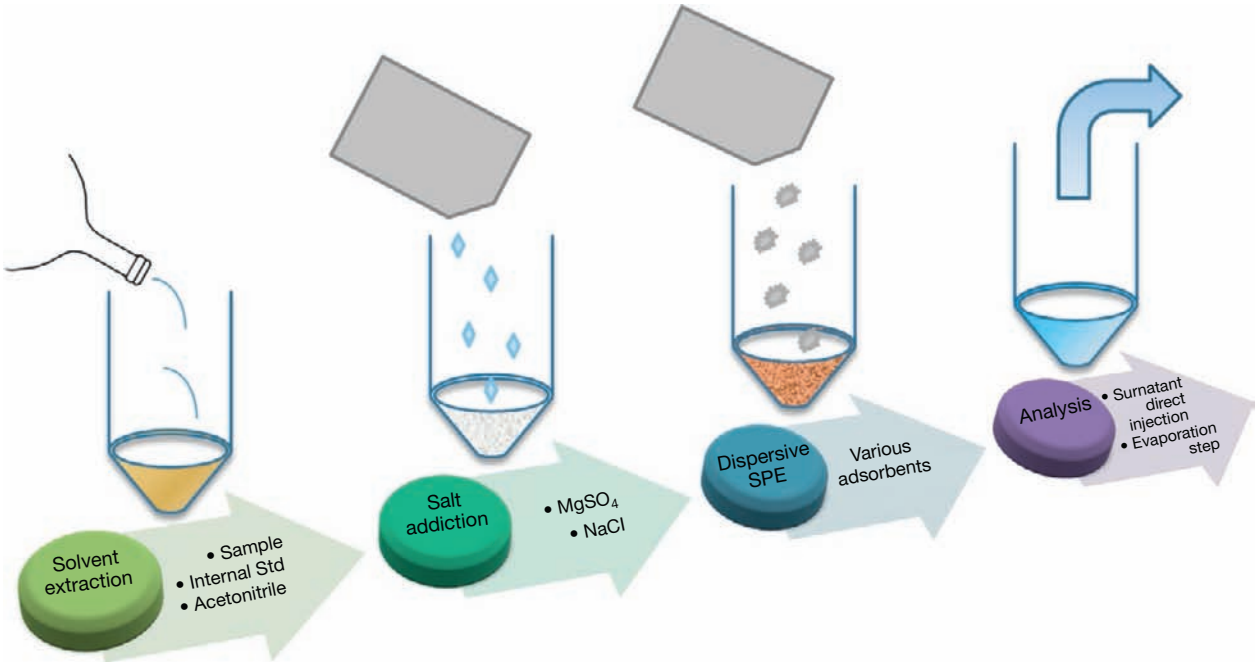

Figure 1 Graphic representation of a typical QuEChERS extraction. Usually, samples are extracted with acetonitrile using $MgSO_4$ and NaCl (to induce a better phase separation and analyte partition into organic extractant), while cleanup is conducted with dispersive SPE. Adsorbent choice depends on the matrix and on the analytes (i.e., C18, PSA, and polymeric). The supernatant is generally evaporated under nitrogen, filtered, and finally analyzed.

Screening Methods

Besides chromatographic techniques, the most used methods for screening veterinary drugs in foods relies on microbiological inhibition assay and immunoassay. For the latter, there have been rapid advances in the development of single tests that combine the usual advantages, concisely listed in Table 3, along with the main drawbacks, with the ability to detect multiple residues simultaneously within different food matrices.

Microbiological methods use susceptible microorganisms to detect antibiotics in foodstuffs. If the UV/Vis detection is applied and no residues are present in the food sample, the organic acids produced during the bacteria growth change the indicator color, permitting 'naked-eye' or photometric detection; on the other hand, if antibiotics occur over their limit of detection, either a zone of inhibition or no color change is observed. Regarding the assay format, microtiter plates and paper disks are the most used ones. Multiresidue analysis is possible using more than one plate, each seeded with a different organism. Due to cost-effectiveness and broad spectrum characteristics, they are preferred for large-scale monitoring programs and are the only rapid tests recognized by the EU for the screening of penicillins. However, long incubation times (18–24 h), short expiry dates, and difficulty in measuring the inhibitory halos are serious limitations for their use in routine analyses. In recent years, several in-house and commercial tests have been introduced and validated according to the European Decision 2002/657/EC.

Immunoassays are based on the binding properties of labeled antibodies with antigens and can be classified on the basis of the detection label. ELISA (enzyme-linked immunosorbent assay) use enzymes that, reacting with an appropriate substrate, produce a visible-sensitive chromogen. Even if ELISA usually focuses on the detection of a single analyte or a single group of analytes, multiclass immunoassay has been achieved preparing a bihapten antigen and a broad-specific antibody for simultaneous determination of penicillins and tetracyclines. Fluorescence immunoassay (FIA) and time-resolved fluorescence immunoassay (TR-FIA) are techniques that use fluorescent labels excited by the light of a suitable wavelength. Although their development has been incentivized by the necessity to overcome some drawbacks of ELISA (see Table 3), FIA is characterized by a high background fluorescence level that affects sensitivity. This problem is solved with TR-FIA that, relying on fluorophores (chelates of lanthanum, europium, etc.) with narrowband emission lines and long fluorescence half-lives, is able to reach a sensitivity superior to that of LC-MS in the screening of sulfonamides and tetracyclines.

Biosensors are analytic devices that combine a biological recognition element (enzyme, antibody, and receptor) with a transducer to produce a signal proportional to the extent of interaction between recognition element and analyte (i.e., to the analyte concentration). For the screening of drug residues in food, immunosensors with electrochemical or optical transducer systems are the most commonly used systems. Particularly, surface plasmon resonance immunosensors are able to detect fluoroquinolones, sulfonamides, and phenicols without the need for labels, allowing the monitoring of the biological interactions in real time. Functionalized magnetic beads (MBs) and screen-printed carbon electrodes constitute an attractive platform to perform immunoreactions and electrochemical detection, respectively. In particular, MBs minimize matrix effect, allow fast assay kinetics and, just after a simple dilution

Table 3 Main screening techniques and their features

	Advantages	*Drawbacks*
Microbiological methods		
– Tube tests, single or multiplates assay/diameter of inhibition zones, color change or UV/Vis detection	– Cost-effectiveness – Entire antibiotic spectrum within one test	– Lack of specificity – Long incubation periods – False-positive results
Immunologic methods		
– Enzyme-linked immunosorbent assay (ELISA) – Fluorescence immunoassays (FIAs) – Time-resolved fluorescence immunoassays (TR-FIA)	– Easy to use – Available kits for families of compound – Large number of samples per kit – Reduced analysis time (2–2.5 h) – Sensitivity – Specificity – Possibility of automation and to use within the food-processing facility	– Interferences giving some false-positives – Semiquantitative analysis – Lack of stability – Lengthy development time required for immunoreagent preparation – High background (ELISA and FIA) – Large number of incubation and washing steps (ELISA)
Biosensors	– Easy to use – Results available in short time – Multiple residues analyzed in one shot – Full automatization – High throughput	– High costs – Instability of biological-sensing component
HPLC or UPLC-MS methods		
HPLC/UPLC-triple quadrupole (HPLC/UPLC-QqQ) HPLC/UPLC-time of flight (HPLC/UPLC-ToF) HPLC/UPLC-Orbitrap	– Identification – Short run time – High selectivity and sensitivity – High throughput	– Expertise required – Need of sample preparation – High initial investment and operative costs – Time-consuming

of milk samples, are able to detect selectively tetracyclines and sulfonamides.

Molecularly imprinted polymers (MIPs) are materials obtained by polymerizing functional and cross-linking monomers around a template molecule, which is subsequently removed, leaving a cavity complementary to the target compound. For their recognition ability, they are compared to synthetic antibodies, but without sharing their storage and stability problems. Recently, MBs were used to construct MIP-based electrochemical sensors whose operating principle is concisely explained in Figure 2. These devices can be considered as the next-generation sensors due to the high sensitivity, simple instrumentation, and excellent compatibility with miniaturization techniques; moreover, they can analyze complex samples without any pretreatment and be easily extended to detect other interest molecules by controlling the imprinted target molecules.

Due to their versatility, chromatographic techniques are the most suitable to perform large-scale screening. In particular, the hyphenation, which is continuing to gain ground, is LC coupled to low- or high-resolution MS (more than 100 residues detected in a single chromatographic run). Depending on the objective of the analysis and the available analyzer, most of the published papers deal with multiclass methods based on three different approaches: pretarget screening, posttarget screening, and nontarget screening. Table 2 reports some examples of each approach.

Pretarget screening methods use authentic standards for the ion current preselection and low-resolution (LR) mass spectrometers, such as triple quadrupole (QqQ) operating in neutral-loss scan (NLS), parent-ion scan (PIS), or multiple reaction monitoring (MRM). The MRM scan mode allows the identification of target drugs, whereas NLS and PIS modes can screen a family of compounds.

An attractive alternative is the use of full-scan MS techniques, relying on high-resolution (HR) mass spectrometers such as time of flight (TOF) or Orbitrap. These analyzers allow performing the other two screening modes; moreover, the highest resolving power of Orbitrap (up to 100 000 full width at half maximum (FWHM)) is important to avoid both false-positives and false-negatives. The posttarget screening approach provides that the m/z values of the target analytes are extracted from the full-scan total ion current (TIC) chromatogram after its acquisition using a narrow mass window (± 10 mDa); the identification is based on the retention time window and the measurement of the accurate mass (<5 ppm for Orbitrap and 5–20 ppm for TOF) and the isotopic pattern. This procedure is advantageous because it permits a retrospective data analysis, increasing the number of drugs and/or metabolites determined in a single chromatographic run.

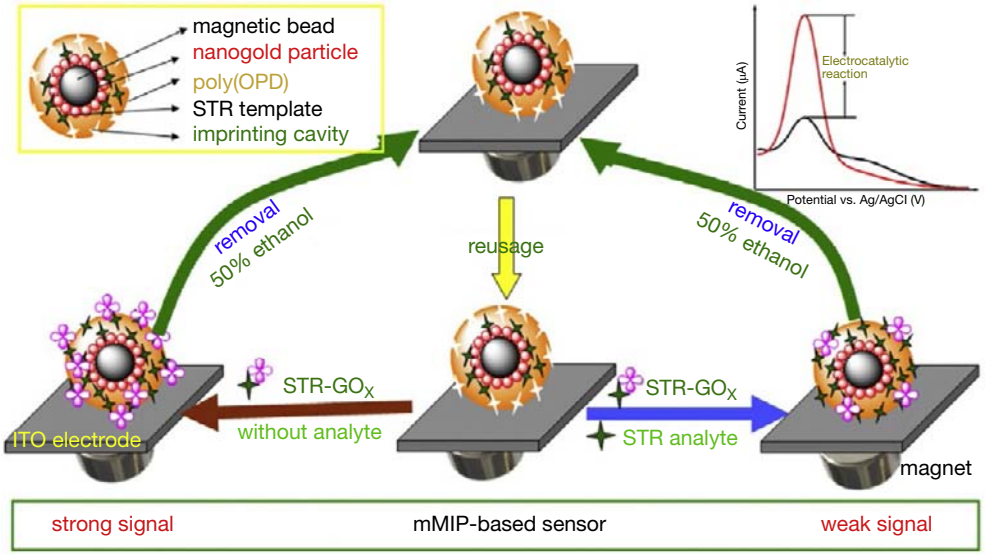

Figure 2 Schematic illustration of a novel sensor, based on redox-active magnetic molecularly imprinted polymer (mMIP) nanospheres. Nanospheres are composed of a nanogold-encapsulated poly(*o*-phenylenediamine) shell on magnetic iron oxide cores. The electrochemical detection of streptomycin residues (STR) is allowed by coupling with bioelectrocatalytic reaction of glucose oxidase (GOx) for signal amplification. When STR occurs in a food sample, the analyte competes with GOx-labeled STR (GOx-STR) for molecular imprints on the mMIP nanospheres. Thence, the conjugation amount of GOx-STR on the mMIP nanospheres decreases, leading to the change in the bioelectrocatalytic current. Reproduced from Liu, Tang, Zhang, et al. (2013). Au(III)-promoted magnetic molecularly imprinted polymer nanospheres for electrochemical determination of streptomycin residues in food. *Biosensors and Bioelectronics* **41**, 551–556, with permission from Elsevier.

Methods utilizing hybrid mass spectrometer, such as QqTOF, can collect product ion data that support the identification of the detected compounds. Nontarget screening methods evaluate the occurrence of residues after the acquisition of the full-scan TIC chromatogram by searching the detected drugs in homemade spectral libraries; here, the analyst tries to identify unknown compounds without having previous information.

Confirmatory Methods

Commission Decision 2002/657/EC has clearly established analytic techniques, requirements, and criteria to perform confirmatory analyses of organic residues in foods. With regard to this, only the chromatographic detection systems that provide structural information can be used, on their own or in combination, for the unequivocal identification of the target contaminants. Nevertheless, with the exception of MS, all the other techniques (UV/visible, fluorescence, etc.) can be applied only for the confirmation of group B substances.

Most of the current publications dealing with this matter are still based on QqQ running in MRM (see Table 2); in these cases, because the analyzer does not record a full-mass spectrum, a system of identification points (IPs) is adopted to support the analyte identification: two MRM transitions allow earning 4 IPs (1 IP for the pseudomolecular ion and 1.5 IPs for each product ion), which are enough to confirm both group B substances (IPs $\geq$ 3) and group A substances (IPs $\geq$ 4). Notwithstanding the high selectivity of this scan mode, the unit resolution of the quadrupole cannot distinguish between the target analytes and coeluting isobaric interferences, giving rise to potential false identifications and/or quantitation. This possibility can be verified by matching the ion ratio of the two selected MRM transitions with the average values obtained for the reference standard in solvent; if the problem is proved, it can be easily solved, improving the chromatographic efficiency in order to separate the intrusive peaks from those of the analytes. Another solution is to use a highly selective MRM acquisition mode allowed by an enhanced resolution QqQ: the Q1 analyzer can be set in enhanced resolution (0.1 Da at FWHM) and the Q3 analyzer in unit resolution (0.7 Da at FWHM) maintaining a good sensitivity. After years characterized by a constant focus on typical acquisition modes of LRMS, the use of HRMS is emerging for some figures of merit such as resolution, accuracy, and duty cycle. Nevertheless, as mentioned in the previous paragraph, LC-HRMS is mainly applied for screening purposes, while it could be a valuable alternative to MRM-based confirmation analysis for those contaminants that, under collision-induced dissociation, generate only one diagnostic fragment ion; as a matter of fact, the Commission Decision 2002/657/EC states that one precursor ion and one fragment ion, produced by a mass spectrometer with a resolution of 10 000 FWHM, generate a number of 4.5 IPs (2 + 2.5 IPs) enough to confirm permitted and forbidden substances. An HR instrument suitable to this end is QqTOF but, if the HR instrumentation allows using only the pseudomolecular ion, a resolution of 50 000 FWHM and a corresponding narrow window width are needed to obtain a selectivity comparable to tandem MS. Figure 3 is explanatory in this sense. A performance comparison of QqQ, TOF, and Orbitrap has demonstrated that the latter can discriminate isobaric interferences better than TOF (12 000 FWHM, but QqTOF can reach 50 000) due to its superior mass resolution. Nevertheless, a

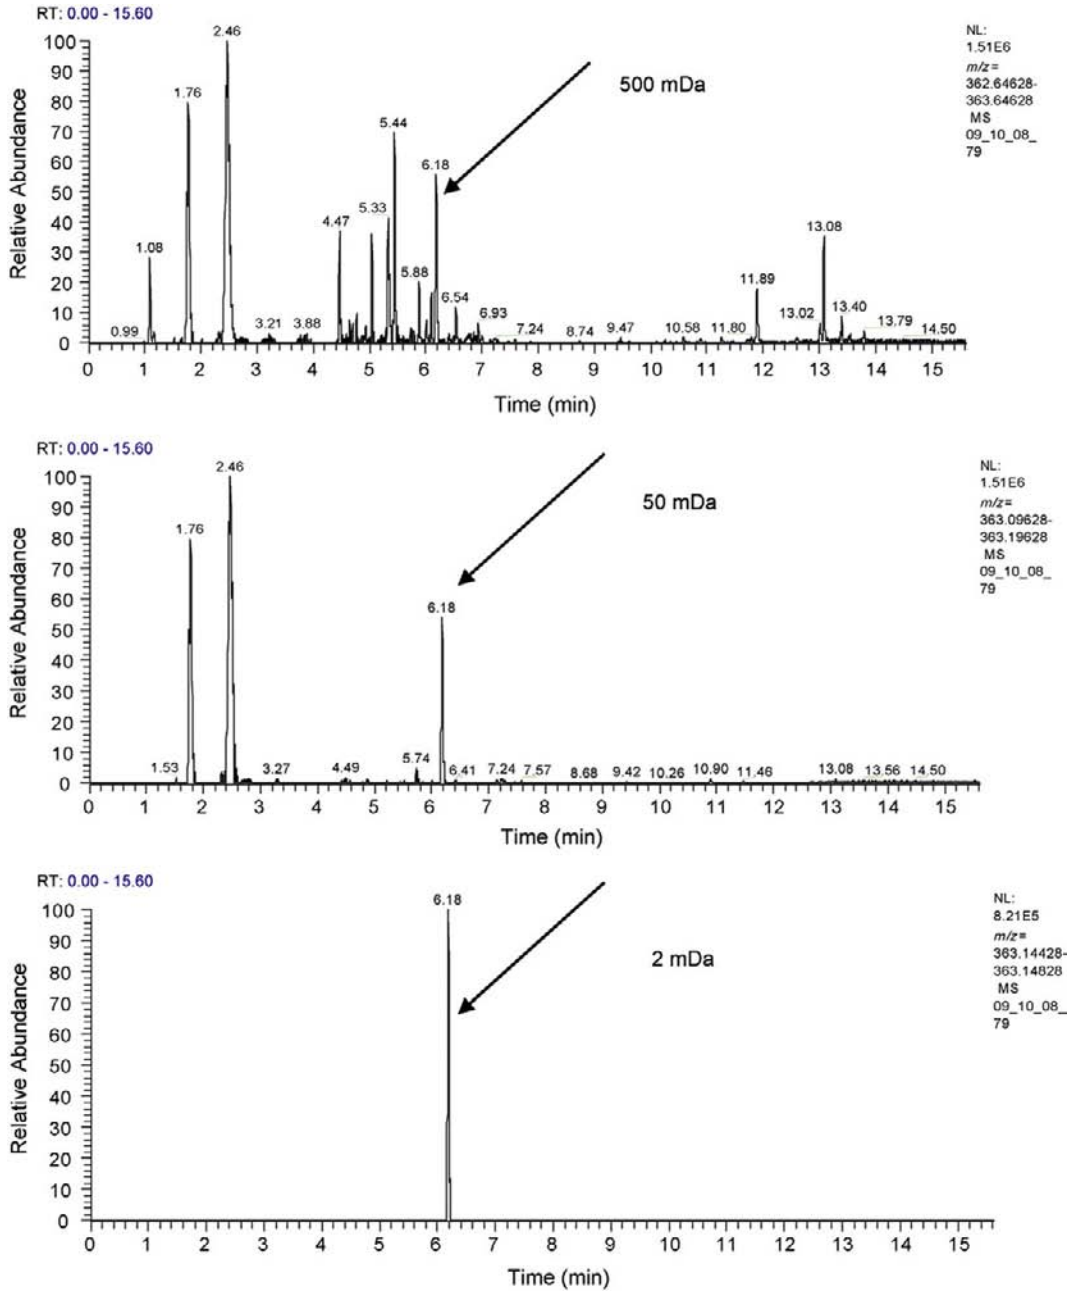

Figure 3 Effect of mass window width on selectivity of a high-resolution mass spectrometer (Orbitrap operated at a resolution of 10 000 FWHM). The example is related to the detection of the pseudomolecular ion $[M+H]^+$ of marbofloxacin at m/ 363.14628 in a liver extract (50 g l^{-1} fortification level). Several intrusive peaks from matrix are detected with a 500 mDa mass window (corresponding to unit resolution). Selectivity increases notably when the mass window is narrowed down to 2 mDa and only the analyte peak is visible. Reproduced from Kaufmann, Butcher, Maden, Walker and Widmer (2010). Comprehensive comparison of liquid chromatography selectivity as provided by two types of liquid chromatography detectors (high resolution mass spectrometry and tandem mass spectrometry): "Where is the crossover point?" *Analytica Chimica Acta* 673, 60–72, with permission from Elsevier.

cumbersome aspect of the single-stage Orbitrap is related to a phenomenon of postinterface signal suppression that affects sensitivity in detecting small-molecular-weight compounds. This event occurs when dirty extracts from protein-rich food are injected into the LC-MS system, causing entrapment of multiple-charged proteins in the C-trap (a focusing device analogous to a linear ion trap) and losses of low m/z ions.

Conclusions and Future Trends

Veterinary drugs include both registered drugs (groups B1 and B2) and banned substances (group A). Owing to the vast range of compounds, routine monitoring tasks have become time- and cost-demanding, accelerating the trend toward the simultaneous analysis of different families of veterinary drugs irreversibly. For

group B substances, the screening with inexpensive microbiological tests or portable biosensors competes with sophisticated and high-priced UHPLC-HRMS systems, which can analyze up to 300–500 substances in one chromatographic run of c. 5 min. It is exactly within this context that the scientific community is continuing to invest its efforts. On the one hand, with the aid of nanotechnology have been designed miniaturized and/or automatized biosensors with enhanced functionality and economic attractiveness. On the other hand, the superior performances of the latest generation mass spectrometers combined with a reduced sample preparation have allowed high-throughput analyses. If LC-MRM is still the gold standard method for confirming drug residues in food, flexible open strategies relying on full-scan HRMS techniques are expected to dominate in the near future. Parallel to the evolution of these approaches (i.e., targeted and untargeted LC-MS methods), there are two opposite trends related to the sample preparation. The first concerns the ongoing development of new nonselective treatments to maximize the number of compounds screened via LC-HRMS. Obviously, these procedures are less suitable for confirmatory methods since a severe matrix effect compromises detection limits, sensitivity, selectivity, and maintenance frequency. In this case, a more extensive purification is demanded to obtain a reliable quantification and, to this end, constant energies are channeled into the development of new sorbent materials and automatic devices for speeding up also routine confirmatory analysis.

Antinutritional Factors in Legume Seeds: Characteristics and Determination

VR Mohan, PS Tresina, and ED Daffodil, V.O. Chidambaram College, Tuticorin, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Plants commonly synthesize a range of secondary metabolites as part of their protection against attack by herbivores, insects, and pathogens or as a means to survive in adverse growing conditions. If farm or domestic animals or humans consume these plants, these compounds may cause adverse physiological effects. The terms antinutrient or natural toxicant have been widely employed to describe plant-defense metabolites in the food and nutrition literature. Legumes are a rich source of antinutrients in the human diet. In food legumes, the presence of some well-defined antinutritional factors has been documented. Antinutritional factors like protease inhibitors, amylase inhibitors, lectins, goitrogens, and antivitamin factors constitute heat-labile antinutritional factors, whereas nonprotein amino acids, alkaloids, cyanogenic glycosides, tannins, saponins, flavones, isoflavones, pyrimidine glycosides, and flatus-producing oligosaccharides form the heat-stable antinutritional factors. Some of the antinutritional factors are discussed below.

Protease Inhibitors

Protease inhibitors isolated from soybean fall into two main categories: the Kunitz inhibitor and the Bowman–Birk inhibitor. The Kunitz inhibitors have a molecular weight of about 21.5 KDa with two disulphide bridges and possess a specificity directed mainly against trypsin. The Bowman–Birk inhibitors have a molecular weight of about 8 kDa with a high proportion of disulphide bonds and the capability of inhibiting chymotrypsin and trypsin at independent binding sites.

The Kunitz inhibitor consists of 181 amino acid residues, with the reactive site (site directly involved in its interaction with trypsin) located at residues Arg 63 and Ile 64. This molecule combines with trypsin in a stoichiometric fashion; that is, one molecule of the inhibitor inactivates one molecule of trypsin. The complex that forms is analogous to an enzyme–substrate complex that, unlike the usual enzyme–substrate complex, is very unstable. The amino acid sequence of Bowman–Birk has two independent binding sites: a trypsin-reactive site (Lys 16 and Ser 17) and a chymotrypsin-reactive site (Leu 43 and Ser 44). In contrast to the Kunitz inhibitors, the Bowman–Birk inhibitors are very rich in disulphide bonds, possessing seven disulphide bridges. This feature is responsible for the very tight, compact, three-dimensional structure revealed by X-ray crystallography and nuclear magnetic resonance. The sequence of amino acids surrounding these two reactive sites are remarkably similar to each other, and a high degree of homology has been found between the Bowman–Birk inhibitor and a number of other low-molecular weight inhibitors that have been isolated from other legumes. In common beans, lima beans, cow peas, and lentils, protease inhibitors have been characterized as members of the Bowman–Birk family. Trypsin/chymotrypsin inhibitors from red kidney bean, Brazilian pink bean, lima bean, and soybean are closely related with high homology. Trypsin inhibitor content of some of the common legumes and underutilized legume seeds have been determined and tabulated (Table 1).

Nutritional Significance

Purified fractions from soybean, which are enriched with trypsin inhibitor activity, are in fact capable of inhibiting the growth of rats, chicks, and mice, an effect that is generally accompanied by a depression in the digestibility of protein in the diet. Furthermore, feeding rats with a raw soybean extract from which the trypsin inhibitors have been removed by affinity chromatography on immobilized trypsin showed improved growth performance when compared with control rats fed diets containing raw soybeans from which the trypsin inhibitors have not been removed. The simplest explanation for the growth inhibition produced by the trypsin inhibitor would be the fact that it interferes with the digestibility of dietary protein. The presence of protease inhibitors such as trypsin and chymotrypsin inhibitors in the diet leads to the formation of irreversible trypsin enzyme–trypsin inhibitor complexes, causing a decrease in trypsin in the intestine and a decrease in the digestibility of dietary protein, thus leading to slower animal growth. As a result, the secreting activity of the pancreas increases, which could cause pancreatic hypertrophy and hyperplasia. Although there is limited information on their specific effects in humans, it is generally considered prudent to remove these protease inhibitors from food prior to consumption. A major beneficial effect of cooking and autoclaving of legume grains is the destruction of protease inhibitors. Significant reduction of trypsin inhibitor (92–99%) content has been noticed after cooking/autoclaving of both raw and presoaked seed samples. Dry-heat treatment also reduces trypsin inhibitor activity (93%). Boiling, however, may be insufficient to deactivate these substances fully. So dry heat (roasting, toasting) is the preferred method for processing.

α-Amylase Inhibitors

α-Amylase inhibitors have been purified and partially characterized from different varieties of common beans, including white kidney beans, red kidney beans, and black kidney beans. The content of α-amylase inhibitors differs greatly among legumes, with the highest amounts found in dry beans. α-amylase inhibitors were found in common beans and runner beans (*Phaseolus coccineus*) at levels of 2–4 kg^{-1} of seed meal. Field beans, black-eyed peas, and chickpeas contain low levels of 0.1–0.2 kg^{-1} of seed meal. In lentils, soybeans, peas, winged beans, lima beans, and adzuki beans, α-amylase inhibitor

activity was undetected. The inhibitor blocks the function of mammalian salivary and pancreatic amylases but not plant, fungal, or bacterial α-amylases.

Lectins

Lectins are proteins or glycoproteins that are widely distributed in the plant kingdom and have the unique property of binding to carbohydrate-containing molecules, with a high degree of specificity toward the sugar component. Lectins are able to agglutinate the red blood cells from various species of animals *in vitro*, and depend on their specificity and high binding affinity for a particular carbohydrate moiety on the cell surface. In 1989, Shillmark was the first to observe that a protein fraction of the castor bean, *Ricinus communis*, which he called *ricin*, was capable of agglutinating red blood cells, a property that led to the term phytohemagglutinin (PHA). In 1908, Landsteiner and Raubitcheck showed for the first time that even the seeds of the edible species of some common legumes such as navy beans, lentils, and garden peas also contain these so-called PHAs. One extremely interesting observation was the fact that the relative hemagglutinating activities of various seed extracts were quite different when tested with the erythrocytes from different animals.

In addition to being able to agglutinate red blood cells, the lectins exhibit a variety of other interesting and unusual biological properties, including interaction with specific blood group substances, mitogenesis promotion of cell adhesion, inhibition of fungal growth and an insulin-like effect on fat cells. Lectins are hardy proteins that do not break down easily. They are resistant to stomach acid and digestive enzymes. Lectins may bind to the gut wall and damage the gut lining, are not altered by digestive enzymes, and may alter gut permeability and pass through the gut into general circulation. Lectins can cause alterations in gut function that may be related to colitis, Crohn's disease, celiac sprue, irritable bowel syndrome (IBS), and gut permeability.

Hemagglutinating activity has been detected in more than 800 different plant species, of which more than 600 are in the family Leguminosae. Most lectins appear to have molecular weights ranging from 100 000 to 150 000 and are usually composed of tetramers that may or may not be identical. A smaller number of lectins, such as those isolated from the lentil and lima bean, appear to be dimmers, having about one-half of the molecular weight of the lectins. All lectins bind one transition ion, usually manganese, and one calcium ion.

Amounts of lectin in legumes vary significantly. Lectins account for about 2.4–5% of the total protein (17–23%) in kidney bean seeds, 0.8% in soybean and lima bean protein (34% and 21%, respectively), and around 0.6% of the total protein (24–25%) in garden peas.

Nutritional Significance

Some legume and cereal lectins can inhibit the growth of experimental animals and reduce the digestibility and biological value of dietary proteins. The antinutritional effects are most likely caused by some lectins that can impair the integrity of the intestinal epithelium and alter the absorption and utilization of nutrients. The lectins from the field bean (*Dolichos lablab*) are toxic when injected into rats; when fed at a level of 2.5% of the diet, they inhibit the growth of rats and cause zonal necrosis of the liver. Thus, dietary lectins have generally been considered toxic and antinutritional factors. However, many lectins are nontoxic, such as those from lentils, peas, chickpeas, and faba beans.

Several studies have suggested a strong correlation between certain lectin-binding patterns and their biological behavior in various tumors. *Vicia faba* agglutinin, a lectin present in broad beans, stimulated the morphological differentiation and reduced the malignant-phenotype colon-cancer cells. The inclusion in the diet of PHA, a lectin present in raw kidney bean, greatly reduced the growth of a murine non-Hodgkin's lymphoma tumor in the mouse. The reduced growth rate occurred in a dose-dependent manner. Lectin is also being used for the discovery of protein markers of cancer using a natural glycoprotein microarray approach. Multiple lectins can screen serum samples from patients with pancreatic cancer or pancreatitis by selective detection of glycan structures.

Inclusion of raw kidney beans in the diet of obese rats reduced lipid accumulation that was related to a decrease of insulin levels caused by lectins. However, no loss of muscle protein occurred even at high doses, as with normal rats, suggesting a possible use of lectins as therapeutic agents to

treat obesity. The most recent EUREKA study showed that red kidney bean lectin given as an additive to 11–12-day-old piglets greatly enhanced successful weaning at 28 days. This result was achieved by stimulating the digestive tract, thereby accelerating the production of mature intestinal cells.

Lectin can be completely removed from lentil flour after 72 h of fermentation at 42 °C with a flour concentration of 76 gl^{-1}. Cooking effectively removes lectin levels of vegetable peas and significantly reduces protein and amino acid solubility.

Goitrogens

Unheated soybeans have been reported to cause marked enlargement of the thyroid gland of the rat and chick, an effect that could be counteracted by the administration of iodine or partially eliminated by heat treatment. A number of cases of goiter have also been reported in human infants fed soybean milk, a condition that could likewise be eliminated by iodine supplementation. The soybean component responsible for the goitrogenic effect of soybeans is still not known for certain. The factor responsible for goitrogenicity observed in these studies was not identified. On the other hand, the goitrogenic principle has been reported to be a low-molecular-weight oligopeptide. It has also been reported that part of the goitrogenic effect of soybeans can be attributed to soyasapogenol. A soy saponin composition provides high bodily absorption characteristics. In an embodiment, a soyasapogenol composition comprises soyasapogenol B and 3-*O*-D-glucuronopyranosyl soyasapogenol B. Some researchers, however, believe that goiter may result from an increased fecal loss of thyroxine or a simple iodine deficiency. One report showed that female rats that had been fed defatted soybeans with an iodine-free diet for 6–12 months developed thyroid carcinomas. This effect was completely prevented by iodine supplementation.

Rats fed with peanuts also develop enlarged thyroids, but in this instance, the goitrogenic principle has been identified as a phenolic glycoside that resides in the skin. It was suggested that the phenolic metabolites formed from this glycoside are preferentially iodinated and thereby deprive the thyroid of available iodine. Thus, the goitrogenicity of peanuts is effectively prevented by iodine supplementation but not by heat treatment.

Cyanogens

A number of plants are potentially toxic because they contain glycosides from which hydrogen cyanide (HCN) may be released by hydrolysis. As shown in Table 1, the *Phaseolus lunatus* (lima bean) has higher cyanide-producing potential than that of cassava, which is well known as a source of cyanide. In order to be considered acceptable for human consumption, the cyanide concentration of lima beans should fall within the range of 10–20 mg/100 g. The cyanide content of most other legumes is of such low levels that it does not constitute a risk to human health.

Cyanide in the form of HCN is released from the glycoside of lima beans (phaseolunatin, also known as linamarin) through the sequential action of two enzymes, a β-glucosidase and oxynitrilase. Hydrolysis then proceeds quite rapidly during the early stages of the cooking process, but much of the HCN is subsequently lost by volatilization.

Total Free Phenolics and Tannins

Plants produce an amazing array of phenolic compounds such as free phenolics and tannins, which have the potential to react with proteins and other cytoplasmic components. In some cases, the subsequent reaction between phenols and proteins is highly appreciated because it adds flavor, taste, and appearance to products such as tea, coffee, beer, and tobacco. However, from a nutritional point of view, the main concern with phenols in dietary proteins is the way in which they decrease their digestibility and nutritive value.

Phenolic compounds decrease the digestibility of proteins and carbohydrates and the availability of vitamins and minerals. They lower the activity of digestive enzymes such as α-amylase, trypsin, chymotrypsin, and lipase, and may cause damage to the mucosa of digestive tract and also reduce the absorption of nutrients such as vitamin B_{12}.

The negative nutritional effects of the tannins are diverse and incompletely understood, but the major effect is to cause growth depression by decreasing the digestibility of proteins and carbohydrates. This is most likely the consequence of the interaction of tannins with either protein or starch to form enzyme-resistant substrates. Interaction with the enzymes themselves may also lead to an interference with the digestibility of these substrates.

The total phenolic and tannin content of commonly consumed pulses and underutilized legumes is presented in Table 1. Phenolics and tannins are water-soluble compounds and, moreover, are concentrated in the seed coat. They can be eliminated by common processing methods such as decortication, soaking and heat treatment, or the cooking process.

The potential health benefits of common beans are attributed to the presence of secondary metabolites such as phenolic compounds that possess antioxidant properties. Pulses with the highest total phenolic content (lentil, red kidney, and black beans) exert the highest antioxidant capacity assessed by 2,2, diphenyl-1-picrylhydrazyl free radical scavenging, ferric-reducing antioxidant power, and oxygen radical absorbance capacity. Phenolics have been suggested to exhibit health-related functional properties such as anticarcinogenic, antiviral, antimicrobial, anti-inflammatory, hypotensive, and antioxidant activity.

Phytic Acid

Phytic acid (myoinositol hexaphosphate or $InsP_6$) is a major phosphorus storage form in plants, and its salts, known as phytates, regulate various cellular functions such as DNA repair, chromatin remodeling, endocytosis, nuclear messenger RNA export, and potential hormone signaling important for plant and seed development. It is often regarded as an antinutrient because of its strong mineral, protein, and starch binding properties, thereby decreasing their bioavailability. Although

the ability of phytate to influence the availability of minerals no doubt accounts for its major antinutritional effect, it is also true that phytate strongly interacts with the basic residues of proteins. As a consequence of this nonselective binding to proteins, phytate has been shown to inhibit the action of a number of enzymes important in digestion, including pepsin, trypsin, and alpha amylase. Though phytate inhibits the digestion of protein when studied *in vitro*, binding of phytate to proteins may be direct (phytate: protein) or indirect (through a cation bridge). These complex interactions vary with pH, time, and relative concentrations. At low pH (e.g., in the stomach), phytic acid forms electrostatic linkages with the basic arginine, lysine, and histidine residues, resulting in insoluble complexes.

In vivo and *in vitro* studies have demonstrated that phytic acid exhibits significant anticancer (preventive as well as therapeutic) properties. It reduces cell proliferation and increases differentiation of malignant cells, with possible reversion to the normal phenotype, and is involved in host defense mechanisms and tumor abrogation. Phytic acid delays postprandial glucose absorption, reduces the bioavailability of toxic heavy metals such as cadmium and lead, and exhibits antioxidant activity by chelating iron and copper. Dietary and endogenous phytic acid has protective effects against cancer and heart disease and may be responsible for the cancer-protective effects of high-fiber foods. The anticarcinogenic properties of phytic acid may result from numerous factors, including its ability to chelate metal ions; this depends on the phytate retaining its integrity in the colon, a profuse microbial ecosystem.

The phytic acid content of some common legumes and underutilized legume seeds is shown in Table 2. Hydration-induced reduction in phytate content in legumes may be attributed to the activity of phytase and diffusion of the products. An increase in phytase activity with a decrease in the level of phytate as a result of hydration in faba beans has been reported. Previous reports on the effects of germination on phytic acid in beans indicated that as a result of increased enzyme activity, 20–70% or more of the phytic acid is hydrolyzed during germination, depending on the type of bean and the increase in phytase activity. The reduction of phytic acid indicated that an increase in hydrolysis of phytates during germination led to the liberation of inorganic phosphates for plant growth from an organic phosphorus-containing compound (phytate). Because phytic acid has been considered one of the factors responsible for reducing mineral availability, the reduction during germination may have enhanced the nutritional quality of beans.

Saponins

Saponins comprise a large family of structurally related compounds containing a steroid or triterpenoid aglycone (sapogenin) linked to one or more oligosaccharide moieties. They are characterized by their hemolytic activity and foaming properties and are responsible for imparting a bitter taste and astringency to plant materials containing a high concentration of saponins. Saponins are very poorly absorbed. Most of the saponins form insoluble complexes with 3-*b*-hydroxysteroids and are known to interact and form large mixed micelles with bile acids and cholesterol. Although saponins were shown to lower cholesterol in some animal species, the hypocholesterolemic effects of saponins in humans are more speculative. In addition, they form insoluble saponin–mineral complexes with iron, zinc, and calcium. The most common saponins in legumes include the soyasaponins, which are classified into group A, B, and E saponins on the basis of the chemical structure of the aglycone. Field pea extracts were initially thought to contain soyasaponin I (S-I) and then soyasaponin VI (S-VI) as the only soyasaponin, but recently field pea extracts were shown to contain dehydrosoyasaponin I (D-I) minor component. This triterpenoid saponin dehydrosoyasaponin I is a natural product present in chickpeas and other legumes, and is known to be a potent calcium-activated potassium channel opener, and as such can be used for treating cardiovascular, urological, respiratory, neurological, and other disorders.

Saponins have been reported in many edible legumes. The major sources of dietary saponins are legumes, and many types of saponins can be present in the same bean. Saponin content may vary even among the same species of edible legumes (Table 3).

Recent *in vivo* studies have established that the health benefits of legume saponins are several, such as the hypocholesterolemic effect and anticarcinogenic, antioxidative, antitumor, antivirus, antihepatic, antidiabetic, and hepatoprotective properties; they can also be beneficial for hyperlipidemia. In addition, they reduce the risk of heart disease in humans who consume a diet rich in food legumes containing saponins. Epidemiological studies suggest that saponin may play a major role in protection from cancer. Research on colon cancer cells suggests that it is the lipophilic saponin cores that may be responsible for the biological activity.

Oxalate

Oxalate salts are poorly soluble at intestinal pH, and oxalate is known to decrease calcium absorption in monogastric animals. For instance, oxalate binds to calcium to form complexes (calcium oxalate crystals). These oxalate crystals prevent the absorption and utilization of calcium by the body, causing diseases such as rickets and osteomalacia. The calcium crystal may also precipitate around the renal tubules, thereby causing renal stones. The formation of oxalate crystal is said to take place in the digestive tract. Oxalate is a concern in legumes because high-oxalate diets can increase the risk of renal calcium absorption, as calcium is made unavailable to the body due to the presence of oxalate. Legumes such as lentils, red kidney beans, and white beans have been analyzed for oxalate. The highest and lowest contents are present in Anasazi beans (80 mg, 100 g, 100 g^{-1} wet weight) and black-eyed peas (4 mg, 100 g, 100 g^{-1} wet weight), respectively.

Pyrimidine Glycosides

Vicine and convicine are generally present in *Vicia faba* and belong to the group of pyrimidine glycosides, which are composed of one molecule glucose linked to one pyrimidine nucleoside. In contrast, other grain legumes (e.g., *Pisum sativum*) and

oil seeds contain only negligible amounts compared to faba beans. Vicine and convicine act by reducing glutathione and glucose-6-phosphate dehydrogenase activity, which may result in hemolytic anemia due to biochemical abnormalities of blood cells.

Alkaloids

Alkaloids are naturally occurring toxic amines produced by plants mainly as a defense mechanism to protect themselves against herbivores. The main toxic effects of alkaloids result in disturbances of the central nervous system, digestive processes, reproduction, and the immune system. Within grain legumes, mainly lupins are known to contain alkaloids in considerable amounts, while faba beans, peas, and oil seeds are devoid of alkaloids. The major alkaloids of *Lupinus albus* are lupanine (700 mg g^{-1} total alkaloids), albine (150 mg g^{-1} total alkaloids), and 13 α-hydrolupanine (80 mg g^{-1} total alkaloids), while predominant alkaloids of *L. luteus* were identified as lupanine (600 mg g^{-1} total alkaloids) and sparteine (300 mg g^{-1} total alkaloids). The average alkaloid content of recently harvested cultivars of low-alkaloid lupins, also referred to as sweet lupins, is below 0.288 kg^{-1}. In 1981, Dike reported the presence of bioactive compounds such as nicotine, physostinginine, and serotonin present in the *Mucuna* seeds.

Oligosaccharides

Oligosaccharides, which are common in legume seeds, are thought to be the major producers of flatus. These saccharides contain one, two, or three galactose units jointed to α-1,6 galactosidic linkages. They cannot be hydrolyzed and absorbed in monogastric animals because of the lack of α-1,6 galactosidic activity in the small intestine. Microorganisms in the large intestine utilize these sugars, leading to the production of flatus gases (H_2, CO_2, and small amounts of CH_4) and causing abnormal rumbling, diarrhea, and discomfort. Oligosaccharide content of some of the common legumes and underutilized legume seeds have been tabulated (Table 4).

Maximum reduction of oligosaccharides has been observed in legume seeds when processed by autoclaving. Soaking for 20 h in tamarind pulp extract or sodium bicarbonate solution followed by autoclaving causes loss of α-galactosides to the extent of 68–71% and 68–70%, respectively. Moreover, the oligosaccharides are also markedly reduced when subjected to the natural fermentation process (62.68%). Sprouting for 48 and 72 h seems to reduce maximum content (77–94%) of total oligosaccharides. However, among the various processing methods, the crude α-galactosides obtained from a weed, *Cassia serisea*, exhibit promising results. It almost completely removed the galactosides via raffinose (79–85%), stachyose (95–98%), and verbascose (82–83%).

Toxic Amino Acids

Several toxic nonprotein amino acids occurring in higher plants, which are especially abundant in certain legumes (Vicieae, Phaseoleae, Mimosoideae, and Caesalpinioideae), have been detected that resemble protein amino acids. If nonprotein amino acids are taken up by herbivores, microorganisms, or other plants, they may interfere with several targets. They can be accepted in ribosomal protein biosynthesis in place of the normal amino acid, leading to defective proteins (e.g., Canavanine, 3,4-dihydoxyphenylalanine, azetidine-2-carboxylic acid). They can inhibit the charging of aminoacyl-tRNA synthetases or other steps of protein biosynthesis, or they may competitively inhibit uptake systems for amino acids. In vertebrates, effects may be fetal malformations, neurotoxic disturbances, hallucinogenic effects, hair loss, diarrhea, paralysis, liver cirrhosis, hypoglycemia, and arrhythmia, among others.

Mimosine

In 1977, the National Academy of Sciences published a monograph that described the high potential value of the legume

Leucaena leucocephala as a forage crop for livestock and human feeding. One of the principle factors limiting the use of this plant is the presence of an unusual amino acid, mimosine. It comprises 3–5% of the dry weight of the protein. This amino acid is responsible for the poor growth performance of cattle when this plant provides more than one-half of the diet. This adverse effect on growth has been traced to the underproduction of thyroxine, presumably because the rumen bacteria convert mimosine to 3,4-dihydroxypyridine, which acts as a goitrogen. In nonruminants such as the horse, pig, and rabbit, the goitrogenic effect is not very marked, but the animals nevertheless do very poorly on diets containing *Leucaena*, one of the characteristic symptoms being loss of hair. In fact, it has even been suggested that mimosine might be used as a defleecing agent in sheep. Certain segments of the human population, particularly in Indonesia, are known to consume portions of *Leucaena* in their diet, and a loss of hair has frequently been observed among individuals who have eaten the leaves, pods, and seeds in the form of a soup. As far as is known, mimosine has no effect on the meat or milk of ruminants that can be harmful to humans.

In 1951, Matsumoto et al. reported that the mimosine content of the seeds and leaves of *Leucaena* could be decreased by storing the plant at temperatures in excess of 70 °C in the presence of moisture. Adding ferrous sulfate to diets containing unhealed Leucaena also reduced its toxicity to rats. The latter effect has been attributed to an interference with the absorption of mimosine from the gastrointestinal tract.

Djenkolic Acid

Consumption of *Pithecolobium lobatum* seed sometimes leads to kidney failure, which is accompanied by the appearance of blood and white, needle-like clusters in the urine. The latter substance is a sulfur-containing amino acid known as djenkolic acid, which is present in the free state in the bean to the extent of 1–4%.

Canavanine and Canaline

Canavanine, a potentially toxic arginine antimetabolic, and canaline, its primary metabolite also a toxic nonprotein amino acid, are found in seeds of *Canavalia* species. Investigation of these two in *C. ensiformis* has shown that these were synthesized from homoserine and that the degradation of canavanine and canaline was similar to the arginase-medicated hydrolysis of canavanine to canaline in the process of canavanine metabolism. The toxicity of canavanine is due to the structural similarity of arginine. The effect of canavanine is to inhibit the nitric oxide pathway and thereby affect peristalsis. Canaline is a structural analog of citrulline and hence affects the ornithine cycle. Canaline is also toxic due to its ability to react with aldehydes (vitamin B_6) to form oximes and with keto acids. In 1972, Schlueter and Bordas isolated and purified canavanine from *C. gladiata* by hot methanol extraction followed by ion exchange chromatography.

3,4-Dihydroxyphenylalanine

The nonprotein amino acid, 3,4-dihydroxyphenylalanine (L-DOPA), was first isolated by Guggenheim about 70 years ago from the fruits of *Vicia faba*. Since then, its occurrence has been observed in other plants, mostly from leguminous species. Several investigators have reported fairly high levels of L-DOPA from different species of the genus *Mucuna* (Table 2). High levels of L-DOPA in the (unboiled) seeds of *M. utilis* have been reported. The presence of high levels of L-DOPA in the uncooked seeds of *M. utilis* has been implicated to be responsible for causing skin eruptions and an increase in body temperature of the consuming Kanikkars, a South Indian hill tribe.

The L-DOPA extracted from *Mucuna* seeds is used in the preparation of a drug that is administered for the treatment of Parkinson's disease in humans. Although L-DOPA medicine is synthetically manufactured today, *Mucuna* as a source of L-DOPA continues to receive attention. Clinical trials also show higher effectiveness of *Mucuna* powder over synthetic L-DOPA. However, the administration of L-DOPA has been reported to have some serious side effects in patients treated for Parkinson's disease, such as toxic confusional state and hallucination in addition to gastrointestinal disturbances such as nausea, vomiting, and anorexia. It has also been shown to be toxic in individuals with glucose-6-phosphate dehydrogenase deficiency in their erythrocytes, and induce favism.

In 1997, Takasaki and Kawakishi reported that the oxidation product of L-DOPA conjugates with SH compounds (cystein) of proteins to form a protein bound 5-*S*-cysteinyl dopa cross-link and it leads to polymerization of proteins. This might be one of the factors that could be responsible for the lowering of protein and starch digestibility. However, L-DOPA is found to be soluble in water, and it could be possible for consumers to remove/reduce it by adopting simple house-processing methods such as water soaking with boiling. In an earlier study, it was demonstrated that the level of L-DOPA gets significantly reduced by repeated soaking and boiling of seeds. The L-DOPA content in *Mucuna pruriens* is significantly eliminated by dry-heat treatment, cooking, and autoclaving. In 2003, Janardhanan et al. demonstrated that repeated boiling of seeds in water followed by decanting this water seven times resulted in a substantial reduction in the quantity of L-DOPA.

The maximum decrease in L-DOPA level (~51–69%) was achieved by germinating the seed for 3 days, then boiling it for 1 h and dehulling it. In 2002, St. Laurent et al. reported that complete extraction of L-DOPA from *Mucuna* bean is <5 min by placing 0.1 g of powdered seed into 15 ml of distilled water (150 parts of water to 1 part of seed) and placing it in an ultrasonication bath for 5 min.

Antivitamin Factors

The inclusion of raw soybean meal in the diet of chicks may cause rickets unless higher-than-normal levels of vitamin D_3 are added to the diet. This rachitogenic response can be eliminated by autoclaving the soybean meal, but supplementation with calcium or phosphorus is ineffective. It appears that the rachitogenic effect of soy protein isolated may be simply because of phytate, although evidence on this point is inconclusive. Raw kidney beans have been reported to contain an antagonist of vitamin E, as evidenced by liver necrosis in rats and muscular dystrophy and low levels of plasma tocopherol

in chicks. The antivitamin E effect of raw kidney beans can be partially eliminated by heat treatment. Isolated soybean protein has been demonstrated to increase chick requirement for α-tocopherol, as measured by growth, mortality, exudative diathesis, and encephalomalacia. No explanation was offered for this effect, although it has been suggested, but not proven, that α-tocopherol oxidase shown to be present in soybeans may be responsible for the destruction of this vitamin.

Conclusion

Legumes contain antinutritional factors such as protease inhibitors, lectins, cyanogens, total free phenolics, tannins, phytic acid, saponins, toxic amino acids, antivitamins, and oxalate. Legumes also have complex sugars such as raffinose, stachyose, and verbascose, which are responsible for flatulence. These compounds reduce protein digestibility and availability, and are considered antinutritional factors. But some antinutritional factors in legumes have been reported to have health benefits, so these secondary metabolites are currently marked as functional food and nutraceutical ingredients. Further research may determine if they should be preserved or eliminated in each main nutritional situation.

Antioxidants: Characterization and Analysis

HR Griffiths, Aston University, Birmingham, UK

Defining Antioxidants in Foods

Plants thrive on ultraviolet (UV) light to generate energy. Significant by-products of UV exposure include free radical species that damage lipids, proteins, and DNA. Consequently, plants have adapted to manage free radicals effectively and minimize damage. A number of small molecules in plants act as scavengers of free radical species and so have been classified as antioxidants, and several methods are used to characterize antioxidant scavenging specificity and activity. These are reviewed in section '**Characterizing Antioxidant Properties**.' However, even if antioxidants are highly reducing *in vitro*, whether these molecules act as antioxidants in physiological systems has been hotly debated.

Diets rich in many of these molecules with *in vitro* antioxidant activity have been linked to good health through epidemiological studies. For example, the studies of Gey and others in the late 1980s showed that higher levels of vitamin E in plasma are associated with reduced cardiovascular risk. Yet, of the many intervention studies that followed, very few showed any beneficial effect from vitamin E supplementation, and some studies reported more harmful outcomes in those receiving the supplements than in placebo groups. This led to a number of emerging concepts, which should be considered when interpreting antioxidant intervention studies:

- A number of related molecules form vitamin E (tocopherol isoforms). Alpha-tocopherol is at the highest concentration in humans and is predicted to show the greatest antioxidant-like activity *in vivo*. Other tocopherols and metabolites have been postulated to exert effects on signaling via nonantioxidant mechanisms. However, the biological effects of vitamin E may not be due to the antioxidant properties of the molecule(s). Other classes of phenolic 'antioxidants' (e.g., flavonoids) are also widely reported to act as regulators of cell signaling.
- Antioxidant activity in tissue is affected by a combination of absorption, distribution, metabolism, and excretion. Only the metabolites of a given antioxidant may be available biologically (e.g., for flavonoids) because nutrients or bioactive dietary compounds are formed by metabolism in the gut. The efficiency of metabolism may, therefore, affect the rate of absorption, availability, and antioxidant bioactivity.
- Dietary antioxidants act in synergy with endogenously synthesized antioxidants, particularly the tripeptide glutathione, which is the major intracellular defense against free radicals. Glutathione synthesis is carefully regulated by redox state. Dietary antioxidants may suppress endogenous glutathione synthesis by altering cellular redox state and so disable the cellular adaptive response.
- Antioxidant networks that comprise molecules with similar redox potentials exist in physiological systems and regenerate reduced 'antioxidants' of lower redox potential (**Figure 1**). Disruption of the network by overloading with a single micronutrient may prevent effective regeneration networks and lead to failure to adapt to stress.
- Bioactive molecules in plant foods may exert secondary antioxidant effects through upregulating phase 2 enzymes and glutathione levels; glucosinolates (GLS) are effective phase 2 inducers.

The take-home messages from these concepts are that (1) accurate measurement of different micronutrient isoforms, where they exist, should be undertaken; (2) 'antioxidant-like' activity can be achieved by direct radical scavenging and hydrogen donation, as well as by induction of new protein expression, so evaluation of antioxidant activity should include all possibilities; and (3) knowledge of 'antioxidant' bioavailability, metabolism, and bioactivity of metabolites should also be considered.

Characterizing Antioxidant Properties

An antioxidant is, chemically speaking, a reducing agent. Reducing agents are defined as molecules that can receive electrons and/or donate hydrogen. There are a number of ways in which reducing activity can be assessed. These vary based on the nature of the radical species being scavenged. Consequently, it is appropriate to consider using several different methods for analysis when seeking to define antioxidant properties – see Prior et al. on standardized methods for antioxidant capacity measurements of phenolics, which suggests three core assays, the oxygen radical absorbance capacity (ORAC) assay and the Folin–Ciocalteu and Trolox equivalent antioxidant capacity methods that are based on electron transfer and give reducing capacity, normally expressed as phenolic contents.

The USDA published a website detailing the ORAC capacity of specific foods, but this was later withdrawn owing to the lack of evidence for value of nutrients via antioxidant effects.

Different approaches commonly used to measure antioxidant activities are reviewed in the succeeding text. These include scavenging the peroxy-radical generator 2,2′-azobisisobutyramidinium chloride (AAPH), ferric ions, and nitric oxide. Naively, these assays can be considered as a competition between indicator and antioxidant for the oxidizing source. With many of these assays, there is an important caveat, however. The real situation is more complex as the antioxidant may, in fact, reduce the oxidized indicator directly rather than interact with the oxidizing species. In many cases, the indicator is readily reducible (e.g., 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid), ABTS), so any reaction rate recorded may relate to the direct reduction of the oxidized indicator.

Oxidation of ABTS and Reduction of $ABTS^{+}$

The oxidation of ABTS by AAPH results in the formation of a colored product, the ABTS cation radical that can be determined spectrophotometrically at 734 nm. Antioxidants may

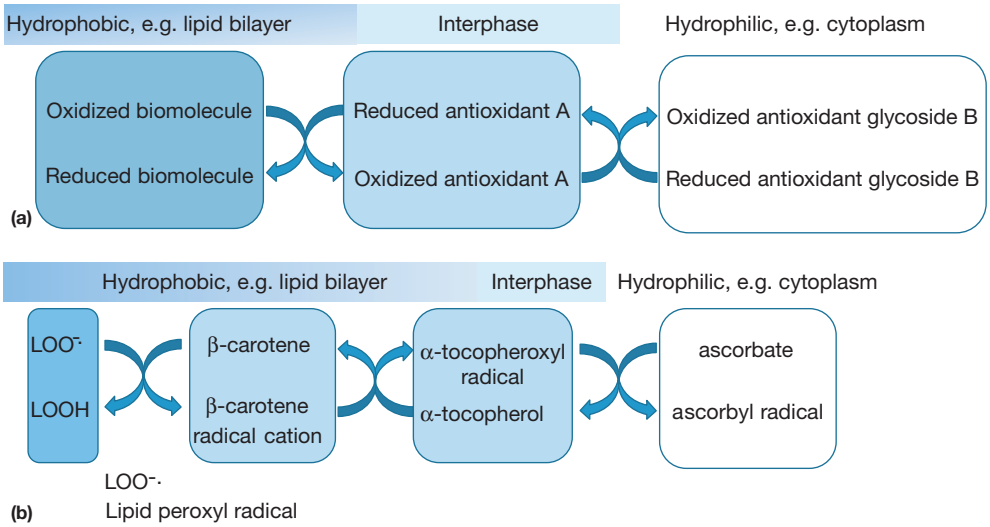

Figure 1 How an antioxidant network could work – (a) theory, (b) thermodynamically feasible reactions. Caution: dietary forms of an antioxidant, metabolized and absorbed from the gut; proximity of antioxidant to a radical; reversibility of the reactions; and relative concentrations of radicals and reducing agents will influence the biological reactions.

delay the onset of the reaction, and the duration of the delay (induction time) is proportional to the concentration and activity of the antioxidant. An alternative to this, which overcomes the caveat, is to simply quantify the reducing potential of the molecule in a reduction assay. Reduction assays are precise because they determine the difference between absorbances of the stable, colored $ABTS^{+}$ before and after addition of antioxidant. In this assay, $ABTS^{+}$ is preprepared by oxidation with potassium persulfate.

Ferric Reducing Ability of Plasma

Ferric reducing ability of plasma (FRAP) is based on the reduction of a colored ferric complex to ferrous ion at low pH, causing the colored ferrous tripyridyltriazine complex to form. Values are obtained by comparing the absorbance change at 593 nm in test reaction mixtures with those containing blue ferrous chloride. The only antioxidant class that is insensitive in FRAP is thiol-active molecules. At low pH, the hydrogen-donating effects of thiols are poor, rendering them undetectable.

Nitric Oxide Scavenging

Nitric oxide scavenging activity can be measured by a variation of the Griess assay, which is commonly used to measure nitrite. Weakly buffered saline solution (pH 7, 40 mmol l^{-1} phosphate is a radical scavenger) and methanol containing the antioxidant are mixed with the nitric oxide donor, sodium nitroprusside. The nitrite produced on decay of sodium nitroprusside is measured at 540 nm after reacting with sulfanilamide and *N*-(1-naphthyl)ethylenediamine dihydrochloride. The greater the antioxidant capacity to scavenge nitric oxide, the lower the nitrite concentration produced.

Standard Electrode Potential Determination

In a cellular system, where multiple scavengers of radical species exist, including amino acids, polyunsaturated fatty acids, and DNA bases, it is important to understand the rates of reaction with radicals and also standard electrode potentials. Pulse radiolysis and electron paramagnetic resonance offer powerful approaches to study one-electron reduction potentials of radical cations. It is also possible to study the transfer of electrons from amino acid radicals to scavengers and vice versa. The standard electrode potential data emerging from these studies, summarized in Table 1, vary according to the solvent system used and pH. This information can provide insight into whether specific scavengers can in fact reduce an amino acid/lipid radical or if they are more likely to transfer electrons to lipids or amino acids and cause oxidation. Biologically speaking though, further important considerations include the (1) rates of the reverse reaction under the same conditions, (2) concentrations and compartments where antioxidants are found, and (3) proximity to the radical they scavenge. Figure 1 provides an overview of our current understanding of an

Table 1 Published redox potentials of biological radicals and dietary antioxidant radicals

Class of redox-active molecules	*Species*	$E^{o\prime}$ *(V)*
Lipids	Lipid peroxyl radical	1.00
Proteins	Trp radical	0.64–1.00
	Tyr radical	0.78–0.91
	Cys radical	0.13–0.27
Vitamin E	α-Tocopheryl radical	0.48
Vitamin C	Ascorbyl radical	0.28
Carotenoids[a]	β-Carotene cation radical	0.5, 0.69, 1.06
	Zeaxanthin cation radical	0.54, 1.03
	Lycopene cation radical	0.98
Polyphenols	Caffeic acid	0.54

antioxidant network. Newer electrochemical methods are being applied to study redox cycling and standard electrode potentials of antioxidants in foods.

Induction of Phase 2 Enzymes

At least nine classes of phase 2 enzyme inducers have been proposed. While they are chemically reactive with thiol entities in proteins, they may act as oxidizing, alkylating, or reducing agents. Phase 2 enzyme inducers are not able to participate in radical or redox reactions. However, their activity changes the redox potential of cells in favor of a reducing environment by inducing the expression of enzymes such as glutathione synthetase, glutathione transferase, and thioredoxin.

A simple reporter assay can be used to measure the potential of a molecule to act as a phase 2 enzyme inducer. Cells that take up antioxidants are transfected with the antioxidant response element (ARE) consensus sequence, which is required for the induction of phase 2 enzymes, and linked directly to a reporter gene such as luciferase. When the cell receives an inducing signal, a chemiluminescent signal is produced that is proportional to the extent of cell activation.

Persistent oxidative stress over an extended time frame tends to overcome the adaptive response, leading to maladaptation and, ultimately, chronic diseases. The ability to adapt and respond via antioxidant enzyme induction is believed to be critical for cellular survival and is thought to decline with age.

Analysis of Antioxidants

The following section reviews knowledge about the biological forms of major classes of antioxidants and antioxidant inducers. Details of analytic approaches are provided for vitamins C and E and carotenoids, about which most are known. Summary overviews of methods for polyphenols and GLS are included at the end of this article. Readers should refer to the recommended texts for further details about polyphenol analysis.

Vitamin C

Consistent with its role as an antioxidant, first identified by Szent-Györgyi in 1932, ascorbic acid is a highly labile entity that readily undergoes oxidation to dehydroascorbic acid. Recommended daily intake varies by country ranging from 40 to 90 mg day^{-1}. Uptake is either via anion transporter – in an energy-requiring process (reduced form) – or via glucose transporters (oxidized form).

Several authors have shown the food matrix does not influence the bioavailability of vitamin C. Acidification of the extraction buffer increases the stability of vitamin C after cells have been ruptured, and, under these conditions, proteins and DNA are also removed. This approach is suitable for measurement of vitamin C in plants or humans. Typically, 10% metaphosphoric acid is used as a stabilizer although others have described the use of equal volumes of ice-cold 0.54 mol l^{-1} perchloric acid. Typically, plasma from blood collected into ethylenediaminetetraacetic acid (EDTA) is analyzed for vitamin C. It is likely the addition of EDTA or DTPA – as chelators – to extraction buffers (2 mmol l^{-1}) that provides additional stability for ascorbate extracted from plant foods. Despite this acidification, ascorbate can still undergo oxidation, even at −80 °C, and is best analyzed within 1 month of sample collection. An extract suitable for analysis is generated after the addition of metaphosphoric acid and centrifugation. High-performance liquid chromatography (HPLC) analysis of vitamin C is relatively straightforward, offering sensitivity and specificity. Sufficient sensitivity can be achieved after derivatization to measure intracellular concentrations of ascorbate in mammalian cells.

Depending on the purpose of analysis (i.e., quantify total or only reduced ascorbic acid), it may be necessary to reduce existing dehydroascorbic acid. This can be achieved effectively with the addition of several compounds, including cysteine and tris(2-carboxyethyl)phosphine hydrochloride.

Several different columns have been used for vitamin C analysis. This is partly due to individual preference but is also largely driven by the detection method. The simplest approach is UV detection based on the ascorbic acid absorbance maxima at 245 and 260 nm. However, the absorbance is sensitive to pH fluctuations with absorbance lost at pH 9. It is important to include standards in each run to compensate for any error in pH. An external standard curve should also be generated from freshly prepared ascorbate serially diluted prior to spectrophotometric analysis.

Direct analysis at 245 and 260 nm, under acidic pH, favors ionization of ascorbate, meaning an amino column can be used successfully in normal phase mode with UV detection. To improve sensitivity and specificity for the analysis of dehydroascorbic acid, ortho-phenylenediamine can be derivatized prior to separation on an amino column with fluorescence detection. The optimal mobile phase has been determined as 0.2 mol l^{-1} KH_2PO_4/H_3PO_4 (pH 3) containing 2 mmol l^{-1} EDTA, delivered at 1 ml min^{-1}.

Newer detection methods favor the application of electrochemistry, such as a Coulochem array detector with +200 mV electrode potential. The array produced is unique for ascorbate and improves both specificity and sensitivity of analysis. Some methods have moved over to reverse-phase C18 columns, using acidic buffers, which are either phosphoric- or acetic acid-based and contain metal chelators (e.g., EDTA and DTPA) and freshly added paired-ion reagent. When applied to analysis of foodstuffs, Proteggente et al. showed that broccoli has an equivalent fresh weight vitamin C content to fresh orange.

Vitamin E

Lipophilic by nature, vitamin E comprises several tocopherol and tocotrienol isoforms (α, β, γ, and δ). Tocotrienols share many of the biological properties of isolated tocopherols *in vitro* and are detectable in plasma after supplementation, but little is known of their accumulation in tissues at present. The study of physiological effects of dietary tocotrienols is an emerging area for study and offers an interesting avenue for future research.

The naturally occurring tocopherol isomers are RRR, whereas synthetic forms tend to be D-isomers. α-Tocopherol is considered to be the major antioxidant in animal foods. However, although the composition is variable, the majority of plant foodstuffs have similar levels of α- and γ-tocopherol. In oils and fats, tocopherols are readily bioavailable, but bioavailability from small seeds and nut fragments is lower. Tocopherol absorption from the gut follows emulsification

and is, generally, associated with lipids. An important biological function of α-tocopherol is its ability to donate hydrogen and so reduce lipid hydroperoxides directly or via β-carotene. In doing so, the oxidized polyunsaturated fatty acids are restored and the tocopheroxyl radical is formed. Regeneration of α-tocopherol may be achieved via the reducing action of ascorbate, which in turn is converted to dehydroascorbate (Figure 1). γ-Tocopherol has been suggested to be a powerful scavenger of peroxynitrite.

Recommended daily intake of α-tocopherol varies by country with mean recommendations lying in the range 6–14 mg day^{-1}. However, there are no such criteria for the other tocopherol isoforms. More recently, attention has been focussed on cell signaling-related effects of tocopherols, and a review of this topic by Hussain et al. is recommended.

Analysis of tocopherols requires extraction from biological samples using organic solvents. Tocopherol acetate is a useful internal standard, which can be added prior to extraction to enable recovery calculations to be undertaken. For extraction, the preferred method uses hexane to which 2,6-di-*tert*-butyl-4-methylphenol (BHT) is added as an antioxidant to minimize oxidation. Phase separation of organic (tocopherol containing hexane) from biological samples is achieved by centrifugation. To improve recovery, further extraction of the remaining aqueous phase can be achieved using an equal volume of hexane. The organic phases should be combined and evaporated to dryness under reduced pressure before the pellet is dissolved in methanol for HPLC. For analysis, a reverse-phase C18 column can be used and tocopherol eluted using 100% methanol. Freshly prepared standards should be used for each analysis with standards and unknown samples determined at 292 nm.

Many laboratories undertake analysis of several lipophilic antioxidants simultaneously. This can be achieved using photodiode array with MS–MS detection, the latter being more sensitive and more suitable for small sample volumes. For MS methods, ionization of analytes is essential, and, in addition to methanol as eluent, the presence of ammonium formate improves sample ionization. One advantage of MS–MS methods is that internal standards can be exactly the same as the analytes of interest, except they are deuterated, which means losses during extraction or analysis, particularly with respect to ionization, are the same for standards as the samples of interest.

Interpretation of plasma α-tocopherol measurements also merits some consideration: given its lipophilicity, α-tocopherol is transported by lipoproteins. Individuals who are hyperlipidemic tend to have a higher plasma α-tocopherol concentration, but this may still be insufficient to protect low-density lipoproteins (LDL) from oxidation. A better index of α-tocopherol antioxidant capacity is its concentration per LDL molecule, which eliminates lipid peroxides. When expressed as α-tocopherol/LDL, concentrations are lower in hyperlipidemic individuals than in (apparently) healthy controls and correlate well with lipid oxidation.

Analysis of α-tocopherol in foods reveals that nuts, in particular almonds, have very high vitamin E content per gram. Whether this is bioavailable is less clear since this is affected by digestion, metabolism, and absorption. Nevertheless, Choudhury et al. showed in an intervention study that increased intake of dietary almonds is associated with increased plasma α-tocopherol/LDL in healthy subjects.

Carotenoids

Beyond the effects of chlorophyll in green vegetables, the color of many plant foods is due to their carotenoid content. First chemically characterized by Willstatter in 1907, the concentration of carotenoids in plants is affected by exposure to light and nitrogen supply.

Up to 600 carotenoids have been described, but the major carotenoids found in foodstuffs, plant- and animal-derived, are α- and β-carotene, lutein, lycopene, β-cryptoxanthin, and zeaxanthin. Natural forms tend to be *cis*-forms, although *trans*-forms can be found in processed foods. There are no dietary requirements laid down for carotenoids, largely because no known deficiency states exist. However, the requirements are likely to be age-dependent, and deficiency of carotenoids has been associated with both dementia and age-related macular degeneration. Guidance from many countries to eat five to seven or more portions of (colored) fruits and vegetables each day will determine the carotenoid concentrations found in plasma. A review of current concepts in carotenoids by Hammond is recommended.

Astaxanthin, one of the oxygen-containing carotenoids (xanthophylls), is attracting recent interest because it was approved for use in fish farm feed to enhance flesh color; it is via this route that it enters the human food chain where it appears to have similar properties to the other major carotenoids in the human diet.

Bioavailability of carotenoids is similar to tocopherols; due to their lipophilicity, they are released from cooked digested food to form mixed micelles, which are, subsequently, absorbed. The distribution of carotenoids in plasma is achieved by lipoproteins. The hydrocarbon carotenoids, β-carotene and lycopene, are mainly transported by LDL, while the more polar carotenoids, lutein and zeaxanthin, are carried by high-density lipoproteins.

Metabolism of β-carotene is complex, and there are many gaps in our knowledge. About 30% of the dietary vitamin A intake in industrialized countries is from β-carotene. However, for developing countries, β-carotene is the most abundant source of vitamin A and in some instances the only one. The review by Shete and Quadro covers the state of the art in carotenoid metabolism. A better understanding of β-carotene metabolism and requirements is essential to reduce risks that may be associated with high levels of intake (above normal dietary intake). Indeed, no health benefits have been reported from supplementation with β-carotene, and deleterious outcomes have been reported in heavy smokers who were also deficient in ascorbic acid. This again supports the importance of maintaining a network of antioxidants where interactions between them may be critical for outcome (Figure 1). Peroxynitrite is scavenged effectively by carotenoids, particularly lycopene.

Lycopene has attracted significant research interest, which is well described by Wang. It is a powerful inducer of phase 2 enzymes, via the transcription factor Nrf2, which activate ARE. Thus, the biological role of carotenoids as 'antioxidants' may be indirect as well as direct (radical scavenging). It is important to note that these effects are largely determined from chemical and studies *in vitro* rather than intervention studies.

Extraction from the biological matrix is necessary for the analysis of carotenoids *in vivo*. Their lipophilicity favors organic

extraction, as with tocopherols. A combination of isopropanol/hexane/dichloromethane (1:5:1) in the presence of BHT with sonication has been used successfully to release carotenoids. After centrifugation, the organic supernatant is removed and retained while the aqueous phase is reextracted. The combined organic phases can be evaporated to dryness under nitrogen before being resuspended for analysis. Others have adopted a simpler ethanol extraction approach for plasma samples with good recovery. Equal volumes of ethanol and plasma are combined, followed by sonication, phase separation, and evaporation to dryness as described earlier. Samples can be resuspended in methanol/acetonitrile/2-propanol (5:4:2) prior to HPLC. The columns used for separation are, typically, non-end-capped silica suitable for the separation of small zwitterions. Carotenoids are eluted with methanol/acetonitrile/2-propanol and determined by photodiode array or absorbance at 460 nm. Others have used reverse-phase chromatography with methanol/water as eluent.

The use of MS–MS for detection can offer advantages in carotenoid identification using precursor and product ions consistent with standards because of the many closely related isoforms that occur biologically and are formed during food processing. Electrochemical detection has shown similar levels of sensitivity to MS, but it provides less selectivity: The measured dominant oxidation potentials are not unique to individual compounds, and unknown interfering compounds may also be present.

Polyphenols

There are six major classes of polyphenols in the human diet: chlorogenic and ferulic acids, flavones and flavanols, catechins, isoflavones, and lignans. There are no recommended daily intakes for these bioactive compounds because they are not nutrients and, although associated with optimal health, it has not been possible to identify the range or extent of intake required. The polyphenols are subject to a number of metabolic reactions: many undergo oxidation, hydrolysis, and condensation in the gut. Bioavailability is affected by gut microflora, as shown in studies where radiolabeled polyphenols have been administered to animals in order to determine the fate of their metabolites. Many studies *in vitro* on the effects of polyphenols in cell culture have been criticized for failing to use the physiological (metabolized) form (without the sugar moiety) or for using concentrations in excess of those likely to be observed *in vivo*.

Extraction is critical in the analysis of polyphenols, and the methods vary according to the analyte of choice. These have been considered in an article by Inat et al. Liquid–liquid, solid–liquid, and supercritical fluid extractions are the favored approaches. Once extracted, both spectrophotometric and HPLC methods have been adopted for analysis. The Folin–Ciocalteu assay is a common spectrophotometric method albeit increasingly criticized. The majority of HPLC methods favor reverse-phase chromatography with either photodiode array or tandem mass spectrometry detection methods.

Glucosinolates

The cruciferous vegetables, which include broccoli, cabbage, and cauliflower, are an excellent source of GLS. GLS coexist in plants with myrosinase, the enzyme that controls its degradation. Isothiocyanates are the major metabolites of GLS and are formed in the gut after plant walls have been ruptured. GLS are highly reactive with thiols and preferentially bind to glutathione and albumin in the systemic circulation. Thiol interaction has been implicated in GLS biological activity as a phase 2 enzyme inducer.

Analysis of GLS frequently involves conversion to desulfo derivatives that can be more easily determined by reverse-phase HPLC with UV detection by diode array. However, standards are lacking, and the identification of GLS is difficult or even impossible to determine unequivocally. The use of MS offers a solution for a more robust identification of GLS, as with other antioxidant enzymes.

Conclusions

Advances in analytic methods, particularly around the use of mass spectrometry, have enabled a new level of confidence in analysis as well as improved sensitivity in many cases. This has led to rapid advances in studying the metabolism of dietary 'antioxidant' molecules within cells as either the parent molecule or metabolite(s). By combining this new knowledge with biological studies to explore molecular mechanisms of action, and chemical evaluation of rates of reaction in simulated systems, we are moving toward a better understanding of the role of dietary antioxidants in human health. The epidemiological data are clear: diets rich in antioxidants are good for health. To date, however, our approach has been too simplistic, and there is a need for improved understanding of why antioxidant-rich diets are good for us. This will be aided by improved analyses and systems biology approaches.

Oxygen is essential element for life. Human cells, as well as those of other aerobic organisms, use oxygen to break down nutrients and provide energy. In the mitochondrial energy-generating system, oxygen is reduced to water, and energy is stored inside ATP molecules. However, this process is a natural phenomenon, as it is essential for life and can be harmful to our body at the same time. Different chemical entities that contain partially reduced oxygen are called reactive oxygen species (ROS). They are continuously produced in the mitochondrial respiratory chain and some other biochemical reactions and have very important signaling role in various cellular processes. Most of them are very reactive, with great affinity to vital molecules of human cells – proteins, lipids, and deoxyribonucleic acids (DNA). Oxidative damage of macromolecules can lead to the disturbance of their function and the development of various diseases. However, in normal conditions, the levels of ROS are low, and human cells protect themselves from their action with efficient antioxidant machinery. Surprisingly, the human body can even use the deleterious action of ROS to help the immune system, destroy foreign substances, and combat infectious diseases. Undoubtedly, the delicate balance between physiological effects of ROS, as signaling molecules and efficient component of immune cells, and their pathological effects is under the control of complex system of antioxidant defense and represents a key aspect of life. However, in pathological states, production of ROS can overcome the capacity of antioxidants. This state is called oxidative stress. The precise definition given by Sies in the early 1990s describes oxidative stress as an "imbalance between oxidants and antioxidants in favor of the oxidants, potentially leading to damage." So, it is not just about the increase in ROS (if it induces more efficient antioxidant defense) or about the decrease in antioxidants (if the level of ROS are low); it is a disturbance in their balance that could end with the damage of our body.

ROS is a term that encompasses all highly reactive, oxygen-containing molecules, including free radicals. ROS includes superoxide ($O^{2}\bullet\ -$), hydroxyl ($\bullet OH$), peroxyl ($ROO\bullet$), lipid peroxyl ($LOO\bullet$), alkoxyl ($RO\bullet$) radicals. Reactive nitrogen species (RNS) include nitric oxide ($NO\bullet$) and nitrogen dioxide ($NO^{2}\bullet$). Oxygen and nitrogen free radicals can be readily converted to other nonradical reactive species that are also dangerous for health. Hydrogen peroxide (H_2O_2), ozone (O_3), singlet oxygen ($^1O_2$), hypochlorous acid (HOCl), nitrous acid (HNO_2), peroxynitrite ($ONOO-$), dinitrogen trioxide (N_2O_3), and lipid peroxides (LOOH) are not free radicals but generally named oxidants and can easily lead to free radical reactions in living organisms.

All ROS and RNS are capable of reacting with membrane lipids, nucleic acids, proteins and enzymes, and various small molecules, resulting in cellular damage.

Mechanisms of ROS Generation

ROS can be produced from both endogenous and exogenous sources. Production of ROS in the body is continuous and a normal part of our physiology.

Endogenous sources of ROS include the following:

Mitochondrial respiratory chain (*MRC*). It is the main source of ROS, particularly $O_2^{\cdot-}$, the most crucial one as it can induce formation of several other reactive oxygen intermediates. $O_2^{\cdot-}$ is formed by reduction of molecular oxygen with electron 'leaked' from the MRC.

Respiratory burst and NADPH oxidase. Respiratory burst is the process by which phagocytic cells consume large amounts of oxygen during phagocytosis, mainly via activation of NADPH oxidase and $O_2^{\cdot-}$ release into the extracellular space or phagosomes. NADPH oxidase is an enzyme present in the plasma membrane and phagosomes of phagocytes such as monocytes, macrophages, neutrophils, and eosinophils. Relocation of the cytosolic components of NADPH oxidase to the cell membrane induces its activation. Enzyme is normally latent in phagocytes but is activated in the membrane before respiratory burst. There are six homologues of NADPH oxidase, collectively called the NOX family of NADPH oxidases.

Xanthine oxidase (*XO*). It is found on the outer surface of the plasma membrane and in the cytoplasm. It catalyzes oxidation of hypoxanthine to xanthine and, further, to uric acid as part of purine catabolism. Both reactions generate $O_2^{\cdot-}$. However, $O_2^{\cdot-}$ has a short half-life and is readily reduced to H_2O_2, so is not considered as highly reactive. Additionally, due to charged moiety of $O_2^{\cdot-}$, it cannot pass through lipid membranes. The production of xanthine and XO is greatly enhanced during ischemia, accompanied with the loss of antioxidant enzymes. O_2 is an electron acceptor and cofactor for XO, thus generating $O_2^{\cdot-}$ and H_2O_2, a major ROS in ischemia, causing damage to ischemic cells and tissues of different origins.

Lipoxygenases (*LOX*). They are nonheme iron enzymes that catalyze dioxygenation of polyunsaturated fatty acids and formation of hydroperoxyl derivatives that can be subjected to reduction and give corresponding hydroxyl derivatives, including leukotrienes and lipoxins. In humans, oxidation of arachidonic acid by LOX generates ROS. Five LOX enzymes identified in humans, named based on position of oxygenated residues, catalyze four different reactions that produce fatty acid hydroperoxides. LOX are deeply involved in the process of atherogenesis.

Myeloperoxidase (*MPO*). It is a heme enzyme localized in lysosomes of neutrophils, macrophages, and monocytes. It catalyzes the reaction of H_2O_2 to highly reactive HOCl and an oxidation of thiocyanate (SCN^-) to hypothiocyanite ($OSCN^-$).

Nitric oxide synthase (*NOS*). It is a heme-containing monooxygenase that generates NO. Three different isozymes of NOS have been identified: constitutively expressed neuronal NOS (nNOS or NOS I), endothelial NOS (eNOS or NOS III), and endotoxin- or cytotoxin-inducible NOS (iNOS or NOS II). All types of NOS catalyze the oxidation of L-arginine to an intermediate, *N*-hydroxy-L-arginine, followed by generation of L-citrulline and NO. NOS can also generate H_2O_2 within a reaction with $O_2^{\cdot-}$ at low L-arginine levels. $NO^{\cdot}$ is a weak oxidant, but in reaction with $O_2^{\cdot-}$ generates $OONO^-$. NO and $OONO^-$ can further form very stable nitrite (NO_2^-) and nitrate (NO_3^-) ions, which accumulate in cells, and form reactive intermediates: NO_2, N_2O_3, and $^{\cdot}NO$. They are capable to nitrate and nitrosate important biological macromolecules such as DNA, RNA, proteins, and lipids and disrupt their function. 8-Nitroguanine, a nitration product of DNA and RNA, is a potent prooxidant and mutagen.

Cyclooxygenase (*COX*). It is a bifunctional enzyme with both COX and peroxidase activities. COX releases arachidonic acid (AA) from membrane phospholipids and catalyzes further conversion of AA to prostanoids. There are two isoforms of COX, COX-1 and COX-2. COX catalyzes oxidation of AA to unstable cyclic hydroperoxide (PGG_2) and further its reduction of PGG_2 endoperoxide due to its peroxidase activity (PGH_2). PGH_2 is converted to stable prostanoids such as PGE_2, prostacyclins, and thromboxane A_2. The peroxidase activity of COX generates $NAD^{\cdot}$ and $NADP^{\cdot}$ radicals, which can further generate $O_2^{\cdot-}$.

Transition metals. Transition metal ions such as iron (Fe^{2+}) and copper (Cu) are involved in the Fenton reaction that generates $HO^{\cdot}$ and $OH^{\cdot}$ from H_2O_2, and they are oxidized to Fe^{3+} and Cu^{2+}, respectively. The generation of $HO\cdot$ through this pathway accelerates lipid peroxidation.

Oxidative stress can also be triggered by external factors acting as direct or indirect sources of ROS:

Radiation and chemotherapy. Ionizing radiation can produce $HO^{\cdot}$ by radiolysis of water or other ROS via secondary reactions. Particularly, susceptible systems are the cerebrovascular, gastrointestinal (GI), and hematopoietic systems. Cancer chemotherapy induces generation of ROS and decrease in vitamin E and beta-carotene levels that often cause toxic side effects.

Cigarette smoke. It is a significant contributor to oxidative stress as source of a large number of free radicals and other oxidative and aromatic agents acting as direct or indirect ROS generators.

Xenobiotics including drugs, food, and alcohol. Food can contain different ROS or compounds that can generate ROS within a human body (iron, copper, trans fatty acid, and acrylamide). Thermally treated lipids and alcohol can be significant contributors to oxidative stress. Increase in oxidative stress has been observed in postprandial states after high-fat and/or high-sugar meals. Many drugs (glucocorticoids, anesthetics, and nonsteroidal anti-inflammatory agents) and xenobiotics generate free radicals. This is also an important feature of a great number of anticancer agents, which often act as therapeutic through generation of ROS.

Mental stress. It can trigger the production of free radicals as toxic by-product of intensive metabolism. In addition, hormones that mediate stress reaction in the body (cortisol and catecholamine) decompose into destructive free radicals.

Pollutants. Air pollutants (asbestos, benzene, carbon monoxide, chlorine, formaldehyde, ozone, and toluene), chemical solvents (cleaning products, glue, paints, paint thinners, perfumes, and pesticides), and water pollutants (chloroform and other trihalomethanes) are potent generator of free radicals. Burning of organic matter during cooking, forest fires, and volcanic activities also can generate free radicals.

Antioxidant Defense System

Nature has endowed each cell of our body with adequate antioxidant mechanisms for protection against any harmful effects of ROS generated within the body or those that entered our body from the environment. Endogenous antioxidant defense system (ADS) comprises enzymatic and nonenzymatic antioxidants. Besides endogenous antioxidants, different substances or agents that can scavenge reactive oxygen metabolites, block their generation, or enhance capacity of endogenous antioxidants act as exogenous antioxidants. Dietary compounds, including vitamins, minerals, polyphenols, isothiocyanates, and carotenoids, are the most important exogenous antioxidants. The fact that they are safe, cheap, and orally bioavailable resulted in their most often use as antioxidant supplements in the prevention or therapy of stress-related diseases. Antioxidants act as radical scavengers, hydrogen donors, electron donors, peroxide decomposers, singlet oxygen quenchers, enzyme inhibitors, enzyme inducers, synergists, or metal-chelating agents.

Endogenous Enzymatic Antioxidants

The major antioxidant enzymes in human cells are superoxide dismutases, glutathione peroxidase, glutathione reductase, and catalase. SOD and catalase provide major antioxidant defenses against ROS.

Superoxide dismutases (*SOD*) are enzymes that catalyze dismutation of $O_2^{\cdot-}$ into O_2 and H_2O_2. There are three isoforms of SOD in humans: cytosolic copper- and zinc-containing SOD (Cu-Zn-SOD), manganese-containing mitochondrial SOD (Mn-SOD), and extracellular copper- and zinc-containing SOD (EC-SOD). Mn-SOD is essential for life.

Glutathione peroxidase (*GPX*) converts glutathione into oxidized glutathione (glutathione disulfide, GSSG) and simultaneously reduces H_2O_2 to H_2O and lipid hydroperoxides (ROOH) to corresponding stable alcohols. This reaction is coupled to the reaction catalyzed with glutathione reductase (GSSG-R), the enzyme responsible for maintaining optimal reduced glutathione (GSH) levels. Neurons are characterized by very low levels of GSH and thus are particularly vulnerable to free radical damage. GPX has very important role in protecting cells from the harmful effects of peroxide decomposition. There are eight isotypes of GPX in humans, and most of them have selenocysteine residues at their active site, crucial for their action.

$O_2^{\cdot-}$ formed in the mitochondria is converted to H_2O_2 by the action of Cu-Zn-SOD of the mitochondrial intermembranous space and Mn-SOD of the mitochondrial matrix. Formed H_2O_2 is reduced by GPX present in the mitochondrial matrix. Uncharged H_2O_2 passes the mitochondrial membranes and

can be scavenged in the cytosol by cytosolic Cu-Zn-SOD or catalase.

Catalase is a heme enzyme located mainly in peroxisomes. Liver and kidney cells, as well as erythrocytes, are rich in catalase. It converts H_2O_2 to H_2O and O_2.

Glutathione reductase (*GR or GSR*) is a homodimeric flavoprotein disulfide oxidoreductase. It reduces oxidized glutathione (GSSG) to GSH. GSH is an important antioxidant, and thus, GR's main role is to protect red blood cells, hemoglobin, and cell membranes from oxidative stress.

Heme oxygenase (*HO*) catalyzes degradation of heme and formation of CO, biliverdin, and iron. It does not have a direct antioxidant enzymatic function, but indirectly, via its products, it can protect cells against oxidative stress. It exists in two isoforms, inducible HO-1 and constitutively expressed HO-2. HO-1 expression is induced by heat shock, UV radiation, or ischemia/reperfusion injury.

Endogenous Nonenzymatic Antioxidants

Glutathione (*GSH*), a tripeptide consisting of glutamate, cysteine, and glycine, is found in all eukaryotic cells and represents one of the key nonenzymatic antioxidants in the body. It is mainly present in its reduced form, GSH. It is accompanied by three enzymes involved in its homeostasis: GR, GPX, and glutathione *S*-transferases (GST). They form the glutathione system. In the gut mucosa, the GSH system serves as an antioxidative barrier.

Thioredoxin system is composed of thioredoxin (Trx) and thioredoxin reductases (TrxR). Trx is disulfide-containing oxidoreductase that modulates activity of redox-sensitive transcription factors. In its dithiol form, it scavenges ROS and recovers from the formed oxidized Trx state (Trx-S-S) via reduction catalyzed by a flavoenzyme TrxR and NADPH.

Melatonin is a hormone of the pineal gland but can be found also in the retina, lymphocytes, GI tract, and bone marrow. It neutralizes $HO^{\cdot}$ and peroxyl radicals, $CO_3^{\cdot -}$, NO_2, $O_2^{\cdot -}$, and HOCl. The characteristic of this antioxidant is that it is irreversibly oxidized, so it is often called a suicidal or terminal antioxidant. It is a valuable protector of the mitochondria against oxidative stress, as it can pass through the mitochondrial membrane, and thus, it is an important protector of the liver from oxidative stress induced by alcohol consumption.

Exogenous Antioxidants

Vitamin C or ascorbic acid is the primary antioxidant in the plasma and cells. It is a water-soluble vitamin found in all body fluids. As an essential nutrient, it needs to be taken from foods, mainly fresh fruits and vegetables. It donates two electrons from C-2 and C-3 double-bond carbons, which results in the formation of an intermediate free radical, semidehydroascorbic acid E. The resulting ascorbate free radicals reduce to a neutral ascorbate molecule. It can react with various ROS, RNS, sulfur radicals, O_3, nitrosating compounds, and HOCl.

Vitamin E and α-tocopherol, as the most active form of this vitamin, protect cell's lipids from peroxidation by scavenging ROS, but they can also act as prooxidants and reduce transition metals. The mode of action depends on the level of α-tocopherol.

Carotenoids and vitamin A are thought to be antioxidants, but they can act as either prooxidant or oxidant depending on the level of $O_2^{\cdot}$ and carotenoids.

Minerals (zinc (Zn), copper (Cu), manganese (Mn), iron (Fe), and selenium (Se)) are antioxidant micronutrients as they are cofactors of important antioxidant enzymes. Zn, Mn, and Cu are cofactors of superoxide dismutase (Cu/Zn-SOD), and Fe is a component of catalase. Se is a major antioxidant as it is a component of selenoproteins. Se deficiency can result in toxicity through increased $O_2^{\cdot -}$, NO, and lipid peroxidation.

Bioactive plant polyphenols are secondary plant metabolites, widely distributed in fruits and vegetables. Plant polyphenols are important dietary antioxidants, and dietary intake of these compounds can be up to 1200 mg day^{-1}. Main polyphenol classes are flavonoids, phenolic acids, and procyanidins, and they all posses strong antioxidant potential confirmed in chemically based assays. However, their direct antioxidant potential is compromised by their low bioavailability and extensive metabolism, resulting in very low levels of the parent compounds (in aglycone from) and metabolites. They can also be susceptible to the metabolic transformation by intestinal microbiota resulting in a wide variety of simple compounds, which bioactivity still needs to be confirmed. Polyphenols are shown to be potent inhibitors of XO, COX, LOX, GST, microsomal monooxygenases, and NADH oxidase and are capable to chelate transition metals and indirectly suppress ROS production. Isothiocyanates are bioactives of cruciferous vegetables, present in the form of their precursors, glucosinolates. They do not exert direct antioxidant activity, but are potent inducers of antioxidant enzymes, such as GST, and induce increase in cellular glutathione levels. They can also be cytotoxic depending on their concentration and the side chain. Less lipophilic isothiocyanates enter the cell in a time-dependant manner and react with GSH, and the decrease in GSH levels is a signaling factor for GST induction, resulting in net increase of cellular GSH levels. More lipophilic ones enter the cell very fast resulting in immediate deprivation of GSH levels and induction of cytotoxic effects. Dietary levels of isothiocyanates cannot exert toxic effects on normal cells.

Levels of Antioxidant Action

An antioxidant is a molecule stable enough to donate an electron to a rampaging free radical and neutralize it, thus reducing its capacity to damage. These antioxidants delay or inhibit cellular damage mainly through their free radical-scavenging property. Antioxidants interact with free radicals and terminate chain reactions by removing free radical intermediates and inhibit other oxidation reactions by being oxidized themselves. A large number of antioxidants, acting this way, including glutathione, ubiquinol, and uric acid, are produced in the body during normal metabolism. Other antioxidants are obtained from a diet.

The ADS assumes several different acting levels such as prevention, radical scavenging, repair and *de novo* synthesis, and adaptation as the lines of defense.

The first line of defense comprises preventive antioxidants, able to suppress the formation of free radicals. GPX, GST, phospholipid hydroperoxide glutathione peroxidase (PHGPX), and peroxidase are known to decompose lipid

hydroperoxides to corresponding alcohols. PHGPX is unique as it can reduce hydroperoxides of phospholipids integrated into biomembranes. Glutathione peroxidase and catalase reduce hydrogen peroxide to water.

The second line of defense comprises antioxidants that scavenge the active radicals to suppress chain initiation and/or break the chain propagation reactions. The examples include both hydrophilic (vitamin C, uric acid, bilirubin, albumin, and thiols) and lipophilic (vitamin E and ubiquinol).

The third line of defense is the repair and *de novo* synthesis of antioxidants. The proteolytic enzymes, proteinases, proteases, and peptidases, present in the cytosol and in the mitochondria of mammalian cells, recognize, degrade, and remove oxidatively modified proteins and prevent their accumulation. The DNA repair systems also play an important role in the total defense system against oxidative damage. Various kinds of enzymes such as glycosylases and nucleases, which repair the damaged DNA, are known.

The fourth line of defense is another adaptation mechanism, where the signal for the production and action of reactive species induces formation and transport of the appropriate antioxidant to the right site of action.

Antioxidants in Human Diet

Vitamin C cannot be stored in the body and should be included in regular diet. Important sources include citrus fruits, green peppers, broccoli, green leafy vegetables, strawberries, raw cabbage, and potatoes.

Vitamin E (*tocopherols and tocotrienols*) is a fat-soluble vitamin that can be stored in the liver and other tissues. It is often indicated for a range of states, from aging delay to sunburn healing. Important dietary sources of vitamin E are wheat germ, nuts, and seeds.

Beta-carotene, as the most studied of more than 600 different carotenoids that have been discovered, protects dark green, yellow, and orange vegetables and fruits from solar radiation damage. It is hypothesized that it plays a similar role in the body. Carrots, squash, broccoli, sweet potatoes, tomatoes, kale, collards, cantaloupe, peaches, and apricots are particularly rich sources of beta-carotene.

Selenium is an important component of antioxidant defense. Selenium should be taken from foods, as large doses that can be present in supplements can exert toxic effects. Good food sources include fish, shellfish, red meat, grains, eggs, chicken, and garlic. Vegetables can also be a good source if grown in selenium-rich soils. Cereals contain selenomethionine, a naturally occurring amino acid that is the most important nutritional source of Se.

Plant bioactives. In addition to many vitamins and minerals as nutrients, plants are rich sources of nonnutritive dietary compounds and plant secondary metabolites – phytochemicals – and many of them are bioactive, influencing different processes of the human body. One of the most investigated activities is their antioxidant potential, confirmed in numerous chemically based assays. However, very often, their metabolites, which are the form of bioactives that can be found in the circulation, lose the antioxidant potential of the parent compounds. Still, they have been shown to affect redox states in the cell by acting as signaling molecules. Depending on the particular class or subclass of polyphenols, main dietary sources of these bioactive compounds are numerous. Rich sources of phenolic acids are berry fruits, kiwi, cherries, aubergine, chicory, artichoke, potatoes, corn flour, ciders and coffee. Berry fruits are also the main dietary source of anthocyanins (subclass of flavonoids) that are also present in substantial quantities in grapes, plums, and wine. Bioactives of other flavonoid subclasses can be found in onion, kale, tomato, cherry, broccoli, berry fruits, apricots, apples, green and black tea, and beans (flavonols); parsley, celery, and capsicum pepper (flavones); citrus fruits and juices (flavanones), soy and soy products (isoflavones); and chocolate, beans, apricots, grapes, peach, apple, green and black tea, and wine (monomeric flavanols). Isothiocyanates are the main bioactives of cruciferous vegetables including broccoli, cauliflower, cabbage, kale, watercress, garden salad, turnip, and horseradish.

Glutathione (*GSH*) protects cells from toxins including free radicals. The human body produces GSH from the synthesis of three key amino acids: cysteine, glycine, and glutamic acid. Food sources with the highest amounts of naturally occurring GSH include asparagus, avocado, grapefruit, squash, potato, cantaloupe, peach, zucchini, spinach, broccoli, watermelon, and strawberries. Fish, meat, and foods that yield sulfur-containing amino acids (e.g., eggs) are the preferred sources for maintaining and increasing bodily GSH levels.

Peroxidase is an enzyme occurring especially in plants, milk, and leukocytes and consisting of a protein complex with hematin groups that catalyzes the oxidation of various substances. Food sources of peroxidase are horseradish root, soybean, mango fruit, and turnip.

Cysteine is an important antioxidant in cellular systems. Cysteine is incorporated in the cellular glutathione, which works along with vitamin E to protect cells against free radical oxidant damage. Cysteine is a nonessential amino acid, synthesized in the liver from methionine. Animal proteins are better sources of sulfur amino acids compared to proteins from vegetables. Therefore, a balanced diet that includes both animal and vegetable proteins (from grains and beans) would provide adequate cysteine intake. Excessive intake of cysteine can result in liver damage, kidney stone formation, or even some forms of neurological disturbances.

Role on Health and Prevention

Oxidative Stress and Disease

In physiological conditions, the human body is in a steady state with ROS being continuously generated and quenched. In pathological conditions, in the state of 'oxidative stress,' increased levels of ROS can cause long-term damage that has been implicated in numerous degenerative diseases. Oxidative stress has been demonstrated by depressed levels of antioxidant substances (e.g., carotenoids, vitamin C, glutathione, vitamin E, and uric acid); change in overall antioxidant capacity of plasma using different chemically based assays, including total reactive antioxidant potential, the Trolox-equivalent antioxidant capacity, the ferric reducing/antioxidant power, the oxygen radical absorbance capacity, or the ferrous oxidation-xylenol orange assays; low levels of enzymes that are important parts of the ADS or their activity (SOD, GPX, and CAT); and

increased levels of oxidation products (e.g., malondialdehyde, 8-hydroxy-2-deoxy-guanosin, oxi-LDL, and protein carbonyls) or markers of macromolecular damage (comet assay for DNA degradation and skin markers for protein degradation). Oxidative stress, as a result of either excessive generation of reactive species or disturbed antioxidant defense, has been implicated as underlying cause of various diseases. Most of previous research was targeted to the elucidation of its role on the pathogenesis of cardiovascular diseases, cancer, and neurodegenerative diseases. However, the putative list of diseases and pathological conditions considered to be associated with oxidative stress should include atherosclerosis, coronary heart disease, an impaired immune system, and increased risk of infectious disease; diabetes (both noninsulin-dependent and insulin-dependent diabetes); autoimmune conditions including rheumatoid arthritis; various respiratory diseases; and eye diseases including cataracts and retinal damage leading to age-related macular degeneration.

The effects of antioxidants on the prevention of these pathologies were supported by the results of large prospective studies (Nurses' Health Study (NHS), Health Professionals Follow-Up Study (HPFS), the European Prospective Investigation into Cancer and Nutrition (EPIC), etc.), suggesting an inverse association between diet rich in fruits, vegetables, and whole grains and the incidence of major chronic diseases, including cancer and cardiovascular diseases. Evaluation of obtained data by focusing on particular class of antioxidants or particular disease or risk factors provides more precise information. However, initiated by epidemiological studies, a great number of intervention trials were conducted in the past aiming to investigate the effects of antioxidants in the prevention (primary, secondary, or tertiary) or therapy of chronic diseases, in healthy subjects or participants with the diseases. And the results of recent meta-analyses vary between supportive, inconclusive, and even disappointing, depending on the type of antioxidant and the targeted population. However, there are many gaps that still need to be filled before the final conclusion about the relevance of antioxidant activity (both direct and indirect) as a mechanism of action of dietary compounds in the prevention and therapy of various diseases. Based on their expertise and experience drawn from up-to-date evaluations, European Food Safety Authority's (EFSA's) Panel on Dietetic Products, Nutrition and Allergies (NDA), responsible for verifying the scientific substantiation of the health claims, published a guidance document on the scientific requirements for health claims related to antioxidants, oxidative damage, and cardiovascular health. Regarding the effects of antioxidants, major concerns were related to the causal correlation between certain biomarkers and health benefit (biomarkers of plasma antioxidant status), their specificity (Comet assay and plasma markers of protein oxidation), and applied methodology (ELISA). Still, numerous studies using valid biomarkers show promising results. However, meta-analyses of studies on markers of diseases instead on markers of disease risks were less supportive. Some authors share opinion that disappointing results obtained with exogenous antioxidants are not a proof of their inefficiency but rather indicate a misleading approach with the whole body antioxidant defense as a target instead of focusing on disease relevant sites, where the disturbance has been shown and correlates with the pathogenesis. Accordingly, a strategy that will include an approach similar to that in pharmaceutical research could lead to a discovery of new, advanced, and more efficient antioxidant nutraceuticals.

Antioxidants and Cardiovascular Disease

Animal and human data implicate increased levels of ROS associated with oxidative stress in the pathogenesis of cardiovascular disease. However, in numerous clinical trials, at least with small-sized antioxidants, supplementation failed to reduce cardiovascular morbidity or mortality. Even the results from German EPIC study on the associations between vitamin/mineral supplementation and cancer, cardiovascular, and all-cause mortality were unsupportive or at least inconclusive. On the contrary, recent data from the Cancer Prevention Study II Nutrition Cohort indicated an association of flavonoid consumption with lower risk of death from CVD. Surprisingly, associations were strongest with intermediate intakes, suggesting that even relatively small amounts of flavonoid-rich foods may be beneficial. Another prospective study showed inverse association between anthocyanin intake and myocardial infarction risk. This was confirmed in large number of intervention trials, showing beneficial effects of polyphenols intake on variety of CVD risk factors and biomarkers. As shown in numerous intervention studies, polyphenols in general exert pleiotropic effects on cardiovascular health. It is still questionable if these effects were a result of direct or indirect antioxidant effects or more specific interactions with relevant molecular and cellular targets. Cruciferous vegetable consumption is associated with a reduced risk of total and cardiovascular disease mortality. Results from intervention trials were promising as well, suggesting relatively new area of isothiocyanate research.

Antioxidants and Cancer

Cancer is uncontrolled cell growth, in which cells lose their natural function and spread throughout the blood in the entire body. Oxidative stress is involved in the process of the development of cancer and tumors, due to the damage of the macromolecules by generated ROS. Beyond direct effect on DNA, ROS-induced oxidation products of lipids (malondialdehyde) can cause mutations or breaks in the DNA double chain or modifications in guanine and thymine bases and sister chromatid exchanges, which can affect the activities of signal transduction, transcription factors, and gene tumor suppressors. Oxidative damage or genetic defects in enzymes that repair mutations favor age-dependent cancer. Importantly, some chemotherapeutics or radiation therapy increases ROS and decreases antioxidant content, producing a state of severe oxidative stress, causing side effects. However, it was shown that if generation of ROS is deeply involved in the mechanism of action of anticancer agents, supplementation with antioxidants could compromise the final outcome of the therapy.

Based on Cochrane reviews, there is no scientific evidence for the effects of antioxidant supplementation in the prevention of GI cancers, lung cancer, or skin cancer. On the contrary, some antioxidant supplements seem to increase overall mortality in general population and cancer patients.

Natural compounds such as polyphenols, in particular (−)-epigallocatechin gallate and resveratrol, were shown to have a promising future as antioxidants and anticarcinogenesis agents. However, at this moment, the evidence for polyphenol intake associations with cancer incidence is mostly limited to the cancers of gastrointestinal tract. In substantial number of prospective studies, intake of cruciferous vegetables was positively associated with lower risk of breast, colon (but not rectal), prostate, and lung cancers.

Generally, the discrepancies between epidemiological data and clinical trials with supplements (mainly vitamins and minerals) might be due to the synergistic effects of various bioactives in the whole food (antioxidants, vitamins, and minerals) compared to the effects of isolated compounds.

Antioxidants and Immune Function

The protective function against external pathogens carried out by the immune system is by itself a source of ROS, since activated neutrophils produce free radicals to a significant extent. Frequent claims suggest that antioxidants benefit the immune system, but recent meta-analyses indicated that the results are uncertain even for vitamin C and its beneficial effects on common cold, despite long history of use, and null for vitamins and minerals in general, as supportive therapy in pneumonia or asthma.

Antioxidants and Gastrointestinal Diseases

The GI tract is an important source of ROS. This is a putative mechanism of various GI diseases including ulcers, malignancies, and inflammatory bowel disease. Dietary antioxidants, mainly polyphenols, have been shown to exert beneficial effects on oxidative stress in GI tract. They provide support to the protective function of epithelial barrier against deleterious effects of prooxidants and proinflammatory agents in the gut lumen through their prebiotic properties on GI microbiota, anti-inflammatory effects on GI epithelial cells, and direct interaction with their lipid bilayer. In addition to the beneficial effect of plant bioactives on the prevention of GI cancers, several studies postulated an effect on other diseases of GI tract.

Antioxidants and Aging

For many people, the greatest interest is in antioxidants' anti-aging potential. Since the body's production of its own antioxidants decreases with age, few doubt the potential value of dietary sources. However, there is no evidence that supplementation with antioxidants will stop hair graying, prevent wrinkles, or provide a 'fountain of youth.' However, promising results were obtained in a study investigating the effects supplementation with vitamins and mineral antioxidants (SU.VI.MAX) on cognitive performance. A direct correlation was also shown for cognitive performance and total flavonoid intake in a prospective Nurses' Health Study. In general, cognitive function is considered as a very promising target for the action of polyphenols and is relevant, considering the rise in the percentage of aged population in developed countries.

Antioxidants and Macular Degeneration

Some positive messages were expected from studies of particular antioxidants in macular degeneration, the major cause of blindness in elderly people. The proposed mechanism is based on the fact that ROS, produced in retina during light absorption, are deeply involved in the progression of the disease. Some (but not all) studies initially suggested that specific antioxidant supplements help in the protection against further degeneration. The final conclusion drawn in the most recent Cochrane review was supporting, with the limitation that most of the data were taken from one randomize trial. The results for age-related cataract were negative, showing no effects of antioxidants (beta-carotene, vitamin E, and vitamin C) in the prevention and progression delay. There are also some evidences of benefits from vegetables and fruits rich in lutein and zeaxanthin as antioxidants. Egg yolk is also a good source of these compounds. A recent and extensive review reports no benefits of vitamin E, beta-carotene, or any antioxidant supplements for preventing age-related macular degeneration.

Antioxidants and Neurodegenerative Diseases

Oxidative processes have been implicated in the pathogenesis of neurodegenerative diseases including Alzheimer's and Parkinson's diseases. The suggestion that they are triggered, at least in part, by oxidative and nitrosative stress and sustained by inflammatory cytokine production rationalizes the protection of the central nervous system against these damaging mechanisms with antioxidants as a useful prophylactic and therapeutic approach. The results of both the Rotterdam Study and the Cache County Study supported the hypothesis that high dietary intake of vitamin C and vitamin E may lower the risk of Alzheimer's disease, but not cognitive decline and dementia in general. Additionally, based on the systematic review of the literature, other antioxidants that could be effective in the prevention of Alzheimer's disease include garlic extract, curcumin, melatonin, resveratrol, Ginkgo biloba extract, and green tea. Generally, the Kame project confirmed a hypothesis that polyphenol-rich fruit and vegetable juice intake may exert beneficial effects in delaying the onset of Alzheimer's disease, particularly among susceptible individuals. Recent studies support the use of antioxidants specifically targeted to the mitochondria as promising therapy of Parkinson's disease.

Appetite Control in Humans: A Psychobiological Approach

M Dalton, C Gibbons, S Hollingworth, G Finlayson, and JE Blundell, University of Leeds, Leeds, UK

© 2016 Elsevier Ltd. All rights reserved.

Defining the Issue

One of the most salient features of appetite control in humans is that we are omnivores. Unlike herbivores or carnivores, humans have the capacity to consume a larger and more diverse range of food materials. Therefore, there is no standard or uniform pattern of human food consumption. Although there is a strong biological component to the basic drive that motivates humans to seek food, there is not a strong biological control over the types of foods that humans put into their own mouths. The food selected for ingestion is heavily influenced by culture, economy, geography, climate, and social conditions – in other words, by the environment. Therefore, the human system has the capacity to adapt to many different types of diet, and humans have the ability to learn to deal with foods according to their availability. Considering the diverse types of food items consumed by humans in different parts of our planet, it can be deduced that this aspect of appetite is not heavily programmed; rather, the system is adaptable. However, once a range of foods has been presented for consumption, some clear biological principles start to exert an influence (e.g., through hedonic processes). In seeking explanations for the way in which humans seek, select, and consume (and overconsume) food, it is important to recognize the influences of biology and culture – and how they interact.

The Psychobiological System of Appetite Control

The control of appetite is based on a network of interactions that form part of a psychobiological system. This system can be conceptualized on three levels: firstly, the level of psychological events (e.g., hunger perception, hedonic sensations, and cravings) and behavioral operations (e.g., meals, snacks, macronutrient, and energy intakes); secondly, the level of peripheral physiology and metabolic events; and, finally, the level of neurotransmitter and metabolic interactions in the brain. Appetite reflects the synchronous operation of events and processes in these three levels and when appetite is disrupted – as in certain eating disorders – these three levels become desynchronized. While neural events trigger and guide behavior, each act of behavior involves a response in the peripheral physiological system; in turn, these physiological events are translated into brain neurochemical activity. This brain activity represents the strength of motivation to eat and the willingness to refrain from feeding. The lower part of the psychobiological system illustrates the satiety cascade (see Figure 1), which depicts the events that stimulate eating and motivate organisms to seek food. It also depicts those behavioral actions that actually form the structure of eating, in addition to the processes that follow the termination of eating – referred to as either postingestive or postprandial events.

Prior to food reaching the mouth, physiological signals are generated by the sight and smell of food. These events comprise the cephalic phase of appetite, and they function to anticipate the ingestion of food and are generated in many parts of the gastrointestinal (GI) tract. During and immediately following eating, afferent information (sensory stimulation from the taste and texture of food) provides the major control over appetite. Further to this, it has been noted that the afferent information from ingested food acting in the mouth provides primarily positive feedback for eating; that from the stomach and small intestine is primarily negative feedback.

Signals of Appetite Control and the Drive to Eat

Traditionally, a distinction has been made between the short-term regulation and the long-term regulation of appetite; however, the connotation of episodic and tonic is more functionally appropriate. Episodic signals of appetite control are for the most part inhibitory, although they can be excitatory, and are typically generated in response to an eating episode. These signals oscillate throughout the day in accordance with the pattern of eating, and most are closely associated with the signaling of satiety. Tonic signals arise from the body's energy stores – including the adipose tissue and fat-free mass – and exert a tonic pressure on the expression of appetite. These two sets of signals – one set responding sharply to changes in behavior (episodic) and the other providing a slow modulation (tonic) – are integrated by complex brain networks that control the overall expression of appetite (see Figure 2).

Tonic Signals

The tonic signals of appetite arise from the body's energy stores and exert a tonic pressure on the expression of appetite. When in a state of energy balance, the control of appetite is considered to be largely under the influence of homeostatic mechanisms with strong defenses to guard against substantial loss of body weight and fat mass but comparatively weak mechanisms in place that mitigate long-term increases in these variables.

Fat-free mass, resting metabolic rate, and the drive to eat

For many years, the main focus of investigations on appetite control has centered on the termination of eating; however, 50 years ago, there was an equal emphasis on the excitatory features of appetite in an attempt to explain what the driving forces were behind the motivation to seek out food. Around this time, a group of physiologists posited that energy expenditure was the main driver for appetite. However, due to the large daily fluctuation in levels of physical activity, Edholm found no within-day relationship between energy intake and energy expenditure. More recently, this proposition has been reexamined with the suggestion that resting metabolic rate

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00039-8

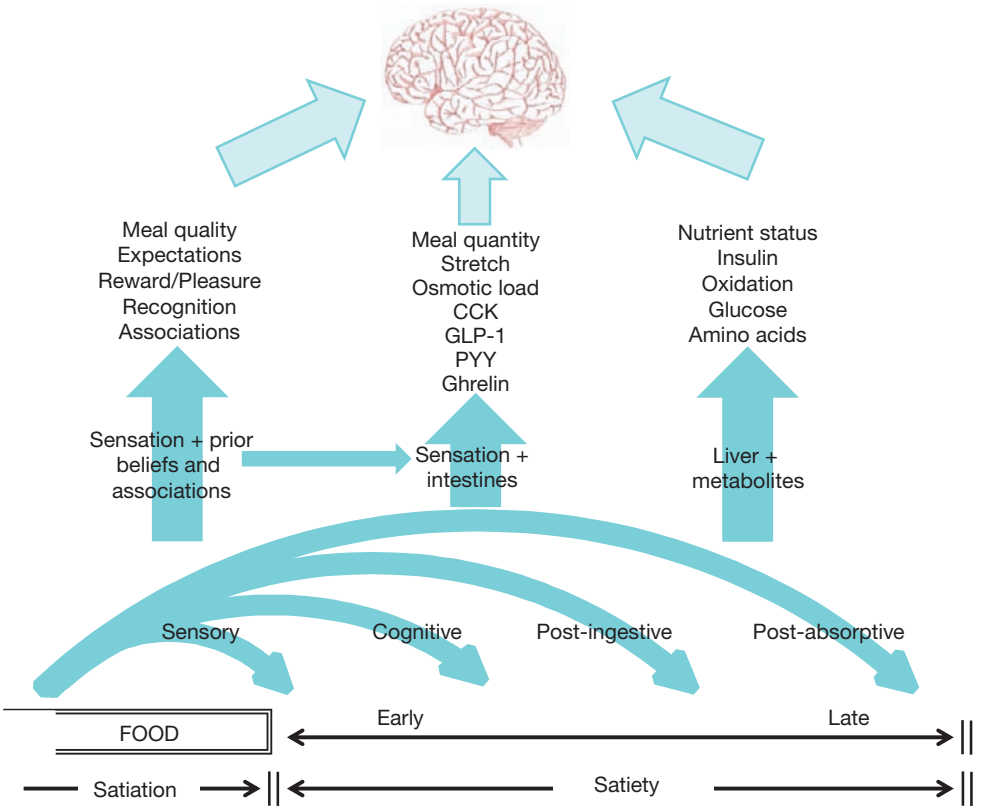

Figure 1 The satiety cascade. The satiety cascade describes the sensory, cognitive, postingestive, and postabsorptive processes. Reproduced from Blundell, J. E. (1991). Pharmacological approaches to appetite suppression. *Trends in Pharmacological Sciences 12*, 147–157.

(RMR) – the largest component of daily energy expenditure – may act as a regulator of food intake and appetite control. Blundell and colleagues examined this proposition in a sample of overweight and obese individuals using a novel energy balance framework, which included controlled measures of body composition and resting metabolism, and objectively measured within-day food intake and sensations of appetite. They demonstrated that fat-free mass was closely associated with self-determined test meal intake and overall daily energy intake whereas BMI and fat mass were not. In a follow-up study, Caudwell et al. demonstrated that RMR was a strong predictor of daily food intake and that individuals with the highest levels of RMR also reported the highest levels of hunger in the periods between laboratory test meals. These findings have subsequently been confirmed in other studies examining obese individuals.

The association between fat-free mass/RMR and the motivation to eat helps to explain why obese individuals, who carry large amounts of stored energy, still experience strong feelings of hunger and an increased drive to eat. By recognizing that obese individuals have, in addition to a large amount of adipose tissue, an increased level of fat-free mass, which results in a proportionally raised RMR and coincides with their apparent increased drive to eat. Furthermore, the enhanced drive to eat is quite compatible with, and independent of, the accumulation of fat stores and development of leptin resistance, as fat mass makes a relatively minor contribution to RMR in comparison to fat-free mass.

Signals from adipose tissue: role of leptin

While recent evidence supports a role for the activity of fat-free mass/RMR as a driver of appetite, a classic theory of appetite control concerns a signal that informs the brain about the state of the adipose tissue stores. This idea has given rise to the notion of a lipostatic or ponderstatic mechanism. Indeed, this is a specific example of a more general class of peripheral appetite signals believed to circulate in the blood reflecting the state of depletion or repletion of energy reserves that directly modulate brain mechanisms. In 1994, in a landmark study, Zhang et al. identified the mouse gene responsible for obesity. This led to the identification of a hormone termed leptin that is mainly expressed by adipocytes but is also present at lower levels in the gastric epithelium and circulates in the blood. To date, the exact association between leptin and weight regulation has not been completely determined. However, it has been reliably demonstrated that the amount of leptin in the plasma is greater in obese human and nonhuman animals compared to their lean counterparts. Therefore, while leptin serves as a signal from the adipose tissue to the brain, high levels of leptin do not prevent weight gain or obesity but rather reflects the amount of adipose tissue within the body. This suggests that obese individuals are resistant to the anorectic effects of leptin, which may be the result of slower transportation across the blood–brain barrier or defective signaling in the leptin responsive neurons. Moreover, under normal conditions of appetite control, leptin does not appear to exert any appreciable influence on food intake. This is quite different of course

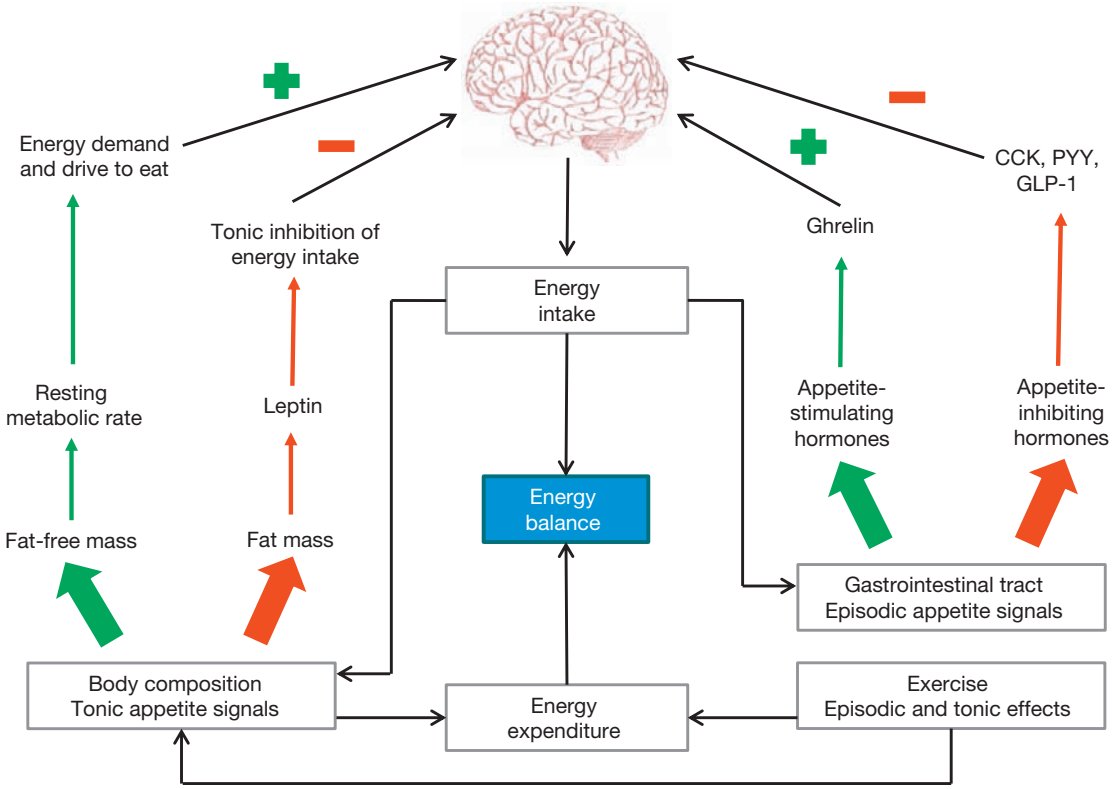

Figure 2 A new formulation for appetite control developed by Blundell et al. (2012). Role of resting metabolic rate and energy expenditure in hunger and appetite control: A new formulation. *Disease Models & Mechanisms* 5(5), 608–613.

from the effect of leptin in those rare individuals who are leptin deficient.

Episodic Signals: The Satiety Cascade

Eating in omnivores is not a single continuous process but occurs in episodes (usually called meals). The types of signals involved in terminating a meal, the process of 'satiation,' and preventing further consumption, the process of 'satiety,' can be represented by the satiety cascade. Developed more than 25 years ago, the satiety cascade provides a conceptual framework from which to examine the processes that influence the frequency and size of eating episodes and the intervals between them. The amount of food consumed in a meal (satiation) is heavily influenced by the weight and volume of the food itself and by the energy density of the food items. High-energy dense foods, such as those high in fat, lead to unnecessary intake of calories. This process is termed 'passive overconsumption.' The satiety cascade (see Figure 1) indicates the different overlapping processes – arising from eating – that influence the intensity and duration of satiety.

Brain signals of hunger

Although it seems that hunger is driven by the energy requirements of the body reflected in RMR (and FFM), this motivation must be routed through the brain and will be encoded in physiological pathways. One hormonal biomarker seems to be ghrelin. Ghrelin is primarily secreted from the stomach (although it is synthesized and secreted in many other tissues) and was the first orexigenic peptide to be identified in the periphery. Ghrelin plays a role in meal initiation with circulating levels being elevated before and then suppressed following food intake. Consistent with this, both peripheral and central infusions of ghrelin have been shown to stimulate food intake in rats and mice. In addition, postprandial ghrelin levels within physiological range have been shown to be associated with both hunger and energy intake. While predominantly an episodic hormone, ghrelin may also be considered as a tonic hormone as it has been shown to correspond with the body's energy stores. For example, Shiiya et al. demonstrated that obese individuals have lower levels of acylated ghrelin compared with their normal weight counterparts. However, contrary to expectations, they did not demonstrate that lower levels of ghrelin observed in obese individuals were associated with lower levels of hunger or desire to eat suggesting that decreased sensitivity to ghrelin signaling following weight gain may contribute to impaired appetite control. Neuropeptide Y (NPY) is expressed in both the central nervous system and the peripheral nervous system and is released from the hypothalamus during periods of fasting and in situations that demand an increase in energy (e.g., exercise). Bannon et al. demonstrated that NPY knockout mice had a lower food intake compared to wild-type mice in response to fasting supporting a role for NPY in mediating food intake.

Signals of satiety and the termination of eating

Much current thinking favors the view that hormones released from the GI tract play a role in either the termination of an eating episode (satiation) or the inhibition of eating after the

meal has finished (satiety). One celebrated hormone is cholecystokinin (CCK). CCK is released from the small intestine shortly following food consumption and has been shown to mediate satiation. Peripheral administration of CCK has been demonstrated to decrease food intake. The consumption of fat specifically has been shown to stimulate the release of CCK, and fats in the form of free fatty acids of carbon chain lengths C12 and above produce pronounced CCK releases. GLP-1 is an incretin hormone (one that stimulates the release of insulin), which is released from the gut into the blood stream in response to intestinal nutrients. Peripheral administration of GLP-1 has been found to inhibit food intake in both human and nonhuman animals, and in normal weight males, infusions of synthetic human GLP-1 during the consumption of a fixed breakfast test meal have been demonstrated to enhanced ratings of fullness and satiety when compared to a placebo. PYY is released from endocrine cells in the distal small intestine and large intestine. PYY is released predominantly after rather than during a meal and causes a decrease in gastric emptying (the so-called ileal brake) and is therefore more associated with postmeal satiety. Research has shown that peripheral administration of PYY decreases food intake in both human and nonhuman animals. More recently, reports suggest that obese individuals have an attenuated meal-stimulated PYY response across a range of caloric loads suggesting that PYY may have a role in the control of body weight.

The adaptability of the appetite system is apparent in the GI response to different types of nutrients. GI peptide release (CCK, GLP-1, insulin, and PYY) varies with the fat, protein, and CHO content of the food ingested. Consequently, different profiles of peptides can be shown to produce an equivalent degree of satiety. There does not appear to be any unique satiety peptide or any single unique pattern. The search for a biochemical identity of a satiety biomarker has been driven by the belief in a molecular explanation for behavior. Considering the inhibition of food intake in the postprandial period, the role of the stomach should not be overlooked. The characteristics for gastric distension and the mechanisms of gastric emptying constitute physiological processes, which operate to modulate the feeling of fullness and the motivation to eat (this means that they influence the intensity and time course of satiety).

Homeostatic and Hedonic Processes of Appetite Control

Energy balance depends on both what and how much food is consumed in relation to energy expenditure. The qualitative aspects of eating behavior (what to eat) depend in part on the direction of food preferences, driven by the anticipation and experience of pleasure derived from food. The quantitative aspects of eating behavior (how much to eat) reflect a general drive and inhibition of this drive to eat (the processes of satiation and satiety). This distinction between drive and direction is often framed in terms of homeostatic and hedonic systems of appetite control. The homeostatic system refers to the regulation of food intake that arises from biological need and acts to maintain the body's energy stores and internal environment. It comprises a network of brain neurotransmitters and GI peptides described previously and depicted in Figure 1. The hedonic system refers to the sensory and external examination of food intake and considers that eating behavior is motivated by external cues in the environment and does not solely arise as a result of energy need. Studies in nonhuman animals have reported that the hedonic system of appetite control is underpinned by the brain's reward circuitry and involves opioid and dopamine neurotransmission that underpins the liking (subjective pleasure experienced from food) and wanting (attribution of incentive salience to the reward and its associated cues) components of reward, respectively. While the homeostatic and hedonic systems of appetite control are underpinned by distinct neural substrates, there is considerable functional overlap between the two systems in the control of appetite.

Psychological Components of Liking and Wanting for Food

The terms 'liking' and 'wanting' are not only used to refer to the core processes of reward identified in behavioral neuroscience research but also discussed in relation to subjective states and objectives behaviors that correspond to the more everyday meaning of these terms. Like the core processes of reward identified in behavioral neuroscience, liking and wanting as psychological constructs are believed to be distinct. Liking is typically defined as the perceived or expected hedonic value of a food, the appreciation of its sensory properties, or a judgment of the degree of pleasure it elicits. In this context, liking for food appears to be a relatively enduring characteristic within an individual that varies only slightly under specific circumstances. For instance, researchers have demonstrated that ratings of liking for food are greater when individuals are in a hungry compared to a fed state. Further to this, liking for a recently consumed food has been shown to decrease in a manner consistent with sensory specific satiety. Therefore, liking is thought to be more important in establishing the range of foods eaten and in determining the motivational value of a food.

On the other hand, wanting refers to subjective states of desire and craving that are triggered by the food itself or its related cues within in the environment. Importantly, rather than being a constant drive, such as hunger, the wanting component of reward implies a target with a direction that may vary according to a number of factors, including level of hunger, time of day, and the degree of attentional resources available. To this end, wanting for food is created anew on each encounter with the food or its associated cues. Furthermore, research suggests that the target of wanting may vary from being relatively broad to being relatively focussed. For instance, it has been reliably demonstrated that, independent of BMI, in a fasted state, individuals have a greater wanting for food in general compared to when they are in a fed state. Further to this, there is some evidence to suggest that wanting may become focussed to specific food items (and at times dissociated from liking) under certain conditions in which one food is wanted to a greater extent than the available alternatives. For example, Griffioen-Roose et al. assessed the impact of a 14-day high- or low-protein dietary intervention on ad libitum energy intake (over 2.5 days) and food reward. With regard to energy intake, they found that participants following a low-protein diet consumed a significantly greater amount of protein

compared to those who adhered to a high-protein diet. Further to this, following a low-protein diet, implicit wanting (assessed using the Leeds Food Preference Questionnaire) was enhanced for high-protein foods, which was consistent with the participants' actual eating behavior but was not observed in the subjective measures of reward.

Individual Differences in the Control of Appetite

The expression of appetite involves the interaction of both homeostatic and hedonic processes. The pleasurable response to food that may stimulate consumption will be coordinated with the satiation and satiety processes that inhibit eating, and it is important to recognize that the expressed pattern of eating will be dependent upon influences from both systems and that both hedonic and homeostatic processes influence the regulation and potential dysregulation of appetite control. As follows, overeating and obesity may arise due to either some defect in homeostatic signaling that fails to inhibit the motivation to eat or due to excessive or inappropriate responding to the hedonic aspects of food.

Obesity and Weight Gain

Individual differences in the neural response to the rewarding aspects of food have been identified as a risk factor for overeating, weight gain, and the development of overweight and obesity. One theory of the role of reward in obesity proposes that obese individuals have a hypofunctioning reward system, which causes them to overeat palatable, rewarding foods as a means of compensating for this deficit. In a landmark positron emission topography study, Wang et al. demonstrated that extremely obese individuals ($BMI > 40\ kg\ m^{-2}$) had reduced striatal dopamine D2 receptor binding compared to lean individuals. In addition, functional magnetic resonance imaging studies have shown that compared to their lean counterparts, obese adolescents show less activation in the dorsal striatum in response to the consumption of a palatable milk shake versus a tasteless control solution. However, it should be noted that research regarding reduced dopamine availability and obesity has been mixed. An alternative theory for the role of reward in obesity is the reward surfeit model, which posits that individuals who experience a greater amount of reward from food are at risk of overeating and weight gain. For example, Dimitropoulos et al. found that compared to normal weight individuals, obese individuals exhibited an increased neural response to high- and low-calorie food images in brain regions associated with reward despite having low levels of hunger. Furthermore, Yokum et al. demonstrated in a sample of female adolescents that greater activation in the orbitofrontal cortex during the initial orientation of attention to palatable food images was associated with an increase in BMI at 1-year follow-up.

Satiety Responsiveness

Impaired appetite control may be attributed to a weakened satiety response to food. For example, some obese individuals report that their own eating patterns bear little or no relation to their feelings of hunger or fullness, which suggests they may have an altered or weakened recognition and response to these internal sensations. Barkeling et al. examined obese patients who reported either a 'good relationship' between their appetite and eating (i.e., start eating when hungry; stop eating when full) or 'no relationship' between their appetite and eating (i.e., never hungry before meals; never full following meals). While Barkeling et al. found no difference in sensations of desire to eat, hunger, or fullness in relation to fixed-energy test meals consumed in the laboratory, they did report that those with 'no relationship' between appetite and eating exhibited a relatively weaker suppression of prospective consumption (i.e., how much additional food could be eaten) immediately after meals. Further research by Drapeau and colleagues has identified some of the psychobiological characteristics of individuals who experience a weakened satiety response to food – termed the 'low-satiety phenotype.' The low-satiety phenotype displays a cluster of disadvantageous tendencies that can stimulate eating and prevent its termination. Individuals show many different ways of expressing appetite and there is no single dominant pattern. Humans are omnivores and an adaptable appetite system is a feature that reflects biological variability in response to environmental opportunities and challenges. An obesogenic culture confronts humans with numerous problems that can compromise healthy appetite behavior.

Sources and Production

Apples (*Malus domestica*) are some of the most ancient, widely cultivated, and consumed tree fruits (Figure 1). The cultivation of apples can be traced back to 4000 years ago in Asia, and currently, more than 7500 different cultivars of apples are grown in all continents in the temperate and subtropical zones. Cultivated apples have been consumed fresh or processed into beverages, vinegar, sauces, jellies and jams, and used in pastry. People enjoy eating apple for its sweet and fruity aroma; its juicy tastes that vary from sour, to tart, to sweet; and its crispy and crunchy texture. In addition to the great flavor and taste, apples are also liked because of its rich nutrient content.

While many commercial varieties have been developed, only a few dozen are commercially grown. Many factors can affect the consumer preference and thus the production of different varieties. In addition to texture, taste, and flavor and nutritional attributes, preference of apple also depends on the region and cultural background. North Americans and Europeans tend to favor sour-tasting apples, while Asians generally like very sweet apples. Golden Delicious apple continues to be the most popular variety in Europe, followed by Gala, Idared, Red Delicious, and Jonagold, whereas in the United States, the top five most popular varieties are Red Delicious, Gala, Fuji, Golden Delicious, and Granny Smith and recent introductions such as Honeycrisp and Ambrosia. Most of the commercial apple cultivars are bred for fresh consumption with a few specifically for cooking or cider making. In Canada, for example, 59% of the apples were consumed fresh, 36% as juice, and 5% in processed forms.

Apples ranked number 17 of the 20 top agricultural commodities and the second globally in the fruit category after grapes. Apples are produced in every continent. According to the United Nations Food and Agriculture Organization, in the early 1960s, the United States was the leading apple producer, followed closely by mostly European countries including Italy, France, and the Union of Soviet Socialist Republics (USSR). That order changed dramatically throughout the 1970s and 1980s when the USSR became the world's largest apple producer by tripling its production (Table 1). Meanwhile, China became the third largest apple-producing country in the early 1980s, and the growth continued. In 1991, total productions of apples from USSR, China, and the United States were nearly the same. However, from the beginning of the twenty-first century, China became the sole leader of the world's apple production, producing 20 million metric tons annually in 2001 and nearly 36 million metric tons in 2011, while productions in other top five countries stayed relatively at the same level during the same period. In recent years, India has become one of the top five apple producers in the world. In 2012, China produced 37 million metric tons of apples, contributing more than 15 billion dollars to its economy, followed by the United States, Turkey, Poland, and India at 4.11, 2.89, 2.88, and 2.20 metric tons, respectively (Figure 2).

Patterns of Consumption

Apples are most often consumed fresh. The entire fruit except for the seeds in the apple core (Figure 1) is edible, although in certain cultures such as in Asia, apples are often peeled before consumption. In recent years, minimally processed fresh-cut apple slices have become increasingly popular. Eden is a newly developed (GMO) nonbrowning apple cultivar in Canada, suitable for fresh-cut market. Apples are processed by pressing or milling to produce beverages to be either consumed as is or mixed with other fruit juices. Most clear apple juices or beverages containing it are filtered and pasteurized, and packed in cans, bottles, or juice boxes, and can be kept at room temperature and usually sold in stores with shelf life extending over a year. Nonfiltered apple juice (or apple cider in North America), particularly nonpasteurized apple cider, is more flavorful but normally sold in refrigerated display cases or produce sections of stores with a shelf life of $\sim$2 weeks. Apple juice is also fermented to produce hard cider (in North America) and other alcoholic beverages and further to produce apple vinegar. Cider apples are traditionally classified according to the tannin and acid contents; however, recent advances in technology have led to the proposal of a new method of classification.

In addition to the various apple-based beverages, apples are also cooked or processed to make different products or ingredients of products. Cooking apples may include some cultivars for fresh consumption but are normally special cultivars that are tart and more acidic. These are made into applesauce or apple butter, which can be used as a condiment or dipper or served alone as a dessert. Apples are also made into treats and confectionaries such as caramel apples. Apples are also an important ingredient of baked desserts such as apple pie and apple crisp in Western culture.

Nutrient Contents of Apple

As one of the most nutritious fruits, apple is a rich source of minerals, vitamins, dietary fibers, and phytochemical antioxidants such as polyphenols. There is no better exemplification than the old English adage 'An apple a day keeps the doctor away,' which sends a clear and accurate message on the nutritious and health promotional value of apple consumption.

Apples are high in dietary fiber, low in fat, and rich in vitamins. One medium-sized apple (3″ diameter, 182 g) contains 18% of the recommended daily value of dietary fiber, 14% vitamin C, 6% potassium, 5% vitamin K, 4% vitamin B6, 3% iron, 3% riboflavin, and many other nutrients (Table 2). These

Figure 1 A typical apple variety – Gala.

components provide some of the most essential nutrients to humans and collectively contribute to the healthful properties of apples. However, these nutrients alone may not explain the health benefits of apples. Recent studies have shown that phytochemicals, particularly polyphenols, contribute significantly to the risk reduction and health-promoting effects of apples. Polyphenols in apples are mostly found in the skin. In addition to simple phenolic acids such as gallic acid and ferulic acid, flavan-3-ols such as catechin and epicatechin and their oligomers such as procyanidins B1 and B2 are found to exist in the skin, and flavonols such as quercetin and its glycosides are mostly found in the flesh. Structures of the major polyphenolic compounds found in apple and the concentrations are shown in Figure 3 and Table 3.

Availability, Absorption, and Metabolism

Reviewing and discussion on the physiological effects and mechanism of action of all nutrients in human body are beyond the scope of this article as there have been plenty of research on how essential nutrients such as vitamins and minerals are absorbed and metabolized and how the bioavailability of these nutrients is affected by various factors in humans. Instead, discussion in this section will be focussed on the most prevalent bioactive phytochemicals, the polyphenols. Emphasis will be given particularly on the stability, bioaccessibility, and bioavailability of apple polyphenols and how these compounds are metabolized and absorbed into important tissues and organs to exert various biological functions.

Just as in all plants, the biosynthesis of phytochemicals such as the polyphenols can be affected by genetics and environment. The latter factor may include geographic location (e.g., temperature, altitude, rainfall, and soil), agronomic practice, growing season, and postharvest storage conditions and processing methods (in the case of producing juice, cider, and other apple-based foods or food ingredients). All these factors are known to affect the quality and quantity of the total and individual polyphenolic contents, consequently the bioavailability of these compounds. Farming practice, that is, organic versus conventional, does not seem to affect the bioavailability of polyphenols of apple.

In general, apples have a very long shelf life compared to other fruits. Under low temperature and controlled atmosphere, apples can be stored for up to a year. Research showed that polyphenols of four different apple cultivars (Jonagold, Golden Delicious, Cox's Orange Pippin, and Elstar) and the concentrations of the major individual compounds such as flavonols, catechins, phloridzin, and chlorogenic acid and the antioxidant activities were not affected by long-term storage, both at refrigerator temperature (25 weeks) and under controlled atmosphere (52 weeks) conditions. Other studies have in fact suggested that concentrations of polyphenols such as catechin and phloridzin can be significantly increased during storage. Processing can significantly reduce the concentration of polyphenols. Studies showed that the levels of flavonoids and chlorogenic acid in conventionally produced juice were reduced to between 50% (chlorogenic acid) and 3% (catechins) compared to the respective fresh apples, because most of the polyphenols were retained in the pomace rather than being transferred into the juice. Novel production method can markedly enhance the extraction of the polyphenol antioxidants into the juice. The levels of flavonoids and chlorogenic acid in juice made by novel method were between 1.4 (chlorogenic acid) and 9 (quercetin glycosides) times higher than in conventional apple juice. The stability of polyphenols in apple juice can be affected by temperature and the presence of oxygen, but the effect was found to be minimal. Different compounds had different sensitivities to these factors; for example, phloridzin and chlorogenic acid are relatively more stable than quercetin glycosides and epicatechin. The polyphenolic content and antioxidant activity of enriched apple juice were found to be quite stable at ambient or refrigerated storage conditions up to half a year. Processing can also affect the health effect of apple. Apple juice made from fresh apples was consistently found to have better efficacy on improving serum lipid profile and other biomarkers than apple.

Polyphenols in fresh or processed apples must also be stable during human ingestion, reach the colon, and made available at certain concentrations in target tissues and organs in order for these bioactives to have favorable physiological effects. Studies have shown that polyphenols in general are not as biologically available as vitamins. The plasma concentrations of ascorbic acid (vitamin C), α-tocopherol (vitamin E), coenzyme Q10, and naringenin glycoside (a flavonoid) were found to be 72, 19, 0.4, and 0.33 μM, respectively, in young women consuming 16 oz of grape juice for 3 months. An *in vitro* model simulating gastrointestinal (GI) digestion, including dialysability, was used to assess free soluble polyphenols from apples. Results indicated that polyphenols were mainly released during the gastric phase (~65% of phenolics and flavonoids compared to <10% during intestinal digestion). Anthocyanins were only present in the gastric phase. Dialysis experiments using a semipermeable cellulose membrane showed that free soluble dialyzable polyphenols and flavonoids were approximately 20% and 30% lower than those of the GI digesta. The antioxidant capacities of dialyzable antioxidants were related to the corresponding concentrations of individual compounds. Studies have shown that polyphenols of apple are absorbed from or metabolized in the small intestine. In patients with

Source: Tsao, R., Yang, R., Young, J. C. and Zhu, H. (2003). Polyphenolic profiles in eight apple cultivars using high-performance liquid chromatography (HPLC). *Journal of Agricultural and Food Chemistry* **51**, 6347–6353.

ileostomy bags, less than 33% of the oral dose of polyphenols was recovered in the bags, indicating the levels of polyphenol that may reach the colon. Bioaccessibility and bioavailability of polyphenols were found to be related to the structure, particularly to the glycosidic pattern of the polyphenolic compounds. Phloretin 2′-*O*-glucuronide as a product of polyphenol metabolism and very minor amounts of unmetabolized polyphenols were recovered in the ileostomy effluent, which would reach the colon under physiological conditions. It is likely that polyphenols that ultimately reach the colon may cause the prevention of colorectal carcinogenesis, a positive effect resulting from apple consumption. A recent study on the bioavailability and metabolism of apple polyphenols during intestinal transit has provided valuable information on how these bioactives are affected in the digestive tract. In this series of experiments, apple polyphenols were incubated under *in vitro* digestive conditions with saliva (for 5 min) and simulated gastric or duodenal juice (4 or 10 h, respectively) or separately with rat hepatocytes (4 h) under aerobic conditions and with ileostomy fluid under aerobic conditions for 10 h. The polyphenol profile in human serum (8 h later) and renal elimination in urine (24 h later) were also investigated after consumption of 1 l apple juice. The study revealed that in the presence of native saliva or ileostomy fluid, polyphenol glycosides such as those of phloretin and quercetin were hydrolyzed to produce aglycones, although the degree of hydrolysis depended on the glycosidic moiety. Oligomeric proanthocyanidins such as procyanidin B2, a dimer of two (−)-epicatechin molecules connected via a four to eight bond in the beta position, were depolymerized in simulated gastric juice (pH 1.8). Epimerization of flavan-3-ols, that is, (+)-catechin to (−)-epicatechin and (−)-epicatechin to (−)-catechin, was observed in artificial duodenal juice (pepsin, pancreatin, and bile extract, pH 7.2), but procyanidin B2 was degraded completely within 8 h because no (−)-epicatechin was detected. Under these conditions, however, the dihydrochalcones (phloretin and its glycosides) and flavonol glycosides (mainly quercetin glycosides) were stable over the entire 24 h incubation period. The released aglycone, quercetin, was found to be completely metabolized to smaller molecules including phloroglucinol, 3,4-dihydroxybenzoic acid, and 2,4,6-trihydroxybenzoic acid. Hydroxycinnamic acids, such as the *p*-coumaroylquinic acid, were transformed to its 3- and 5-isomers and their corresponding methyl esters in the lower gut duodenal juice. When these apple polyphenols were incubated with rat hepatocytes, in addition to the aforementioned metabolites, products of phase II metabolism were also found; these include two phloretin 2′-*O*-glucuronides and eight quercetin 3-*O*-glucuronides. Further *in vivo* study with five healthy volunteers who drank one liter of cloudy apple juice showed that six phenolic compounds, 5-*O*-caffeoylquinic acid, *p*-coumaroylquinic acid, caffeic acid, (−)-epicatechin, phloretin, and quercetin, were present in both serum and urine (5.3% and 3.5% of the amounts consumed, respectively) after samples were treated with β-glucuronidase/sulfatase. Bioavailability as measured by the maximum human serum concentration varied significantly among the six metabolites, with 5-*O*-caffeoylquinic acid to be the most bioavailable at 0.73 μM, followed by quercetin at 0.25 μM. (−)-Epicatechin was the least bioavailable with a maximum serum concentration of 0.05 μM. Most of these metabolites reached the maximum serum concentration between 0.7 and 2.1 h after apple juice consumption, with a half life between 2.3 and 6.0 h. Nearly 20% of the total polyphenols consumed were metabolized to more hydrophilic compounds and excreted in the urine.

Health Effects

Studies of the health beneficial effects of apples have at least partially instigated by the old adage 'An apple a day keeps the doctor away.' While the overall health benefits can be the result of a combined effect of all bioactive components in apple, including vitamins, minerals, dietary fiber, and the various phytochemicals, the contribution of the polyphenols can be of special significance. In fact, many of the health effects of apples may be triggered by the finding that vitamin C contributed nearly none to the total antioxidant capacity of apple juice. The antioxidant activity of apples was confirmed by many researchers, including the author of this article, that it was the polyphenols in apples that gave the strong antioxidant activity. It has also been found that not all apples are the same in terms of the total and individual polyphenol contents and that the majority of the polyphenols of apple are in the skin. While the antioxidant activity of apple polyphenols is an important indicator of the potential health benefits of apples, due to the relatively low bioaccessibility and bioavailability and low serum concentration of polyphenols, whether these compounds or their metabolites are the actual bioactive components *in vivo* remains unclear. Antioxidants reduce the oxidative stress caused by excess free radicals such as the reactive oxygen species. Polyphenols in apples are strong antioxidants when tested in various *in vitro* chemical-based assays because these compounds are relatively abundant in apple juice or its extract. However, most of these assays are not sufficiently sensitive; thus, when polyphenols or their metabolites are at very low physiological concentrations (nM), no significant antioxidant activities would be detected. Inflammation, on the other hand, has also been linked to the oxidative stress, and long-term inflammation has recently been considered to be the cause of various chronic diseases including immune system dysfunction, cancer, cardiovascular disease, diabetes, and neurodegenerative diseases. Research in recent years also suggests that at physiological concentrations, polyphenols and their metabolites can be actively involved in modulating biomarkers of various cell signaling pathways and therefore can potentially and effectively exert biological activities to promote health after apple consumption.

Anti-inflammation and Effects on the Immune System

In a recent study using immunorelevant human cell lines (DLD-1, T84, MonoMac6, and Jurkat), it was revealed that polyphenols from apple significantly inhibited the expression of NF-κB-regulated proinflammatory genes (TNF-α, IL-1β, CXCL9, and CXCL10), inflammatory relevant enzymes (COX-2 and CYP3A4), and transcription factors (STAT1 and IRF1) in LPS/IFN-gamma stimulated MonoMac6 cells, without significant effects on the expression of housekeeping genes. The same authors further showed that it was procyanidin B2 that was mainly responsible for the anti-inflammatory activity

of the apple polyphenol extract. This corresponds well to the early discovery that procyanidin B2 was the most likely main contributor to the antioxidant activity among apple polyphenols. It was further found that phloretin and procyanidin B1 significantly inhibited proinflammatory gene expression and repressed NF-κB-, IP-10-, IL-8 promoter-, and STAT1-dependent signal transduction in a dose-dependent manner. *In vivo* experiments with rats also showed that antioxidant polyphenols of apple had protective effect against GI damage induced by indomethacin. Previous administration of apple peel extract protected the gastric, intestinal, and colonic mucosa from induced oxidative stress as evidenced by lowered malondialdehyde concentrations and the glutathione/glutathione disulfide (GSH/GSSG) ratio. Treatment of apple polyphenols also lowered the myeloperoxidase activity, suggesting the anti-inflammatory effects were by preventing neutrophil infiltration in the mucosa. It was believed that prevention of macro- and microscopic damage and of barrier dysfunction along the GI tract by the apple polyphenols led to the protection of the indomethacin-treated animals. Similar results were observed by others using different cell lines, but the same rat model. Apple polyphenol extracts were found to lower the xanthine–xanthine oxidase or indomethacin induced injury to gastric epithelial cells by 50%, and catechin or chlorogenic acid (also the main phenolic components of apple extracts) was equally effective as apple extracts. Studies also found polyphenols of apples induced a fourfold increase in intracellular antioxidant activity, which would significantly reduce the oxidative stress, thus inflammation. Most recently, a high-flavonoid apple variety was found to significantly reduce the transcription levels of inflammation-linked genes in mice, compared with another apple variety with regular flavonoid concentration, with decreases of >2-fold for interleukin-2 receptor (Il2rb), chemokine receptor 2 (Ccr2), chemokine ligand 10 (Cxcl10), and chemokine receptor 10 (Ccr10) after a week on supplemented diet. The same study also showed that the inflammation marker prostaglandin E(2) in the plasma of mice fed with this high-flavonoid apple was reduced by 10-fold compared with a regular apple diet and the bacteria counts in the colonic microbiota was 6% higher in mice fed with the former diet after 3 weeks.

Anticancer Effect

No other commonly consumed fruits are like apples in terms of evidence in cancer risk reduction. Among the fruits and vegetables assessed in the Nurses' Health Study and the Health Professionals' Follow-up Study involving over 77 000 women and 47 000 men, apple (together with pear) showed the most significant association with lung cancer reduction in women, but not in men. Other studies have been conducted to specifically evaluate the role of apple consumption and cancer risk. In a case-control study assessing the potential protective impact of apples, it was found that the risk of colorectal cancer was inversely correlated with the daily number of apple servings, but not other fruits, and the most significant reductions were observed for an intake of one or more apple servings daily. In a recent case-control study on apple intake and risk of development of cancer involving 6000 participants, daily consumption of one or more medium-sized apples was found to be associated with a significant reduction in the risk of cancer compared with the consumption of less than one apple a day. Apple consumption particularly lowered the risk of larynx (41%, reduction rate, same for the following), colorectal (30%), esophagus (22%), breast (24%), ovary (24%), and prostate (7%) cancer.

Various animal models have been conducted to confirm these epidemiological findings and the preventative effects of apples and related products on cancer. A review of the findings of colon cancer animal models showed that apple extracts, juice, or related products could significantly reduce the genetic damage, proliferation of carcinoma, aberrant crypt foci of the colon, carcinoma incidence, carcinoma multiplicity, small intestinal adenoma, and spleen weights along other favorable health benefits. In addition to the direct antioxidant activities, apple polyphenols were also found to increase the expression of antioxidant response element-dependent genes, for example, superoxide dismutases 1 and 2 (SOD1/SOD2), glutathione peroxidases 1 and 2 (GPx1/GPx2), γ-glutamylcysteine ligase catalytic subunit to modifier subunit ratio (GCLC/GCLM), glutathione-disulfide reductase (GSR), and catalase (CAT).

Apples are a rich source of polyphenolic antioxidants, particularly in the skins. The mechanism of the anticancer action of apple polyphenols has been investigated *in vitro* in different cell models. A polyphenol-rich extract of apple peel showed significant antiproliferative effect in a dose-dependent manner against the human colon carcinoma cell line HT29. The same effect was not found in a breast cancer cell line MCF-7, suggesting different cancer cells may respond differently. Apple extract rich in polyphenols selectively inhibited the proliferation and induced apoptosis of a cancer cell line adenoid cystic carcinoma M (ACC-M) cells over a normal cell line MRC-5 (cells derived from normal lung tissue). The effects were found to be related to the downregulation of vascular endothelial growth factor receptor-2 expression and the activation of caspase-3 expression. Apple extracts containing polyphenols were found to reduce NF-κB activity, likely mediated via inhibited phosphorylation of IκBα in human umbilical vein endothelial cells.

Effect on Cardiovascular Disease

A team from the United Kingdom recently modeled the effect on vascular mortality such as heart attacks and strokes and concluded that for people over 50 years old, both an apple a day (100 g) and a statin (a cholesterol-lowering drug) a day had the potential to reduce the vascular death significantly with a similar rate of reduction. They also claimed that "the 150-year-old health promotion message is able to match modern medicine and is likely to have fewer side effects." A cohort study following 9208 Finnish men and women 15 years of age or older for 28 years showed that even though the population under study was initially free from cardiovascular disease, only those who consumed apple, a main source of the polyphenol quercetin, had significantly decreased risk of thrombotic stroke. Plasma lipid concentration and abnormal metabolism of lipids are the two most established risk factors of cardiovascular disease that can be caused by many factors, among which atherosclerosis and hypertension are the most common. Polyphenol extract containing high amount of procyanidins was found to inhibit *in vitro* pancreatic lipase activity and lowered

in vivo triglyceride absorption in mice. Polyphenol extract of apple was found to significantly reduce the total and low-density lipoprotein (LDL) cholesterols and increase the high-density lipoprotein (HDL) cholesterol in human subjects after 4 weeks. Meanwhile, atherosclerosis is related to the oxidation of LDL and apple antioxidants therefore have the potential to reduce cardiovascular risk. Apple juices and fresh apple extracts rich in polyphenols were found to significantly inhibit LDL oxidation in an *in vitro* copper-induced human LDL oxidation system. Polyphenols in apples and apple juice were also found to contribute significantly to the improvement of lipid profile and oxidative status *in vivo* in hypercholesterolemic hamsters. Hamsters given a human equivalent of ca. 2.5 large apples or 500 ml of juice daily for 12 weeks significantly improved serum lipid profile by reducing total cholesterol (11% and 24%, respectively) and the ratio of total cholesterol–HDL (25% and 38%), prevented the development of atherosclerosis, and showed favorable effects on antioxidant enzymes in the liver.

Antidiabetic Effect

Only limited information is available on the potential effect of apple or its polyphenol extracts on regulating blood glucose level and other markers related to diabetes. Phenolic extract of apple, particularly that of the peel, showed a strong inhibitory activity against α-glucosidase, a key enzyme regulating blood glucose level. Phenolic compounds in apple juices were found to significantly affect plasma concentrations of glucose, insulin, and other two hormones, glucose-dependent insulinotropic polypeptide and glucagon-like peptide-1, in volunteers, and the result appeared to be consistent with delayed intestinal absorption of glucose. Cloudy apple juice containing higher polyphenols, particularly phloridzin, showed greater effect suggesting they may be the active components. More recently, a low-sugar, fiber- and phloridzin-enriched apple preparation showed significantly improved glucose metabolism in the oral glucose tolerance test (OGTT) in human volunteers by reducing the postprandial glucose response at 15–30 min by approximately twofold and by increasing urinary glucose excretion during the 2–4 h interval of the OGTT by fivefold. This implies that apple or its preparation containing high phenolic content may be used to reduce postprandial glycemia and to improve the health of patients with diabetes. In another most recent study, it was demonstrated that an extract and selected individual polyphenols from apple diminished sodium-coupled glucose transporter 1 mediated glucose uptake *in vitro* and *in vivo*, and the strongest inhibition was observed for phloridzin. An OGTT performed in volunteers with prior administration of the apple extract reduced venous blood glucose and plasma insulin levels. Another comprehensive 5×4-week dietary crossover human study showed that consumption of whole apples (550 g day^{-1}), apple pomace (22 g day^{-1}), and cloudy apple juices (500 ml day^{-1}) significantly lowered serum LDL concentration by 6.7%, 7.9%, and 2.2%, respectively. However, LDL cholesterol concentrations increased by 6.9% with clear juice compared to whole apples and pomace in the study. No effect was found for other biomarkers including HDL cholesterol, triglycerides, weight, waist-to-hip ratio, blood pressure, inflammation, and composition of the gut microbiota or markers of glucose metabolism. The authors suggested that in addition to the polyphenols, the fiber component is necessary for the cholesterol-lowering effect of apples in healthy humans and that clear apple juice may not be a suitable surrogate for the whole fruit in nutritional recommendations.

Summary

Apples (*Malus domestica*) are one of the most ancient, widely cultivated, and highly popular fruits in the world. Apples are produced in all continents of the world, but China is currently the world's largest apple producer, followed by the United States producing one-tenth of that of China. While apples are mostly consumed fresh, they are processed into beverages, jam, jelly, and other forms of foods. In addition to the essential nutrients of apple such as vitamins and minerals and dietary fibers, polyphenols have been found in recent years as the main bioactive components responsible for the various health-promoting effects. There are many factors from the field to fork, such as genetics, environmental and postharvest storage conditions, method of processing, and those such as microflora in the human digestive tract that can affect the stability, bioaccessibility, bioavailability of polyphenols, and the antioxidant and anti-inflammatory effects of polyphenols in apples. The consumption of apple and its processed products or extracts rich in polyphenols have been linked to reduced risk in cancer, cardiovascular disease, diabetes, and many other chronic diseases including asthma. Polyphenols exert these health effects through antioxidant and anti-inflammatory activities and by modulating biomarkers in various cell signaling pathways. While sufficient evidence has been found for some of the health beneficial effects, many of them still require further studies.

Arsenic: Properties and Determination

RW Kapp Jr., BioTox, Monroe Township, NJ, USA

© 2016 Elsevier Ltd. All rights reserved.

Atomic Properties

Arsenic (As – CAS (Chemical Abstracts Service) No. 7440-38-2) has properties of both metals and nonmetals and is properly referred to as a metalloid. Arsenic is located in the pnictogen group of the periodic table, which is group 15 (IUPAC notation) or V_A in the CAS system. It has an atomic number of 33 with an atomic weight of 74.922, an atomic radius of 1.33 Å, an ionic radius of 0.58 Å, an atomic volume of 13.1 $cm^3\ mol^{-1}$, a covalent radius of 1.2 Å, and a cross section (thermal neutron capture) σ_a/barns of 4.3. Arsenic has weak bonding between the layers and is therefore brittle and has a relatively low Mohs hardness of 3.5. The crystal structure is designated as a trigonal–hexagonal scalenohedral class. It has a space group *R*-3*m* with cell parameters $a = 3.7680$ Å, $c = 10.5740$ Å, and $Z = 6$ and a volume of 130 Å. An example of the trigonal–scalenohedral class symmetry is shown in Figure 1.

The electron configuration is $1s^2\ 2s^2p^6\ 3s^2p^6d^{10}\ 4s^2p^3$ with the following electrons per energy level: 2, 8, 18, 5. The number of protons, electrons, and neutrons is 33, 33, and 42, respectively. The electron shell model for arsenic is shown in Figure 2.

Arsenic (As) has about 30 known isotopes. Isotope ^{73}As has the longest half-life of 80.3 days, isotope ^{74}As has a half-life of 17.77 days, and isotopes ^{76}As and ^{77}As half-lives are just over 1 day. Isotope ^{75}As is stable and has no measurable half-life.

Chemical Properties

The three most common arsenic allotropes are yellow, black, and metallic gray, which is the most common. The crystalline gray arsenic has a density 5.727 g cm^{-3} (20 °C), a melting point of 817 °C, and a boiling point 613 °C. Yellow arsenic (metastable) has a density of 1.97 g cm^{-3} and a melting point of 815 °C. If yellow arsenic is exposed to light, it will quickly turn into black arsenic, which is also a metastable nonmetallic, glassy, dense mineral substance that is brittle in its pure form. It is a poor electrical conductor with properties intermediate between gray arsenic and yellow arsenic. Arsenic compounds are generally classified into one of three groups: (1) inorganic arsenic compounds, (2) organic arsenic compounds, and (3) arsine gas. Arsenic can exist in four oxidation states: (−3), (0), (+3), and (+5). The most common oxidation states are (−3) in the intermetallic compounds and (+3) in the arsenites, arsenates (III), and most organoarsenic compounds. The most common naturally occurring arsenic compounds are arsenite (AsO_3^{3-}) and arsenate (AsO_4^{3-}). The most common inorganic trivalent arsenic compounds are arsenic trioxide (As_2O_3), sodium arsenite ($NaAsO_2$), and arsenic trichloride ($AsCl_3$). Arsenic forms colorless, odorless, crystalline oxides that are hygroscopic and form acidic solutions upon exposure to water. Pentavalent inorganic compounds include arsenic pentoxide (As_2O_5), arsenic acid (H_3AsO_4), and arsenate (AsO_4^{3-}). Notable sulfur compounds of arsenic include orpiment (As_2S_3), realgar (As_4S_4), and arsenic pentasulfide (As_2S_5). The most common organic arsenic compounds include arsanilic acid ($C_6H_8AsNO_3$), methylarsonic acid (CH_5AsO_3), dimethylarsinic acid (cacodylic acid) ($C_2H_7AsO_2$), and arsenobetaine ($C_5H_{11}AsO_2$).

Occurrence

Arsenic can be found almost everywhere in the environment and is the 20th most common element in the Earth's crust with an overall concentration of about 1.5 ppm. The World Health Organization (WHO) estimates that about one-third of the atmospheric flux of arsenic is of natural origin – primarily volcanic activity. Environmental arsenic levels are a result of the weathering of the 200+ arsenic-containing natural minerals, while anthropomorphic contributions include mining, smelting of nonferrous metals, burning of fossil fuels, the use of arsenical pesticides, the leaching of wood preservatives, and disposal of industrial wastes. Because of the general environmental arsenic contamination and potential toxic exposure, the use of arsenic-containing pesticides and arsenic wood preservatives (e.g., chromated copper arsenate) has been discontinued. Commercial use of elemental arsenic is primarily as an additive for alloys. High-purity gallium arsenide (GaAs) is utilized in the manufacture of devices such as integrated circuits, infrared light-emitting diodes, laser diodes, solar cells, and optical windows. Indium arsenide (InAs) is used for the construction of infrared photovoltaic photodiode detectors for the wavelength range of 1–3.8 μm and diode lasers. Closely related organoarsenics arsanilic acid ($C_6H_8AsNO_3$), roxarsone ($C_6AsNH_6O_6$), and carbarsone ($C_7H_9AsN_2O_4$) have been used in the United States for many years as veterinary drugs and/or feed additive to promote growth and as antiprotozoal drugs to prevent or treat dysentery and as a coccidiostat in poultry and swine. In September 2013, the FDA announced that the two US manufacturers would voluntarily withdraw current roxarsone, arsanilic acid, and carbarsone from the market. Only one organoarsenic animal drug remains on the market with an FDA approval in place for use in animal food: nitarsone ($C_6H_6AsNO_5$).

The soil contents of arsenic range from 1 to 10 ppm; open ocean water averages approximately 1.6 ppm. Arsenic is also found in surface freshwaters with concentrations generally below 10 μg l^{-1}. It is present in many mineral species – primarily in its sulfide form in complex minerals containing silver, lead, copper, nickel, antimony, cobalt, and iron – the most common of which is arsenopyrite (FeAsS). The mean total arsenic concentration in air in remote areas ranges from 0.02 to 4 ng m^{-3}, while urban area samples range from 3 to 200 ng m^{-3}. Inorganic arsenic particulate matter found in urban/industrialized areas

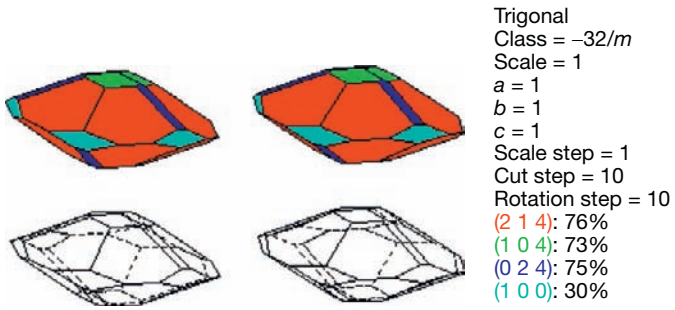

Figure 1 Example of the trigonal–scalenohedral class symmetry. From www.webmineral.com, with permission.

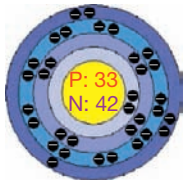

Figure 2 Shell model for arsenic. From http://www.chemicalelements.com.

includes both the tri- and pentavalent forms with the pentavalent form being the predominant species. Arsenic is found in surface freshwaters at concentrations generally below 10 $\mu g\,l^{-1}$ and in groundwater averages about 1–2 $\mu g\,l^{-1}$. High levels of inorganic arsenic can be found in groundwater used as drinking water in various locations throughout the world. Bangladesh is notorious for having some of the highest levels of groundwater arsenic in the world. Arsenic concentrations in soil range from 1 to 40 mg kg^{-1}, with a mean value of about 3 mg kg^{-1}. Organoarsenic compounds such as arsenobetaine ($C_5H_{11}AsO_2$), arsenocholine ($C_5H_{14}AsO$), tetramethylarsonium salts (C4H13As.X), arsenosugars ($C_{10}H_{21}AsO_7$), long-chain hydrocarbons such as 1-dimethylarsinoyl all-*cis*-4,7,10,13,16,19-docosahexaene, and saturated fatty acids with terminal dimethylarsinoyl moieties are all found in marine animals although some of these compounds have also been found in terrestrial species. Arsenoglycerolipids such as glycerophosphorylarsenocholine, diacylglycerophospho-2-hydroxypropyl-5-deoxy-5-(dimethylarsinoyl)-β-ribofuranoside, and arseno-glycophospholipid are found primarily in marine organisms, however, at very low levels. Interestingly, it has been shown that some of these organoarsenics have also been found in terrestrial species.

According to the EPA, bioaccumulation is the net accumulation of a chemical by aquatic organisms as a result of uptake from all environmental sources, such as water, food, and sediment, whereas bioconcentration is the uptake of a chemical by an aquatic organism through water. The level of arsenic in seawater is fairly uniform globally ranging between 0.5 and 2 $\mu g\,l^{-1}$. Marine plants and animals normally contain organoarsenic residues because they are capable of bioaccumulating arsenic both directly from inorganic forms of arsenic in ambient water and from food. The arsenic can be biotransformed from microbes or by internal mechanisms from the plants and animals themselves. Arsenic bioaccumulates in all aquatic organisms; however, the bioaccumulation factor is more prominent in saltwater organisms than in freshwater organisms as evidenced by the fact that freshwater concentrations of arsenic are usually <1 mg kg^{-1} with marine organisms containing arsenic ranging from 1 to >100 mg kg^{-1}. The levels of arsenic present in marine organisms are primarily organic. The major bioaccumulation transfer occurs between water and algae, at the lowest level of the food chain that ultimately has a significant impact on the levels of arsenic found in fish. Biomagnification has not been observed in aquatic food chains. Terrestrial biota may accumulate arsenic through the roots from the soil or by deposition of airborne arsenic particles on the leaves at concentrations usually <1 mg kg^{-1}.

Speciation of Arsenic

As previously described, arsenic exists in elemental, organic, inorganic, and gaseous (arsine) forms. Generally, metallic arsenic is nontoxic because it is insoluble in body fluids and/or water and it remains stable upon exposure to biological systems. On the other hand, inorganic arsenics are toxic and the degree to which they are toxic is dependent on valence state. The toxicity of the trivalent state (As^{3+}) exhibits greater toxicity than the pentavalent form (As^{5+}) state. The oral LD_{50} values for inorganic arsenic compounds range from 4 to 20 mg kg^{-1} body weight. Interestingly, Fowler's solution (1% solution of potassium arsenite ($LD_{50} = 14$ mg kg^{-1})) has been used to treat various diseases, including malaria, syphilis, asthma, chorea, eczema, and psoriasis. Organoarsenics also vary in toxicity; however, the degree of toxicity is minimal in most cases. Arsenobetaine and arsenocholine (with LD_{50}s of about 10 000 and 6500 mg kg^{-1}, respectively) are found in marine invertebrates and fish that contain arsenic residues ranging from <1 to more than 100 mg kg^{-1}. However, not all organoarsenics are as nontoxic as arsenobetaine and arsenocholine. Recently, two arsenosugar metabolites – dimethylarsinic acid (DMA(V), also known as cacodylic acid) (oral $LD_{50} = 644$ mg kg^{-1}) and thio-dimethylarsinic acid (thio-DMA(V)) – were shown to be toxic to cells in *in vitro* cell cultures; thio-DMA(V) was slightly more cytotoxic than arsenite. Therefore, these metabolites DMA(V) and thio-DMA(V) are toxic to humans. Arsine is a highly toxic arsenic gas, and exposure usually occurs in industrial settings when arsenic-containing ores or metals vaporize or come into contact with acidic solutions off-gassing arsine.

Historically, in most cases, arsenic exposure is evaluated by examining for the total arsenic concentration in the blood or urine sample. This is termed determination and is basically the identification of elemental arsenic in a sample, but does not

provide enough information to evaluate the effects the arsenic may have on the environment or on an organism since the bioavailability and metabolic processes depend upon the chemical form of the arsenic. The multiple valence/activity states and significant differences in toxicity following arsenic exposure make it essential to identify the specific species in order to assess the toxic impact of arsenic exposure. This process of differentiation between the various forms of arsenic is referred to as speciation. More specifically, speciation is a process of assessment of the chemical form of a compound in which arsenic occurs in both nonliving and living systems. The specific form directly relates to the bioavailability of arsenic to an organ or organism. The process can separate inorganic arsenics such as arsenite (As[III]) ($LD_{50} = 4–5$ mg kg^{-1}) and arsenate (As[V]) ($LD_{50} = 14–18$ mg kg^{-1}) as well as less toxic metabolites monomethylarsonic acid (MMA) ($LD_{50} = 1800$ mg kg^{-1}) and dimethylarsinic acid (DMA) ($LD_{50} = 2600$ mg kg^{-1}) from nontoxic arsenicals of marine food origin, namely, arsenobetaine and arsenocholine. For instance, seafood can yield a significant increase in total urine arsenic within 10 h of ingestion. Therefore, the normal consumption of marine seafood can simulate exposure to inorganic arsenic if exposure is not detected by arsenic speciation analysis. This underscores the fact that speciation of arsenic is essential to differentiate toxic inorganics from the generally nontoxic organics to understand the true risk of arsenic exposure.

A detailed discussion of arsenic speciation of water, urine, soil, and seafood is beyond the scope of this review; however, it suffices to say the topic of arsenic environmental and biological chemistry is highly complex and is still evolving. There have been several thousand scientific articles over the last two decades describing the determination and speciation of arsenic alone. In order to assess the chemical form of arsenic, one must conduct arsenic speciation, which is the assessment of the chemical form of a compound in which arsenic occurs in both nonliving and living systems.

Preparing Samples for Analysis

Speciation is commonly accomplished in three steps: (1) sample preparation, (2) species separation, and (3) detection. Sample preparations consist of the isolation of different species from the sample matrix. Biological samples are highly complex, and the arsenic species to be analyzed are usually very dilute. Sample preparation is a very critical step necessary to solubilize the sample into a solution while attempting to minimize loss by vaporization. The most commonly utilized extraction methods include solvent extraction, enzymatic hydrolysis, solid-phase extraction (SPE), solid-phase microextraction (SPME), heating blocks, and microwave extraction. According to the Association of Official Analytical Chemists, in determining arsenic levels in food, it is recommended that the sample be heated in an oven at 150 °C for several hours with HNO_3. The container is sealed with the HNO_3 and ammonium hydroxide as a tissue solubilizer. The result is that the organoarsenic compounds are decomposed to inorganic arsenate.

Solvent extraction is frequently used to determine the organoarsenic content of biological samples. This method utilizes a methanol/water mixture for the extraction of minimally polar organoarsenics. The extract is then purified via a stationary phase cartridge or centrifugation and/or filtration. The sample is subjected to gel-permeation, ion-pair, ion-exchange, and buffered ion-exchange chromatographies in order to maintain stability and decomposition. Preparation of foods can also employ tetramethylammonium hydroxide in an alkaline medium to solubilize the sample.

The use of proteolytic enzymes is another method of sample preparation. The concept is that this method promotes biomolecular hydrolysis under neutral pH and room temperature releasing the various analytes from the sample matrix without chemical species changes. It has been shown that utilizing sonification reduces the time of the extraction process and improves the extraction.

Microwave-based procedures involve sample extraction with trifluoroacetic acid/H_2O_2 and measurement of arsenate by anion-exchange HPLC/ICP-MS using aqueous malonic acid. Extraction procedures using dilute acid or organic solvents at relatively low temperatures can be augmented by focussed-microwave ovens. It has been shown that upon microwaving, food samples for organoarsenic compounds, such as MMA, dimethylarsinic acid, arsenobetaine, and tetramethylarsonium ion, all remained stable.

SPE is used for preconcentration and separation according to the partitioning between the respective liquid (sample) and solid (sorbent) phases. SPE is a highly sensitive procedure that results in either the desired analytes of interest or the undesired impurities in the sample that are retained on the stationary phase. SPME is a sample preparation technique that employs the use of a fiber coated with either a liquid or a solid that extracts arsenic from various types of media. There are many methods for the evaluation of soil samples, and other abiotic samples are extracted using aqueous solutions of varying ionic strengths/pH/redox potentials to release arsenic bound to the various mineral phases in the samples. In one method, hydrochloric acid is heated at low temperatures with the sample followed by filtration that ultimately is subjected to hydride generation atomic absorption spectroscopy.

Arsenic in water can be evaluated utilizing adsorption. Chemisorption filters activated with various ions such as Cu^{2+}, Al^{3+}, and Mg^{2+} are used to as absorbents to remove arsenic from water. Another method for the preparation of water samples in the separation of As(III) and As(V) species involves the use of two resins – a strong base anion exchange (SBAE) and a hybrid (HY). The process permits the resins to separate the As(V) from the As(III) by retaining As(V) and allowing the AsIII to pass through. Yet another procedure can be used with low levels of water arsenic that involves the coprecipitation of the arsenic with ferric hydroxide following pretreatment with potassium permanganate.

Organoarsenic compounds such as those found in seafoods are extracted with methanol or a 1:1 methanol/water mixture. Other procedures include extraction with chloroform/methanol/water followed by sonification. The extract is then purified via a stationary phase cartridge or centrifugation and/or filtration. The sample is next subjected to gel-permeation, ion-pair, ion-exchange, and buffered ion-exchange chromatographies in order to maintain stability and decomposition. Preparation of foods can also employ tetramethylammonium hydroxide in an alkaline medium to solubilize the sample.

Different Methods of Analysis

The most commonly used method for speciation of arsenic species is high-performance liquid chromatography (HPLC) in its various derivatives. As(III), As(V), MMA, dimethylarsinic acid (DMA), and arsenobetaine are generally separated by HPLC and determined online by ICP-MS. Two forms of HPLC are generally used – ion pairing and ion exchange. The detection limits for arsenic range between 50 and 300 pg. If an ICP-MS detector is used in combination with HPLC, the detection limits for arsenic species are significantly enhanced to ranges of 10–30 pg.

Previously, basic colorimetric and gravimetric methods such as Reinsch's method, Marsh's test, and Gutzeit's test were considered the 'gold standard' for use in detecting arsenic. However, these methods lack the sensitivity and quantification necessary to adequately analyze for individual arsenic species. With the development of various analytic equipment such as high-performance liquid chromatography/inductively coupled plasma mass spectrometry (HPLC/ICP-MS), it has now become one of the most frequently used method for precise arsenic determination. The advantage of the HPLC/ICP-MS versus other analysis techniques such as atomic absorption and inductively coupled plasma atomic emission spectroscopy (ICP-AES) since the accuracy and level of detection is far superior. Further, it has a higher volume throughput than the graphite furnace atomic absorption spectroscopy (GFAAS). In addition, the HPLC/ICP-MS provides isotope data for more complete analysis. An ICP-MS converts the atoms of the elements in the sample to ions. These ions are then separated and detected by the mass spectrometer.

A brief summary of some of the commonly used methods for the determination of total arsenic in biological samples is found in Table 1.

Table 2 presents brief summary of some of the commonly used methods for the determination of total arsenic in water and food samples.

Table 3 presents brief summary of some of the commonly used methods for arsenic speciation in biological samples.

Table 4 presents brief summary of some of the commonly used methods for arsenic speciation in food and water.

Certified Reference Materials

For quality control, analytical chemists employ certified reference materials (CRMs) that are also referred to as standard reference materials (SRM®) by the National Institute of Standards and Technology (NIST), the United States. NIST currently supplies industry, academia, government, and other users with over 1300 SRMs. In the EU, the European Commission's Joint Research Centre (JRC) currently provides over 800 different reference materials under the BCR®, IRMM, and ERM® brands in the fields of food and feed analysis, environmental analysis, engineering, and health applications. NIST uses the trademarked term SRM® to denote a CRM that satisfies additional specific criteria. Similarly, the term European reference material (ERM®) is a trademarked term referring to CRMs produced by the European reference materials consortium. CRMs are also produced by the following agencies:

- National Research Council of Canada (NRCC) by the Canadian Certified Reference Materials Project (CCRMP), Ottawa, Canada. The NRCC CRM program is operated by the Measurement Science and Standards portfolio and provides CRMs for environmental, biotoxin, food, nutritional supplement, and stable isotopic analysis. NRCC has about 100 CRMs available for analytic use.
- International Atomic Energy Agency (IAEA), Terrestrial Environment Laboratory, Vienna, Austria. The IAEA provides approximately 90 reference materials for various applications.
- Japan National Institute for Environmental Studies (JNIES), Tsukuba-shi, Ibaraki, Japan. The JNIES has about approximately 15 reference materials for chemistry applications.
- Korea Research Institute of Standards and Science (KRISS), Daejeon, Republic of Korea. KRISS provides almost 400 reference materials for various applications.

CRMs allow the analytical chemist to link his or her results with those of internationally recognized standards. In addition, CRMs enable the chemist to verify his or her performance with respect to comparative accuracy. The certified value of a CRM is defined by the applied method following a very strict

analytic protocol, for example, a standard. CRMs are most commonly used as follows:

1. Pure substances or solutions to be used for calibration and/or identification: pure substances are usually certified by establishing the maximum amount, in mass fractions, of the impurities that remain in the purified substance.
2. Materials of a known matrix composition for the calibration of a specific type of comparison.
3. Matrix reference materials that represent the particular matrix being analyzed and have certified matrix content.

A number of CRMs for total arsenic are available, although only a few are available for speciation. **Table 5** lists some of the more commonly available arsenic CRMs from the agencies noted earlier.

Arsenic Occurrence in the Environment

Arsenic is found ubiquitously in the natural environment. In nature, arsenic ranks 20th in order of abundance in the Earth's crust, 14th in seawater, and 12th in the human body. Arsenic cannot be eliminated from the environment; however, it can change its form and attach to or separate from existing particular matter in the environment. Arsenic is a major constituent in more than 200 minerals, hence its wide distribution. The Committee on Medical and Biologic Effects of Environmental Pollutants of the National Academy of Sciences established that the average arsenic content of the Earth's crust is 2.5 mg kg^{-1} with the concentration in soil ranging from 0.1 to 50 mg kg^{-1}, which varies considerably among various regions in the world.

Arsenic is generally introduced into the environment from either naturally occurring geologic sources or anthropogenic sources such mining, smelting, petroleum refining, and numerous types of chemical manufacturing. In addition, trace amounts of arsenic also enter the soil and water through various biological sources that contain arsenic such as plants and aquatic biota. Arsenic contained in soil is usually found in larger particles. These particles settle to the ground and are subsequently separated from the particle by air or rain. Arsenic that is attached to very small particles may be windblown and remain aloft for many days and travel long distances. Many of the more common arsenic compounds can dissolve in water and therefore can be found in lakes, rivers, or underground water by dissolving in rain or snow. Ultimately, most arsenic ends up in the soil or sediment.

Another source of environmental arsenic was through agricultural use in pesticides such as Paris Green (an arsenic pesticide); herbicides such as monosodium methanearsonate (CH_4AsNaO_3), sodium arsenite ($NaAsO_2$), and disodium methanearsonate ($CH_3AsNa_2O_3$); and phosphate fertilizers. Besides elemental arsenic, these materials reportedly also release calcium arsenate, magnesium arsenate, zinc arsenate, zinc arsenite, and lead arsenate into the soil. With the exception of monosodium acid methanearsonate (MSMA), virtually all arsenic-containing pesticide has been restricted by the US government. Arsenic that accumulates in the environment can be subject to various biotransformations – reduction, oxidation, and methylation. For instance, some plants, fish, and microorganisms affect the redistribution of arsenic through their inherent bioaccumulation and biotransformation and eventual volatilization. Some transformation results in less toxic forms of arsenic. Methylation of inorganic arsenic in some bacteria under anaerobic conditions can occur. Similarly, some marine algae can transform arsenate into less toxic nonvolatile methylarsonic acid and dimethylarsenic acid in seawater. On the other hand, some fungi transform inorganic and organic arsenic compounds into highly toxic methylarsines. The arsenic concentrations in agricultural plants are reported to range from 0.007 to 7.50 mg kg^{-1} while the arsenic concentration in some fish can be as high as 100 mg kg^{-1} (in organic forms).

In addition to the normal levels of arsenic in air, water, soil, and food, human exposure to arsenic can occur because of proximity to hazardous waste sites containing high levels of arsenic, or occupational exposure to arsenic from copper or lead smelting, wood treating, and pesticide applications; use of arsenic-treated wood or arsenic-containing pesticides; or drinking water with high levels of arsenic. The elemental form of arsenic is commonly used in alloys for lead-acid batteries and cable sheaths. Arsenic compounds are also used in semiconductors and light-emitting diodes. The result is that humans are exposed to arsenic from a myriad of places including food. In fact, the primary route of arsenic exposure for the general population is via the ingestion of contaminated food or water. The daily intake of total arsenic from food and beverages is believed to be in the range of 20–300 μg per day. In 2001, the World Health Organization (WHO) determined that the daily dietary intake of total arsenic in Japan is higher than that of both Europe and the United States. WHO subsequently estimated that approximately 25% of daily dietary arsenic intake is from inorganic sources and arsenic intake is typically higher in men than in women and children. The estimated arsenic intake levels for various grouping are as follows:

- 1.3 μg per day for infants <1 year of age
- 4.4 μg per day for 2-year-olds
- 9.9 μg per day for 25–30-year-old men
- 10 μg per day for 60–65-year-old women
- 13 μg per day for 60–65-year-old men

Based on these numbers, one could speculate that a daily requirement for humans would be about 12–15 μg per day for individuals consuming approximately 2000 calories of a mixed-food diet. The Contaminants in the Food Chain (CONTAM) Panel of the European Food Safety Authority extensively examined the arsenic content of foods in the European Union and published the results in 2009. Most food categories contained low levels of arsenic (<0.02 mg kg^{-1}): some mean values include water (0.003 mg kg^{-1}), rice (0.14 mg kg^{-1}), and seafood/shellfish (5 mg kg^{-1}). The highest value reported was for a species of algae (30.9 mg kg^{-1}). The mean arsenic levels found in various food categories as determined by EFSA in 2009 are presented in Table 1.

The CONTAM Panel reviewed the provisional tolerable weekly intake (PTWI) of 15 μg kg^{-1} established by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 1989 and determined that dietary exposure to inorganic arsenic should be reduced. The panel calculated that people consumed 0.3–8 μg kg^{-1} per day of inorganic arsenic. EFSA reexamined the arsenic levels in food in 2014 and calculated a lower dietary exposure when compared to that published in the 2009 EFSA opinion ranging from 0.09 to 0.38 μg kg^{-1} per day. The EFSA report suggests that several factors could account for the discrepancies including the use of a more detailed codification to classify the foods (FoodEx), the exhaustive evaluation of the occurrence data carried out in the latter

Data from EFSA (2009).

report, and the different occurrence data used and how they were handled.

In all cases, EFSA found the main contributor to dietary exposure to inorganic arsenic was 'grain-based processed products (nonrice-based)' – specifically wheat bread and rolls. Other important contributors to inorganic arsenic exposure were rice, milk and dairy products, and drinking water.

Absorption

Inhalation

Inorganic arsenic occurs in the atmosphere as particulate matter, and studies reveal that these particles are absorbed into the lungs via two basic mechanisms:

1. Deposition onto the lung surface
2. Absorption of arsenic from the deposited material

It is estimated that the overall rate of absorption of inhaled arsenic is 30–34%.

Organic arsenic is also thought to be absorbed via the inhalation route; however, there are no publicly available studies that definitively address organic arsenic via the inhalation exposure route.

Oral

The major site of absorption of inorganic arsenic is the small intestine via a proton (H+) gradient. The optimal pH for arsenic absorption is 5.0. Studies in humans indicate that arsenates and arsenites are well absorbed as much as 95% across the gastrointestinal tract; however, gastrointestinal absorption may be considerably lower if highly insoluble forms of arsenic are ingested. Studies reveal that 75–85% of organoarsenics such as MMA (CH_4AsNaO_3) and DMA ($C_2H_6AsO_2$) are absorbed across the gastrointestinal tract.

Dermal

Dermal exposure leads initially to arsenic binding to the skin, and it has been shown that the bound arsenic may only very slowly be taken up into the blood although it can occur post-exposure because it is stored in the skin.

Metabolism

Because of the presence of arsenic in the environment for millions of years, living organisms have evolved a variety of resistance mechanisms to overt arsenic exposure. The most prominent of these include the following:

1. Extracellular precipitation
2. Chelation (bonding arsenic to nonmetal ions)
3. Intracellular sequestration (bonding it to another ion or molecule rendering it chemically inert)
4. Active extrusion (removal via active transport through the cell membrane)
5. Biochemical/bioelectrical transformation through reduction/oxidation reactions
6. Biochemical transformation through methylation

Inorganic Arsenicals

Although a single, clear mode of action of toxicity has not been delineated for arsenic, data suggest that arsenic may replace phosphate in various biochemical reactions throughout the cell. Metabolic processes appear to be similar whether exposure is by the inhalation, oral, or parenteral route. The metabolism of inorganic arsenic has been extensively studied in humans and animals. There are two primary metabolic processes found in higher organisms:

(1) Reduction/oxidation reactions
(2) Methylation reactions

The result of these processes is the reduction of inorganic arsenate to arsenite, methylation to MMA(V), reduction to MMA(III), and methylation to DMA(V).

Exposure of humans to either arsenates or arsenites results in increased levels of arsenite, arsenate, and MMA and DMA in urine. Greater than 75% of the absorbed arsenic dose is excreted in the urine. It is when the system is overwhelmed that the exposure then results in arsenic toxicity. DMA is the principal metabolite following long-term arsenic exposure, with lower levels of inorganic arsenite, arsenate, and MMA. Studies in humans reveal the relative proportions are approximately 40–75% DMA, 20–25% inorganic arsenics, and 15–25% MMA.

An alternative biotransformation pathway has been proposed for arsenic involving the nonenzymatic formation of glutathione complexing with arsenite yielding arsenic triglutathione. The arsenic triglutathione is subsequently methylated by arsenic (+3 oxidation state) methyltransferase (AS3MT) to form monomethyl arsenic glutathione. Depending upon the concentration of glutathione, either MMA (at low levels of glutathione) or DMA (at high levels of glutathione) is formed. Studies have shown that methylation of arsenic results in lower tissue retention of inorganic arsenic, and this process is considered to be a detoxification mechanism.

Organic Arsenicals

Organoarsenic or organic arsenicals such as MMA and DMA appear to undergo scant metabolic change when ingested by humans. On the other hand, almost 85–90% of ingested

arsenosugars are excreted within 90 h; however, arsenosugars have been shown to undergo metabolism. Arsenosugars per se are generally not toxic; however, arsenosugar degradation can result in toxic urinary metabolites such as trivalent methylated arsenic. While DMA is the common metabolite from both inorganic sugars and arsenosugars, thiolated intermediate forms of DMA can be formed and present considerably higher toxicity.

Excretion

Inhalation

Urinary excretion of arsenic appears to account for a large part (30–60%) of the inhaled dose suggesting that most of the arsenic found on respirable particles deposited in the lungs is excreted in the urine. The primary forms of arsenic found in the urine of inhalation-exposed humans are DMA and MMA. Inorganic arsenic constitutes <25% of the total urinary arsenic.

No data were available for inhaled organic arsenicals.

Oral

Urinary excretion in humans accounts for 55–87% of ingested inorganic arsenic. In contrast, ingestion of the highly insoluble arsenic triselenide (As_2Se_3) showed little urinary excretion indicating that mostly soluble forms of arsenic are found in urine. Studies measuring arsenic excretion in humans indicate that minimal inorganic arsenic is excreted in the feces and that approximately 50% is excreted in urine within 1–5 days. Arsenic is also excreted in the bile in the form of two arsenic–glutathione complexes (arsenic triglutathione and methylarsenic diglutathione).

Studies of organoarsenicals in humans indicate that ingested MMA and DMA are excreted mainly in the urine (~80%) within 24 h, and these materials are found in both the feces and urine mostly unchanged.

Dermal

No studies were available on the excretion of dermal exposure of either inorganic arsenicals or organoarsenicals.

Biochemical Function and Nutritional Essentiality

Animal studies conducted in 1975 demonstrated that arsenic deprivation increased stillbirths of rat pups and depressed the growth of those that survived. Other later studies revealed a decrease in fertility among animals deprived of arsenic in the feed. These and other nutritional studies have suggested that arsenic may be essential for reproduction and maternal milk production. Arsenic deficiency has resulted in histological changes in the mitochondria of the skeletal muscles and liver tissue. While specific intakes of arsenic are still not precise, it has been shown that dietary consumption of $<50\ \mu g\ kg^{-1}$ is arsenic-deficient. The range considered normal background for arsenic in feed is $350–500\ \mu g\ kg^{-1}$.

Arsenic active transport systems in cellular membranes are found in nearly all organisms. Interestingly, some microorganisms have evolved to be able to utilize arsenic as a metabolic energy source through either arsenite oxidation or arsenate reduction. There is evidence that a trace amount of arsenic may be necessary in several metabolic processes including methylation metabolism. Arsenocholine ($C_5H_{14}AsO$) can replace choline in phospholipids indicating that arsenocholine might have a role in the metabolism of labile methyl groups. Arsenic also appears to have a role in the conversion of methionine to various metabolites such as *S*-adenosylmethionine ($C_{15}H_{22}N_6O_5S$) and taurine ($C_2H_7NO_3S$). Since arsenic binds to sulfhydryl groups, it is possible that its presence may decrease enzymatic catalysis as is commonly noted with other metals. There is limited evidence that arsenic may be necessary along with zinc in protein synthesis and degradation and possible uric acid metabolism. Additional studies have also shown that arsenic may also control gene expression at the transcriptional level via changes in the methylation of core histones.

A recent study indicates that arsenic may be crucial for longevity. Telomeres are complexes of tandem repeats of DNA and protein that constitute the eukaryotic chromosomes. Telomeres shorten with normal aging and studies have shown that this process can be accelerated by increased oxidative stress, kinase activity, and cellular inflammation. There is significant evidence that telomere length may be affected by environmental chemicals that have frequently been associated with chronic diseases such as black carbon, benzene, toluene, polycyclic aromatic hydrocarbons (PAHs), and *N*-nitrosamines. Decreasing the length of telomeres is generally associated with advancing age and exposure to a vast array of environmental chemicals resulting in increased oxidative stress, increased kinase activity, and inflammation associated with some chronic diseases. However, short-term arsenic exposure was shown to be associated with increases in telomere length begging the question of what constitutes the underlying mechanism and whether or not it could be a factor in longevity. It should be noted, however, that there is little definitive evidence showing that arsenic is essential for humans. If arsenic is an essential element, it has a very limited range of safety, which might be from >12 to about 250 μg per day. More than this range could be toxic while less may not permit certain biochemical functions as noted in the preceding text. The only available data are from animals from which some guesstimates can be made with respect to a daily requirement for arsenic in humans. Common foods contain 11.5–40 μg total arsenic.

Acute Toxicity

Acute data are mixed showing a variety of target organs. The lethal dose of acute inorganic arsenic ranges from 100 to 300 mg, while the Risk Assessment Information System database states that "the acute lethal dose of inorganic arsenic to humans has been estimated to be about $0.6\ mg\ kg^{-1}$ per day" with death usually occurring within 24 h to 4 days. The clinical features of oral ingestion initially involve the gastrointestinal system due to a direct irritation of the gastrointestinal mucosa including nausea, vomiting, abdominal pain, and copious watery diarrhea. Other symptoms of inorganic arsenic toxicity can include excessive salivation, acute psychosis, skin rash,

cardiomyopathy, seizures, respiratory failure and pulmonary edema, renal failure, general central nervous system malfunctions with acute psychosis, multiorgan failure, and eventually death. Hematological effects have been reported to include hemoglobinuria, coagulation, bone marrow depression, severe pancytopenia, and normocytic normochromic anemia and basophilic stippling. Acute, high-dose exposure can lead to encephalopathy, with clinical signs such as confusion and hallucinations.

In survivors of arsenic exposure, bone marrow depression, hemolysis, hepatomegaly, melanosis, polyneuropathy, and encephalopathy – with clinical signs such as confusion and hallucinations – may be observed. After acute poisoning, atomic absorption spectrometry studies reveal that the highest concentration of arsenic is in the kidneys and liver. In both fatal and nonfatal inorganic arsenic exposure of humans, nausea, vomiting, and watery diarrhea are the most common symptoms.

Chronic Toxicity

Six-month dietary dog studies showed a dose-dependent decrease in feed consumption and body weights and increased levels of aspartate aminotransferase suggesting hepatotoxicity at dose levels of 4 and 8 mg kg^{-1} per day of arsenite; however, no confirmatory histopathology was noted. Conversely, histological alterations in the kidney and liver were observed in rats exposed to 50 mg sodium arsenate per milliliter for 320 days in drinking water.

In humans, clinical features of chronic inorganic arsenic toxicity reveal significant variations among individuals, population and various subpopulation groups, and geographic locations. Therefore, persons exposed to chronic arsenic poisoning exhibit a wide range of clinical features generally with an onset of nonspecific symptoms of abdominal pain, diarrhea, and sore throat. The most serious resulting effect of this exposure is an increased risk of cancer of the skin, lungs, bladder, and/or kidneys. Other effects include skin changes in pigmentation and hyperkeratosis with chronic toxicity diarrhea occurring in recurrent vomiting. Chronic exposure also causes direct myocardial injury, cardiac arrhythmias and cardiomyopathy, and hypertensive heart disease. The most frequent neurological finding is a peripheral neuropathy. The arsenic-related effects also include changes in behavior and memory loss. Increased prevalence of cerebrovascular disease has also been observed after long-term arsenic exposure in drinking water. Exposure to high concentrations of arsenic is associated with an increased risk of diabetes mellitus and neutropenia. In chronic arsenic ingestion, it has been shown that arsenic accumulates in the liver, kidneys, heart, and lungs and smaller amounts in various other tissues and organs. After about 2 weeks of ingestion, some arsenic is deposited in the keratin-rich tissues, namely, nails, hair, and skin.

Reproductive/Developmental Toxicity

Studies conducted in 1975 previously demonstrated that arsenic deprivation increased stillbirths of rat pups and depressed the growth of those that survived. Other studies showed that only 58% of arsenic-deprived goats and 62% of arsenic-deprived miniature pigs produced offspring compared with 92% and 100% of control animals. Fertility was severely depressed. These and other data suggest that too little dietary arsenic could be detrimental and there is a threshold for arsenic toxicity. Data from numerous animal studies have demonstrated that excess arsenic can produce developmental toxicity, including malformation, death, and growth retardation, in several species. Animal studies of oral inorganic arsenic exposure have reported developmental effects; however, these effects were only observed at maternally toxic concentrations. The most sensitive species is the rabbit, which presented increased resorptions and mortality with decreased viable fetuses/litter at 1.5 mg kg^{-1} per day and a developmental no observed adverse effect level ($NOAEL_{developmental}$) of 0.4 mg kg^{-1} per day of As. Oral dose studies indicate that death and growth retardation are produced by arsenic exposure. Arsenic has been shown to transfer to the fetus and produces developmental toxicity in embryo cultures. Studies have identified increased inorganic or organic arsenic exposures to result in decreased fertility and pregnancy rates in both rats and mice. When females were dosed preimplantation and during pregnancy, the primary effect of arsenic on reproduction was a dose-dependent increase in fetal mortality and in postnatal growth retardation. On balance, the animal studies suggest that arsenic exposures are primarily a risk to the developing fetus. Human data are limited but show an association with spontaneous abortion and stillbirth; however, interpretation of these studies is complicated because of multichemical exposure history. There are no definitive data on the effects of reproduction in humans experiencing arsenic exposure. However, exposure to arsenic in drinking water has been associated with adverse reproductive outcomes showing increases in spontaneous abortions in women drinking water at 0.008 mg kg^{-1} per day for 5–10 years. Chronic exposure of pregnant women to arsenic in the drinking water has been associated with low infant birth weights. Similar associations have been made between late fetal mortality, neonatal mortality, and postneonatal mortality and exposure to 0.86 mg l^{-1} of arsenic in drinking water. These data are not definitive because of lack of sufficient study controls; however, arsenic can cross the placenta and has been found in fetal tissue and in breast milk.

Genotoxicity

In vitro studies of inorganic arsenic in bacterial assays have generally been negative for gene mutations. However, *in vitro* arsenic studies in various human, mouse, and hamster cells and Syrian hamster embryo cells have been positive for DNA damage and repair and enhancement or inhibition of DNA synthesis and chromosome aberrations and sister chromatid exchanges. Arsenic has also been shown to be positive in the Comet assay. Animal and human data indicate that inhaled inorganic arsenic causes chromosomal aberrations. Chromosomal abnormalities in rats given oral doses of sodium arsenate (4 mg kg^{-1} per day) for 2–3 weeks produced an increase in the number chromosomal aberrations. In contrast, studies

in mice given sodium arsenite (50 mg kg^{-1} per day) for up to 8 weeks showed no consistent increase in chromosomal aberrations in either gonadal or somatic cells. Data from two populations of individuals exposed to mean concentrations of either 5 or 109 μg l^{-1} in drinking water found no significant differences in the frequency of chromosomal aberrations or sister chromatid. These studies suggest that ingested arsenic may cause chromosomal effects, but these data are too limited to draw a firm conclusion. While ingested arsenic studies suggest that arsenic may cause chromosomal effects, these data have yet to be confirmed.

Several studies on organoarsenicals reveal that DMA and roxarsone may be able to cause chromosome aberrations, mutations, and deoxyribonucleic acid (DNA) strand breaks. However, *in vitro* studies with MMA did not find significant increases in the occurrence of chromosome aberrations, bacterial mutations, or unscheduled DNA synthesis. Other data show reversible DNA damage in *in vivo* rat and mouse tissue at 1500 mg kg^{-1} of DMA. Interpretation of these data with respect to health risk is unclear.

Carcinogenesis

Animal studies of both inhalation and oral exposure to inorganic arsenic have not resulted in increased incidence of cancer formation in adult animals. However, there is strong evidence that inorganic arsenic exposure to pregnant mice results in their offspring showing transplacental carcinogenesis. Further, one study in mice exposed to pentavalent arsenic in drinking water at 500 mg per day for 2 years showed an increased incidence in tumors of the lungs, liver, gastrointestinal tract, and skin. The organoarsenic DMA has been shown to be carcinogenic in a 2-year drinking water study in rats.

Evidence for the association of cancer in humans exposed to arsenic in drinking water comes from studies in five areas of the world with extremely elevated levels of naturally occurring inorganic arsenic. These areas include the following:

- China/Taiwan
- Chile
- Argentina
- Bangladesh
- India

Additionally, inorganic arsenic has been shown to be a human carcinogen by both the inhalation and oral exposure routes. There is a large body of evidence that inhalation exposure of humans to arsenic significantly increases the risk of lung cancer. In addition, there is evidence that the incidence of skin, liver, and gastrointestinal tumors can occur following inhalation exposure. The strongest evidence that arsenic is responsible for the observed lung cancer comes from quantitative dose–response data relating specific arsenic exposure levels to lung cancer risk. Cumulative exposure to 0.75 mg m^{-3} over a year has been associated with an increased risk of lung tumors. Most of the study data have been from arsenic exposure at copper smelting operations. A limitation of the inhalation studies is the inability to control for exposure to other chemicals, such as sulfur dioxide, and cigarette smoking. It should also be noted that arsenic has been referred to as a 'paradoxical' human carcinogen since the animal data are mostly negative for carcinogenesis and are not judged to be reliable for determining the levels of significant human exposure. The American Conference of Industrial Hygienists (ACGIH), the USEPA, the International Agency for Research on Cancer (IARC), the Maximale Arbeitsplatz-Konzentration (MAK) of Germany, the National Institute for Occupational Safety and Health (NIOSH), the National Toxicology Program (NTP), and the Occupational Safety and Health Administration (OSHA) concur that inorganic arsenicals are human carcinogens and have officially classified them as such.

Other Effects of Arsenic Exposure

The primary incidental effect of long-term oral exposure to inorganic arsenic is a pattern of skin changes. These skin changes are also associated with changes in the blood vessels of the skin, which result in patches of darkened skin. These patches are usually accompanied by small wart-type blemishes on the palms of the hand and soles of the feet (palmar keratosis and solar keratosis, respectively). Leukonychia striata can occur with arsenic exposure. This is a condition also referred to as Aldrich–Mees' lines, which are lines of discoloration across the nails of the fingers and toes. Other incidental effects from inorganic arsenic ingestion could include a decreased production of red and white blood cells, which may ultimately cause fatigue, abnormal heart rhythm, blood vessel damage resulting in bruising, and impaired nerve function. The nerve damage can cause the sensation of 'pins and needles' in the hands and feet. Inhalation of inorganic arsenic can present throat and respiratory irritation, while dermal contact can be irritating to the skin causing both erythema and edema. Arsenic inactivates almost 200 enzymes involved in cellular energy pathways and DNA synthesis and repair. Hence, the effects are widespread.

Children residing in areas of known high natural or anthropomorphic arsenic are at higher risk because of the tendency of young children to consume nonnutritive objects (pica), specifically soil or clay (geophagy). Because of this pica activity, children are at higher risk than adults because it is an additional pathway to arsenic exposure. There is also some limited evidence that suggests that long-term exposure of developing children to inorganic arsenic may contribute to lower IQ scores. There is some evidence that transplacental exposure to arsenic during gestation and overt arsenic exposure during early childhood may increase mortality in young adults.

Therapeutic Uses of Arsenic

Historically, elemental arsenic was available as solutions, tablets, and pastes and in injectable forms and used as a healing agent after Greek physicians Galen and Hippocrates popularized its use. In the eighteenth century, Fowler's solution (1% arsenic trioxide) was used for the relief of various ailments and remained very popular for over 150 years. Fowler's solution was used to treat leukemia, skin conditions (psoriasis, dermatitis, and eczema), stomatitis and gingivitis in infants, and Vincent's angina up until the 1950s. Salvarsan (also

known as arsphenamine) is an organoarsenic with a chemical formula of $C_{12}H_{12}As_2N_2O_2$. It was the primary treatment for syphilis from its discovery by Drs. Sahachirō Hata and Paul Ehrlich in 1910. In fact, arsenicals were the drug of choice in the treatment of syphilis until the advent of penicillin during World War II. Some of the side effects from salvarsan included rashes, liver damage, and risks of life and limb and were thought to be due to the fact that salvarsan was highly unstable in air and has an IV LD_{50} range of 37–91 mg kg^{-1}. The organoarsenic melarsoprol is still used in the treatment of African trypanosomiasis, Chagas disease, and West African sleeping sickness and has toxicity similar to that of the inorganic arsenics with an IV LD_{50} range of 788–2400 mg kg^{-1}.

Based on the induction of apoptosis via the apoptosis-inducing factor (AIF), arsenic trioxide (As_2O_3) is widely used to induce remission in patients with acute promyelocytic leukemia. In China, arsenic sulfide (realgar) is used to treat psoriasis, syphilis, asthma, rheumatism, hemorrhoids, cough, and pruritus and is used as an anti-inflammatory agent. In India, some hematological malignancies are treated with arsenic-containing medications, while in Korea, arsenic is used in herbal preparations to treat hemorrhoids.

Clinical Management of Arsenic Exposure

Acute arsenic poisoning must be managed aggressively with life support monitoring along with electrolytes and fluid balance to try to minimize cerebral and pulmonary edema. Gastrointestinal irrigation is indicated in cases of arsenic poisoning. The use of activated charcoal or bentonite is sometimes contraindicated because of the nausea and vomiting associated with the arsenic exposure. Nasogastric suction can be used to remove recirculating biliary secretions. Chronic arsenic exposure is less aggressive; however, gastric decontamination with activated charcoal is indicated with oral ingestion.

The medical treatment of both acute and chronic arsenic toxicity is also generally conducted with chelating agents. These agents link the arsenic molecules forming a complex ringlike structure converting the arsenic to a chemically inert form that can be excreted without further interaction with the body. Arsenite inhibits the binding of steroids to the glucocorticoid receptor, but not other steroid receptors; therefore, binding of arsenite to protein at nonessential enzyme sites is believed to be one detoxification mechanism. Chelators have been used clinically as antidotes for acute and chronic poisoning. The most common chelators include dimercaprol, DMSA, and Dimaval. D-Penicillamine was a chelator used previously, but is no longer recommended because of serious reactions involving the hematologic system (thrombocytopenia, leukopenia, agranulocytosis, and aplastic anemia) and renal system (proteinuria, hypoalbuminemia, and nephrotic syndrome). Dimercaprol or British anti-Lewisite was developed by British scientists as an anecdote to an arsenic-containing weapon called lewisite. DMSA (meso-2,3-dimercaptosuccinic acid) was developed as a chelator for mercury poisoning. All three chelating agents bind with arsenic to form a stable 1,2,5-arsadithiolane that effectively inactivates the arsenic. Although body burden is not reduced, chelators bind free arsenic and serve to reduce the biologically active arsenic. Serious side effects occur with the administration of these agents such as nausea, vomiting, gastrointestinal distress, and hemolysis and elevated liver enzymes. Since each of these chelators has its limitations, additional research is ongoing seeking better treatment for arsenic exposure. Hemodialysis in arsenic-exposed individuals has shown that only very minimal amounts of arsenic are removed, and it is only used where there is renal failure. Dimaval of DMPS was also developed for mercury poisoning; however, it is only approved for use in Germany and Taiwan and not in the United States.

Regulations/Guidelines/Legislation

The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), as amended in 1986, by the Superfund Amendments and Reauthorization Act (SARA), required that the Agency for Toxic Substances and Disease Registry (ATSDR) develop jointly with the US Environmental Protection Agency (EPA) a list of hazardous substances most commonly found at facilities on the CERCLA National Priorities List, prepare toxicological profiles for each substance on the priority list of hazardous substances, and determine the associated acute, subacute, and chronic health effects. The ATSDR Minimal Risk Levels (MRLs) were developed as an initial response to that mandate to derive substance-specific health guidance levels for nonneoplastic end points. An MRL is defined as an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. These substance-specific estimates, which are intended to serve as screening levels, are used to identify contaminants and potential health effects that may be of concern at hazardous waste sites. While the MRLs do not have the force of law, they are highly regarded guidelines from which other regulations have been derived. Since arsenic was one of the listed hazardous chemicals found on the CERLCA National Priorities List, the following oral MRLs have been established:

- Acute oral exposure ($\leq$14 days) to inorganic arsenic: MRL of 0.005 mg kg^{-1} per day
  - No intermediate-duration oral MRL was derived for inorganic arsenic.
- Chronic oral exposure ($\geq$1 year) to inorganic arsenic: MRL of 0.0003 mg kg^{-1} per day
  - No acute-duration oral MRL was derived for MMA.
- Intermediate-duration oral exposure (15–364 days) to MMA: MRL of 0.1 mg kg^{-1} per day
- Chronic oral exposure ($\geq$1 year) to MMA: MRL of 0.01 mg kg^{-1} per day
  - No acute- or intermediate-duration oral MRLs were derived for DMA.
- Chronic oral exposure ($\geq$1 year) to DMA: MRL of 0.02 mg kg^{-1} per day
  - No acute-, intermediate-, or chronic-duration inhalation MRLs were derived for inorganic or organic arsenic compounds.

From about 1850 to the introduction of organic pesticides in the 1940s, inorganic arsenic compounds were the primary pesticides used in the United States. These included calcium

Table 2 Arsenic guidelines and regulations

[n]Chickens are not to be fed with arsenic supplements within 5 days of slaughter.
[o]Known human carcinogen.

arsenate, lead arsenate, and sodium arsenite. The use of many inorganic arsenic compounds in agriculture was voluntarily terminated by the mid-1960s. However, lead arsenate was not officially banned by the EPA until 1988. While uses on food crops and the use of arsenic acid as a defoliant on cotton plants were voluntarily terminated in 1993, EPA officially canceled the last agricultural use of arsenic acid in the United States on 3 November 1999. All arsenic-containing pesticides were officially restricted in the United States in 2013 with only MSMA remaining on the market as of the date of writing of this article. In 1987, USEPA terminated the use of inorganic arsenic for nonwood pesticides. Effective 31 December 2003, treatment of wood with CCA for residential uses was completely phased out by both EPA and the EU. However, CCA is still used in some far eastern Pacific Rim countries as of the date of writing of this article. Arsenic is no longer produced in the United States; all of the arsenic used in the United States is imported.

The EPA's Integrated Risk Information System (IRIS) has derived a chronic oral reference dose (RfD) of 0.0003 mg As/kg/day for inorganic arsenic. This value was based on a no observed adverse effect level (NOAEL) of 0.0008 mg As/kg/day for dermal effects, and possible vascular complications of individuals exposed to arsenic in well water using an uncertainty factor of 3 (to account for the lack of reproductive data and uncertainty in whether the NOAEL accounts for all sensitive subpopulations of individuals) were applied. No reference concentration (RfC) for chronic inhalation exposures to arsenic was reported. EPA has been assessing the IRIS document on inorganic arsenic since 2003. As of late 2014, this revision/reassessment is still in progress.

In 2008, FDA set 23 ppb as the 'level of concern' for inorganic arsenic in apple and pear juices based on noncarcinogenic effects. In 2011, the 'Dr. Oz' television show broadcast a program revealing results of its own testing of apple juice samples revealing 36 ppb arsenic in apple juice, but their studies neglected to separate inorganic from organic arsenic. Later that year, Consumer Reports magazine tested 88 samples of apple and grape juices and found that 25% of the samples exceeded federal drinking water standards of 10 ppb. Consumer Reports recommended that the arsenic limit for apple juice be set at 3 ppb; however, based upon these data and public pressure, in July 2013, FDA revisited the 23 ppm value and determined that it should be the same as the preexisting arsenic limit for bottled drinking water – 10 ppb. The January 2015 issue of Consumer Reports reviewed the FDA data on rice and grains and conducted tests on 697 samples of its own. They developed and proposed a point system for managing rice exposure since the inorganic arsenic content of rice varies greatly depending on the type of rice and where it was grown. Based upon the test data, they have identified better choices with much lower levels of inorganic arsenic exposure, including white basmati rice from India, Pakistan, or California and sushi rice grown in the United States. Additionally, they call upon FDA to set standards for arsenic in rice-based foods.

IARC indicates that there is sufficient evidence of a relationship between exposures to arsenic and inorganic arsenic compounds and human cancer to classify arsenic as a group 1 carcinogen (carcinogenic to humans). EPA has determined that arsenic is a human carcinogen by both the inhalation and oral routes and is classified as a group A carcinogen. EPA has calculated an oral cancer slope factor of 1.5 mg kg^{-1} per day and a drinking water unit risk of 5×10^5 μg l^{-1} for inorganic arsenic based upon human dose–response data. The inhalation unit risk for cancer is calculated to be 0.0043 μg m^{-3}.

Advisory values are generated by ATSDR, ACGIH, IARC NIOSH, and WHO targeting public health professionals involved in preventing health risks of environmental exposures, as well as specialists and authorities involved in the regulation of chemicals. While they provide a scientific basis for legally enforceable standards, the values generated by these organizations alone are not enforceable. The EPA RfDs are not enforceable standards. However, EPA uses RfDs as risk assessment benchmarks to generate regulations to maintain levels not to exceed the RfD. The more common global arsenic guidelines and regulations are presented in **Table 2**.

Ascorbic Acid: Physiology and Health Effects

ZAM Daud, A Ismail, and B Sarmadi, Universiti Putra Malaysia, Serdang, Malaysia

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Vitamin C also known as L-ascorbic acid is an essential dietary nutrient required for numerous biological processes of the body. Human and several other animal species including primates and guinea pig are unable to synthesize it due to a deficiency of L-gulonolactone oxidase, a terminal enzyme in the biosynthetic pathway of ascorbic acid, because of mutation in the gene encoding for the enzyme. Therefore, vitamin C must be solely obtained from the diet to maintain a normal metabolic functioning of the body. Many fruits and vegetables including citrus fruits, guava, tomatoes, red and green peppers, kiwifruit, and broccoli are the predominant sources of vitamin C supplying more than 80% of the daily needs. Thus, consumption of adequate serving of fresh fruits and vegetables daily will ensure vitamin C adequacy. Diet insufficient in vitamin C (defined as plasma vitamin C levels of $<11\ \mu mol\ l^{-1}$) leads to a lethal condition known as scurvy, characterized by gingival changes, pain in the extremities, and hemorrhagic manifestation leading to death. On the other hand, marginal and suboptimal plasma and vitamin C levels have been associated with increased risk of death from all cause of mortality and cancer.

Over the years, vitamin C has received a greater scrutiny beyond its antioxidant function. Research trends in vitamin C have moved forward from preventing deficiency to investigating its therapeutic value. In conjunction with this, the recommendation for vitamin C intake is being reviewed in light of new evidences pertaining to the role of vitamin C in health and diseases. In fact, this issue remains a debatable topic, as there is no common ground on the amount needed to maintain optimum health. Vitamin C has been controversially used to prevent or delay the occurrence of chronic diseases and to treat certain illnesses. The aim of this article is to discuss briefly the established aspects of vitamin C physiology and its relation to health and disease conditions. Current evidences on the therapeutic role of vitamin C in several chronic illnesses including cardiovascular disease (CVD), cancer, and respiratory illnesses will be discussed.

Physiology of Vitamin C

Ascorbic acid is present in all parts of the body at varying concentration in the plasma, bone cells, and cellular immune system. Body stores of vitamin C can be affected by dietary intake, excretion rate in renal tubule, fecal losses, and metabolic losses. Most of the physiological functions of vitamin C are related to its oxido-reduction properties. It acts as a cofactor for hydroxylases and monooxygenase enzymes involved in the synthesis of collagen, carnitine, and neurotransmitters. Ascorbic acid maintains the metal ions' active center in reduced form to keep hydroxylase and oxygenase in their optimal activity and thereby enhance hydroxylation functions. These will be described briefly in the following subsections.

Absorption, Metabolism, Storage, and Excretion

Upon ingestion of vitamin C, the intestinal absorption that takes place is based on two known pathways (Figure 1): (1) the facilitated diffusion mediated by the facilitative glucose transporter (GLUT) and (2) a saturable-substrate transport mechanism via ascorbate-specific transporter (sodium vitamin C transporter (SVCT)). Oral vitamin C is absorbed for approximately 70–90% at moderate intake (30–180 mg day^{-1}), but absorption rate falls below 50% at intake above 1000 mg day^{-1}. Pharmacokinetics studies revealed that consumption of at least 200 mg day^{-1} of vitamin C in healthy young adults leads to plasma concentration of more than 50 μM, which is a nearly complete oral bioavailability, indicated by leukocyte saturation and minimum urinary excretion. This suggests that ingestion of vitamin C orally produces plasma concentrations that are tightly controlled.

Absorbed vitamin C is transported in the plasma as free anion ascorbate and is distributed to all tissues. At cell levels, particularly in the osteoblast, muscle, and retinal cells, an oxidized form of vitamin C known as dehydroascorbic acid (DHA) is taken up by GLUT and then reduced internally to ascorbic acid. Because DHA shares the same transporter as glucose, this leads to competitive inhibition particularly during altered serum glucose levels such as hyperglycemia secondary to diabetes. On the other hand, active transportation of ascorbate via SVCT is subjected to substrate feedback inhibition indicating a regulatory role in maintaining ascorbate concentration in the cells.

In terms of body store, a total body content of vitamin C in healthy adults ranges from 300 mg to 2 g with higher concentrations maintained in the leukocytes, eyes, adrenal glands, pituitary gland, and brain. Excessive vitamin C intake that is not metabolized is excreted mainly in the urine, although some can also be found in the feces. Maximum metabolic losses of vitamin C in healthy nonsmoking men range from 40 to 50 mg day^{-1}. Smokers are found to have 50% higher metabolic losses than nonsmokers.

In human, the main route of removal of ascorbic acid is through urinary excretion. For this purpose, ascorbic acid is oxidized to dehydroascorbic acid, which is subsequently hydrolyzed to diketogulonic acid. The catabolism of ascorbic acid is completed by decomposition of diketogulonic acid to various compounds such as oxalic and threonic acids (Figure 2).

Safety Levels and Toxicity

Generally, vitamin C is relatively safe even at doses up to several grams per day. This is due to the fact that the

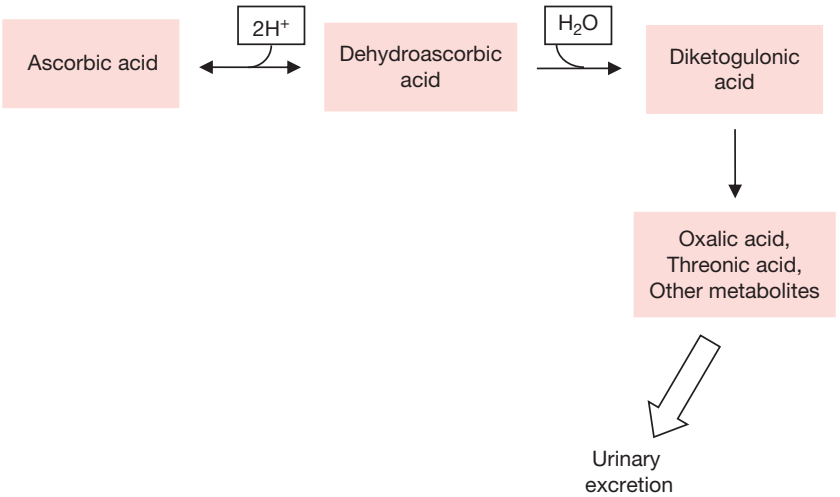

Figure 2 Catabolic pathway of vitamin C.

physiological concentration of vitamin C in the body is tightly regulated by alteration in the intestinal absorption, kidney excretion, and cellular transport. The upper tolerable level, the highest level of daily nutrient intake at which it is likely to pose no risk of adverse effects for most individuals, of vitamin C for adults is set at 2 g day^{-1}. Vitamin C intake at dose beyond 3 g day^{-1} is associated with gastrointestinal disturbance due to the unabsorbed ascorbate. However, participants that were administered intravenous vitamin C up to 100 g per infusion within a few hours in a pharmacokinetics study did not report any adverse effects, demonstrating the safety of this vitamin at megadose.

Nevertheless, high doses of vitamin C are contraindicated in special population including chronic kidney disease patients and hyperoxaluria due to inability to excrete excessive oxalate from metabolic conversion of vitamin C. Meanwhile, in patients with glucose-6-phosphate dehydrogenase deficiency, high doses of vitamin C could induce acute hemolysis. Moreover, high doses of vitamin C could hamper copper absorption and thus inhibit copper-containing superoxide dismutase, an important enzyme in antioxidant defense. On the other hand, very high doses of vitamin C could enhance intestinal iron absorption to a dangerous level among individuals with hereditary diseases such as hemochromatosis and thalassemia. It has been shown in some studies that excessive vitamin C intake (>1 g day^{-1}) may induce severe urine acidification, leading to impaired excretion of weak acids and bases, resulting in deposition of cystinate and urate in the urinary tract and formation of kidney stones.

Mechanism of Action of Vitamin C

Vitamin C is a water-soluble vitamin that is mostly known for its antioxidant function, which is defined as "any substance that, when present at low concentration compared to those of an oxidizable substrate, significantly delay or prevent

oxidation of that substrate." This is attributed to two major properties of vitamin C as an ideal antioxidant:

(1) The ability to readily scavenge free radicals including reactive oxygen species and nitrogen species such as superoxide, hydroperoxyl radicals and nitroxide radicals, single oxygen, nitrogen dioxide, and hypochlorite species, thus protecting substrates (e.g., protein, lipids, carbohydrates, and nucleic acid) from oxidative damage
(2) Stability and low reactivity of ascorbyl radical formed from these scavenging activities

When ascorbate quenches free radicals by donating electrons, ascorbyl radical with low reactivity is generated. Ascorbyl radical reacts with another radical to form DHA. The ascorbyl radical and DHA can be returned to reduced form (ascorbate) by electron donors like glutathione and NADPH.

Vitamin C acts as an electron donor to several enzymes – some participate in collagen hydroxylation and some other in carnitine and catecholamine biosynthesis. Vitamin C acts as cosubstrate to reduce the active center of metal ion of various mono- and dioxygenases and maintain them in a reduced state. Moreover, vitamin C has also been shown to spare other intercellular antioxidants such as glutathione by maintaining them at reduced state. Vitamin C can also regenerate α-tocopherol from the α-tocopheroxyl radical; thereby, it acts as an important co-antioxidant in the absence of which vitamin E can act as a pro-oxidant. Similarly, vitamin C could also regenerate one-electron oxidation products of various antioxidants including urate, glutathione, and β-carotene (Figure 3). However, *in vitro* experiments demonstrate that vitamin C could also act as pro-oxidant. Its pro-oxidant activity is agreed to be dependent on the concentrations used and on the presence of transition metal ions like copper and iron. It has been reported that high doses of exogenous iron (200 mg) and ascorbic acid (75 mg) release iron from iron-binding proteins and promote *in vitro* serum lipid peroxidation of guinea pigs. Ascorbate reduces these metals, which may react with H_2O_2 and subsequently •OH production; this reaction is known as Fenton chemistry. Reduced metals may also react with lipid hydroperoxides that results in production of lipid alkoxyl radicals; subsequently, these lipid alkoxyl radicals can initiate and promote lipid peroxidation. However, such effect is preventable in the presence of sufficient antioxidants (like glutathione). In addition, since metal ions have the capacity to transfer one electron, in biological systems, they bind to proteins; thus, these metal ions become less effective than free-radical catalysts. In line with this, no convincing data are available to demonstrate that this actually occurs in human.

Despite a wealth of knowledge on the antioxidant function of vitamin C from cultured cells and experimental animals, data in human are relatively scarce. This is partly attributed to the fact that human studies may be cofounded by various factors including the bioavailability, presence of illnesses, genetic variations especially with regard to vitamin C transporter, erroneous in dietary estimation, and lack of specific biomarkers. The most conclusive evidences to demonstrate antioxidant effects of vitamin C may be coming from lipids, DNA, and protein oxidation biomarkers. Several lines of evidence indicate that supplementation with vitamin C significantly reduced lipid peroxidation biomarkers (e.g., F_2-isoprostanes) and DNA damage (e.g., lymphocyte DNA damage – comet assay). Nevertheless, this effect is dependent on baseline vitamin C concentration. Supplementation with vitamin C cannot further reduce the oxidative damage if tissues levels of vitamin C are already saturated.

Dietary Intake and Recommendation

Various factors have been identified to affect vitamin C requirement. These include bioavailability, nutrient-to-nutrient interactions, and gender. There are various dietary guidelines available from diverse professional bodies pertaining to vitamin C intake recommendation. One of the commonly referred to is dietary references intake that was developed and maintained by the Institute of Medicine of the National Academy (see 'Further Reading' section). Based on this guideline, adult male requires 90 mg day^{-1} of vitamin C, while nonpregnant and lactating women require 75 mg day^{-1}. Deutschland-Austria-Confoederatio Helvetica (D-A-CH, 2013) and the European Food Safety Authority (EFSA, 2013) recommend higher intake (D-A-CH: 100 mg day^{-1} for adults regardless of gender; EFSA: 110 mg day^{-1} for men and 95 mg day^{-1} for women >18 years old) to outweigh the benefit of higher intake on the reduction in the risk of chronic diseases. Generally, vitamin C requirement is increased in special population including pregnant and lactating women as well as smokers when compared to their age group counterpart (Table 1). This is to reflect the different physiological requirements in these groups. In pregnant women, higher requirement is needed to account for expansion of blood volume and active transfer to the fetus, while for lactating women, to account for vitamin C transfer to breast milk. For heavy smokers (i.e., smoking more than 20 cigarettes per day), higher intake is needed to account

Table 1 Dietary reference intake for vitamin C

	Gender	
Age group	*Male (mg day^{-1})*	*Female (mg day^{-1})*
0–6 months[a]	40	40
7–12 months[a]	50	50
1–3 years	15	15
4–8 years	25	25
9–13 years	45	45
14–18 years	75	65
≥19 years	90	75
Pregnancy/lactation		
14–18 years	–	80/115
≥19 years	–	85/120
Smokers	Additional 35 mg day^{-1}	

[a]For age group of 0–12 months, the DRI was calculated based on adequate intake (AI), while the rest of the age group was based on recommended dietary allowance (RDA). Source: Institute of Medicine. (2000). *Vitamin C. DRI Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium and Carotenoids*, pp. 95–185. Washington, DC: National Academy Press.

for reduced absorption and increased daily turnover pertaining to higher oxidative stress in this population.

Vitamin C intake in various nutrition surveys in the United States and Europe indicated adequacy levels. For example, based on the National Health and Nutrition Examination Survey of the United States (NHANES 2009–10), average levels of vitamin C intake among males and females over 20 years old are 95.6 and 82.7 mg day^{-1}, respectively. Similarly, average vitamin C intake (excluding supplements) among adult males and females in European countries ranges from 69 to 139 mg day^{-1} and 65 to 138 mg day^{-1}, respectively. However, vitamin C intake in some Asian countries may not reach the adequacy levels. This has been demonstrated in a publication from India that showed that the available supply of vitamin C is 43 mg per capita per day, which ranges from 27 to 66 mg day^{-1} depending on locality. This is supported by the fact that plasma levels of vitamin C among native South Asian populations are relatively much lower when compared to South Asian living abroad. It is to acknowledge that differences in methodologies may have an impact on the accuracy of this country-to-country comparison.

Role of Vitamin C in Human Health and Diseases

There is substantial amount of literature from *in vitro* animal model and human studies that investigate the role of vitamin C in health and chronic diseases. For the purpose of this article, only studies involving human will be included for discussion. This is based on the fact that ascorbic acid is not an essential nutrient for most animals – thus, studying genetically variant strain incapable of synthesizing ascorbic acid may not fully recapitulate vitamin C transport functions and imitating disease condition associated with vitamin C depletion and supplementation as in human. The role of vitamin C in human health and disease with its potential mechanism of action is summarized in Table 2.

Collagen Biosynthesis and Wound Healing

Collagen is the main structural protein in various connective tissues, including those found in tendons, ligaments, skin, cornea, cartilage, and blood vessels. Different types of collagens that are the main components of the extracellular matrix comprise ≈30% of total protein mass. The main structural protein of the interstitial extracellular matrix is type I collagen, whereas type IV collagen is found predominantly in the basement membrane. In the extracellular matrix, collagens behave as chief constituents of the physical barrier against invasion of cancer cells. In human skin fibroblasts, ascorbate has been suggested to stimulate the generation of types I and III collagen. Vitamin C plays an essential role during collagen biosynthesis, acting as a specific electron donor for proline hydroxylase, lysine hydroxylase, and procollagen-proline 2-oxoglutarate 3-dioxygenase, all of which take part in the posttranslational hydroxylation of peptide-bound proline and lysine residues of collagen, imperative for stable collagen helices formation. Procollagen is a precursor molecule to the protein collagen that contains unusual amino acid sequence: hydroxyproline and hydroxylysine, converted from proline and lysine after the procollagen molecule has been synthesized. The enzyme involved in this process of hydroxylation, prolyl hydroxylase, requires ascorbic acid, iron, and α-ketoglutarate to catalyze the formation of hydroxyproline. Throughout the process of hydroxylation, the enzyme-bound iron is oxidized (Fe^{3+}) and then ascorbic acid reduces the iron to ferrous state (Fe^{2+}), thus reactivating the enzyme. In a comparable reaction, ascorbic acid acts as a cofactor for a copper-dependent lysyl hydroxylase that contributes in the hydroxylation of lysine to hydroxylysine. Therefore, deficiency in vitamin C results in impaired collagen biosynthesis.

Wound healing process also heavily relies on dietary sufficiency, especially of vitamin C. Ascorbic acid plays an important role in all phases of wound healing. During 'inflammatory phase,' (i.e., the body's natural responses to injury), vitamin C is required for neutrophil apoptosis and clearance as well as to neutralize free radical formed as part of scavenging process. As the wound progresses to 'proliferation phase' (i.e., the wound is rebuilt with new granulation tissues comprising collagen and extracellular matrix), vitamin C is needed as a cofactor for synthesis of collagen tissues. While during 'maturation phase' (i.e., remodeling of collagen from type III to I, occurring after the wound has closed), vitamin C is needed to maintain integrity of collagen production and scar formation. Such role has been demonstrated in a randomized, double-blind, placebo-controlled trial involving 20 trauma patients with disorders in wound healing. Supplementation with antioxidant (including vitamin C) has been shown to reduce time to wound closure. Even though the exact role of vitamin C cannot be ruled out due to the mixture with some other antioxidants in the supplementation, vitamin C may act synergistically with the other antioxidant nutrients to promote wound healing. In addition to collagen, ascorbic acid plays a role in the synthesis of other connective tissue constituents, like fibronectin, elastin, proteoglycans, bone matrix, and elastin-associated fibrillin.

Table 2 Role of vitamin C in health and diseases and its potential mechanism of action

Health and disease condition	*Vitamin C role*	*Possible mechanism of action*
Cancer	Pro-oxidant (high dosage) for adjunct cancer treatment	AA needs to be administered intravenously in order to achieve effective concentration. High dosage of vitamin C has been shown to – create pro-oxidant environment and accelerate irreversible damage of the tumor cells, – stimulate apoptotic pathway of the tumor cells, – result in intermediate formation of H_2O_2 via ascorbate radicals, which in turn causes breaks in DNA and mitochondria – prevent cancer spread by increasing collagen synthesis, inhibiting hyaluronidase, increasing extracellular matrix, and walling within the tumor cells
	Antioxidant for cancer prevention (anticarcinogenic effect)	Normal to high physiological levels of plasma AA to neutralize mutagenic free radicals, reduce oxidative stress, and prevent DNA damage
Cardiovascular diseases	Antioxidant/anti-inflammatory properties	AA reduced oxidizability of LDL. LDL oxidation is one of the key steps in atherosclerosis. AA decreases adherence of monocytes to endothelium, inhibits proinflammatory cytokines, and improves production of the endothelium-dependent nitric oxide
	Antihypertensive effect	AA enhances production of nitric oxide, a potent vasodilator, by increasing intracellular concentration of tetrahydrobiopterin, a cofactor for nitric oxide synthase. AA also improves nitric oxide bioavailability
	Lipid-lowering effect	Suboptimal AA intake affects the activity of two cholesterol-regulating enzymes, namely, ACAT and CETP. Increase in ACAT leads to higher LDL-C, while increase in CETP will result in lower HDL-C. AA as an antioxidant may protect VLDL and promote its removal from plasma. Moreover, AA may increase fatty acid utilization in hepatocytes by enhancing carnitine synthesis. Taken together, increased VLDL removal and β-oxidation of fatty acids lead to lower TAG
Cataract and ocular diseases	Antioxidant	Lens is prone to opacification due to its high protein content. Maintaining adequate blood levels of AA may reduce the risk of cortical, nuclear, and PSC cataract by providing protective effect against oxidative stress-related etiology
Collagen biosynthesis and wound healing	Acts as electron donor to specific enzymes of collagen biosynthesis	AA is involved in the synthesis and cross-linkage of collagen and has impact on vascular integrity and capillary bed strength
Iron absorption	Potent enhancer/ physiological role	AA enhances intestinal absorption of nonheme iron by chelating/maintaining iron in reduced form. AA may interact and reduce dietary inhibitors of iron including phytates
Osteoporosis and fractures	Acts as electron donor to specific enzymes of collagen biosynthesis	Collagen is an essential component of bone tissue. AA mediates osteoclastogenesis and osteoblastogenesis. AA is also involved in bone collagen synthesis, by acting as a cofactor of hydroxylation reaction within collagen fiber
Sepsis	Antioxidant	Low levels of AA in critically ill patients are correlated with multiple organ failure. AA inhibits apoptosis of endothelial cells, stimulates proliferation, and prevents the loss of barrier function in sepsis condition

Note: AA, ascorbic acid; DNA, deoxyribonucleic acid; LDL, low density lipoprotein; VLDL, very low density lipoprotein; HDL, high density lipoprotein; TAG, triacylglyceride; ACAT, acyl-CoA:cholesterol acyltransferase; CETP, cholesterylester transfer protein.

Synthesis of Neurotransmitter

Vitamin C is considered as a cosubstrate for copper-containing dopamine-β-monooxygenase that converts neurotransmitter dopamine to norepinephrine by hydroxylation of the dopamine side chain. In addition, ascorbic acid seems to play a role in the hydroxylation of tryptophan that results in the formation of serotonin in the brain. It has been shown that glutamatergic and dopaminergic neuron activity has been closely associated with changes in concentrations of extracellular ascorbic acid in the brain. Results of animal model and cell culture experiments suggested that ascorbic acid plays an important role in the developing nervous system, mainly for the growth and maturation of glial cells and myelin.

Vitamin C and Iron Absorption

Dietary vitamin C is known to enhance the intestinal absorption of nonheme iron by reducing intraluminal iron to a more absorbable ferrous form. In addition, ascorbic acid can interact with dietary inhibitors of iron absorption. Increase in iron absorption with vitamin C may not cause adverse consequences in healthy people. However, such enhancement of iron absorption following consumption of high doses of vitamin C can be of concern in case of iron overload, like β-thalassemia and homozygous hemochromatosis, as vitamin C can worsen iron overload and cause tissue damage.

In addition, while vitamin C increases iron absorption, it can interact with iron and promote oxidative damage. This is an additional concern about high supplemental intakes of

vitamin C that worsen iron overload and, subsequently, its related pathology. Although high dose of iron intake may not be an important factor in overloaded iron, iron-ascorbate couple has been reported to have a strong pro-oxidant nature, and elevated levels of serum ascorbic acid have been shown to restrain the ferroxidase activity of ceruloplasmin; as a result, oxidative damage will be enhanced by amplified ferrous iron.

Cardiovascular Health

CVD including coronary heart disease (CHD), strokes, cardiomyopathy, and other heart diseases remain to be the leading causes of morbidity and mortality worldwide. Although CVDs have been previously described as a 'wealthy nation disease,' it is projected that by 2020, CVD will be the major cause of death in most developing nations. Major risk factors associated with CVD include increasing age, male gender, dyslipidemia, hypertension, cigarette smoking, family history, obesity, and physical inactivity.

Oxidative damage of biomolecules such as lipids, DNA, and proteins has become a working hypothesis that is widely accepted in terms of its relation with initiation and development of CVD. Several lines of evidence indicate that oxidation of low-density lipoprotein (LDL) is the key factor contributing to atherogenesis; thus, reduction in LDL oxidizability has become one of the therapeutic targets of vitamin C. Moreover, vitamin C contributes to cardiovascular health through its antioxidant properties, decreasing adherence of monocytes to the endothelium and improving the production of endothelium-dependent nitric oxide (NO). However, studies investigating the relationship between vitamin C consumption and CVD show inconsistent findings. Observational studies present a link between high vitamin C intake and reduced risk of CVD, yet, randomized controlled trials (RCT) on the effects of vitamin C supplementation on endothelial function show conflicting results; some studies indicated improvement in endothelial function, whereas others presented no effect of vitamin C supplementation. Therefore, for the ease of discussion, the evidence will be grouped into three main components:

(1) Relationship and effects of vitamin C on overall mortality and morbidity associated with cardiovascular health
(2) Effects of vitamin C on blood pressure
(3) Effects of vitamin C on plasma lipids

Relationship and effects of vitamin C on overall mortality and morbidity associated with cardiovascular health

Several epidemiological studies have provided quite encouraging results yet inconclusive regarding the relationship of vitamin C intake and cardiovascular health. In a large European prospective cohort study involving more than 20 000 participants, the relationship of plasma vitamin C and incidence of heart failure for a mean follow-up of 12.8 years was assessed. The results showed an inverse association between plasma vitamin C and risk of heart failure after adjustment of cofounders such as age, sex, smoking, systolic blood pressure, and physical activity; every 20 $\mu mol\ l^{-1}$ increase in plasma vitamin C was associated with 9% relative reduction risk of heart failure. This however may reflect overall intake of fruits and vegetables; thus, specific constituents of the diet leading to reduced heart failure risk cannot be ruled out. A meta-analysis of prospective studies to investigate the relationship of vitamin C intake, plasma level, and risk of stroke was published. The analysis included 12 prospective studies on vitamin C intake and six prospective studies on circulating vitamin C (plasma/serum levels). Results of this analysis suggest that both vitamin C intake and circulating vitamin C are significantly inversely associated with the risk of stroke.

From the clinical trial perspective, a 6-year antioxidant supplementation (vitamin C and E) among 520 subjects with the end point of common carotid artery intima-media thickness. The supplementation was associated with significant regression of atherosclerotic lesions in participants with low baseline plasma vitamin C concentration. However, most data from recent RCTs that evaluate role of vitamin C for prevention of CHD or stroke are not as consistent as the population studies and thus failed to produce convincing evidence to advocate supplementation. Some of the limitations of RCTs and the reason for disparate finding between epidemiological studies have been discussed elsewhere. These include limitation in dietary recalls to estimate vitamin C intake and the failure of the intervention study to exclude subject who already achieved saturation in circulating vitamin C as supplementation may not provide any additional benefit. Furthermore, duration of supplementation and sample size are relatively small in many RCTs.

Effects of vitamin C on blood pressure

Vitamin C has also been hypothesized to confer antihypertensive effects. This is basically derived from the fact that vitamin C enhanced endothelial functions via nitric oxide production. Furthermore, epidemiological study has also shown inverse correlation between plasma levels of vitamin C and blood pressure. A meta-analysis of RCTs to examine the effects of vitamin C supplementation on blood pressure was conducted. A total of 29 trials were included in the analysis with a median vitamin C supplementation of 500 $mg\ day^{-1}$ for a median duration of 8 weeks. It was found that vitamin C modestly reduced blood pressure, with the pooled changes in SBP and DBP being – 3.84 mm Hg and – 1.84 mm HD, respectively. Nevertheless, this analysis was cofounded by heterogeneity of the data, relatively small sample size, and, more importantly, variable control of antihypertensive medications for each of the trials. In short, further evidence is needed to outweigh the benefit of vitamin C supplementation on blood pressure.

Effects of vitamin C on plasma lipids

In line with epidemiological evidence that vitamin C has an inverse association with the development of atherosclerosis, it has also been hypothesized that this effect could be mediated by lipid-modifying effects. In a meta-analysis involving 13 RCTs, it was found that supplementation with at least 500 $mg\ day^{-1}$ vitamin C among hypercholesterolemic subjects led to significant reduction of LDL-C ($-7.9\ mg\ dl^{-1}$) and triglycerides ($-20.1\ mg\ dl^{-1}$). Nevertheless, the magnitude of changes is considered modest, thus the need for further evaluation on the cost-effectiveness of the supplementation.

Cancer

Carcinogenesis, or development of malignant cells, is a multistage process. It is generally accepted that free radicals developed by carcinogens are implicated in the carcinogenesis process. Vitamin C has received a great scrutiny in terms of its role in the prevention and treatment of malignancy. However, the effect of vitamin C on treatment and prevention of cancer is very inconsistent despite a vast number of studies in this area. In a recent meta-analysis based on the epidemiological studies involving more than 8000 lung cancer cases, it was found that vitamin C decreased risk for lung cancer in a dose–response manner; lung cancer risk decreased by 7% for every 100 mg day^{-1} increased in the intake of vitamin C. Similarly, another meta-analysis of cohort studies that investigated the relationship of plasma antioxidant levels (α-tocopherol, retinol, and vitamin C) with the risk for breast cancer revealed that plasma level of vitamin C was significantly lower in breast cancer subjects when compared to control. However, when these data were controlled for menopausal status, continent, and study design, the significant relationship between plasma vitamin C and breast cancer was only seen in case–control type of study. Vitamin C may not be effective in treatment of active cancers when used alone; its supplementation has been suggested to enhance life quality and longevity of cancer patients; thus, it is being studied as an adjuvant in cancer therapy. Some of the proposed mechanisms include vitamin C role in protecting cells from oxidative DNA damage, thus blocking initiation of carcinogenesis. This is supported by several studies that showed that plasma vitamin C at normal to high physiological level (60–100 μmol l^{-1}) concentration neutralized mutagenic free radicals, reduced oxidative stress, and thus prevented DNA damage. The evidence from population studies however does not translate into similar results in randomized controlled trials. A recent meta-analysis of RCTs and also a prospective cohort study reported no survival advantages and no effects of oral vitamin C supplementation on the incidence and mortality from prostate cancer. On the other hand, vitamin C has also been used in the treatment of malignancy by taking advantage of its pro-oxidant capacity. Extracellular ascorbate can destroy cancer selectively, with no effects on normal cells possibly through production of hydrogen peroxide. Pharmacological doses of ascorbate can be attained only by intravenous (IV) administration, due to the fact that orally administered vitamin C is hampered by limited absorptive capacity of the intestinal tract. Thus, this hypothesis provides a plausible explanation for the failure of many orally supplemented studies discussed earlier. In a systematic review that covered 39 articles from RCTs, phase I and II, and observational study, the authors concluded that high-quality studies on IV vitamin C are limited; however, current studies provide some basis for pharmacological benefits of IV vitamin C, thus justifying needs for a larger clinical trials. Some of the positive effects of IV vitamin C observed in these studies include a decrease in chemotherapy-related side effects such as nausea, insomnia, and constipation and improved time to relapse and quality of life of the patients.

In a pilot RCT, administration of high doses of IV vitamin C (75 g or 100 g per infusion) twice a week for 6 months during chemotherapy and an additional 6 months after chemotherapy among stage III/IV ovarian cancer patients leads to fewer side effects/toxicities related to chemotherapy and less adverse event when compared to the control group. Some of the proposed mechanisms include that IV vitamin C acted as pro-oxidant to induce DNA damage and depleted cellular energy (adenosine triphosphate (ATP)). Moreover, pro-oxidant ascorbate stimulates ATM/AMPK pathway leading to mTOR inhibition and death of ovarian cancer cells. Another proposed mechanism for IV vitamin C includes intermediating formation of extracellular hydrogen peroxide (H_2O_2). H_2O_2 diffusion into tumor cells causes DNA and mitochondria to break leading to cell death. Moreover, IV vitamin C therapy has also been shown to work synergistically with chemotherapy drug, gemcitabine, by sensitizing cancer cells to chemotherapy, leading to a synergistic cytotoxic response.

Despite some promising outcomes in many of the uncontrolled trials and case–control studies related to IV vitamin C, these data are subjected to criticism. Risk of bias in these studies is high due to heterogeneity of the study design, small sample size, nonstandardized dosage, and incomplete information on the pharmacokinetics and pharmacodynamics of IV vitamin C.

To summarize, the evidences available to date provide an interesting finding; however, they are not conclusive to suggest any clinical benefits of vitamin C in the prevention and treatment of malignancy.

Cataract

Cataract is characterized by increase in lens opacity or cloudiness leading to decrease in vision and eventually blindness. The World Health Organization revealed that cataract remains the leading cause of visual impairments worldwide, responsible for 51% of all causes of blindness worldwide. During the aging process, the lens undergoes biochemical, physiological, and functional changes especially on its protein constituent as a result of exposure to various insults including free radicals.

Vitamin C is naturally present in the lens at 50-fold of the concentration found in the plasma. Several lines of evidence indicate that aging process is associated with lower ascorbate content of the lens that may compromise lens functions. Many of the epidemiological studies demonstrated that higher vitamin C levels are associated with diminished risk of cataract. Interestingly, based on a systematic search and meta-analysis of the observational studies, it was found that plasma ascorbate is inversely associated with age-related cataract in the Asian population but not in the Western population.

Data from RCTs, however, are not as encouraging. In a meta-analysis that included nine randomized control trials involving more than 117 000 individuals, supplementation with one or more antioxidants (i.e., vitamin C, β-carotene, and vitamin E) for the purpose of prevention of cataract yielded negative results. The study concluded that there is no evidence to recommend antioxidant supplementation as means to prevent or slow the progression of age-related cataracts. Data from the Swedish Mammography Cohort, involving more than 24 000 women that were followed for 8.2 years, revealed even alarming results. In this study, it was found that vitamin C supplement users among women aged ≥ 65 had actually increased risk of cataract by 38%.

Asthma and Respiratory Illnesses

Asthma is a chronic inflammatory airway disease characterized by variable, reversible airway obstruction and episodic symptoms of wheezing, chest tightness, and/or cough. Asthma can develop at any stage in life but often starts during early childhood. According to the Global Asthma Report (2014), it is estimated that more than 300 million people suffer from asthma and 14% of the world's children were likely to have had asthmatic symptoms last year. Asthma is often triggered by environmental insults, including common colds caused by respiratory viruses.

Vitamin C is one of the major antioxidants present in lung tissue and lining fluid. This is to reflect its role in providing antioxidant protection against exposure to oxygen, as well as air pollutant including ozone and nitrogen oxides. Similarly, vitamin C may also implicate in inflammatory response during asthmatic attack by providing protection against oxidative damage. A cross-sectional study indicates that ascorbate concentration in the lung of subjects with mild asthma is reduced. In a population study involving more than 2000 patients, vitamin C intake was associated with enhanced pulmonary function. A systematic review on intervention with vitamin C to reduce common cold-induced asthma was done. In this article, the author described three intervention studies involving a total of 79 subjects. Vitamin C doses provided in all of the three studies were ranged from 1 to 5 g day^{-1}, so as the outcome measures (one study on asthma exacerbation and the two studies on bronchial sensitivity to histamine). These studies provide a positive indication in which vitamin C supplementation is found to reduce the occurrence of infection-induced asthma attacks by 78% and decrease bronchial hypersensitivity. However, further study with larger sample size is needed to confirm these observations. Similarly, in another meta-analysis, it was found that vitamin C is able to alleviate exercise-induced asthma.

Another common respiratory illness is 'common cold.' The term 'common cold' basically refers to viral infection of the upper respiratory tract, characterized by a group of symptoms including nasal discharge and obstruction, sore throat, cough, lethargy, and fever. Although common cold is non-life-threatening, however, it is the leading cause of doctor visits and absenteeism from work/school. Vitamin C has traditionally been claimed to be useful in the prevention and treatment of the common cold. Despite a large number of publications on this aspect, the evidence to support the use of vitamin C supplements to reduce the incidence and duration of common cold is relatively weak. In a recent meta-analysis involving 29 trials that include more that 11 000 participants, it is found that regular supplementation of vitamin C (200 mg day^{-1} or more) had no effect in reducing common cold incidence but had modest effect in reducing the duration of common cold symptoms. However, the authors recommend further evaluation in special population including runners, skiers, swimmers, and soldiers working in subarctic conditions given some positive data on this population.

Osteoporosis and Fractures

Osteoporosis is a progressive deterioration of bone mass and bone tissues leading to bone fragility and increased risk for fracture. Globally, osteoporosis is responsible for more than 8.9 million fracture cases annually. It has been estimated that 1 in 3 women and 1 in 5 men over the age of 50 will experience osteoporotic fracture. Vitamin C plays an important role in maintaining bone integrity by several mechanisms including mediating osteoclast differentiation and accentuating osteoblastogenesis and bone collagen synthesis in osteoblasts, an important process in bones remodeling, maintenance, and repair. *In vitro* and *in vivo* studies demonstrated that vitamin C deficiency leads to decrease in bone matrix stability and weakening bone structure. Quite a handful population-based cohorts demonstrated positive association of vitamin C intake and higher bone mineral density. However, data in human intervention studies are scarce. An RCT involving 90 subjects was conducted. The studied subjects were supplemented with either placebo ($n=30$), or 500 mg vitamin C + 400 IU alpha-tocopherol ($n=30$), or 1000 mg vitamin C + 400 IU alpha-tocopherol for 12 months ($n=30$). The study showed that the intervention with 1000 mg vitamin C and 400 IU of alpha tocopherols led to significantly lower hip bone loss compared to control group. The extent of vitamin C role in preventing bone density loss is questionable due the presence of alpha-tocopherol. In short, more high-quality human intervention trials are needed to rule out the therapeutic role of vitamin C in preventing or delaying bone loss.

Conclusion and Recommendation for Future Study

Vitamin C has undoubtedly been proved to confer significant antioxidant effects in *in vitro* and animal studies. Similarly, several lines of evidence indicate the potential of vitamin C in counteracting with inflammation and oxidative stress, an underlying process of many chronic and acute diseases. Many of the epidemiological studies have generally shown potential therapeutic roles of vitamin C in the prevention and treatment of chronic diseases. However, this has not been translated, at least conclusively, in many RCTs. This is attributed by the fact that our understanding of vitamin C effects at the molecular level in human physiological system is incomplete. Nevertheless, future research in vitamin C should be streamlined by considering several issues including characteristics of study population that may benefit from vitamin C intervention and assessment of baseline vitamin C status, as patient with saturated levels of plasma vitamin C may unlikely benefit from additional oral supplementation. With emergence of 'omics' technology, it is hoped that this will address some of the limitations and controversies observed in animal and human studies by designing a high-quality mechanism-based intervention study.

Vitamin C

Sources

Vitamin C is widely distributed in plants (80–90% in fruits and vegetables) and animals. Fruits with the most vitamin C include cantaloupe; citrus fruits and juices, such as orange and grapefruit; kiwi fruit; mango; papaya; pineapple; strawberries; raspberries; blueberries; cranberries; guava; and tomatoes and tomato juice. Vegetables with the most vitamin C include broccoli, Brussels sprouts, cauliflower, green and red peppers, spinach, turnip greens, and other leafy greens, sweet and white potatoes (skins), and winter squash. Some cereals and other foods as well as beverages are fortified with vitamin C. Vitamin C is also available as caplets, tablets, capsules, drink mixes, multivitamin and antioxidant formulations (solid and liquid), and stand-alone supplements. Tablet and capsule contents range from 25 to 1500 mg vitamin C.

Chemistry

General properties

L-Ascorbic acid ($C_6H_8O_6$) is the trivial name for vitamin C and is also the biochemical nomenclature name accepted by the International Union of Pure and Applied Chemistry–International Union of the Biochemistry and Molecular Biology. However, its systematic chemical designation is 2,3-enediol-L-gulonic acid-γ-lactone, which was formerly known as *hexuronic acid* (Figure 1). Vitamin C is the generic name for all compounds exhibiting qualitatively the biological activity of ascorbic acid (AA). These include esters of AA (e.g., ascorbyl palmitate) and synthetic forms (e.g., 6-deoxy-L-AA, 33% relative activity) and the primary oxidized form of L-AA, L-dehydroascorbic acid (L-DHAA).

L-AA has chiral centers at carbons 4 and 5 and can exist in four stereoisomeric forms. Enantiomeric pairs are L- and D-AA and L- and D-araboascorbic acid. L-AA and D-araboascorbic acid (more commonly known as D-isoascorbic acid), or erythorbic acid, are epimers differing in the orientation of hydrogen and hydroxyl on carbon 5. Structures of various AA forms are shown in Figure 2. Isoascorbic acid is not present in foods, but is synthesized commercially because of its antioxidant capacity and is used commonly in cured meat products to prevent oxidation and protect color. The stereoisomers have no biological activity other than a small amount from isoascorbic acid (2.5–5% relative to L-AA). Most of the analytic techniques used are unable to differentiate between the epimers. Since isoascorbic acid is used in some processed foods, erroneously high vitamin C content will be determined where more sophisticated techniques are not used.

L-AA and L-DHAA are the primary dietary sources of vitamin C. L-DHAA is considered to have up to 80% bioequivalency with L-AA, but some studies reported it is as low as 10%. If true for the biological activity of L-DHAA in humans, many foods that combine L-AA and L-DHAA composition values for total AA would need to be revised.

Physical properties of L-AA and its salt and ascorbyl palmitate are shown in Table 1. L-AA is a white to slightly yellow crystalline powder with high water solubility (30 g 100 ml^{-1}) at room temperature. It forms salts, the most important of which are with sodium and calcium salts, which are strongly acidic in aqueous solutions. The salts also have greater water solubility. L-AA complexes with disulfides (e.g., oxidized glutathione), but does not reduce the disulfide bonds. L-DHAA reacts with several amino acids to form brown-colored products (Maillard reaction), which contributes to the spoilage of foods. L-DHAA is not ionized in environments of weakly acidic or neutral pH environments, meaning it is relatively hydrophobic and is better able to penetrate plasma membranes than L-AA.

Spectral properties

The absorption properties of L-AA are dependent on the ionic species present and, therefore, dependent upon the pH of the aqueous media. E1% 1 cm values for L-AA are 695 at pH 2.0 and 940 at pH 6.0. Above pH 5.0, L-AA exists predominantly as the monoanion and the maximal absorption occurs at 265 nm. Associated, at more acidic pH levels, maximal absorption occurs at 244–245 nm. Dissociated, above pH 12.0, maximal absorption occurs at 300 nm. L-AA does not fluoresce, but derivatization with *O*-phenylenediamine (OPD) to form a highly fluorescent product is used advantageously in chemical and liquid chromatography (LC) methods.

Stability

Crystalline L-AA is highly stable in the presence of oxygen when water activity remains low. Due to its strong reducing properties, L-AA is readily oxidized through one- or two-electron transfer. In aqueous solution, L-DHAA is unstable and is hydrolyzed irreversibly to the biologically inactive

Substance	*Molar mass*	*Solubility*	*Melting point (°C)*	*Crystal form*
L-Ascorbic acid ($C_6H_8O_6$)	176.13	Soluble in water (30 g 100 ml^{-1}) Slightly soluble in alcohol Insoluble in ether, $CHCl_3$, benzene, petroleum, oils, and fats	190–192	Monolithic platelets and needles; white or yellow
Sodium ascorbate ($C_6H_7O_6Na$)	198.11	Soluble in water (90 g 100 g^{-1})		White to slightly yellow powder
Calcium ascorbate $(C_6H_7O_6)_2Ca$	390.31	Soluble in water (5 g 100 g^{-1}) Slightly soluble in alcohol Insoluble in ether		White to slightly yellow crystalline powder
Ascorbyl palmitate ($C_{22}H_{38}O_7$)	414.54	Slightly soluble in oils Soluble in alcohol (22 g 100 ml^{-1})		White to slightly yellow powder

2,3-dioxo-L-gulonic acid. Reducing agents can convert the dehydro form back to L-AA in biological systems. Enzymatic conversion of L-DHAA to L-AA by glutathione dehydrogenase is an important biological defense against oxidative stress.

L-AA can oxidize through one- or two-electron transfer. One-electron reduction utilizes the transition through the L-AA free radical (semi-DHAA). At physiological pH, a bicyclic radical is formed with the loss of a proton, which subsequently becomes a radical anion that is relatively inert, due to its resonance stabilization, but diassociates to L-AA and L-DHAA. The anion radical is an intermediate in the reversible redox system formed by L-AA and L-DHAA. Thus, it is an effective quencher of free radicals, such as singlet oxygen ($^1O_2$).

It reduces ferric (Fe^{3+}) to ferrous (Fe^{2+}) iron (and other metals analogously) and the superoxide radical (O_2^-) to hydrogen peroxide and is oxidized to monodehydroascorbic acid in the process. Reducing agents and glutathione dehydrogenase convert L-DHAA back to L-AA, completing the oxidation-reduction cycle. Classic free-radical termination occurs through reduction of a free radical with L-ascorbate. An electron is transferred to the free radical from L-ascorbate, producing an L-ascorbate radical, which acts as a redox agent. The L-ascorbate radical reacts with itself to form a 1:1 mixture of L-AA and L-DHAA. Two-electron reduction occurs when transition metals catalyze L-AA oxidation. A ternary complex forms between the metal, L-AA, and oxygen, and two p-electrons shift from L-AA to oxygen via the transition metal. The complex then dissociates with the formation of L-DHAA, hydrogen peroxide, and the metal ion. Unless converted back to L-AA, L-DHAA can be quickly hydrolyzes to biologically inactive 2,3-diketo-L-gulonic acid (Figure 2).

Oxygen, temperature, light, transition metal catalysis, pH, the presence of thermal processing conditions, oxidizing lipids, reducing substances, and the possible presence of AA oxidase in biological systems interact to produce a complex set of interactions influencing oxidative stability and the degradation rates of L-AA. Losses during cooking depend on the duration of heating, leaching into the cooking medium, surface area exposed to water and oxygen, pH, presence of transition metals, and other factors that facilitate the oxidation of L-AA and its conversion to inactive forms. The extreme vulnerability of L-AA at or near physiological pH is a primary consideration in most analytic methods. Since routine processing and storage conditions can stimulate the conversion of L-AA to L-DHAA in significant amounts, analytic methods that rely on the oxidation of L-AA to L-DHAA to give a measure of total L-AA are irrelevant. High-performance liquid chromatography (HPLC) detection of L-AA and L-DHAA simultaneously has been reported for biological samples (e.g., plasma stabilized with metaphosphoric acid (MPA)) since early 1990s.

Determinations

L-AA is the only water-soluble vitamin not determined microbiologically. Methodologies have advanced from the bioassays to instrumentally advanced spectrophotometric, fluorometric, electrochemical (EC), and chemiluminescence methods. Chromatographic procedures, especially HPLC, ultraperformance liquid chromatography (UPLC)–mass spectrometry (MS), and capillary electrophoresis (CE), provide an excellent means to resolve L-AA, L-DHAA, and D-isoascorbic acid simultaneously. These separation techniques used with ultraviolet (UV)–visible, fluorescence, or EC detectors are selective and sensitive for quantify L-AA and its isomers from complex biological matrices.

Before a method can be used, it needs to be validated to ensure it is suitable. Guidance documents on method validation, recommended by numerous international reputable organizations, are available such as the Association of Official Analytical Chemists (AOAC), Food and Drug Administration (FDA), Food and Agricultural Organization (FAO), International Conference of Harmonization (ICH), International Union of Pure and Applied Chemistry (IUPAC), and the European Commission. However, there is no single recommended approach for analytic method validation, but there are common elements to validation, for example, selectivity, linearity, stability, accuracy, precision, and the lower limit of quantification (LOQ). Parameters such as limit of detection (LOD), reproducibility, and robustness are also relevant. All these parameters are usually applied for HPLC methodology. For LC–MS, the determination of possible matrix effects (MEs) should be included, especially if MS mode is used in electrospray ionization (ESI).

Extraction and Sample Preparation Procedures

Extraction procedures are designed to stabilize the vitamin before further processing. Careful attention must be given to sample collection and subsequent handling prior to analysis; otherwise, L-AA may not reflect concentrations in foods as consumed. Extraction solutions should maintain an acidic environment, chelate metals, inactivate AA oxidase, and limit soluble oxygen as well as precipitate starch and proteins. The choice depends on the sample matrix and the analytic procedures. Reagents that usually limit L-AA destruction to $<5\%$ include 3–6% MPA containing acetic or sulfuric acid or 0.005 mol 1–1 ethylenediaminetetraacetic acid (EDTA).

MPA, while not compatible with some LC methods, is used most commonly in other methods. MPA inhibits L-AA oxidase and metal catalysis and precipitates proteins that aid in extract clarification. MPA is often combined with other acids and/or organic modifiers (acetic acid, methanol, acetonitrile, trichloroacetic acid (TCA), and citric acid) and stabilizers ((EDTA) and monosodium glutamate) to prevent degradation. Adding ethanol or acetone to the MPA extract precipitates solubilized starch from vegetables, such as potatoes, legumes, and maize for spectroscopic methods. Acetone is also useful to remove metabisulfide and sulfur dioxide from dried fruit products and fruit juices. EDTA is added as a metal chelator in vitamin C extractants to sequestrate copper in MPA and TCA but is ineffective for oxalic acid.

All extraction procedures should be completed rapidly in subdued or yellow light (570–590 nm) to limit oxidation. In general, fresh rather than frozen samples are better for L-AA analysis, since L-AA degrades during freezing or freeze-drying. Homogenization of samples should avoid heating. Samples should be in liquid nitrogen during storage. Freeze-drying is not recommended for sample concentration or storage since vitamin C stability decreases in the porous matrix. It has been reported that L-AA content is higher when food samples are prepared and analyzed on the same day rather than analyzed

from frozen samples (losses of up to half). It has also been reported that L-AA losses during the entire freezing process range between 10% and 80% (average *c*.50%). When samples with high moisture content are blended, the stabilizing solution should be added before blending. Stability of total AA (L-AA + L-DHAA) in serum can be extended with the addition of dithiothreitol or MPA (50 g l^{-1}), which effectively stabilizes the vitamin at −70 °C.

It has been shown that L-AA degrades significantly in autosampler vials during HPLC analysis. This is because the internal surface of the glassware contains materials, such as metal, which promote degradation. Sample tubes for collection, processing, and storage are also subject to this problem. Procedures such as soaking the vials in 0.5 mol 1-1 NaOH or 1 mol 1-1 HCl (30 min) before rinsing with distilled deionized water and soaking in and rinsing with distilled deionized water have been recommended to prevent degradation of L-AA. Similarly, handling and storage have been shown to impact stability of L-AA prior to analysis. For example, vitamin C is higher in pears prepared and sampled with minimal cutting, to reduce induction of ascorbate oxidase and other oxidases that catalyze L-AA oxidation, freezing each sample in liquid nitrogen and storage at −80 °C. Thus, it is necessary to undertake a validation study, to determine stability for embarking on analysis of a food. More research is also necessary to compare the stability of L-AA under ideal conditions compared with those typically used.

Traditional Methods

Oxidation–reduction methods

2,6-Dichloroindophenol (DCIP) titration is an established method to determine L-AA content. DCIP works on the principle of L-AA reduction to a colorless solution from the deep blue color of the oxidized dye. Subsequently, L-AA is oxidized to L-DHAA and any excess dye is pink in the acidic solution, forming a visual end point for the titration. The end point can be determined visually (518 nm). There are a few drawbacks to this method, the most important being titration is limited to quantitation of L-AA only. L-DHAA cannot be measured, unless it is first reduced to L-AA. The titration is also unable to differentiate between L-AA and isoascorbic acid, meaning this method cannot be used with processed and cured meats containing isoascorbic acid. DCIP titration is suitable for fresh juices and multivitamin supplements that do not contain significant quantities of copper or iron. However, highly colored extracts from fruits and vegetables, for example, can mask color changes at the end point. In this respect, solid-phase extraction (SPE) can extend DCIP titration to highly colored samples such as multivitamins, soft drinks, fruits, and vegetables, because cleanup removes copper, iron, sulfite, and other interfering reducing substances, such as cysteine and glutathione. The method can be adapted for L-DHAA by reducing it to L-AA with cysteine before cleanup. This relatively simple approach increases the sensitivity of DCIP, and inclusion of SPE would decrease limitations of the established method.

AOAC Official Method 967.21, Ascorbic Acid in Vitamin Preparations and Juices, 2,6-Dichloroindophenol Titrimetric Method, AOAC Official Methods of Analysis 45.1.14 (AOAC Method 967.21) has been recommended for the analysis of L-AA in beverages and juices for the purpose of nutrition labeling. The AOAC Official Method 985.33, Vitamin C ((Reduced AA) in Ready-to-Feed Milk-Based Infant Formula) (Chapter 50.1.09), is also based on the DCIP titration. The method differs from Method 967.21 at the extraction stage of the method. AOAC International has updated the change of method for vitamin C determination in infant formula and adult/pediatric nutritional formula (AOAC SMPR 2012.012) in its newest edition (19th edn. 2012).

Derivatization methods

There are two types of derivatization methods, *o*-phenylenediamine (OPD) condensation and 2,4-dinitrophenylhydrazine (DNPH). OPD condensation with L-DHAA is one of the most useful derivatization reactions to determine total vitamin C and gives a highly fluorescent quinoxaline product (Ex $\lambda = 350$ and Em $\lambda = 430$). AOAC Official Method 967.22, Vitamin C (Total) in Vitamin Preparations, Microfluorometric Method – The AOAC Task Force on Methods for Nutrition Labeling recommended that Method 967.22 be used for most food matrices. The manual microfluorometric method has been modified to semiautomated analysis with DCIP and *N*-bromosuccinimide oxidation replacing Norit oxidation and the direct addition of Norit slurry in MPA to the food sample to oxidize L-AA and L-DHAA during extraction (AOAC International Method 984.26, Vitamin C in Food, Semiautomated Fluorometric Method (Chapter 45.1.16)). The modified method is rapid (40 assays per hour) with the same sensitivity and specificity as the AOAC International Method 967.22.

DNPH reacts with ketone groups of L-DHAA under acidic conditions to form a red osazone derivative. DNPH is useful for the analysis of total AA if sugars are not present. Norit and DCIP oxidize L-AA to L-DHAA. Derivatization is completed with the addition of DNPH and the color produced on acidification with sulfuric acid. Maximal absorption occurs between 500 and 550 nm. Most methods measure the DNPH derivative at 520 nm. DNPH has not been used commonly compared with OPD derivatization. This method does not compare in specificity and simplicity to the microfluorometric method for total AA. Hence, a rapid DNPH-based microtiter plate assay for the determination of AA in plasma and leukocyte has been developed. The method is capable of high sample throughput and small sample volumes and requires smaller amounts of reagents than traditional DNPH methods.

Enzymatic methods

Enzymatic conversion of L-AA to L-DHAA coupled to a determinative step (e.g., spectrophotometry), OPD and other derivatizations, and EC determinations of oxygen uptake have been used to assay L-AA in biological samples. Ascorbate oxidase and ascorbate peroxidase activities, represented by the following equations, convert L-AA to L-DHAA. Total vitamin C and isoascorbic acid can be quantified at levels as low as 0.2 μg g^{-1}. L-DHAA can be quantified by omitting enzymatic oxidation.

Ascorbate oxidase

$$\text{L-AA} + {}^{1}/_{2}\,O_2 \rightarrow \text{L-DHAA} + H_2O$$

Ascorbate peroxidase

$$\text{L-AA} + H_2O_2 \rightarrow \text{L-DHAA} + 2H_2O$$

Spectroscopic and optical methods combined with flow injection and sequential injection analysis

L-AA can be assessed spectrophotometrically, based on the redox properties of L-AA on reaction with hexacyanoferrate (III) and oxidation using the Cu (II)–neocuproine complex or determination of iodine in reaction with AA. The reduction of Fe^{3+} to Fe^{2+} and Cu^{2+} to Cu^{+} is frequently incorporated in newer methods. Metal ion reduction is associated with the creation of a reduced metal ion complex with various dyes, which exhibit concomitantly a color change. Such color changes, while easily measured spectrophotometrically, can also be used for more simple visual tests or test strips for the present/not present determination and/or approximation of vitamin C content. Dyes that have been used include 2,2′-dipyridyl, pyridine-2,6-dicarboxylic acid, *p*-carboxyphenyl fluorone, 4-(2-pyridylazo) resorcinol, 1,10-phenanthroline, 2,4,6-tri(2-pyridyl)-1,3,5-triazine and ferrozine, and many others.

Other optical methods for vitamin C include chemiluminescence. Some researchers have determined the L-AA content of samples using flow injection analysis and the more advanced sequential injection analysis (SIA), as well as combined approaches. Spectrophotometric and electrochemical detection (ECD) methods are most commonly used with both analyses.

Advances in Vitamin C Analysis

Capillary electrophoresis

CE has been used extensively for the analysis of fat- and water-soluble vitamins, including vitamin C in pharmaceuticals, and fruit or vegetable products. Two basic techniques that have been used most for vitamin C analyses are capillary zone electrophoresis (CZE) and micellar/microemulsion electrokinetic capillary chromatography (MECC). These techniques are highly versatile, faster, more efficient, and more cost-effective than alternatives, but they are also less sensitive than HPLC. CZE is very useful for higher-concentration matrices, dietary supplements, and fruits and vegetables. It is normally applied with water-soluble samples while MECC is able to resolve neutral samples on the basis of partitioning between the aqueous electrolyte and a pseudostationary phase (PSP) of charged molecules. Hence, MECC is more adaptable to complex food matrices. However, hydrophobic analytes (e.g., fat-soluble vitamins) can precipitate out during electrophoresis due to their low solubility in the aqueous MECC buffers.

More recently, adaptations to MECC (MEECC) have been developed to overcome its inherent weakness with hydrophobic analytes. Microemulsions are stable, isotropically clear, systems containing oil (e.g., octane) and water, stabilized by a surfactant and cosurfactant. The adapted method (MEECC) uses micelles as the PSP in CE. The separation mechanism is based on electrophoresis coupled with chromatography, which makes it possible to separate neutral and charged analytes simultaneously. For instance, a novel microemulsion system consisting of sodium dodecyl sulfate (SDS), Brij 35, 1-butanol, and heptane has been developed for 10 fat- and water-soluble vitamins (including vitamin C), which can be separated in 35 min. In addition, using an SDS microemulsion, modified with 21% 1-butanol and 18% acetonitrile as the running buffer, allowed 13 water- and fat-soluble vitamins to be separated, simultaneously, in 30 min.

LC for vitamin C determination

LC methods, especially HPLC, are the preferred method for the analysis of L-AA, L-DHAA, and isoascorbic acid from natural sources. Previous reports have compared the efficacies of traditional methods with HPLC where they demonstrate similar results for only a limited number of samples. HPLC methods, which demonstrate high selectivity and sensitivity, are essential for the analysis of L-AA in many foods because of their complexity. Furthermore, both L-AA and L-DHAA can be quantified using appropriate HPLC methods.

Since L-AA is nonvolatile and hydrophilic in nature, reversed-phase HPLC is most commonly used, although ion-exchange, ion-exclusion, and hydrophilic interaction LC have also been used (Table 2). The validation parameters for different L-AA HPLC methods are shown in Table 2 (published between 2010 and 2014). There are a set of widely accepted key elements for the validation of HPLC methods: selectivity, linearity, stability, accuracy, precision, and the lower LOQ. Additional parameters that may be relevant include LOD, reproducibility, robustness, and ruggedness.

For the analysis of liquid samples, direct injection into the HPLC system, after dilution with the mobile phase, is a common procedure. For solid samples, solid–liquid extraction is usual. In LC-based methods, MPA (with and without glacial acetic acid) has been used most commonly for extraction. Samples are homogenized thoroughly with the solvent, centrifuged or filtered, and injected in the HPLC, again following dilution with the mobile phase. UPLC has also been applied to the analysis of L-AA in foods, with the main advantages of shorter analysis times and much less solvent compared with conventional HPLC. Mobile phase pH is usually adjusted to below the L-AA pK_a (4.17) to prevent degradation. An HPLC chromatogram for L-AA in a standard solution and in grapefruit is shown in Figure 3(a).

L-AA presents a strong absorption in the UV region (245–270 nm), making UV absorbance the most popular detection technique. In addition, fluorescence detection (FD) and ECD have also been used as well as MS after LC separation. MS is the most sensitive analytic technique for the identification of the molecular masses of unknown compounds in various modern research disciplines, including food science and nutrition. The mass spectrum of L-AA is shown in Figure 3(b). The LOD ranged between 0.02 and 0.16 $\mu g\,ml^{-1}$ for ECD, 1.2×10^{-3} and 7.2 $\mu g\,ml^{-1}$ for UV, and $\sim$0.27 $\mu g\,ml^{-1}$ for FD (Table 2). Usually, ECD is more sensitive than UV, although the wide LOD ranges make it difficult to perform an accurate comparison. Fluorescence is also more sensitive than UV, even though derivatization makes it more time-consuming than UV. The low levels of L-DHAA in most samples make quantitative analysis with any HPLC detector difficult. Hence, L-DHAA is often reduced to L-AA before chromatographic separation, and it is measured as total AA, that is, the sum of L-AA and L-DHAA. This procedure requires two separate

Table 2 An overview of validated HPLC methods for vitamin C determination in various food samples

chromatographic runs, and L-DHAA is calculated by the subtraction of L-AA from total AA.

External standard calibration is usual for vitamin C quantification (Table 2) due to its simplicity and use of the same calibration curve for different matrices. Internal standards (IS) have also been used, but these must be selected carefully so characteristics and physical/chemical behavior are as close as possible to L-AA without causing interference. The best IS is, therefore, stable isotope labeled L-AA.

EC determination of vitamin C

EC techniques for L-AA have received considerable interest because of their sensitivity, rapid response, simple operation, and low costs. Since minimum requirements are needed for sample pretreatment (extraction), these techniques are often preferred compared with laborious instrumental methods for L-AA determination where results can be obtained in complex media. EC determination of L-AA is due to electrooxidation of L-AA to L-DHAA, which involves two electrons.

Among the EC methods applied for L-AA determination, researchers have used polarography and voltammetry. Polarography is not widely used because it requires removal of interfering compounds using separation techniques such as extraction, ion exchange, and chromatography. Voltammetric/amperometric analysis using different electrodes (e.g., modified metal or carbonaceous electrodes and nanoparticle and ceramic composites with suitable chemical and biochemical sensors) has been developed more recently. For example, glassy carbon and carbon-paste electrodes, platinum electrode, and hanging drop mercury electrode have been used in L-AA determination. Since L-AA is one of the most electroactive biomolecule, it is difficult to determine its concentration at unmodified carbon or bare metal electrodes, due to the occurrence of surface reactions associated with its previously described EC behavior.

Chronopotentiometry is another EC technique based on oxidation or reduction of analytes on the electrode surface in steady solutions with a constant current. Oxidation (transition) time represents quantitative characteristic, while oxidation potential is a qualitative characteristic of the analyte. It has been found that L-AA content of fermented milk products does not differ significantly when determined using chronopotentiometry or HPLC. Indeed, for some applications, chronopotentiometry is more sensitive, reliable, and rapid.

Recent studies have reported various chemically modified electrodes, such as gold nanoparticles self-assembled on a L-cysteine-modified glassy carbon electrode (GCE), tetraoctylammonium bromide-stabilized 1,6-hexanedithiol-modified gold electrode, multiwalled carbon nanotubes (MWCNTs) with methylene blue-composite film-modified electrode, 3-mercaptopropyl-functionalized silica network gold nanoparticle-modified electrode, and carbon-paste/cobalt Schiff base composite electrodes, with suitable chemical and biochemical sensors, not only decrease excess voltage and enhance electrocatalytic peak current but also solve a common problem encountered at unmodified surfaces, such as the peak overlapping in the determination of L-AA.

MWCNTs are a new type of porous nanostructure in carbon materials, possessing properties such as high electrical conductivity, larger surface-active groups-to-volume ratio, chemical stability, and significant mechanical strength. Modified electrodes based on MWCNTs have been used widely for the study of L-AA, including a carbon nanotube–ionic liquid gel-modified electrode, layer-by-layer assembled functionalized carbon nanotube and polyaniline multilayer film-modified electrode, cytochrome c immobilization on a poly-3-methylthiophene/MWCNTs hybrid-modified electrode, silver hexacyanoferrate nanoparticles/-carbon nanotube-modified electrode, and a chloro-[3,7,12,17-tetramethyl-8,13-divinylporphyrin-2,18-dipropanoato (2-)]iron (III)/MWCNTs (Fe(III)P/MWCNTs).

S., Jifon, J. L., and Patil, B. S. (2012). An improved sample preparation method for quantification of ascorbic acid and dehydroascorbic acid by HPLC. *LWT-Food Science and Technology* **47**(2), 443–449. Copyright (2012), with permission from Elsevier.

A recent report demonstrated functionalized poly(3,4-ethylenedioxythiophene) (PEDOT) films, prepared by the incorporation of two electrospecies (e.g., ferrocenecarboxylic acid [Fc-] and ferricyanide $[Fe(CN)_6]^{4-}$) as doping anions during the electropolymerization of PEDOT at GCEs, from an aqueous solution to prepare composites [PEDOT/Fc- and PEDOT/$Fe(CN)_6]^{4-}$, which could be used as EC sensors. These nanostructured films combine the advantages of PEDOT (high conductivity and stability) with electroactive species (good EC activity) and have been used as EC sensors for the determination of vitamin C in food samples. These sensors have been shown to possess high selectivity with no interference from other potential competing species. This modified electrode was applied successfully for the determination of analytes, such as vitamin C, in urine and serum samples using the standard addition method with satisfactory results.

Uses

L-AA is used widely as a food additive with many functional roles, based mainly on its oxidation–reduction properties. Its functional roles include uses as a nutritional food additive, antioxidant, browning inhibitor, reducing agent, flavor stabilizer, modifier and enhancer, color stabilizer, dough modifier, and many other roles. Ascorbyl palmitate was developed to provide a form with greater lipid solubility for cooking purposes and antioxidant preparations.

Introduction

Food authenticity is of great importance for consumers, food authorities, and food industry because incorrect labeling of foods could be related to various types of fraudulent practices. Diseases related to foodstuff consumption raised the awareness around aspects like geographic origin and agricultural practices. Food authentication became an important issue and has been faced with different analytical approaches like DNA-based technologies, infrared spectroscopy, isotope analysis, separation techniques, mass spectrometry, and NMR. Several 'omics' definitions appeared for the holistic understanding of

different molecular aspects like function, physiology, and pathophysiology of plants and mammals. One above all, namely, 'metabolomics' offers information on the global metabolite composition (metabolome) of a given biological system and its dynamic response towards stimuli. Most suited analytical techniques appears to be NMR, mass, and hyphenated chromatographic techniques (LC–MS, GC–MS, LC-DAD-NMR/MS, etc.), and the high-throughput qualitative screening of a biological sample is defined with the widely accepted term 'metabolic profiling.' The large amount of data obtained by these analytical techniques requires the use of multivariate statistical analysis for sample comparison and discrimination analysis. In this article, selected applications in food authenticity assessment are presented.

Mass Spectrometry

Mass spectrometry (MS) holds a central position in food analysis, and its applications expand in food authenticity-related studies (i.e., traceability or determination of geographic origin and adulteration). MS methods currently yield higher sensitivity when compared to other spectroscopic techniques such as NMR, which normally detects medium- to high-abundance metabolites. MS-based analysis may be targeted or nontargeted. Targeted analysis is a conventional analysis where the method is developed based on standards. Nontargeted analysis theoretically allows the detection and characterization of any compound present in the sample. Two different analytical approaches are followed in nontargeted analysis:

- 'Metabolic profiling' refers to the analysis of a class of chemically related compounds or is associated with a particular metabolic pathway.
- 'Metabolic fingerprinting' refers to the analysis of the total set of metabolites, avoiding focus against certain classes of compounds. When individual metabolites are not identified, 'metabolite fingerprinting' is used for a rapid classification of samples.

In targeted analysis or in metabolic profiling study, selective extractions are needed, and usually, mass spectrometry is coupled to a separation technique such as LC for semipolar compounds; GC for thermally stable, volatile, and semivolatile compounds; or CE for ionic, weakly ionic, and polar metabolites. Data from MS coupled to a separation technique contain the extra information of retention/migration time. MS/MS has been the cornerstone technique for targeted analysis. Several publications on the applications of MS/MS in the detection of contaminants for food quality and safety purposes are present. The QqQ and the IT mass spectrometers give nominal masses and perform MS/MS. The QqQ-MS/MS is one of the most popular instruments for the analysis of complex food samples because of its high sensitivity, selectivity, and specificity for identification and for its quantitation capabilities when operated in MRM mode. The use of new-generation fast-switching QqQ and the hybrid fast-switching QqLIT mass spectrometers significantly enlarges the number of analytes that can be detected in a single MS/MS run up to 200 compounds with 2 SRM transitions. In addition, the IT can be operated in enhanced product ion mode and can perform MS^3 for the characterization of unknowns. To this direction, UPLC-Q-LIT-MS was applied for nontargeted screening and structure identification of the banned azo dye Allura Red AC and its photodegradation products in a beverage. Initially, a nontargeted screening with enhanced MS (EMS) in full scan mode was carried out as a survey scan. When the signal of a detected compound exceeded a defined threshold, the acquisition of both enhanced resolution (ER) and enhanced product ion spectrum (EPI) was automatically activated. In EMS mode, the third quadrupole works as an ion trap, accumulating the ions of interest, while in the ER mode, the isotope ratio is confirmed, and in the EPI mode, the ion trap is used to provide higher abundance of product ions through an enhanced MS/MS scan. The chemical structures of the unknown species formed in the photodegradation process were proposed on the basis of the molecular mass.

HRMSs operating in full scan mode like TOF-MS, Orbitrap-MS, and FT-ICR-MS provide high selectivity and sensitivity and through accurate mass measurements can provide possible identification of unknown compounds and are therefore suitable for nontargeted analysis. High-speed GC-TOF-MS was applied in nontargeted analysis and in particular the fingerprinting of volatile compounds. More than 100 compounds could be identified in coffee in only 7.9 min, and through PCA statistical evaluation, the geographic origin of samples could be determined. Identification was performed by the comparison between experimental and reference/library mass spectra and the comparison between experimental and literature retention indexes. Recently introduced hybrid mass spectrometers such as QqTOF, Q-Orbitrap, and TOF–TOF combine the features of tandem mass spectrometry and accurate mass measurement of fragment ions as an additional tool for confirmation. Additionally, with the hybrids LTQ-TOF, LTQ-Orbitrap, and LTQ-FT-ICR mass spectrometers, multistage MS^n can be used for structural elucidation. LTQ-Orbitrap was applied for the determination of the polyphenolic profiles of unifloral honeys where a total of 43 compounds were detected in less than 5 min and samples were classified according to their botanical origin. Although the chromatographic profiles obtained were similar for all samples, there was a significant difference in the content of some polyphenolic compounds. Floral markers were suggested and honeys derived from perennial plants and from annual plants could be discriminated. Some phenolics were identified and quantified using the available standards, while in the absence of standards, the identification of the corresponding compounds was based on the search for the $[M_H]^-$ deprotonated molecule together with the interpretation of its fragmentations with the help of an Internet database of accurate mass spectrometry data as a reference library. The identification of four different phenolics with almost identical masses was able through the high-sensitivity accurate mass scan. This example points out the main advantages of hybrid mass spectrometry compared to triple quadrupole MS to the screening and identification of unknown compounds, the possibility of using exact mass to calculate the most favorable elemental composition, and the determination of the accurate mass of the product ions in the MS^n data-dependent scan. When the objective is metabolic fingerprinting, the extraction protocol should be nonselective or direct analysis without sample preparation should be followed through direct infusion or measurements on the surface of samples. To this direction, ambient

ionization MS techniques, such as DART, DESI, EASI, and PTR-MS, broke through in the past few years, apart from ESI and APCI sources commonly used with LC and GC, and their applications in foodomics are still being explored. DART-TOF-MS was successfully applied to recognize the origin of beers without any sample preparation and no prior separation procedures. By the same technique, the different olive oil categories could be differentiated, and in addition, olive oil adulteration with hazelnut oil could be revealed. The polar and triacylglycerol profiles were acquired, and additions of 6% and 15% (v/v) hazelnut oil could be detected, respectively. EASI was used to estimate the quality of nut oils through their triacylglycerol profiles. The method allowed the identification of authentic oils and adulterated oils with 5% soybean oil in a few minutes and without sample preparation. PTR-MS allows monitoring of volatile organic compounds (VOCs) through the soft chemical ionization technique used and, although a rather new technique, its capabilities in the field of geographic origin have already been explored in wine, truffles, and Grana cheese. When applied in olive oils, the country of origin could be by 86% classified correctly, 74% of samples were successfully classified according to region of origin, and the district of origin yielded a success rate of only 52%. MALDI-TOF-MS is a widely used technique for the analysis of protein and peptide biomarkers (proteomics) primarily separated through electrophoresis but has become a popular method for direct analysis applied to small molecules. MALDI-TOF-MS has been used to detect adulteration in bovine milk powder with 10% ($m\,m^{-1}$) of non-milk fats and oils through their triacylglycerol profiles and also to determine both qualitatively and quantitatively melamine and its derivatives. Melamine could be determined with an LOQ down to 0.5 $\mu g\,g^{-1}$ and with the limited dried-droplet sample preparation. Significant limitations of direct MS analysis is the ionization suppression and its effect on sensitivity caused by the presence of multiple chemical species and other matrix components that have considerable impact on the ionization of metabolites and also the overlapping of MS signals of isobaric molecules such as structural isomers or enantiomers.

Finally, ICP-MS can also be used to perform food authentication through the elemental composition of food. The fact that isotopic composition of the constituents of agricultural products depends on geographic origin and on production-related factors has made IRMS another promising approach used for assessing traceability. Both techniques have been successfully applied to wines to examine the influences of geographic origin, year of vintage, grape cultivar, and meteorologic conditions.

In any case, the amount of data provided mainly from fingerprinting strategies is of great complexity, and the use of specific software for data treatment is of utmost importance. Usual data-processing steps involve peak detection, integration, data alignment, and normalization before scaling and multivariate statistical analysis.

NMR Spectroscopy

Nuclear magnetic resonance (NMR) is a spectroscopic technique that allows the analysis of samples in all physical states, providing detailed information at molecular level. A single experiment led to analyze several classes of chemical compounds in a noninvasive, highly reproducible way and in a pretty low experimental time. Materials, like foods as well, could be in different aggregation states: crystalline, amorphous, liquid-like, or liquid. Depending on these states, different NMR techniques could be applied, starting from solid-state NMR, going through NMR imaging, and finishing with liquid state. Technology allowed a big drop in the field strength of the magnets: the field strength could vary from very few fraction of tesla up to latest 1.2 gT. Different NMR techniques and instrument requirements result in different data: high resolution (HR), low resolution or low field (LF), high-resolution magic angle spinning (HR-MAS), imaging (NMRI), and site-specific natural isotope fractionation (SNIF) NMR. HR allows both qualitative and quantitative analyses of samples as well as molecular structure determinations in solution; data obtained from complex matrices like foods enable great potentiality in food metabolomics as a tool for monitoring product quality and authenticity. Several studies that appeared in the literature have focused on the combined use of NMR spectroscopy and chemometrics, dealing with geographic origin or quality determination of foodstuffs, olive oil and wine being the major targets. From the NMR point of view, the ^{1}H NMR spectrum of olive oil is dominated by fatty acid signals. For a deeper evaluation of the minor components, such as aldehydes, terpenes, and sterols, accurate spectra recording conditions need to be applied. The first article concerning the geographic characterization of extra-virgin olive oil (EVOO) samples investigated different olive varieties coming from four Italian regions. PCA and HCA performed on selected ^{1}H NMR resonances due to minor components such as sterols, *n*-alkanals, *trans*-2-alkenals, and other compounds led to a very good sample classification according to the origin. Many other studies followed investigating virgin or extra-virgin olive oils of different harvests and cultivars, from different Mediterranean areas, obtaining a good discrimination by applying different statistical protocols on ^{1}H, ^{13}C, ^{31}P NMR, and/or isotopic ratios from ^{13}C and ^{2}H data. The high prices of EVOOs led to adulteration practices with cheaper oils. In this context, a methodology to detect the presence of a percentage of at least 10% of sunflower and red palm oils in EVOOs was proposed, by employing a low-field (0.25 T) unilateral NMR method, performing a non-destructive analysis through sealed bottles. Many other studies focused on the chemometric analysis of NMR metabolite fingerprinting data of wine to investigate provenance, vintage, aging, or grape cultivar. NMR spectroscopy has been employed to analyze other food matrices to assess authenticity, quality, and geographic origin, to detect adulteration, and to assess safety, among them being beer, fruit juice, balsamic and traditional balsamic vinegar of Modena, tea, dairy products, meat, fish, cereals, vegetables, tomato paste, honey, and coffee (Figures 1 and 2). The role of HR NMR in liquid state applied to food chemistry is growing progressively during these last years even though, as far as we know, NMR has never been accomplished as an official analytical methodology, with the only exception of olive oil quality determination for Lazio region in Italy, obtained with a regional law in late 2001.

NMRI is mainly applied to investigate texture or fluid motions/distribution in foods. The relatively low spectral resolution attainable from these studies is largely compensated by

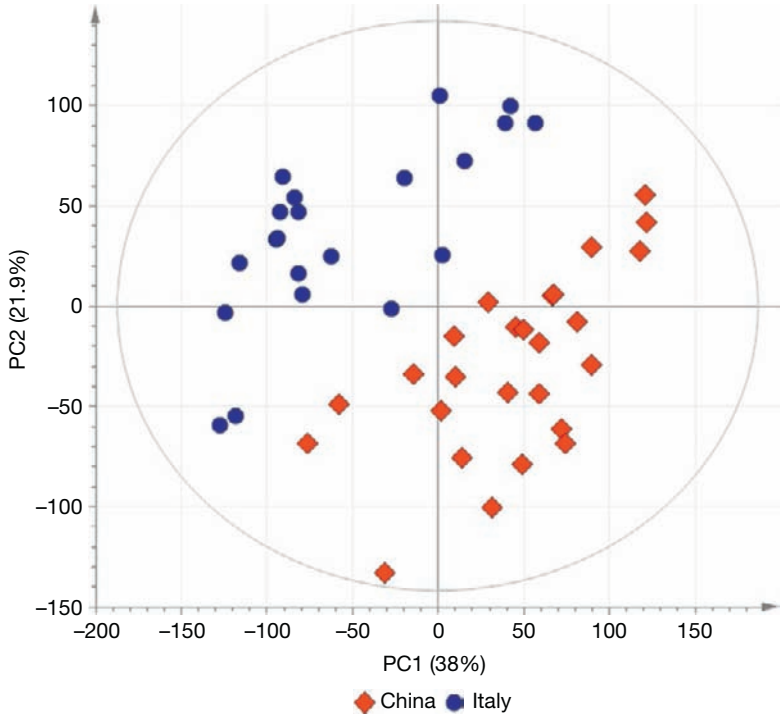

Figure 1 Geographic discrimination between 21 Italian (blue dots) and 26 Chinese (red diamonds) triple-concentrated tomato paste samples by performing PCA analysis on ^{1}H NMR data. Reproduced from Consonni, R. and Cagliani, L. R. (2010). Nuclear Magnetic Resonance and chemometrics to assess geographical origin and quality of traditional food products. *Advances in Food & Nutrition Research* **59**, 87–165.

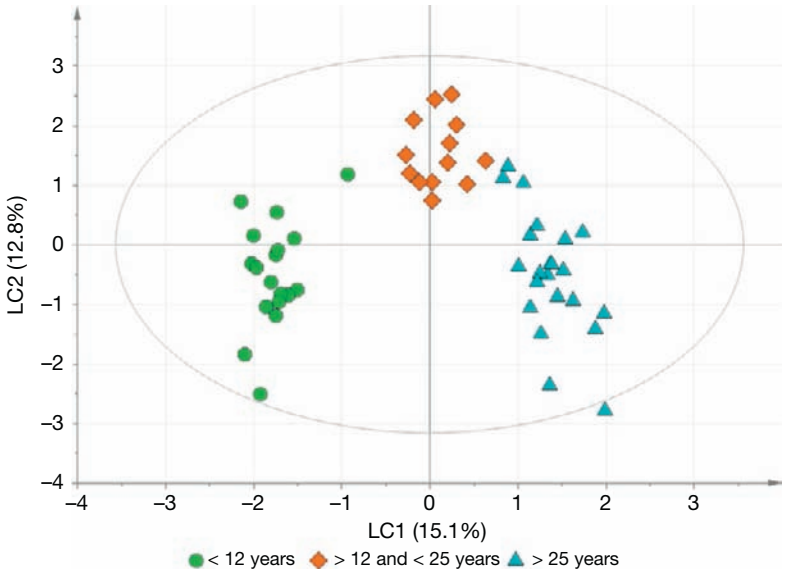

Figure 2 Score plot of hierarchical PLS-DA analysis performed on ^{1}H NMR data of 53 balsamic and traditional balsamic vinegar of Modena: 18 balsamic (green dots), 13 traditional <12 and >25 years (orange diamonds) and 22 traditional >25 years (blue triangles).

3-D images acquired on the basis of relaxation parameters or chemical shift selective values. Water/oil distribution investigations can be easily performed by NMRI, thus allowing maturation studies as well as microstructural studies and compounds/water distribution in intact foods. In the last years, solid-state NMR became a routine spectroscopy in food science, overcoming several technical aspects present in the early stage of this spectroscopy, going through magic angle spinning (MAS), ^{13}C cross polarization (CP-MAS), and ^{1}H high-resolution magic angle spinning (HR-MAS). This NMR spectroscopy was formerly applied to synthetic polymers, in the solid state, to approach crystalline organization. Flour and polysaccharides polymorphisms were first investigated in food analysis, but then, other solid foods were investigated as well.

The last mention is for SNIF-NMR, a relatively old technique, firstly introduced by Prof. G.J. Marten at the University of Nantes more than 20 years ago (patented in 1981) as the most powerful stable isotope techniques in beverage authentication and now the official method of the International Organization of Vine and Wine (OIV) and AOAC International for detecting sugar addition to fruit juice and the natural origin of vanillin. This technique is based on the detection of nonrandom distribution of deuterium in organic molecules.

Vibrational Spectroscopy

Vibrational spectroscopic techniques, both infrared (IR) absorption and Raman scattering, are based on the vibrational transitions of the molecules contained in a sample. In IR spectroscopy, the energy of these transitions is provided by radiation in the IR regions of the electromagnetic spectrum, between the visible and the microwave wavelengths, with mid-infrared (MIR) and near-infrared (NIR) being among the most useful in food authentication studies, as revealed by a large number of related reports. The MIR region lies between 2500 and 25 000 nm (4000–400 cm^{-1}), while the range of wavelengths for NIR is from 780 to 2500 nm (approx. 12 820 to 4000 cm^{-1}). For a particular vibration to be IR active, it must exhibit a change in dipole moment during the vibration. Different chemical bonds absorb at different wavelengths depending on the atoms connected, the surrounding molecules, and the type of vibration occurring. MIR may be used to study fundamental (i.e., stretching and bending) vibrations and associated rotational–vibrational structure, while the higher-energy NIR can excite overtones or combination bands mainly due to the fundamental bonds involving hydrogen atoms. Even though the spectrum obtained by NIR contains more complex structural information comprising broad, overlapped peaks, it may be a characteristic of a sample and may act as a 'fingerprint.' MIR spectra, apart from the peaks associated with characteristic vibrations of the functional groups, contain also the molecular fingerprint region (1500–500 cm^{-1}) with well-defined bands that could provide spectral features useful to identify a sample. The spectral peaks observed in case of MIR are narrow, often sharper, and better resolved than NIR. Sample presentation may take a variety of forms depending on the physical state of sample, including reflectance, transmittance, transflectance, or fiber optics with respect to NIR. In MIR, sampling techniques include transmission-based methods using transmission cells (e.g., KBr disks and ZnSe windows) and methods in reflectance mode, such as attenuated total reflectance (ATR) and diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS). The introduction of Fourier transform technique in vibrational spectroscopy has increased its use in food analysis, as there is no scan speed limitation compared to the original dispersive instruments. FT-IR is a powerful tool for food authentication due to its capability to obtain information about many constituents simultaneously in a single spectral analysis. The combined use of FT-IR with multivariate analysis has been applied to distinguish extra-virgin olive oils from four different European countries. A similar approach has been used for the discrimination of 250 saffron samples from Greece ($n = 40$), Iran ($n = 87$),

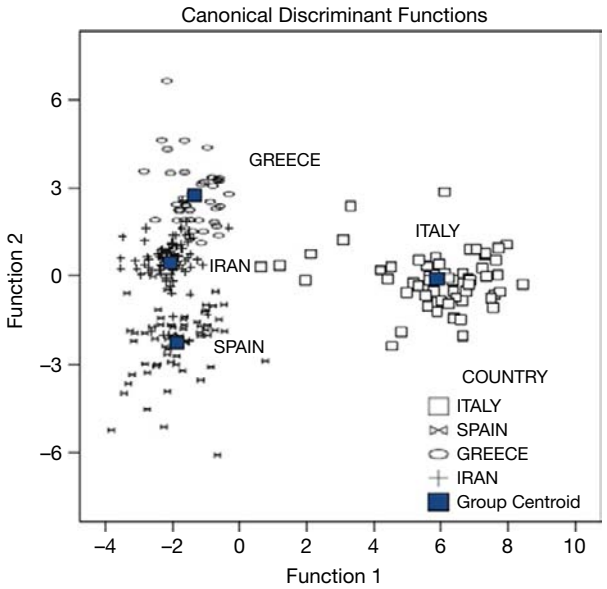

Figure 3 Plot obtained by stepwise canonical discriminant analysis of 250 saffron samples from four different countries, that is, Greece, Iran, Italy, and Spain, based on FT-IR analysis of their volatile extracts. Reproduced with permission from Anastasaki et al. (2010). *European Food Research and Technology* **230**, 71–577.

Italy ($n = 60$), and Spain ($n = 63$). The mid-IR spectra of saffron filament samples and their nonpolar volatile extracts were collected and 93.6% of the samples were correctly classified. Overall, the correct classification rates for samples from Greece, Iran, Italy, and Spain were 90.0, 89.5, 96.7, and 98.4%, respectively (Figure 3).

NIR has allowed the identification of maturity, origin, and variety of white wine grapes. Two varieties, Chardonnay and Viura, were tested and 97.2% of grapes were correctly classified according to their variety, while the correct classification of Chardonnay grapes according to their origin was 79.2%. The application of NIR spectroscopy in combination with Vis spectroscopy and chemometrics has been investigated for the geographic classification of wine. Different multivariate methods were used to classify Australian and Spanish Tempranillo red wines according to their geographic origin, and the best models reported correctly classified 100 and 84.7% of the Australian and Spanish wine samples, respectively.

As regards Raman spectroscopy, the samples are excited with a source of monochromatic radiation that may be in the visible (Vis) or NIR regions of the electromagnetic spectrum. While IR spectroscopy detects vibrations during which the electrical dipole moment changes, Raman spectroscopy is based on the detection of vibrations during which the polarizability changes. Bonds that connect two similar parts of a molecule (e.g., C=C group) tend to be more active in Raman than in IR spectroscopy, as the symmetrical stretches are more intense in Raman spectra. On the other hand, groups such as C=O, N–H, and O–H, with strong mid-IR absorption bands, present very weak vibrations in Raman spectroscopy, since the bonds are only weakly polarizable. Thus, water is practically 'invisible' in the Raman spectroscopy, which is quite useful for

water-based foods. However, dispersive Raman spectroscopy suffers from interference by fluorescence. The use of NIR laser sources can prove beneficial, while FT-Raman instrumentation with an excitation source at 1064 nm results in significantly lower fluorescence and photochemical degradation of samples. Complementary information on fundamental vibrational modes can be obtained from Raman and MIR spectra, since some vibrations are detected primarily by MIR and others primarily by Raman scattering. Raman spectroscopy is becoming increasingly important in food analysis. Significant work has been undertaken to evaluate authenticity and possible adulteration of olive oil. FT-Raman spectroscopy coupled with multivariate calibration has been applied for determining adulteration of Greek extra-virgin olive oils (EVOOs) with sunflower oil at levels lower than 5% by weight. By employing Raman spectroscopy and PCA, pure EVOOs can be distinguished from EVOOs adulterated with hazelnut oil. In addition, the combination of Raman spectroscopy with chemometrics has been evaluated for authenticating the PDO labels of six French virgin olive oils (VOOs) and for determining the fatty acid and triacylglycerol (TAGs) compositions of VOOs. According to the classification model built, 92.3% of French PDOs and 100% of PDO samples made with only one principal cultivar were correctly classified. Raman spectroscopy has been similarly investigated to confirm botanical and geographic origin of European honey, indicating that the major differences among the honey samples were mainly due to their botanical origin. Among the more advanced Raman techniques, surface-enhanced Raman scattering (SERS) and surface-enhanced resonance Raman scattering (SERRS) present many advantages for the development of selective and sensitive analytical procedures. SERS is a very sensitive technique, employing roughened metal substrates (e.g., gold and silver nanoparticles or surfaces) to largely enhance the Raman scattering signal (typically 10^{3-6} over conventional Raman scattering). Another advantage is that fluorescence is quenched from adsorbed molecules, and also, positive identification of an analyte or an analyte mixture may be provided with high selectivity. As a key example, SERS combined with multivariate statistical approaches has been used for the reliable quantification of the banned food dye Sudan I in chili powder over the range of 10^{-3} to 10^{-4} mol l^{-1}. Other modern techniques include transmission Raman spectroscopy (TRS), confocal Raman microscopy, and Raman sensing using fiber optics. Both Raman and IR spectral profiles are currently used for hyperspectral (HIS) or multispectral imaging (MSI). IR and Raman are also emerging techniques in 2-D correlation spectroscopic approach, which employs MIR, NIR, and Raman spectroscopic probes.

During the last two decades, the number of reports on the use of NIR, Raman, and mainly MIR spectroscopy for food authenticity issues (i.e., adulteration, geographic origin, production process, and traceability) has increased significantly. The range of applications includes various foods and beverages such as cereal and cereal products, coffee, dairy products, edible oils and fats, fish, fruits and vegetables, fruit juices, honey, meat and meat products, spices, and wine. By integrating vibrational spectroscopy with multivariate data analysis (chemometrics) strategies, potential analytical tools are developed for industries and regulatory agencies. Such methods are time-saving and nondestructive, require minimal or no sample pretreatment, and enable the cost-effective characterization of samples during the development, processing, quality control, and inspection of foodstuffs. Handheld, portable FT-IR and Raman instruments are also becoming more widely available to bring the benefits of these techniques out of the laboratory. Vibrational spectroscopy may not eliminate the need for more sophisticated analyses, but compared to classical reference methods that typically rely on 'wet chemistry,' it can provide greener analytical methods for screening samples prior to further examination.

Separation Techniques

Among the separation techniques, liquid chromatography, gas chromatography, and capillary electrophoresis make feasible separation and identification of almost any kind of compounds present in a food sample, thanks to continuous advances in both separation and detection capabilities. Their wide applicability in quality control laboratories due to such an efficiency and the affordable capital cost made them candidates to examine food conformity with their label, namely, the origin (geographic and varietal species) and/or the production practice (organic vs conventional). Groups of compounds (targeted analysis), or even the whole spectra/electropherogram serving as a 'fingerprint' containing the maximum information (nontargeted analysis), are examined usually with pattern recognition methods (supervised or unsupervised) to identify possible marker(s) for food authenticity. Nonetheless, the validity of the findings depends on the experimental design of sampling (number, number of harvests, sampling areas, etc.).

The geographic origin and the cultivar employed for virgin olive oil production are often related to its health benefits and the particular sensory properties. Thus, finding markers that could address these two issues became of high importance to protect both the producers and the consumers. This is highlighted by the fact that even for products officially registered as, for example, protected designation of origin (PDO), the availability of a certain analytical method to verify the claim in the label is not necessarily available. The profile of triacylglycerols (TAGs) and that of fatty acids (FA) have been used since many decades for geographic origin discrimination between countries or regions within the same country. Characteristic example is the discrimination of 10 main producing areas in Greece based on the FA content of 1293 samples belonging to 24 harvests after treatment with nonlinear discriminant analysis. The data from both profiles have been even combined to increase classification efficiency. The composition of FA and TAGs is genetically determined; however, pedoclimatic conditions and agronomical practices may have a certain influence justifying their usefulness. Sterols, hydrocarbons, aliphatic alcohols, and sesquiterpenes have also been used, and lately, polar phenolics have also been proposed. All these markers can be detected by GC and HPLC techniques following in most cases official protocols but coupling data to chemometric treatment (Figure 4).

Olive oils produced in different countries are usually facile to be distinguished even based solely on FAs. Focusing on studies regarding PDOs in the same country, the findings are rather controversial. Sesquiterpenes, namely, α-muurolene and α-farnesene contents except for discriminating Apulian from foreign oils, were found suitable to differentiate subbrands of Terra di Bari PDO oils produced in the neighboring areas of the

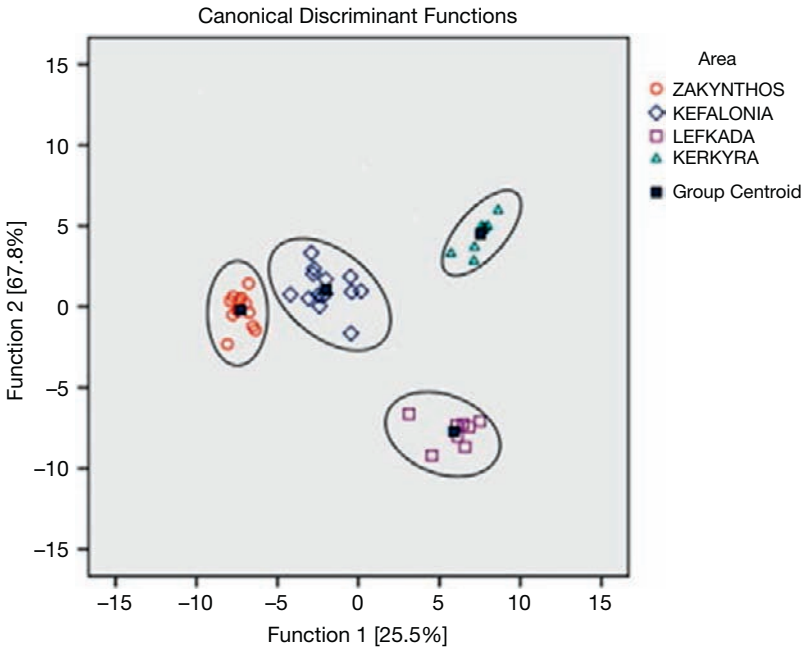

Figure 4 Classification of olive oil samples from western Greece according to geographic origin using selected volatile compositional data. Reproduced with permission from Poularekou et al. (2011). *Journal of Chromatography A* **1218**, 7534–7542.

Apulian region. However, such a finding derived from the analyses of 21 samples and data was considered preliminary. In a study with a larger amount of samples (914 samples and three production seasons), the discrimination of the Ligurian PDOs ($n = 210$) from oils of other regions in Italy as well as from other countries ($n = 704$) based on volatile profile obtained with solid-phase microextraction/GC-ion trap MS resulted in properly recognized and predicted with 90.1% and 81.1%, respectively. These findings were achieved using artificial neural network as a tool. Other studies point out that discrimination may be a difficult task and overlapping can take place in cases where PDOs are produced in close geographic regions and derive from the same cultivar or from a mixture of cultivars presenting compositional similarities (coupage). For example, studies carried out over a 6-year harvest period for five French PDOs showed that Aix-en-Provence and Vallée des Baux derived via blending of same cultivars even at different portions could not be clearly distinguished with the combined information of TAGs and FAs. Such a difficulty was also stressed regarding the analysis of Spanish PDOs for two consecutive harvest years. The oils produced in the various provinces of Andalusia presented overlapping even if 64 compounds obtained by GC and HPLC (fatty acids, sterols, alcohols, and hydrocarbons) were treated with LDA. In the same study, however, the importance of sophisticated statistical approach combined with a multidisciplinary strategy was demonstrated. Thus, employing artificial neural network improved significantly the classification (>90%). Even so, the findings for PDOs presented the highest error of prediction in comparison to those related to sample discrimination from other countries, regions, and provinces.

Similarly, regarding the botanical origin (cultivar), a single marker is also difficult to be proposed due to the complexity of the oil matrix and the variety of factors affecting its composition. The markers with discrimination power are rather comparable to those used for the geographic origin and consequently determined with the same separation methods. It has been stressed however that though FAs and TAGs provide basic information for the cultivars, minor components such as sitosterol and avenasterol, tyrosol and hydroxyltyrosol, (E)-hex-2-enal, lutein, and β-carotene can be more informative for the botanical origin differentiation.

Consistent markers capable of differentiating oils on the basis of cultivation practice are not yet available. However, due to the growing interest in organic olive oil by the consumers, further studies are under way.

Concerning wine authenticity studies, phenolic compounds, biogenic amines, and volatiles have been proposed as useful markers, and within phenolic compounds, both flavonoids and nonflavonoids have been identified. Significant is the contribution of anthocyanin as markers to differentiate European from South American wines. These compounds are determined with LC. Usually, studies regard different countries; nevertheless, there are some concerning different zones. For example, using the content of 13 phenolic compounds and chemometrics, the discrimination of wines from three different Spanish appellations, namely, Penedes, Rioja, and Ribera del Duero, was feasible with a classification rate higher than 96%. As evidenced, characteristic markers were, for example, gallic acid for Penedes, *trans*-coumaroyl tartaric and *trans*-caffeoyl tartaric acids for Rioja, and the flavonol myricetin for Ribera del Duero wine samples. The multivariate curve resolution (MCR) technique allows the resolution of the chromatographic peaks obtained assisting more accurate quantification of phenolics and increasing the information via revealing the presence of coeluting peaks. The application of sub-2 μ particle columns that allows the separation of several isomers seems to be important. With the latter material and LC–MS/MS analysis of phenolic compounds, several wines

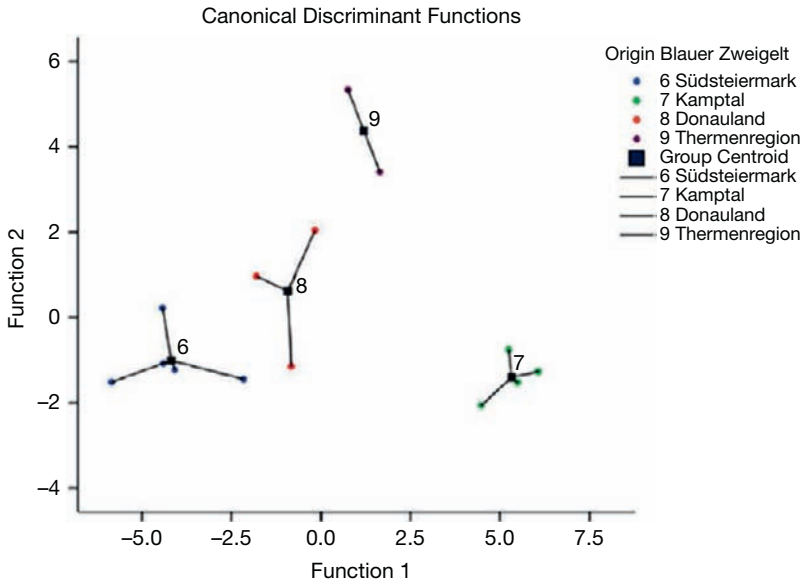

Figure 5 Geographic origin-based discriminant analysis of the grape variety Blauer Zweigelt originating from the region Südsteiermark, Kamptal, Donauland, and Thermenregion (Austria) based on LC–MS/MS phenol analysis. Reproduced with permission from Jaitz et al. (2010). *Food Chemistry* **122**, 366–372.

from 11 Austrian regions could be classified employing multivariate statistics (Figure 5).

Nonetheless, there are also various studies where phenolic compounds are combined with other compositional data (ethanol, calcium, etc.) within the frame of multistrategic approaches for efficient classifications as exemplified for a series of rose Spanish PDO wines, namely, Ribera del Duero, Rioja, Valdepeñas, and La Mancha. The combination with data regarding the levels of biogenic amines made feasible differentiation of wines from different regions of Italy such as Basilicata (cis-resveratrol, total polyphenols, spermidine, and tryptamine), Calabria and Campania (agmatine and trans-resveratrol), and Puglia (cadaverine, ethanolamine, histamine, putrescine, and tyramine) regions. Wine volatiles have been shown adequate for the geographic origin of monovarietal wines from the Azores, Canary Islands, and Madeira islands. The volatile pattern was obtained with solid-phase extraction/GC–MS and treated with chemometrics.

Similar markers have been proposed for the discrimination of grape wine varieties, though among the most recommended are the volatiles. A useful approach to discriminate wines from white grape varieties is based on the determination of shikimate content and the protein profile analysis, whereas for red wines, the shikimate content combined with anthocyanin profile. Shikimate can be determined with the combination of C18 and a cation exchange column according to the method suggested by the International Organization of Vine and Wine, whereas proteins and anthocyanins with CE and high-performance reverse-phase chromatography, respectively.

Information about possible discrimination between organic and conventional wines is rather scarce. Biogenic amines have been reported to be lower in organic wines, whereas phenolic compounds and other compositional parameters were not able to make a clear discrimination despite some quantitative differences. Further studies are on the way to obtain more consistent results.

DNA-Based Technology

A growing consciousness of the food composition led to an increased DNA-based investigations for food authentication also due to the bovine spongiform encephalopathy (BSE) crisis. The incorrect labeling of foods could represent a commercial fraud, and moreover, the nondeclared potential allergens content could cause health problems for consumers. The majority of works was focused on DNA analysis employing polymerase chain reaction (PCR) to amplify specific areas of DNA that could be analyzed with different methods such as the commonly spread electrophoresis techniques.

The application of PCR in authentication of food involves mostly analysis of meat-based foods, fish, and seafood products, which are highly priced foodstuff often susceptible to adulteration. Several studies concerned the detection of different kinds of not declared meat in foods; a species-specific PCR assay targeting mitochondrial D-loop region for the identification of pork in raw, heat-treated samples and in adulterated ones up to 0.1% has been developed. Furthermore, by PCR amplification of the COI gene and detection of species-specific sequences by hybridization, a multidetection test for the identification of different meat species like pork, beef, lamb, horse, cat, dog, and mouse has been achieved resulting in a suitable method for routine inspections. The identification of fish species is usually based on morphological analysis, but this approach resulted however very difficult and not suited to investigate fishes available in the market. As a matter of fact, fishes are often sold in pieces or have been subjected to processes altering the natural aspect. In this context, several DNA-based methods, mainly based on the amplification of

mitochondrial DNA, have been developed, allowing the detection and even the differentiation of closely related fish species. PCR-RFLP technique followed by polyacrylamide gel electrophoresis (PAGE) was proposed for the identification and the discrimination of ten salmon species based on the amplification of a region of the cytochrome *b* mitochondrial gene. Furthermore, the differentiation of closely related species of flatfish such as the sole and Greenland halibut was achieved by species-specific PCR targeting a nuclear gene and by PCR-RFLP of a mitochondrial gene. Moreover, DNA-based methods have been applied for authenticity assessment of dairy products as well, allowing the identification of milks from different biological sources such as the identification of bovine milk in buffalo dairy products. This was achieved by using a high-resolution melting (HRM) as post-PCR method allowing the detection and the quantification of bovine milk in buffalo mozzarella, butter, cream, yogurt, and other buffalo products. The same approach, resulting in a very cost-efficient high-throughput method, has been employed successfully to check the authenticity of Leguminosae species, grapevine cultivars, and PDO sweet cherry cultivar (Tragana Edessis) and to differentiate *Citrus* species and hybrids and bilberry from other berry species. DNA-based methods are also used to detect genetically modified organisms (GMOs) or food allergens; for example, rice, maize, and soybean were investigated and the presence of potential food allergens in, for example, almond and hazelnut was searched in foods. In this context, a tetraplex real-time PCR method was used very recently to quantify simultaneously traces of four allergens such as soy bean, celery, and white and brown mustard in commercially available foods. This latter approach resulted in a powerful method for routine analysis being time-saving with respect to singleplex real-time PCR systems. Finally, DNA analysis is furthermore employed for detecting gluten, normally evaluated with protein analysis, in declared 'gluten free' foods, resulting in most of the cases comparable to ELISA test. In conclusion, the latest results obtained with the most adopted analytical techniques have been presented, highlighting their great potentiality in food authenticity issues. These studies pave the way for possible future investigations aimed to increase the knowledge in food science.

Avocado Fruit Production

History, Cultivation, and Fruit Growth

Avocado originated in Central America, and the fruit has been consumed as part of the diet by the indigenous peoples of that region for more than 5000 years. The word 'avocado' derives from a corruption of the Spanish words 'ahuacate' or 'aguacate,' which are adaptations of the Aztec 'ahuacatl.' The fruit of the first vegetatively propagated cultivar 'Fuerte' is pear-shaped, and this characteristic probably resulted in the inappropriate colloquialism, 'avocado pear.' However, the horticulturally and agriculturally correct term for the fruit is simply avocado.

The botanical name for avocado is *Persea americana* Mill., and three ecological or horticultural races (in some of the literature erroneously referred to as botanical varieties or subspecies) are recognized. The Mexican race has been referred to as *Persea americana* var. *drymifolia*, the Guatemalan race as *Persea americana* var. *guatemalensis*, and the West Indian race as *Persea americana* var. *americana*. However, some researchers have concluded that the validity of these 'botanical varieties' is questionable and requires further study. We suggest the use of ecotype, or horticultural race, which is embedded in the avocado literature. Fruits of the tropical lowland West Indian ecotype are usually large with a thick peel and have a low flesh oil content (<8%) and higher water and sugar content. Trees of the Mexican ecotype yield fruits with high oil content (up to 30%). Those of the Guatemalan ecotype are recognized as having the most horticulturally desirable traits, have intermediate oil content, and are characterized by a 'nutty' flavor. Among the most important commercial cultivars of the 'subtropical' avocado are 'Hass', 'Fuerte', 'Ettinger', and 'Pinkerton', which were all selected from chance seedlings with superior fruit quality. Several countries have extensive selection and breeding programs, which are starting to produce fruit of improved quality. 'Hass' is overwhelmingly the most sought-after subtropical cultivar, having eclipsed 'Fuerte' in Europe and the United States, and forms the basis of the subtropical avocado export industry to Europe and the United States. Several new selections of 'Hass'-like cultivars with improved quality have recently been commercialized.

Resequencing studies to resolve avocado genetic diversity using wild accessions from Mesoamerica and Central America have shown that although avocado is a subtropical tree crop and a predominantly outcrossing plant, genetic variation is very low in comparison with temperate species and much lower than in annuals. The Mexican and Guatemalan ecotypes, whose progeny today form the basis of the technologically advanced 'subtropical' avocado industries, are indigenous to subtropical and tropical highland climates. The so-called 'West Indian' avocados are lowland tropical in origin. Mexico (by far the largest producer), California, Israel, Spain, Chile, South Africa, Peru, Columbia, and Australasia *inter alia* all have industries based on Guatemalan and Guatemalan × Mexican hybrid cultivars. However, virtually all subtropical countries grow avocados to some extent. Large crops of 'West Indian' and 'West Indian' × Guatemalan hybrid avocados are also produced in tropical countries, from less technologically advanced industries. Tropical avocado industries, with the conspicuous exception of Florida, the United States, are usually based on seedling (not grafted) trees. The fruits, although making a substantial contribution to the diets of mostly poor, tropical lowland peoples, are horticulturally and nutritionally inferior to the selected subtropical cultivars.

The avocado tree is evergreen and flowers in early spring, and fruitlets are usually visible by late spring/early summer. Typically, careful and correct orchard management practice is required to ensure the production of quality fruit. Among the most important ecophysiological factors that affect fruit production are irradiance, temperature, water stress, and salinity. Botanically, the fruit of the avocado is described as a berry. Fruit growth continues for anything from 20 to 60 weeks or more, depending on the cultivar, environment, and cultural practice. The fruit is harvested when horticulturally mature as it does not ripen on the tree. Harvested fruit are washed, graded, occasionally waxed, and packed in cartons typically holding 4–6 kg of uniform fruit. European markets prefer the individual fruit weight to be in the range of 200–350 g, for which higher prices are usually paid. It is now known that the final fruit size of avocado is the result of the number of cell divisions during fruit set and fruit growth. Cell division is dependent on *inter alia* isoprenoid biosynthesis, carbohydrate metabolism, maintenance of plant hormone homeostasis, and mineral nutrition. Nitrogen is used as a 'manipulator element' to control tree vigor and must be managed appropriately as excessive tree vigor is counterproductive to yield and good fruit quality. The production of quality fruit in high summer rainfall areas typically requires the application of zinc, boron, potassium, and calcium, the latter from liming. Indeed, quality is associated with relatively high calcium and low nitrogen in the fruit flesh.

Today, there is an increasing global concern about the potential negative effects of commercial agriculture-derived greenhouse gas (GHG) emissions and, in particular, those from intensive production systems like avocado. The energy balances and GHG emissions from the production of export avocados in Mexico (the largest producer and supplier) show no significant difference between 'organic' production and conventional production. Energy consumption and GHG emissions of these two cultivation methods have been quantified at 55 and 56 GJ ha^{-1} and 3.30 and 3.57 ton CO_2 equiv ha^{-1}, respectively. Organic production systems consume three times more renewable energy than conventional production, and dependence on fossil fuel inputs, machinery, and synthetic/organic N-fertilizers negates any difference. Even

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00049-0

so, experience has shown that it is extremely difficult to control the devastating *Phytophthora cinnamomi* root rot pathogen in 'organic' orchards, where tree injections or foliar sprays of phosphonate chemicals are prohibited.

Fruit Maturity and Ripening

Oil content and/or dry matter of the fleshy pulp, comprising the mesocarp and with a thin layer of endocarp, which surrounds the single large seed, is used by most producers to determine harvestable maturity and consumer acceptability. For the cultivar 'Fuerte', a minimum oil content of 8% (dry mass) was applied in California for many years, but today, this has been replaced by a minimum dry matter standard of ~21%, depending on the cultivar and region. This is based on the percentage moisture (determined using a microwave oven), which is an indirect measure of oil content based on the cultivar-specific constant of the sum of percentage moisture and percentage oil. By 1983, percentage flesh dry matter (or its reciprocal, percentage moisture) had become standard for the determination of avocado fruit maturity and is now used worldwide. Persistence of a living seed coat (not a testa) until horticultural maturity and full fruit size, and then seed coat drying and browning, is an additional maturity criterion. Mature fruits do not shrivel postharvest and will have acceptable eating quality.

Avocado fruits are classified as climacteric (i.e., fruits that can be harvested mature, but hard and unripe, and then undergo normal softening and ripening). An increase in ethylene biosynthesis is typical of climacteric fruits. Maximum ethylene production usually coincides with maximum respiration rate (amount of carbon dioxide released). Cold storage delays and reduces this climacteric rise in respiration.

Although detachment of the fruit is not a prerequisite for ripening of most climacteric fruit, avocado fruits do not ripen while firmly attached to the tree. Postharvest, avocado fruits typically ripen within 5–20 days at temperatures between 15 and 24 °C. However, 'Hass' displays large heterogeneity and is unpredictable in the time taken to reach edible ripeness. Detailed analysis of ripening of 'Hass' fruit has revealed five distinct clusters based on ripening speed, viz., fastest ripening, ~9 days; cluster-2, ~13 days; cluster-3, ~17 days; cluster-4 ~20 days; and slowest ripening, >22 days. Whether a similar ripening pattern exists for other commercial avocado cultivars is currently unknown.

Ripening and fruit softening are both delayed by precooling of the fruit immediately after harvest to 5–6 °C. This strategy is used by most producers to maintain fruit quality during transport/export. A return to ambient temperature after a period of cold storage sees the acceleration of the ripening process. Ripening in avocado can also be stimulated by postharvest exposure to the plant hormone, ethylene, and inhibited by ethylene antagonists such as 1-methylcyclopropene (1-MCP).

During ripening, the fruit undergoes marked changes in a variety of biochemical processes. These include an increase in respiration (i.e., consumption of oxygen and release of carbon dioxide), an increase in ethylene production, changes in texture (i.e., fruit softening), and the production of volatiles such as β-caryophyllene (28% of total volatiles), α-copaene (11%), α,β-cubebene (8%), α-farnesene (6%), decanal (6%), and heptanal (3%), which impart flavor.

The substrate for respiration in avocado fruit appears to be carbohydrate and not oil. However, some degradation of oils does take place. Indeed, metabolomic profiling has revealed that accumulation of linoleic acid (C 18:0) occurs more slowly and to reduced levels in slowest ripening fruit.

Sugar import into developing fruit is accompanied by a transition from symplastic (i.e., cell-to-cell) to apoplastic (i.e., across the cell wall/plasma membrane) transport. The early symplastic route in developing fruit leads to the accumulation of starch, whereas the later apoplastic route in more mature fruit supports the accumulation of soluble sugars. In 'Hass' avocado trees, D-*manno*-heptulose, a seven-carbon sugar, and perseitol, a seven-carbon-containing polyol, are the dominant soluble carbohydrates. By monitoring changes in fruit flesh, sugar content, and composition over the course of development until harvestable maturity, the fate of tree-derived sugars could be deduced. Fructose is at high concentration in young fruits and declines from 22% to about 4% of the total soluble sugars at harvestable maturity. Similarly, glucose declines from about 19% to <1% of total soluble sugars. The concentration of perseitol remains fairly constant throughout the avocado fruit growth at about 25%, whereas D-*manno*-heptulose increases from 15% in immature fruit flesh to 53% of the total soluble sugars in fruit near harvestable maturity. Interestingly, D-*manno*-heptulose is abundant in early season 'Hass' fruit flesh but almost absent in late season fruit. After harvest and during ripening, sucrose, glucose, fructose, and D-*manno*-heptulose contents decline as these sugars are consumed during the respiratory climacteric. The inhibition of ripening with 1-MCP and the relatively new palladium-promoted ethylene scavenger (e+™ Ethylene Remover) result in sustained levels of D-*manno*-heptulose and perseitol. So, the inhibition of ethylene action and removal of ethylene affect avocado fruit ripening similarly.

In addition to changes in sugar metabolism, the respiratory climacteric occurs coincident with upregulation of gene expression including polygalacturonase (*PamPG*), putative NAD^+-dependent sorbitol dehydrogenase (*PamSD*), three acyl-CoA synthetases (*PamACoAS1*, *2*, *3*), and accumulation of triglycerides.

Fruit softening is a consequence of changes in cell wall metabolism resulting from alterations in cellulase (EC 3.2.1.4), polygalacturonase (EC 3.2.1.15), pectinesterase (EC 3.1.1.11), and β-galactosidase (EC 3.2.1.23) activities. In some cultivars (e.g., 'Hass'), peel color changes from green to purple/black owing to the accumulation of anthocyanin (e.g., cyanidin 3-*O*-glucoside) pigments. Other changes include a slight increase in the concentration of glucose and fructose in the fruit flesh.

Processing of Avocado

Avocado is usually consumed fresh in salads, as a savory dish, as a sandwich filling, as guacamole, or as a dessert when sweetened. It was the extraction of oils from avocado pulp and the production of guacamole that really started avocado processing. Apparently, the production of guacamole on a commercial scale was started as long ago as 1964 in California,

and by 1981, 6000 tons of fresh avocado was being processed annually. Guacamole is a highly regarded component of Mexican cuisine.

For processing, the preferred cultivar is 'Hass' because of its superior flavor, flesh (pulp) color, 'keeping' quality, and year-round availability. Fruits with a 25% dry matter content (or 13% oil) are considered ideal for processing. Avocado flesh is also marketed frozen, processed into a sauce, dehydrated to a powder, and extracted for its oil.

Guacamole, Avocado Sauce, and Oil

Before processing can take place, fruits are uniformly ripened at 22 °C in the presence of ethylene gas for 2–5 days. When the fruits are soft, they are cooled to 5 °C and surface-sterilized in 200 mg of hypochlorite per liter. After removal of the fruit stalks (pedicels) and seed, the pulp (mainly mesocarp) is mechanically separated from the peel. The pulp is then mixed with the ingredients (usually includes lime or lemon juice, salt, and salsa or picante) to yield a uniform textured guacamole. The guacamole is then placed in containers and stored frozen.

The process for the production of avocado sauce is similar to that used for the preparation of guacamole up to and including pulp separation. For sauce, the pulp is sheared in a high-speed blender with water, emulsifiers, and spices. Sauces are usually packaged in polyethylene containers and then stored frozen.

Dehydration of avocado is by either spray or drum drying in much the same way as for the preparation of milk powder, but the product is less attractive than that of sugar-storing fruits.

Oil is extracted from avocado with organic solvents, hydraulically (pressing), or by centrifugation. The last method is more desirable as the product is free from solvent residue. Nevertheless, solvent extraction allows for the recovery of various fractions, some of which are used in the pharmaceutical industry. For example, avocado unsaponifiables (including hydrocarbons, tocopherols, triterpenes, sterols, and other unidentified compounds) seem to be beneficial in the treatment of periodontal and osteoarticular diseases. They function by stimulating the deposition of repair material in affected areas by enhancing transforming growth factor beta (TGF-β) in articular cartilage. Avocado oil is also used in cosmetic preparations such as skin moisturizers and body lotions. It has cooking properties very similar to olive oil but is more expensive.

Nutritional Status

The Spanish word 'aguacate' (literally 'testicle tree') refers to the widely held belief among native Central Americans in the aphrodisiac properties of avocado fruits. Early exporters developing the European market cunningly exploited this belief to gain acceptance for the then little-known avocado fruit with an 'acquired taste.' Nowadays, avocado is known to be a highly nutritious fruit and contains higher quantities of soluble and insoluble fiber and protein than many other fleshy fruits. Avocado is also a rich source of potassium and the vitamins E and C and β-carotene (provitamin A). Although low, a vitamin A value of 150 mg RE (retinol equivalents) per kilogram has been reported. Furthermore, the monounsaturated fatty acids in avocado effectively reduce blood levels of the undesirable low-density lipoprotein (LDL) cholesterol while increasing the levels of the beneficial high-density lipoprotein (HDL).

Nutrient Composition/Density

Unlike starch staple foods that are described as providing 'empty calories,' the avocado is a nutrition-rich 'protective' fruit. The energy content per 100 g serving has been estimated at 800 kJ, depending on the cultivar and growing conditions. A detailed analysis of the composition of avocado pulp, mainly mesocarp (the edible portion of the fruit) of a typical subtropical cultivar, has revealed a nutritional status summarized in Figure 1.

Avocado pulp contains approximately 2.3% protein on a fresh-weight basis, which is between two and ten times that of most other fleshy fruits and vegetables analyzed. Although avocado contains all of the essential amino acids (i.e., it is 'complete'), it is not generally regarded as nutrient-dense for protein, certainly not in comparison to meat or eggs, for example. A mixture of soluble and insoluble fiber is ideal in the diet, and avocado contains appreciable quantities of both (2.1% and 2.7%, respectively).

In avocado flesh, the sum of percentage water plus percentage oil is constant in the range 88–91%, and for each gram of water lost, there is a 1 g increase in oil, in fruit containing between 8% and 22% oil. Changes in oil content are also associated with changes in fiber and protein. Therefore, the energy value of avocado is almost entirely due to its oil content, and any variation is due solely to changes in the percentage oil. It is probably this observation that led to the mistaken idea that consuming avocado increases body mass. On the contrary, the addition of avocado to the diet has been shown to cause a small but significant average weight loss. One possible explanation is that avocado speeds up the basal metabolic rate in humans. Another hypothesis relates to the type of oil, and avocado is rich in the beneficial monounsaturated fatty acids.

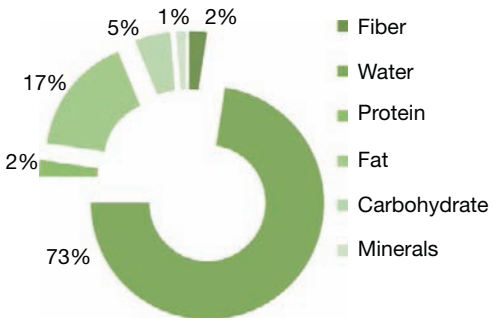

Figure 1 Nutrient content and composition of subtropical avocado fruit flesh. Data are the average between the minimum and maximum values reported by Ahmed, E. M. and Barmore, C. D. (1980). Avocado. In: Nagy, S. and Shaw, P. E. (eds.) *Tropical and subtropical fruits: composition, properties and uses*, pp. 121–156. Westport, CT: AVI; Seymour, G. B. and Tucker, G. A. (1993). Avocado. In: Seymour, G. B., Taylor, J. E. and Tucker, G. A. (eds.) *Biochemistry of fruit ripening*, pp. 53–81. London: Chapman & Hall; Slater, G. G., Shankman, S., Shepherd, J. S. and Alfin-Slater, R. B. (1975). Seasonal variation in the composition of Californian avocado. *Journal of Agricultural and Food Chemistry* **23**, 468–474, and references cited therein.

The fatty acid content and composition of avocado have been iterated in most texts on the physiology and biochemistry of fruit growth and ripening. Avocado lipids can be divided into the following fractions: (1) neutral lipids (tri-, di-, and monoacylglycerols), (2) phospholipids, (3) glycolipids, and (4) free fatty acids. The neutral lipid fraction constitutes 96% of the total lipid content of avocado, and the majority of these are triacylglycerols. The major triacylglycerols identified in avocado are dioleyl palmitin, triolein, dioleypalmitolein, linoleyl oleyl palmitin, and linoleyl diolein. Within each of these triacylglycerols, C18:1, C18:2, C16:0, and C16:1 are the major fatty acids present. The relative concentration (percentage of total lipid) of each is in the range 59–81% (C18:1), 7–14% (C18:2), 7–22% (C16:0), and 3–11% (C16:1). These values are comparable with those for olive oil and make avocado, which is easily digested, an ideal substitute for olive oil in cooking and in the preparation of salad dressings.

The phospholipid composition of the edible portion of avocado fruit is surprisingly much less documented. Nevertheless, by means of high-performance liquid chromatography–electrospray ionization tandem mass spectrometry, phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylinositol (PI), phosphatidic acid (PA), and *lyso*-phosphatidylcholine (LPC) have been unequivocally characterized. PE and PI contain the less unsaturated C16:0/C18:1 fatty acid moieties while PC and PA show a prevalence of C18:1/C18:1, and in LPC, C18:1 prevails.

Unsaturated fats are either mono- or polyunsaturated, and the ratio of polyunsaturated fatty acids to saturated fatty acids (P/S), which is used as an indicator of nutritional value by nutritionists, is about 0.74 for avocado. A diet high in polyunsaturated fatty acids reduces the level of the undesirable LDL, whereas a high dietary level of monounsaturated fatty acids also maintains the levels of the desirable HDL. Thus, it should not surprise that results from trials in which the monounsaturated-rich avocado was used as a dietary component revealed a significant decline in total cholesterol with preservation of the HDL level. Likewise, substituting avocado for butter, margarine, and cheese significantly reduced blood cholesterol levels and increased HDL up to 16%. Accordingly, avocados have gained acceptance by the Heart Foundations of several countries and can even be prescribed for convalescent heart patients.

Fat- and Water-Soluble Vitamins and Antioxidants

The vitamin content and composition of avocado are shown in Table 1. Although vitamin D has been identified in avocado, no values appear to have been published. It has been reported, however, that the vitamin D content of avocado is higher than that of butter and eggs. Vitamins C and E and provitamin A (β-carotene) are believed to function as antioxidants and protect against damage from oxygen 'free radicals.' Although oxygen is essential to life processes, it is also damaging if converted to reactive oxygen species (e.g., the superoxide anion or the hydroxyl radical). These can cause cell mutation and contribute to aging, cancers, arthritis, and heart disease. The three antioxidant vitamins are effective at disarming these reactive oxygen species, and it has been stated that for each of the three and for any given daily kJ proportion, the avocado provides about twice the proportion of this nutrient.

Table 1 Vitamin content and composition of avocado fruit flesh

Component (per 100 g fresh weight)	*Concentration range*[a]
β-Carotene (provitamin A) (IU)	370–750
α-Tocopherol (vitamin E) (IU)	1.6–2.4
Ascorbic acid (vitamin C) (mg)	1.6–30.0
Biotin (mg)	3.2–10.0
Choline (mg)	17–22
Folacin (mg)	30–62
Niacin (mg)	1.4–3.5
Pantothenic acid (mg)	0.25–1.14
Pyridoxine (vitamin B_6) (mg)	0.22–0.62
Riboflavin (vitamin B_2) (mg)	95–230
Thiamine–HCl (vitamin B_1) (mg)	60–240
Phytyl menaquinone (vitamin K) (mg)	0–8
Calciferols (vitamin D)	Unknown

[a]Concentration is dependent on the cultivar and stage of ripening.

Source: Values were derived from data published by Ahmed, E. M. and Barmore, C. D. (1980). Avocado. In: Nagy, S. and Shaw, P. E. (eds.) *Tropical and subtropical fruits: composition, properties and uses*, pp. 121–156. Westport, CT: AVI; Seymour, G. B. and Tucker, G. A. (1993). Avocado. In: Seymour, G. B., Taylor, J. E. and Tucker, G. A. (eds.) *Biochemistry of fruit ripening*, pp. 53–81. London: Chapman & Hall; Slater, G. G., Shankman, S., Shepherd, J. S. and Alfin-Slater, R. B. (1975). Seasonal variation in the composition of Californian avocado. *Journal of Agricultural and Food Chemistry* **23**, 468–474, and references cited therein

Extracts prepared from 'Hass' fruit pulp, containing carotenoids and vitamin E, inhibit growth of both androgen-dependent and androgen-independent prostate cancer cell lines. A putative mode of action appears to be cell cycle arrest at the G_2/M transition and is accompanied by an increase in the expression of the cyclin-dependent kinase inhibitor protein, p27. In addition to the antioxidant vitamins, 2(*R*)-(12*Z*,15*Z*)-2-hydroxy-4-oxoheneicosa-12,15-dien-1-yl acetate and persenones A and B have been isolated from avocado leaves and fruit pulp, respectively, as inhibitors of superoxide and nitric oxide generation. These compounds do not scavenge reactive oxygen species (like the vitamins) but rather suppress free-radical generation and may therefore be effective chemopreventive agents in inflammation-associated carcinogenesis. Indeed, a 4-pyridinyl derivative of 2(*R*)-(12*Z*,15*Z*)-2-hydroxy-4-oxoheneicosa-12,15-dien-1-yl acetate, a polyketide isolated from the leaves due to growth inhibition of silkworm (*Bombyx mori*) larvae, shows cytostatic and proapoptotic activity in human breast cancer cells. Thus, the consumption of avocado may be one way of ingesting more of the antioxidants that help to protect against cancers, heart disease, and aging. Indeed, antioxidant activity in early harvested fruit after storage for 35 days is much higher than that in late harvested fruit after storage for 21 days. Therefore, avocado can be harvested earlier for economic benefits according to the market and can keep high nutritional value for human health benefits.

Mineral Composition

The mineral content and composition of avocado are presented in Table 2. As shown, avocado is a rich source of potassium, which is purported to protect against the risk of strokes in humans and reduce the incidence of strokes by up to

Table 2 Mineral content and composition of avocado fruit flesh

Mineral (mg per 100 g fresh weight)	*Concentration range*[a]
Potassium	340–723
Magnesium	40–60
Phosphorus	20–80
Calcium	10–15
Sodium	5–15
Iron	0.5–2
Boron	1–3

[a]Concentration is dependent on the soil type, cultivar, and cultural practice.

(Perseitol)

Figure 2 Structural formulas of D-*manno*-heptulose and its related acyclic heptitol, perseitol.

40%. One of the confounding factors in the cause of strokes is increased blood pressure, which has been associated with a high intake of sodium. The avocado is as low in sodium as it is high in potassium.

Phosphorus, calcium, and magnesium are abundant minerals in avocado. Most other minerals, including iron, occur in amounts of less than 1 mg per gram fresh weight of edible fruit.

Carbohydrates

During avocado fruit ripening, there is an increase in the flesh (pulp) concentration of glucose and fructose. In addition to these monosaccharides, avocado also contains several unusual sugars including the seven-carbon sugar alcohol, perseitol, and its reduced form, D-*manno*-heptulose. The structures of these are shown in Figure 2. 'Hass' avocado fruit pulp sugar content and composition is given in Table 3.

Studies in the 1940s indicated that ingestion of avocado could lead to the presence of sugar in urine. It was later discovered that D-*manno*-heptulose, the major reducing sugar in avocado, could induce hyperglycemia when administered to humans and other animals orally. Even so, there is no unequivocal information linking the consumption of avocado with diabetic symptomatology. In fact, the D-*manno*-heptulose content of the edible portion of avocado declines by up to 80% as the fruit ripens. Thus, any amounts of D-*manno*-heptulose ingested are likely to be very low, and some cultivars appear to have none in harvested fruit. However, toxicity to avocado fruit reported for some birds and animals may be linked to consumption of hard, unripe flesh.

Table 3 Sugar content and composition of ripe avocado fruit flesh

Sugar (mg per 100 g fresh weight)	*Concentration range*[a]
Glucose	0.14–1.28
Fructose	0.08–0.65
D-*Manno*-heptulose	0–3.82
Perseitol	0–2.06

[a]Concentration is dependent on the cultivar and stage of ripening.
Source: Values were derived from data published by Liu, X., Robinson, P. W., Madore, M. A., Witney, G. A. and Arpaia, M. L. (1999). 'Hass' avocado carbohydrate fluctuations. II. Fruit growth and ripening. *Journal of the American Society of Horticultural Science* **124**, 676–681; Seymour, G. B. and Tucker, G. A. (1993). Avocado. In: Seymour, G. B., Taylor, J. E. and Tucker, G. A. (eds.) *Biochemistry of fruit ripening*, pp. 53–81. London: Chapman & Hall, and references cited therein

Interestingly, D-*manno*-heptulose is regarded as an inhibitor of hexokinase (EC 2.7.1.1) activity with a $K_i = 0.5$ mM. Hexokinase phosphorylates hexose/hexulose during metabolism to give the corresponding 6-phosphate derivatives, which are then metabolized in the glycolytic pathway to provide energy and organic substrates. Whether this biochemical pathway is affected by a diet rich in avocado (and therefore some D-*manno*-heptulose) in humans is unknown.

Nutritional Benefits and Costs

Nutrient Density

The extraordinary nutrient density, at least of the fruits of subtropical avocado cultivars that form the basis of world trade and of consumption in the affluent first world, has been noted. In fact, the subtropical avocado has been described as the most nutritious of all widely grown fleshy fruits. Consumption of avocado is therefore associated with improved overall diet quality, nutrient intake, and reduced risk of metabolic syndrome. Thus, comparatively small amounts of avocado are extremely helpful in upgrading the quality of the diet in an increasingly health-conscious world. Furthermore, the relatively small amounts consumed per serving (80–100 g) are no cause for concern where affluence has contributed to overweight or even obesity. The problem in poor, mostly tropical, third-world countries is very different, and here, the energy and nutrient density of the fruit, even of less nutritious tropical cultivars, can make a substantial contribution to guard against malnutrition.

Protection from Coronary Heart Disease

Coronary artery disease results from the buildup of cholesterol and other lipids in coronary arteries. Cholesterol is carried by

lipoproteins, and LDL causes the most damage. HDL, however, protects vessel walls from atherosclerosis.

Monounsaturated fatty acids increase the blood level of HDL. Avocado is high in monounsaturated fats and contains no cholesterol. A diet rich in avocado therefore has a favorable effect on blood fats, decreases cholesterol, and preserves HDL. Trials have revealed that a diet rich in avocado causes a decline in total serum cholesterol of 16% in healthy individuals. In hypercholesterolemic subjects, a decrease in serum cholesterol of 17%, LDL cholesterol of 22%, and triacylglycerols of 22% was observed, while HDL cholesterol increased by 11%. There has, therefore, been a welcome change in attitude toward avocado consumption in people at risk of coronary heart disease.

Hypersensitivity

Hypersensitivity occurs in latex-allergic individuals who react to avocado (and other fruits including banana, melon, and kiwifruit) within 60 min of ingestion. They typically display one or more of the following symptoms: mouth irritation, angioedema, urticaria, asthma, nausea, vomiting, diarrhea, rhinitis, or anaphylaxis. Allergy to avocado is increasing, especially in the United States and Mexico, and has been estimated at around 1% of the general population. Avocado allergy is of particular importance in the 'latex-fruit syndrome' observed in at least 40% of latex-allergic individuals. As mentioned earlier in the text, the allergens elicit diverse immunoglobulin E-mediated reactions in sensitized individuals. Many of the known plant food allergens are in fact proteins produced either following pathogen attack or after induction of the plant stress syndrome. Thus, avocado fruit proteins are of particular importance in food-related allergies.

A recent proteomic analysis of avocado fruit has revealed at least 1012 different proteins including the well-known avocado allergen *Pers a 1* and several proteins suspected of eliciting allergic responses. Included in the latter are polygalacturonase, a thaumatin-like protein, glucanase, and an isoflavone reductase-like protein.

At least two avocado allergens are known: *Pers a 1* and *Pers a 4*. *Pers a 1* is the most widely studied and is considered the major allergen. The *Pers a 1* allergen is a 32 kDa protein that has endochitinase activity and is recognized by 15 out of 20 avocado and/or latex-allergic individuals. This allergen belongs to the PR-3 family of pathogenesis-related proteins and is induced in plants by ethylene treatment, but allergic activity is lost in heating. This probably explains why plant foods containing this allergen that are consumed after cooking (e.g., green beans) are not usually associated with the latex-fruit syndrome.

Antimycobacterial Activity

A patented blend of D-*manno*-heptulose and perseitol termed AV119, which is prepared by extracting fruit pulp in aqueous alcohol and concentrating the solution to obtain a 5% content of the actives, induces human β-defensin 2 production by normal human keratinocytes and satisfactory recovery of the proinflammatory response. More specifically, AV119 modulates the lipopolysaccharide-induced proinflammatory response by blocking the activation of the transcription regulator NF-κB. In addition, AV119 induces aggregation of yeasts, in particular those that are part of the normal human cutaneous commensal flora, and inhibits penetration into keratinocytes.

Other antimycobacterial metabolites from avocado have been isolated from the pulp of unripe fruit and include fatty alcohol derivatives termed avocadenols and avocadin. Both avocadenols A and B, (2*R*,4*R*)-1,2,4-trihydroxynonadecane, and (2*R*,4*R*)-1,2,4-trihydroxy heptadec-16-ene display antimycobacterial activity against *Mycobacterium tuberculosis* with MIC values of 24, 33, 24.9, and 35.7 μg ml^{-1}, respectively.

B

Bacillus cereus and Other *Bacillus* sp. Causing Foodborne Poisonings, Detection of

F Carlin, INRA, Avignon Université, Avignon, France

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Bacteria of *Bacillus* spp. are widely present in natural environments and are common contaminants of foods. They are Gram-positive and aerobic and many species are facultative anaerobes. *Bacillus* sp. form spores (or endospores) in conditions of nutrient depletion and in response to population signals. Spores are in a dormancy state and allow persistence in the environment and in food raw material and resistance to food processing (heat, chemical treatments, high hydrostatic pressure, UV irradiation, etc.) (Figures 1 and 2).

Vegetative cells emerging after spore germination are adapted to growth at a wide range of temperature, pH, and a_w and therefore can easily multiply in food matrices, where they can cause spoilage. The *Bacillus* species *B. cereus* and to a lesser extent *B. subtilis*, *B. licheniformis*, and *B. pumilus* have also been reported as causes of foodborne poisoning. Among those, *B. cereus* represent the most serious concern for public health and food safety because of the number of reported cases and the severity of some of them. *B. cereus* causes two types of syndromes: a diarrheal syndrome following ingestion of *B. cereus* cells and enterotoxin production in the small intestine and an emetic syndrome caused by cereulide ingestion, a heat-stable cyclic peptide. With some exceptions reporting a high incidence in some countries, the relative incidence of *B. cereus* in most developed countries represents a minority (i.e., a few percent) of the outbreaks of foodborne poisonings. However, it is worth noticing that fatal or very severe emetic *B. cereus* outbreaks are increasingly reported since the early 2000s, in particular attributed to liver failure of patients. As a consequence, the assessment of the risk due to *B. cereus* and other *Bacillus* species requires a quantitative evaluation of consumer exposure (prevalence and/or concentrations in foods) and increasingly a qualitative evaluation of the profile of the strains detected in the food. Most detection methods have been developed for *B. cereus*, much more than for other *Bacillus* sp., because of the frequency and the relative severity of *B. cereus* foodborne poisonings as mentioned earlier. Detection of *B. cereus* in foods and other environments meets three objectives:

(i) Evaluation of the population level that should be controlled in foods or to which the consumer could be exposed. Foodborne poisonings are in most instances caused by the ingestion of foods containing at least 10^5 cfu g^{-1}. Evaluation of *B. cereus* concentrations is a key issue for risk management.

(ii) Characterization of the strains present in a food. *B. cereus* strains are highly diverse. A significant effort is dedicated to the determination of the strain potential to cause foodborne poisonings and to the adaptation to the environment in the food chain.

(iii) Detection and quantification of emetic toxin (cereulide) in foods.

Ecological Niches and Routes to Contamination by Foodborne Pathogenic *Bacillus* sp.

Soil is regarded as the natural habitat of spore-forming bacteria. Spores present in soils can be dispersed and can colonize very diverse environmental niches. *B. cereus* and *B. subtilis* spores can be detected in the gastrointestinal tract of vertebrates and vertebrates including mammals. The food production chain can be contaminated by spores through these sources. Molecular tools developed since the early 1990s, such as random amplification of polymorphic DNA (RAPD methods), have allowed in many circumstances a detailed tracing of contamination routes, from soil, to food unprocessed materials, to stored processed dishes. In dairy farms, concentrations of milk with *B. cereus* can also be correlated to concentrations in cow's feces and to dairy cow's feed. Many *Bacillus* spp. are used in different applications exploiting some of their specific properties, which also contribute to dispersion. Contamination of horticultural crops with *B. cereus* could be a consequence of the spreading of *B. thuringiensis*, applied for the insecticidal properties of its parasporal crystal: *B. thuringiensis* is genetically not distinguishable from *B. cereus*. Spores of *B. cereus*, *B. subtilis*, and *B. licheniformis* may also be used for their probiotic properties in humans, for veterinary applications, or in aquaculture.

The Complex Taxonomy of *B. cereus*

B. cereus is part of the genus *Bacillus*. *B. cereus* is phenotypically close to *B. anthracis*, *B. mycoides*, *B. thuringiensis*, *B. weihenstephanensis*, and *B. pseudomycoides*. These genetically very close species form the *B. cereus* group, also known as *Bacillus cereus sensu lato* (Tables 1 and 2). Recent phylogenetic analysis provides a robust description of the genetic structure

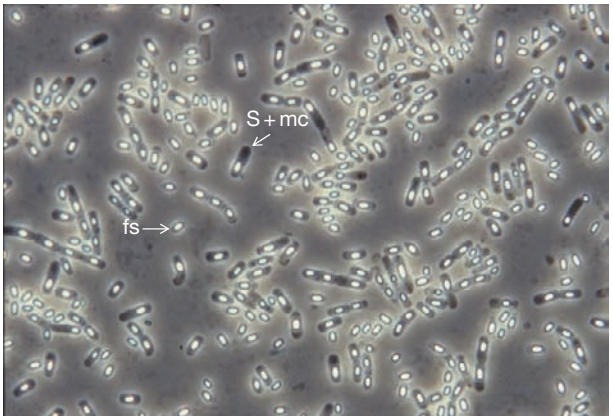

Figure 1 Phase contrast microscopy of *Bacillus* spores under a 1000× magnification. Phase-bright spores (S) are formed within a mother cell (dark phase) (mc) and are released to form free spores (fs). Spore diameter is approximately 1 μm. Picture of Guinebretière MH, INRA PACA.

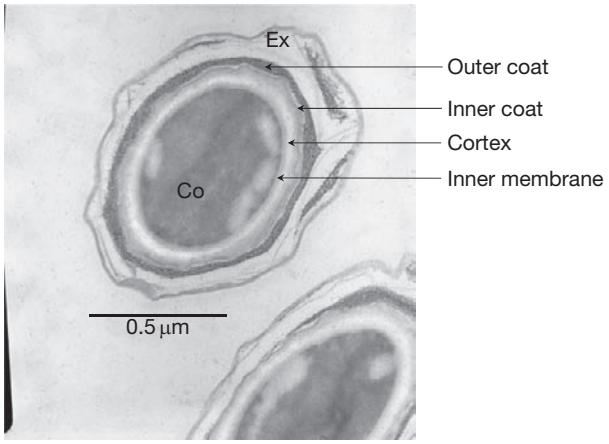

Figure 2 Transmission electron microscopy image of a section of a *Bacillus cereus* spore showing the spore structures. The core (Co) of the spore in dormancy contains DNA protected by small acid-soluble proteins (SASPs). Spore core is highly dehydrated and contains high concentrations of divalent cations (Ca^{2+} and Mg^{2+}) and of dipicolinic acid, specific to bacterial spores. Spore core is surrounded by a membrane similar to that of vegetative cells. The cortex is formed of peptidoglycan, with a structure similar to that of the bacterial cell wall. The cortex is degraded during germination to allow emergence of the vegetative cell and then cell division. Protein coats also contribute to spore protection against some physical and chemical stress. Exosporium (Ex), the outermost structure of spore, has a diverse composition and its role is still poorly known. Exosporium contributes to adhesion of spore to surfaces. Picture of Planchon S and Bornard I, INRA PACA.

of the *B. cereus* group. The correspondence between the phylogenetic groups and the currently defined species is shown in Table 1, together with some phenotypic characterization of the groups and association with outbreaks of foodborne poisonings. The phenotypes of *B. cereus* phylogenetic groups show pronounced variations in the ability to grow at low temperature, low pH, and high salinity and to resist heat. The virulence potential of the phylogenetic groups, evaluated by association (frequency and severity) with foodborne poisonings, shows also marked differences. Some strains of groups III (the one of the emetic strains) and VII have caused the most severe poisonings. In contrast, strains of groups I and VI have almost never been associated with foodborne poisonings. Food authorities do not generally consider this diversity when sampling foods.

Methods for *B. cereus* Enumeration in Foods

Spore Selection and Elimination of Vegetative Cells

B. cereus can contaminate foods as spores or vegetative cells. In some instances, the only enumeration of spores can be recommended, in particular when foods are intended for heat treatment that eliminates vegetative cells. Typically, a few minutes of treatment at approx. 60 °C will inactivate vegetative cells of *B. cereus*, while spores will resist to at least several minutes at 90 °C. Inactivation of vegetative cells prior spore enumeration is therefore achieved with a heat treatment of the samples at 60–80 °C for 10 min or longer. Spores are also unaffected by ethanol in solution unlike vegetative cells. Spore selection and elimination of vegetative cells can also be obtained by exposure of food samples to 95–100% filter sterilized ethanol (ethanol may contain spores) at ambient temperature for 30–60 min at a final concentration of 1:1.

Culture Media and Confirmation Tests

Pure cultures of *B. cereus* can grow on most routine laboratory media such as nutrient or blood agar. Optimal growth is at about 37 °C for most species, except for some psychrotrophic strains (including those identified as *B. weihenstephanensis*), which is more around 30 °C. Selective media for *B. cereus* detection and enumeration have been developed for several decades and are still widely applied worldwide although alternative chromogenic media have been proposed since a few years. Selective PEMBA (polymyxin B–pyruvate–egg yolk–mannitol–bromothymol blue agar) and MYP (mannitol–egg yolk–polymyxin B agar) are based on the resistance of *B. cereus* cells to the antibiotic polymyxin B, which conversely inhibits growth of Gram-negative bacteria and its inability to produce acid from mannitol (no pH reduction diagnosed by no color change of pH indicators such as bromothymol blue or bromocresol purple) and the production of a lecithinase that will precipitate and form a halo surrounding colonies. The addition of trimethoprim has sometimes been suggested for higher selectivity. Colonies are generally large and can coalesce, making plate readings difficult. This problem can be overcome by using large-diameter Petri dishes or reducing the countable colony range to <30. Incubation times and temperature are in the range 30–37 °C for 24–48 h. A method for enumeration of low *B. cereus* counts using MPN (most probable number) determination has been proposed (norm ISO 21871). Cells from colonies presenting the expected *B. cereus* colony aspect should be confirmed as *B. cereus* using confirmation tests. Several have been proposed and differ among national standards. FDA, as published in the Bacteriological Analytical Manual (BAM), proposes identification of those isolates as *B. cereus* that (1) produce large Gram-positive rods with spores that do

Table 1 Phylogenetic groups defined by Guinebretière et al. within *Bacillus cereus sensu lato* and some phenotypic characters

Phylogenetic group	*Current species*	*Association to foodborne poisonings*	*Growth temperature domain*	*Resistance to moist heat*	*Minimal pH, maximal NaCl for growth*
I	*B. pseudomycoides*	N	M	undetermined	4.6, 5%
II	*B. cereus* II *B. thuringiensis* II	M	P	++	<4.3, 8%
III	*B. cereus* III *B. thuringiensis* III *B. anthracis*	H	M	+++	4.6, 10%
IV	*B. cereus* IV *B. thuringiensis* IV	M	M	++	4.6, 10%
V	*B. cereus* V *B. thuringiensis* V	L	MP	++	4.6, 8%
VI	*B. weihenstephanensis* *B. mycoides* *B. thuringiensis* VI	L	P	+	4.6, 6%
VII	*B. cereus* VII or *B. cytotoxicus*	H	MT	+++	<4.3, >10%

Table 2 Main characters distinguishing genetically close species belonging to the *B. cereus* group (*B. cereus sensu lato*)

Species within B. cereus sensu lato	*Character*
B. anthracis	Presence of virulence genes carried by the two plasmids pXO1 and pXO2; nonhemolytic on sheep blood agar. The cause of anthrax in warm-blooded animals
B. thuringiensis	Produces a parasporal crystal consisted of insecticidal proteins. Crystal toxin genes are plasmid-borne
B. mycoides and *pseudomycoides*	Formation of rhizoid colonies
B. weihenstephanensis	Growth at 7 °C and no growth at 43 °C. Presence of certain DNA signatures

not swell the mother cell, (2) produce lecithinase and do not ferment mannitol on MYP agar, (3) grow and produce acid from glucose anaerobically, (4) reduce nitrate to nitrite (a few strains may be negative), (5) produce acetylmethylcarbinol (Voges–Proskauer-positive), (6) decompose L-tyrosine, and (7) grow in the presence of 0.001% lysozyme. The ISO 7932 norm includes aerobic production of acid from glucose, Voges–Proskauer test, and nitrate reduction. The routine French norm NF V08-058 only includes a motility test of presumptive strains and hemolytic activity on blood agar and is easier to perform. MYP or PEMBA is sold ready-to-use by several manufacturers of media and reagents.

Alternative methods are based on the enumeration of colonies on chromogenic medium. These media contain chromogenic substrates that are cleaved by specific enzymatic activities of microorganisms. For example, the chromogenic *Bacillus Cereus* agar (or Brilliance™ *Bacillus cereus* Agar, Oxoid, Basingstoke, UK) contains 5-bromo-4-chloro-3-indolyl-β-D-glucopyranoside that is cleaved by β-D-glucosidase and results in white colonies with a blue-green center. Confirmation tests may not be required using this chromogenic medium, as with Bacara™ (AES Chemunex, Bruz, France), and it is usually claimed that these media present a better selectivity that MYP or PEMBA. Some of these chromogenic media Bacara™ and COMPASS *Bacillus cereus* Agar (Biokar Diagnostics, Beauvais, France) have been validated according to ISO 16140 as alternative media for *B. cereus* enumeration in foods. Bacara™ is also recommended by the FDA in the BAM. Enzyme activities implicated in the chromogenic reactions maybe under the regulatory control of regulators showing some polymorphism and suspected to contribute to a typical growth. Some authors therefore suggest that these chromogenic media should still be considered with care.

In conclusion, there is a large panel of methods available for *B. cereus* culture and confirmation. Comparison performed with a common set of strains within the *B. cereus* group shows that each media has its own limitations: for instance, lecithinase activity may not always been detected on MYP or PEMBA, or chromogenic media may not support growth of some *B. cereus* group strains or give a false-negative reaction.

Detection of *B. cereus* Toxins

Several techniques are available for the detection of the cytotoxins Nhe (for nonhemolytic enterotoxin), Hbl (hemolysin BL), and CytK (cytotoxin K) and cereulide, the main virulence factors associated with the *B. cereus* foodborne poisonings. However, it is generally admitted that *B. cereus* diarrheic syndromes are caused by diarrheic toxin production in the small intestine. Diarrheic toxins are proteins sensitive to different proteases such as pronase, pepsin, trypsin, and chymotrypsin and therefore may be degraded by enzymatic activity during the gastrointestinal passage. Their presence in a food is not a reliable indication of a risk and these tests are more useful for characterization of the toxinogenic potential of the strains. Immunological tests specifically targeted to the main virulence factors have progressively replaced biological tests such as ileal rabbit loop or vascular permeability assay, although tissue culture represents alternative for screening: CHO cells, Caco-2 cells, or Vero cells have been used for screening activity of

B. cereus strains. In addition to antibodies developed for laboratory research purpose, commercial immunological tests are proposed for the detection of some of these toxins. The BCET-RPLA test kit (*Bacillus cereus* enterotoxin, reversed passive latex agglutination) (Oxoid, Basingstoke, UK) detects the L_2 component of the three-component toxin HBL and allows a semi-quantitative determination of toxin concentration in supernatants. The TECRA BDE-VIA (*Bacillus* diarrheal enterotoxin visual assay) (TECRA, Roseville, Australia) detects the NheA component of the three-component toxin Nhe. No commercial test is available for CytK detection. A lateral flow assay allows the detection of both HBL (more precisely of its B component) and NHE (the L2 component) with a single test strip (Duopath® *Cereus* enterotoxins assay, Merck KGaA, Darmstadt, Germany). In contrast to diarrheic toxins, the determination of emetic toxin concentration in a food is a good indication of the risk caused by the presence of emetic strains. As with diarrheal toxins, tests of biological activity have been developed such as culture assays of HEp2 cells, on which cereulide causes vacuolization or inhibition of motility of spermatozoids due to the mitochondrial activity of cereulide (sperm boar assay). These methods are not specifically detecting cereulide, but they are appropriate for screening of *B. cereus* isolates. Moreover, sperm boar assay was shown to correlate with liquid chromatography–mass spectrometry methods, which are developed by several laboratories. Although requiring laborious extraction procedures and requiring costly analytical equipment, these methods are getting the reference for cereulide assay, in particular in foods. No pure standard of cereulide is currently available and valinomycin, which shares with cereulide close common structure (both are cyclic dodecapeptide) and potassium transport properties, is generally used as surrogate standard for cereulide.

Molecular Methods of *B. cereus* Detection

B. cereus detection in current routine practices for microbiological analysis of food material is mostly performed with cultivation methods. Nevertheless, alternative methods using PCR amplification of *B. cereus* DNA sequences, increasingly including quantitative real-time PCR amplification, have been proposed and are continuously under evolution. When applied to foods, the sensitivity and reliability of molecular detection methods depend on the quality of the extracted DNA and protocols (of enrichment, separation, cell lysis, analyte concentration, etc.) must be examined with care. Developments for *B. cereus* detection have been favored by thorough genetic investigations and sequencing on strains of the *B. cereus* group. The genetic structure of the toxin operons and the sequencing of toxin genes *nhe*, *hbl*, *cytK*, and *ces* (cereulide synthetase gene) have been achieved by several research groups, and the genome sequence of nearly 200 strains of *B. cereus sensu lato* was available early 2013. These molecular detection methods therefore target a variety of *B. cereus*-specific sequences of varied genes: 16s RNA or *gyrB* genes (reported to have a better phylogenetic resolution among *Bacillus* spp.) present in all bacteria; or genes encoding for *B. cereus* virulence factors, such as hemolysin, phosphatidylcholine-specific phospholipase C gene (*pc-plc*), diarrheal toxins HBL, NHE, and CytK; or the cereulide synthetase gene (*ces*). In particular, they may allow detection of particular type of strains among the *B. cereus* group (for instance, the emetic strains) that may not be identified using plating methods. Worth noting is a high-molecular polymorphism of the enterotoxin genes *nhl*, *hbl*, and *cytK* and possibly also for the emetic strains that need also to be considered for PCR methods development. For instance, *B. cereus* strains may produce two forms of CytK toxin. Strains producing CytK-1 with a high cytotoxic activity and associated with highly pathogenic group VII strains can be discriminated from Cyt-K2 producing strains by a duplex PCR assays amplifying either *cytK1* or *cytK2* genes. In contrast, the prevalence of strains carrying *nhe* or *hbl* can be underestimated, and the characterization of PCR negative strains should be completed with techniques such as Southern hybridization. Because of its stability, detected DNA does not necessarily indicate living cells. Detection in samples subjected to an enrichment step generally implies the presence of living populations, which can also be quantified using RNA analysis. The addition of the DNA intercalating dye ethidium monoazide inhibits PCR of DNA from dead bacteria. In addition, the presence of toxin genes does not inform about the actual virulence of strains and complementary tests about actual toxin production or toxic activity needs to be performed. Current studies on *B. cereus* proteome or genome favored by high-throughput sequencing reveal new virulence factors and detail *B. cereus* diversity, which contributes to the identification of biomarkers differentiating between virulent and less hazardous strains. Integration of these biomarkers into new diagnostic tools such as microarrays is the likely future of *B. cereus* detection tools.

B. cereus Prevalence and Concentration in Foods

Quantitative Estimation

B. cereus prevalence and concentrations in foods is well documented and many surveys have been performed worldwide. *B. cereus* has been detected in a very wide range of foods and this is in agreement with the large diversity of foods associated with outbreaks of foodborne poisonings. Concentrations before storage is usually lower than 100 cfu g^{-1}. A noticeable exception is herbs and spices, which may contain concentrations greater than 10^3 cfu g^{-1}. A large survey performed in the United Kingdom showed that 0.08% of nearly 17 000 food samples exceeded 10^5 *B. cereus* cfu g^{-1}. Foods implicated in outbreaks of *B. cereus* food poisonings are usually contaminated at such (or greater) concentrations, which is therefore considered as critical.

Characterization of *B. cereus* Contaminating Foods

Surveys increasingly include some elements of characterization of the isolated strains, which is important for a better characterization of the risk due to food contamination. These include the ability to grow at low temperature, which is particularly relevant for foods intended to be stored at refrigeration temperatures. These surveys may also include information about the virulence profile of the isolated *B. cereus* strains. This is established by the detection of the main toxins (or of their genes). Some examples of such surveys are shown in Table 3.

Table 3 *B. cereus* prevalence and/or counts in foods with a phenotypic characterization of *B. cereus* in relation to its growth behavior and its ability to form toxins

Food (country and source)	*Number of samples*	B. cereus *prevalence and/or concentrations*	*Behavior of isolates at low temperature*	*Toxin and/or toxin genes*
Cooked dishes, fresh vegetables, fresh meat (Belgium, Samapundo et al.)	575	374 Positive samples[a]	2.6% Growing at ≤ 7 °C and 87.9% growing at 10 °C, $n = 380$	0% Harboring the *ces* gene; 52.5% harboring *hblA, hb D, hblC nheA nheB, nheC, and cytK*; $n = 80$
Oil(s) and fat(s), fish, meat, milk, vegetable(s) and their products, flavorings, ready-to-eat foods, pastry (The Netherlands, Wijnands et al.)	33 787	0.24% $> 10^5$ *B. cereus* cfu g^{-1}	4.4% of psychrotrophic strains[b], $n = 796$	97%, 66%, and 50% harboring the genes for NHE, HBL, and CytK; 8.2% positive for cereulide-like production
Fresh foods, heat-treated foods, and combinations (Danemark, Rosenquist et al.)	48 901	0.7% $> 10^3$ *B. cereus* cfu g^{-1}, 0.5% $> 10^5$ *B cereus* cfu g^{-1}		Tests on 40 isolates; 1 emetic strain, all NHE producers; 28 with visible parasporal crystal of *B. thuringiensis*
Dairy foods, cooked dishes, vegetable dishes, spices (The Netherlands, van Netten et al.)	1700	0.4% $> 10^3$ *B. cereus* cfu g^{-1}, 0.1% $> 10^5$ *B cereus* cfu g^{-1}	16% Growing at ≤ 7 °C; $n = 596$	37% of strains growing at 7 °C producing HBL; $n = 51$

[a]At least one presumptive *B. cereus* in 25 g.
[b]Based on the detection 16S ribosomal DNA signature.

The sequence of the *panC* gene allows a rapid affiliation to one of the phylogenetic groups defined in Table 1. An online tool has been developed, which is available at https://www.tools.symprevius.org/Bcereus/english.php. These have enhanced our understanding of the *B. cereus* risk in foods. *nhe* is present in almost any *B. cereus* strains. *hbl* genes are present in a vast majority of strains, but not in emetic strains. Emetic strains are relatively rare (only a few percents of all *B. cereus* isolates) but in much higher proportions in nonrandom food and clinical isolates. Psychrotrophic strains able to grow at 5 °C are also relatively rare, but strains able to grow at 10 °C are quite common. Foodborne poisonings by group III, IV, or VII strains, giving the most severe poisonings, will likely be a consequence of storage at abuse temperature because of the poor ability of these strains to grow at low temperature.

Other *Bacillus* spp.

The presence of *B. subtilis*, *B. licheniformis*, and *B. pumilus* in foods has been documented for a long time but to a much lesser extent than for *B. cereus*. Their incidence, as number and importance of outbreaks of foodborne poisonings, is much lower than the one of *B. cereus*. No selective media have been developed for those species. Their prevalence in the environment and in foods is established from strain isolates on nonselective media. Then strain isolates are identified using a panel of molecular methods, although sequence analysis of several genes predominates. These are 16S rRNA sequence genes, *gyrA*, *gyrB* (encoding gyrase subunits A and B), *cheA* (encoding a histidine kinase), *rpoB* (encoding a subunit of bacterial RNA polymerase), etc., as more than one method is necessary for the differentiation of these species that are genetically very close. Phenotypic tests, available, for instance, in miniaturized API tests (BioMérieux, Marcy-l'Etoile, France), can complement identification. Together, the data strongly suggest that the prevalence and concentrations in foods should be rather similar to that of *B. cereus*. Foods implicated in food poisonings contained at least *B. subtilis*, *B. licheniformis*, and *B. pumilus* 10^5 cfu g^{-1}. Symptoms of food poisonings include vomiting, nausea, diarrhea, and abdominal pain. Poisonings likely result of the ingestion of toxins formed in the foods, similarly to the emetic syndrome due to *B. cereus* emetic strains and cereulide. These toxins have been described as lipopeptides, produced from rare (a few %) toxic isolates. They have been identified by the fractionation of toxic culture extracts revealed by tests on cell culture and then identification using mass spectrometry.

Introduction

Bacilli are gram-positive, aerobic, spore-forming bacteria that are widely spread in nature. They are present not only in soil, dust, and water but also in plants, animals, and humans. The genus *Bacillus* contains a very large number of species since it has undergone a vast taxonomic expansion with the use of 16SrRNA sequencing. Some *Bacillus* species, namely, *B. cereus*, *B. clausii*, *B. coagulans*, *B. licheniformis*, *B. pumilus*, and *B. subtilis*, have been used as probiotics in commercial nutritional supplements. This has raised some concern because although most *Bacilli* are nonpathogenic, several species can cause disease in animals and humans by the production of various toxins. These pathogenic species will be the focus of the present article.

Seven closely related species of *Bacilli* are grouped under the taxon *Bacillus cereus sensu lato* (*s.l.*), which includes *B. cereus sensu stricto* (*s.s.*), *Bacillus thuringiensis*, *Bacillus anthracis*, *Bacillus mycoides*, *Bacillus pseudomycoides*, *Bacillus weihenstephanensis*, and the recently described *Bacillus cytotoxicus*. These taxa present a high genomic similarity and could have been considered as a single species. The *B. cereus* group members are globally defined by differences in plasmid encoded-features leading to different spectra of toxicity. While *B. anthracis* and *B. cereus s.s.* are pathogenic for humans and/or mammals, *B. thuringiensis* has been used as biopesticide thanks to its virulence toward insect larvae.

Considering the critical speciation of *B. cereus* group members and the variability in their phenotypic features, a new structure for *B. cereus* populations based on ecological differences and growth temperatures has been proposed. Seven major phylogenetic groups were suggested based on a polyphasic approach combining molecular typing (e.g., amplified fragment-length polymorphism), thermal growth spectra, and psychrotolerance. This new classification was structured in two psychrotolerant (II and VI) groups, three mesophilic (I, III, and IV) groups, one intermediate (V) group, and one moderate thermotolerant (VII) group. All groups contain more than one taxon (e.g., group II contains psychrotolerant *B. thuringiensis* and *B. cereus*; group III includes mesophilic *B. thuringiensis*, *B. cereus*, and *B. anthracis*: and group VI comprises psychrotolerant *B. thuringiensis*, *B. mycoides*, and *B. weihenstephanensis*) with the exception of group I (*B. pseudomycoides*) and group VII (CytK-1-producing *B. cereus*). The last group is constituted by highly toxic, moderate thermotolerant strains that are considered as a novel bacterial species and was consequently renamed *B. cytotoxicus*.

Bacillus anthracis

B. anthracis is the etiologic agent of anthrax, which affects all mammals, including humans. It was used as a bioterrorist weapon in 2001 in the United States under the form of bacterial anthrax powder. *B. anthracis* pathogenesis is elicited by the production of anthrax toxins and the elaboration of a protective capsule. *B. anthracis* is persistent in the environment in a state of dormant spores, which are able to survive for long periods in soil, in spite of adverse environmental conditions. If ingested, the spores can generate vegetative forms, which can grow inside the mammalian host and express various virulence factors.

There are three routes of contamination with *B. anthracis* leading to different types of anthrax: cutaneous (through lesion of the skin), gastrointestinal (through ingestion of contaminated food), and respiratory anthrax (through inhalation of contaminated air). All three forms of anthrax may result in a fatal outcome with highly variable mortality rates. The most benign anthrax is the cutaneous form, which is implicated in about 90% of all human cases with a mortality rate below 1%. It is treatable with appropriate antibiotics (e.g., penicillin and amoxicillin) if early diagnosed. Cutaneous anthrax is characterized by the apparition of a small papule that undergoes ulceration and evolves into a typical black eschar. The lesion, where the bacteria remain located, is accompanied by an edema.

The gastrointestinal anthrax is due to the ingestion of spores while eating contaminated meat, followed by the formation of the classical eschar in the gut system, germination of the spores resulting in multiplication of vegetative cells, and expression of both toxins and capsule. The pathological features reflect the actions of the different virulence factors and result in edema, vascular leakage, and bloody diarrhea. The outcome is often fatal due to the difficulty of posing a correct diagnosis.

The most severe and rapid form of anthrax is caused by the inhalation of spores and results in more than 95% of mortality if the disease is not treated early. The spores, 1–2 μm in diameter, are deposited in the alveolar spaces and are then transported into the lymph nodes where vegetative cells can proliferate and spread through the bloodstream. Large amounts of toxins are then produced and provoke acute symptoms. The illness is therefore characterized by two phases: the first prodromal stage during which mild flu-like symptoms appear and suddenly stop after 48 h to progress to the fulminant illness (second stage) exemplified by fever, tachypnea, cyanosis, tachycardia, moist rales, and evidence of pleural effusion that rapidly evolves to coma and death of the patient..

Bacillus cereus sensu stricto

B. cereus s.s. can be found in a wide variety of niches from soil to the intestines of healthy arthropods and healthy humans. The estimated prevalence of *B. cereus* in the intestinal tract of healthy human individuals ranges from 15% to 40% of the population. Nevertheless, soil is probably the main source of contamination as it has been shown to contain 10^5–10^6 of

spores of *B. cereus* per gram. Due to the strong resistance of its spores toward adverse environmental conditions and its ability to live in soil with low nutrient levels, *B. cereus* can contaminate a large variety of agricultural products. Hence, *B. cereus* can be isolated from a wide range of raw and processed foods, including pasta, rice (unhusked and white), dairy and dried milk products, dried foodstuffs, meat, chicken, vegetables, fruits, and seafood. Two major problems for the food industry are associated with *B. cereus*: food spoilage and human illnesses.

B. cereus s.s. is responsible for various types of non-gastrointestinal diseases, including systemic and local infections such as septicemia, bacteremia, endocarditis, pneumonia, pleuritis, periodontitis, osteomyelitis, meningitis, endophthalmitis, and eye infections. Although the toxins implicated in these cases are not precisely known, a large number of potential virulence factors may contribute to the pathogenesis of *B. cereus* such as hemolysins (cereolysin O, hemolysin II, and sphingomyelinase), phospholipases C, and proteases.

B. cereus also poses foodborne health risk to consumers through two types of gastrointestinal illnesses: emesis and diarrhea. The mechanisms involved in these two syndromes are radically different from each other. The scenario is rather simple for emesis since it results from the consumption of dishes contaminated with a single toxin, cereulide. The fact that the toxin is preformed in food leads to a very short incubation time of 1–5 h. On the opposite, the situation is still unclear for the diarrheal syndrome notably regarding the potential toxins responsible for the disease. It has been postulated that the disease is caused by the ingestion of *B. cereus* cells that grow and generate enterotoxins inside the human intestinal tract, which explains the longer incubation time of between 8 and 16 h. The infective doses of *B. cereus*, typically 10^3–10^5 of colony-forming units per gram, are difficult to assess because they depend on various factors including, for instance, the amounts of toxins produced or the susceptibility of target population. As for numerous other toxi-infections, it is recognized that the more severe forms of the illness are associated with young people and elderly people.

The emetic form of food poisoning was first identified in the 1970s and was associated with the consumption of fried rice. It was only in 1995 that the structure of the causative toxin was identified and named cereulide. The diarrheal type of *B. cereus* food poisoning was first described by Steinar Hauge in 1955, after an outbreak of gastroenteritis that occurred in a hospital and that was related to vanilla pudding contaminated with *B. cereus*.

Different enterotoxins are considered as potential candidates for causing the diarrheal syndrome: the enterotoxin hemolysin BL (HBL), the nonhemolytic enterotoxin (NHE), the necrotic cytotoxin K (CytK), and the enterotoxins FM (entFM) and T (BceT). However, the latter two have never been demonstrated to be directly involved in diarrheal food poisoning. The CytK enterotoxin has been discovered last, following a serious outbreak of gastroenteritis that caused the death of three people in France. Two different forms of CytK, CytK-1 and CytK-2, were subsequently described and CytK-1 displays a greater cytotoxic activity based on cellular tests performed on human intestinal cells. It should be noted that due to the lack of appropriate animal model, the actual contribution of these putative enterotoxins (alone or in combination) in the etiology of *B. cereus* diarrhea should be taken with great care. Further research is clearly needed to get more insights into this particular pathogenesis.

Bacillus weihenstephanensis

B. cereus s.l. strains, which are able to grow below 7 °C and up to 43 °C, are considered as psychrotolerant. They are mostly clustered within the *B. weihenstephanensis* group, notably based on their 16S and 23S rRNA and the presence of a particular variant of the cold shock protein A (*cspA*) gene. However, psychrotolerant strains other than *B. weihenstephanensis* are also present in the *B. cereus* group. Furthermore, some intermediate forms, considering the genetic and phenotypic features between the mesophilic strains and the psychrotolerant strains, may exist.

Both enteropathogenic and emetic *B. weihenstephanensis* have been reported, and these discoveries draw attention to a potential risk of food poisoning from psychrotolerant strains in cooked chilled foods. However, up to now, *B. weihenstephanensis* has not been implicated in food poisoning in spite of the presence of its virulence factors.

Bacillus cytotoxicus

Although several strains of *B. cytotoxicus* were isolated from purees associated with food poisonings, its natural habitat is still unknown. This new species shares high genetic proximity with the *B. cereus s.l.* group but displays distinct phenotypic features, notably its thermotolerant ability (minimal and maximal growth temperatures at 20 and 50 °C, respectively), its inability to hydrolyze starch, and its auxotrophy for tryptophan. As already indicated, the first thermotolerant *B. cereus*-like strain that was isolated (later designated as *B. cytotoxicus*) was related to a lethal outbreak in which three people died of necrotic enteritis. The CytK enterotoxin implicated in this outbreak was further characterized to be a CytK-1, which is a marker for *B. cytotoxicus*. At first, only five strains were clustered in this new genomic species, and three of them originated from France, one from Germany, and one from Norway. However, a recent study performed on the occurrence of *B. cytotoxicus* in potato products taken from retail outlets and from catering showed that the frequency of this thermotolerant species is not negligible and certainly higher than previously thought.

Bacillus thuringiensis

Thanks to its entomopathogenic virulence, *B. thuringiensis* has been extensively used in agriculture as a biopesticide to control insect pests and insect vectors of major human and animal diseases such as dengue, malaria, and yellow fever. The use of *B. thuringiensis* insecticidal toxins in transgenic crops was successful and beneficial, leading to higher yields and to significant reduction in the use of chemical insecticides, which were associated with environmental pollution and chronic human health issues. The crystal polypeptides, or δ-endotoxins,

produced by *B. thuringiensis* possess a highly specific activity against various species of insects belonging to six different taxonomic orders: *Lepidoptera*, *Diptera*, *Coleoptera*, *Hymenoptera*, *Hemiptera*, *and Blattaria*. Certain noninsect organisms such as nematodes, mites, and protozoa are also sensitive to *B. thuringiensis* entomotoxins.

The *B. thuringiensis* entomotoxins are considered as inoffensive for humans, vertebrates, and plants because (i) they are specifically activated in the intestinal tract of target insect larvae (alkaline pH and sensitivity to specific proteases) and (ii) they specifically bind to receptors only present in the intestines of insects. However, one needs to remain cautious since some *B. thuringiensis* strains have been involved in food poisonings and were detected in ready-to-eat foods and in fresh fruits and vegetables. Interestingly, some strains of *B. thuringiensis* are capable of producing potential diarrheal enterotoxins similar to those produced by *B. cereus s.s*. Although the number of food poisonings due to *B. thuringiensis* is extremely limited, the critical distinction between *B. cereus* group members with classical culture confirmation procedures may lead to underreporting.

Occurrence of *B. cereus* in the Environment and in the Food Chain

B. cereus is a ubiquitous soil microorganism and is commonly found in raw, dried, and processed foods. Due to the resistance of *B. cereus* spores to heat, radiation, disinfectants, and desiccation (see preceding texts) and their strong ability to adhere to surfaces, *B. cereus* is also a common contaminant of food production equipment. These characteristics enable the bacterium to contaminate all kind of foods.

Food safety is based on random food testing in order to confirm that the food meets certain control criteria. These criteria should be scientifically determined, for example, by a risk analysis approach, which includes several steps from hazard identification to risk characterization. Considering microbiological risk assessment, the *hazard* is the causative agent present in the food and the *risk* is the probability of adverse health conditions, as stated by the *Codex Alimentarius* Commission and the World Organisation for Animal Health. Total elimination of *B. cereus* contamination from food and food production is unfortunately impossible. Given that normal cooking procedures will make spores germinate and that a subsequent multiplication of vegetative cells and toxin production may occur under improper storage conditions, concern should be raised about practices of food storage in households and restaurants. Furthermore, the vegetative growth may occur over a broad range of temperatures, including refrigerator temperature. This raises concern about the safety of prepacked, ready-to-eat food with regard to *B. cereus*.

Foodborne Outbreaks

The total number of outbreaks caused by *Bacillus* spp. toxins within the EU has increased by 41.9% since 2006. Although not negligible, the accurate number of food poisonings caused by *B. cereus* is not known since it is not a reportable disease and it is not always diagnosed. Sporadic cases are more common than general outbreaks.

Diarrheic Syndrome: Prevalence

Reports on foodborne zoonotic diseases are annually published by the European Union in order to evaluate the impact of zoonosis in the food chain across Europe. Information on foodborne outbreaks is collected from EU member states and helps to compare the prevalence of zoonotic agents between countries although the diversity of conditions regarding the notification of outbreaks impairs this comparison. In these reports, bacterial toxins hold a significant place in the list of reported foodborne outbreaks although no distinction between toxins produced by species from the *Bacillus*, *Clostridium*, and *Staphylococcus* genera is made. In 2012, bacterial toxins were responsible for 14.5% of the total reported outbreaks and *B. cereus* alone involved 2022 human cases, 126 hospitalizations, and three fatalities. Unfortunately, no distinction between emetic and diarrheal types has been made in the reported outbreaks. Yet, the diarrheal type of food poisonings seems to be more frequently reported than the emetic type. Types of foods that are involved in diarrheal food poisoning are also more diverse (e.g., vegetables, meat, desserts, spices, and dairy products).

In Belgium, for instance, *B. cereus* outbreaks are reported every year. The majority of these outbreaks have been associated with the diarrheal syndrome (up to eight outbreaks in 2011), while only one to three emetic cases were reported on a yearly basis. In 2011, *B. cereus* was even the most frequently detected pathogen in reported foodborne outbreaks.

Emetic Syndrome: Cereulide Prevalence

Emetic strains of *B. cereus* have been shown to be very rare in the environment and several studies have determined this low frequency to be around 1–2%. Yet, several cases of emetic intoxications associated with the consumption of rice or pasta dishes have been described worldwide.

Cooked rice and its improper storage represent one of the major risk factors in emetic food poisoning. Indeed, rice is implicated in 95% of the emetic food poisoning cases. Furthermore, two prevalence studies performed in Asian restaurants revealed that *B. cereus* is frequently present (37.5% and 56%, respectively) in the served fried rice dishes. By directly detecting the toxin in rice dishes served in restaurants, a higher prevalence of cereulide was found than previously studied by targeting cereulide-producing strains, even though the toxin concentrations were relatively low (1–4 ng g^{-1} food), as to provoke acute symptoms.

A recent study showed a remarkable high prevalence of emetic strains in sunsik samples (powdered food prepared from grains, fruits, and vegetables) although only a low *B. cereus* contamination level of 10–200 CFU g^{-1} was found. A large-scale prevalence study performed on food samples from general food monitoring programs in Bavaria showed that the incidence of emetic strains is clearly underestimated. This study also indicated that the risk of emetic syndrome is not restricted to starchy foods. These new findings tend to reinforce the

relevance of the hypothesis that emetic *B. cereus* may be more prevalent, and possibly diverse, than previously thought.

Lethal and nonlethal outbreaks due to emetic *B. cereus* have been reported. Severe outcomes are generally observed for children, while adults who had consumed the same meal usually recovered. General outbreaks did also occur and affected up to 116 people. The toxin concentrations range implicated in food poisonings is wide, probably because the victims ate different portions sizes and/or because some victims were more subject to intoxications (e.g., children and elderly people). The total amount of toxin ingested ($\mu g\ kg^{-1}$ body weight) is an essential value to take into account in order to estimate the risk of intoxication since the emesis-inducing dose in humans is currently not known.

Fatal Cases

Although the diarrheal and the emetic syndromes caused by *B. cereus s.s.* are generally mild, some serious outbreaks leading to fulminant death of healthy people have recently put *B. cereus* at the forefront of lethal foodborne pathogens.

Five emetic outbreaks leading to fatal outcome have occurred worldwide and most of them were related to the consumption of pasta or rice. The victims were young (below 20 years old) and the death occurred within hours. Outbreaks due to diarrheal syndromes are more frequently described in the literature but fatal cases are very rare. One fatal outbreak occurred in 1998 in a nursing home for elderly people in France. Forty-four people became ill following the ingestion of contaminated vegetable puree, which led to the death of three people. In Belgium, a fatal case occurred in 2002 in a nursing home. Seventeen people became ill after the ingestion of contaminated minced meat, eleven of them were hospitalized, and two of them died.

Concern about *B. cereus* foodborne outbreak is still largely underestimated despite several fatal cases in recent times. The implication of cereulide in lethal case involving the death of a healthy 20-year-old man has proven that emetic food poisoning could be very brutal and that it does affect other target groups than only children or elderly people.

Conclusion

The genus *Bacillus* contains a large variety of spore-forming species that are widely distributed in nature. With the advance in molecular sequencing, the genus has undergone a profound reclassification and several groups have been defined. Although the majority of *Bacillus* members are nonpathogenic, some of them can cause diseases in humans and animals. Within the *B. cereus* group, species such as *B. anthracis* and pathotypes of *B. cereus* are well known as being pathogenic for humans.

In view of the widespread prevalence of *B. cereus* spp., the presence of its spores in food is inevitable. The high resistance of these spores to adverse conditions ensures that the spores can survive food processing and generate new vegetative cells when returned to favorable conditions.

Besides sporulation, another major issue posed by the pathotypes of *B. cereus* for food safety is their ability to produce toxins. Dietary exposure to toxin-producing *B. cereus* strains leads to gastrointestinal illnesses in humans. The toxin production may occur in food matrices (preformed toxin) or in the human gut (*in vivo* produced toxins) leading to different types of diseases.

Although underestimated, the number of foodborne outbreaks due to this organism is not negligible. Moreover, several lethal cases have been clearly attributed to *B. cereus*. Next to gastrointestinal diseases, *B. cereus* can also cause various clinical conditions notably in sensitive populations like immunocompromised individuals.

Besides *B. cereus*, which is the most prevalent *Bacillus* food poisoning organism, other *Bacillus* species are also raising concern as regards food poisoning or clinical diseases. In contrast, nonpathogenic strains (e.g., *Bacillus toyonensis* and *Bacillus subtilis* subsp. *subtilis*) are currently used as probiotics underlining the high diversity that exist inside the genus *Bacillus*. However, and more than ever, the toxigenicity of *Bacillus* strains seems a crucial issue that should be thoroughly evaluated before using a strain for commercial purpose (Table 1).

Table 1 Representative *Bacillus* species potentially involved in foodborne toxi-infections

Bacillus *species*	*Potential toxins*	*Comments*
B. cereus	Diarrheic pathotypes: enterotoxins Emetic pathotypes: cereulide	Fatal cases reported Inhibition of boar spermatozoa motility (cereulide activity) Some isolates also involved in local and systemic infections
B. weihenstephanensis (*B. cereus* group)	Emetic strains: cereulide	Toxin production observed No food poisoning case reported yet
B. circulans	Cytotoxins	Toxin production observed, but no food poisoning case reported yet Some isolates also involved in local and systemic infections

Bacteriocins

TM Karpiński and AK Szkaradkiewicz, Poznań University of Medical Sciences, Poznań, Poland

Introduction

Bacteriocins are a heterogeneous group of bioactive bacterial peptides or proteins, ribosomally synthesized, displaying antimicrobial activity against other bacteria. Bacteriocins involve peptides or proteins of variable biochemical properties, molecular weight, mechanism of action, spectrum of activity, location, and sequence of amino acids. They manifest antimicrobial activity directed against the same bacterial strains that produced them or against strains of closely related species. Synthesis of bacteriocins takes place under control of genes located in plasmid or chromosomal DNA, which – in parallel – contain genetic determinants of producer's resistance to the produced bacteriocin. Genes that code active protein and genes coding resistance to the protein, genes responsible for export of bacteriocin from the cell, and, occasionally, genes coding for enzymes involved in posttranslational modification of bacteriocins undergo expression in parallel. Bacteriocins are produced both by Gram-positive (*Lactobacillus*, *Lactococcus*, *Streptococcus*, *Enterococcus*, *Leuconostoc*, *Pediococcus*, and *Propionibacterium*) and by Gram-negative bacteria (*Escherichia coli*, *Shigella*, *Serratia*, *Klebsiella*, and *Pseudomonas*). Until now, in the open-access database of BACTIBASE, more than 200 bacteriocins were described (January, 2014). Interest in bacteriocins reflects potential application of the metabolites and bacteriocin-forming microbes in medicine and as natural food conserving agents.

Classification of Bacteriocins

Bacteriocins of Gram-Positive Bacteria

Bacteriocins produced by Gram-positive bacteria were classified for the first time by Klaenhammer in 1993. Classification of bacteriocins undergoes continuous alterations, linked to studies on their structure, amino acid sequence, and recognized mechanism of their action. In this article, classification of bacteriocins was presented, taking into account several characteristics including their molecular weight, manifestation of the YGNGVXC motif, the presence of disulfide bridges, activity toward bacteria of *Listeria* genus, and sensitivity to temperature. The proposed scheme of classification of bacteriocins produced by Gram-positive and Gram-negative bacteria is presented in Figure 1.

Class I encompasses lantibiotics or thermostable peptides of molecular weight below 5 kDa. They undergo posttranslational modification. They contain atypical amino acids, such as lanthionine (Lan), methyllanthionine (MeLan), dehydroalanine (Dha), dehydrobutyrine (Dhb), and D-alanine (D-Ala). Lantibiotics were divided into two groups: lantibiotics of type A and of type B, manifesting distinct structural and functional properties. Type A encompasses linear peptides of a positive charge, acting by permeabilization of the cytoplasmic membrane in sensitive cells, while lantibiotics of type B include globular molecules, carrying negative charge or chargeless, of a variable manner of action. The best recognized bacteriocin of class I is nisin, produced by certain strains of *Lactococcus lactis*.

Class II nonlantibiotic bacteriocins, which in their composition contain no lanthionine, represent thermostable bacteriocins of molecular weight below 10 kDa. Both bacteriocins of class I and class II are secreted by ATP-binding cassette transporter proteins. Bacteriocins of class II are produced as prepeptides, which generally contain a leader sequence consisting of 14–30 amino acids, with a conserved processing site, and which do not undergo extensive posttranslational modification. Their spectrum of targets include Gram-positive bacteria with low content of G + C pairs, lactic acid bacteria (LAB), and bacteria of *Listeria*, *Clostridium*, or *Enterococcus* genera. Differences in structure of bacteriocins permitted to distinguish their four subclasses.

The subclass IIa includes pediocin-like bacteriocins with strong activity against bacteria of *Listeria* genus. They carry a hydrophilic cationic region with a conserved YGNGVXC motif and two cysteines linked by a disulfide bridge. They manifest high homology of sequence (38–80% identity of amino acid sequences), particularly in the N-terminal region of their molecules. On the other hand, the C-terminal region is more hydrophobic and differentiated.

The subclass of IIb encompasses dipeptide bacteriocins. They contain a single disulfide bridge, may contain the N-terminal sequence of YGNGVXC, or may be devoid of it. Their example involves lactococcin G from *Lactococcus lactis*, lactacin F from *Lactobacillus johnsonii*, and plantaricin F from *Lactobacillus plantarum*.

The subclass of IIc encompasses cyclic peptides, which possesses the N-terminal and C-terminal regions covalently linked. They contain a single disulfide bridge, but they carry no N-terminal sequence of YGNGVXC. Enterocin AS-48 is the prototype of this group.

The subclass of IId encompasses bacteriocins that are distinct in their structure, secretion mechanism, and manner of action from bacteriocins classified in subgroups of IIa–IIc. Their example involves enterocins L50 (EntL50A and EntL50B), produced by *Enterococcus faecium* L50. The subclass IId contains also bacteriocins activated by thiol groups, such as lactococcin B. In some classifications, subclass IId is rejected.

Class III includes bacteriocins of molecular weight above 30 kDa. They are thermolabile and they are produced mainly by Gram-positive bacteria. These bacteriocins can generally be subdivided into bacteriolysins (e.g., lysostaphin produced by *Staphylococcus aureus* and enterolysin A produced by *Enterococcus faecalis*) and nonlytic antimicrobial proteins (e.g., helveticin J, produced by *Lactobacillus helveticus*).

M., Szkaradkiewicz, A. K. (2013). Characteristic of bacteriocines and their application. *Polish Journal of Microbiology* 62(3), 223–235.

narrow than that of bacteriocins produced by Gram-positive bacteria. Principal characters of selected bacteriocins produced by Gram-negative bacteria are presented in **Table 1**.

The most extensive group is formed by colicins. They are synthesized by over half of *E. coli* strains and also by *Yersinia pestis* (pesticins) and *Serratia marcescens* (marcescins) and by bacteria of *Shigella* genus, *Klebsiella* (klebicins), and *Pseudomonas* (pyocins). Colicins represent large proteins, manifesting molecular weight of 25–80 kDa. As compared to bacteriocins of Gram-positive bacteria, colicins manifest several differences in organization of gene clusters and operons responsible for their synthesis. Also control of their biosynthesis is distinct. All of them are coded by ColE1 plasmids. They exhibit antimicrobial activity targeted at closely related bacterial strains, which carry colicin-binding receptor on cell surface and produce no resistance proteins, capable of inactivating colicins. Their antimicrobial activity involves the formation of ion channels in cell membrane, which results in depolarization of the membrane. Synthesis and export of colicins are lethal for the producer's cell and result in its lysis.

Microcins, the low-molecular-weight peptides, manifesting thermostability and a hydrophobic character, form a separate

class of bacteriocins produced by Gram-negative bacteria. Their activity is mainly directed against bacteria of closely related strains. Microcins are synthesized by *E. coli* bacteria and by a single strain of *Klebsiella pneumoniae*. In view of their mechanism of action and structure and due to genetic criteria, two classes of microcins are distinguished. The first class includes peptides of molecular weight <5 kDa, which undergo posttranslational modifications and which attack mainly intracellular structures. The other class encompasses peptides of molecular weight ranging between 7 and 10 kDa, which do not undergo posttranslational modifications and which lead to damage and destruction of cell membrane of target cells. In contrast to colicins, synthesis of microcins is not lethal for the producer.

Mechanisms of Bacteriocins Action

The mode of action of bacteriocins can be bactericidal or bacteriostatic, determining death or extension of log phase, respectively. At present, at least four types of antibacterial activity of bacteriocins are distinguished, including

- bactericidal activity due to the formation of pores in cell membrane,
- inhibition of cell wall components biosynthesis,
- effect on activity of autolytic enzymes,
- inhibition of bacterial spores' development.

Overview of the mode of action of bacteriocins is presented in Figure 3.

Most of bacteriocins exert a bactericidal effect on sensitive cells frequently inducing the formation of pores in cell membrane. Currently, a few hypothetical models of bacteriocins activity are known. The so-called wedge model is thought to be the most probable, formed on grounds of the sequence and type of interactions between the model lantibiotic, nisin, and the surface of cell membrane of target cells. The model takes into account characteristic properties of type A lantibiotics, first of all positive charge and elasticity of the peptide molecule. The first contact of bacteriocin with a sensitive cell takes place due to electrostatic interactions between a positively charged, hydrophobic bacteriocin molecule and negatively charged phospholipids in cytoplasmic membrane of a sensitive cell. Penetration of peptides in between the double phospholipid layer induces local destruction of the ordered bilayer structure. Nisin enters into reaction together with the membranous peptide glycate precursor, termed lipid II, representing an anchoring molecule and allowing to bind lantibiotics to cell membrane of sensitive bacteria. The mechanism of bacteriocins action involves formation in the cytoplasmic membrane of sensitive bacteria of a transient pore and ion channel complexes. This is accompanied by a passive outflow of small molecules, such as ions of potassium, magnesium, and phosphorus, amino acids, and ATP. In this manner, a disturbance develops in membrane potential and pH gradient and function of the proton pump becomes inhibited. The low level of ATP and ion deficit in the cell results in the inhibition of DNA, RNA, protein, and polysaccharide synthesis. This finally leads to death of the bacterial cell.

Bacteriocins belonging to class II permeabilize the membrane due to pore formation, using the carpet or the barrel stave mechanism. In the carpet model, individual peptides arrange in parallel to the membrane surface and interact with it with no aggregate formation. A temporary derangement of the membrane bilayer structure develops, which results in a local and transient perforation. In the barrel stave model, hydrophilic parts of amphipathic α-helical peptides form pores in the cell membrane. The outer hydrophobic parts of α-helices interact with chains of fatty acids that form phospholipids. In this binding, elements of mannose phosphotransferase (membrane receptors) play a mediating role. Such a type of interaction was demonstrated, that is, in class IIa bacteriocins of LAB. Lethal activity of the bacteriocins reflects a disturbed ionic equilibrium and loss of inorganic phosphates, escaping from the cells through the formed pores. Also, intracellular levels of ATP become drastically reduced, due to increased consumption of ATP, required for maintenance of electric potential, and due to inability to accumulate ATP due to leakage of phosphates from the cell.

In the case of bacteriocins belonging to IIb class, interactions, in line with the carpet model, demonstrate strongly ion-specific properties. Pores induced by lactococcin G are permeable for, that is, cations Na^+, K^+, and choline; those induced by plantaricin E/F are permeable for, that is, Na^+, K^+, H^+, and choline; and those induced by lactacin F are permeable for K^+ and phosphates. Cell death ensues in particular due to loss of potassium ions, accompanied by hydrolysis of ATP by ATPases. The peptides may independently bind to cell membrane, but for pore formation, a synergistic effect is required, resulting from the interaction of two complementary peptides of a dipeptide bacteriocin.

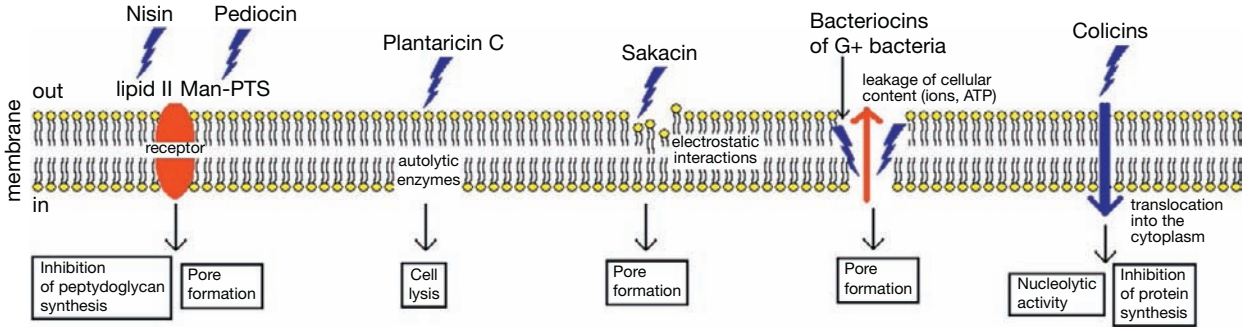

Figure 3 Overview of the mode of action of bacteriocins.

Another mechanism of bacteriocin activity involves their ability to induce lysis of bacterial cells. The process is linked to the interaction of bacteriocins with teichoic, lipoteichoic, and teichuronic acids, representing components of cell membrane. This results in a release and activation of autolytic enzymes, linked to the acids, which results in cell autolysis. Such an action takes place in the case of plantaricin C, produced by *Lactobacillus plantarum* LL441, which induces complete lysis of *L. delbrueckii* subsp. bulgaricus LMG 13551 strain cells. Bacteriocins belonging to lantibiotics class may additionally disturb processes of cell wall biosynthesis. They inhibit synthesis of peptidoglycan at the transglycosylation stage, which is not accompanied by a disturbed biosynthesis of DNA, RNA, or protein. The lantibiotic mersacidin inhibits peptidoglycan synthesis through a specific interaction with the peptidoglycan precursor, lipid II. The sequestering of lipid II prevents its utilization by the transpeptidase and transglycosylase enzymes that install the cross-linked network of the bacterial cell wall. Mersacidin appears to bind to a different portion of lipid II than vancomycin does, indicating that this bacteriocin may prove to have important chemotherapeutic applications.

The mechanism of cell-targeted activity manifested by bacteriocins produced by Gram-negative bacteria includes the depolarization of cell membranes (e.g., colicin E1), damage to DNA (e.g., colicin E2, acting as a nonspecific endonuclease), or inhibition of protein synthesis by inactivation of ribosomal RNA (colicin E3 and cloacin DF13). The bactericidal activity of colicins involves the formation of ion channels in the cytoplasmic membrane of sensitive cells, which leads to depolarization of the membrane also; in the cellular wall of the target bacteria, degradation of peptidoglycan or inhibition of its synthesis may take place. All colicins are coded in Col plasmids. The group of colicin genes consists of a gene coding the toxic protein, resistance-coding gene, and, in most of colicins, the gene coding for a protein facilitating colicin export from the cell and inducing lysis of the cell. Synthesis of colicins may be induced using UV rays or mitomycin C. Colicin E1 is coded by a set of genes representing 'colicin cassette' in ColE1 plasmid. The produced colicin is lethal for the host since its release to the environment results in cell lysis, for which product of *kil* gene is responsible. In normal conditions, the entire system is located in a plasmid in a repressed condition, which results from blocking of the principal promoter (Pcol) by the cellular protein of LexA. Cells, which at a given moment do not produce colicins even if they contain the ColE1 plasmid, are protected from action of exogenous colicin due to a function of *imm* gene product, while the related bacteria containing no such a plasmid become eliminated from the environment. All situations resulting in the destruction of the repressor (LexA protein) and, thus, inducing the cellular SOS system mobilize in parallel colicin production by the entire population of bacteria carrying the plasmid. In standard conditions, synthesis of colicins is switched off in majority of cells and becomes mobilized in stress conditions. In contrast to colicins, synthesis of microcins is not lethal for their producers and is not controlled by the SOS system. Microcins are secreted to medium in the late logarithmic phase of growth, except for microcin Mcc E492, which is produced in the early logarithmic phase.

Medical Application of Bacteriocins

At present, studies are ongoing on the application of bacteriocins in food industry and in medicine. Bacteria of the *Lactobacillus* genus, which produce bacteriocins, are frequently employed in probiotic preparations. The strains of *Lactobacillus* with confirmed probiotic properties belong to the species of *L. bulgaricus*, *L. acidophilus*, *L. casei*, *L. helveticus*, *L. lactis*, *L. salivarius*, and *L. plantarum*. The rods of *Lactobacillus* produce an unfavorable environment for pathogenic bacteria, producing pH-lowering compounds in the alimentary tract and inhibiting growth of the neighboring bacteria. The main duty of probiotic bacteria involves maintenance of microbiological equilibrium in alimentary tract through interactions with pathogenic bacteria. In addition, probiotic preparations manifest an antineoplastic activity.

Inhibiting growth of several pathogenic microbes, probiotic strains reduce incidence of traveler's diarrhea, alleviate the course, and shorten the duration of some bacterial and viral diarrheas (e.g., those induced by *Clostridium difficile*, *Shigella*, *Salmonella*, and enterotoxic strains of *Escherichia coli* or rotaviruses), prevent manifestation, or relieve course of post-antibiotic diarrheas.

To date, studies suggest that selected probiotics exert an antagonistic effect against *Helicobacter pylori*, may lead to their elimination, reduce representation, and/or alleviate inflammatory condition. The experiments indicate differences in antimicrobial effects of *Lactobacillus* genus bacteria. The strain of *L. acidophilus* LB proved to be more active against *H. pylori* than the strain of *L. acidophilus* GG, while the strain of *L. johnsonii* LA1 was found to be more active than the strain of *L. johnsonii* LA10. The bacteriocins with the strongest antibacterial activity against *H. pylori* strains are thought to include lacticins A164 and BH5, produced by *Lactococcus lactis* A164 and *L. lactis* BH5, and bacteriocins produced by *Lactobacillus johnsonii* LA1, *L. casei* YIT 9029, and *L. amylovorus* DCE 471. The studies point also to favorable effects of probiotics in various intestinal inflammatory conditions. It is suggested that just a decreased number of *Lactobacillus* and *Bifidobacterium bacilli* within the alimentary tract may lead to the development of such inflammatory conditions in the intestines.

At present, it is known that bacteria of *Lactobacillus* genus manifest also antagonistic effects toward periodontopathogens, such as *Aggregatibacter actinomycetemcomitans*, *Prevotella intermedia*, and *Porphyromonas gingivalis*. On the other hand, the presence of H_2O_2-producing strains of *Lactobacillus* in periodontal pockets prevents against the development of chronic periodontitis.

Probiotic strains of *Lactobacillus* genus manifest also high ability of adherence to cells of vaginal epithelium and of urinary pathways, forming a layer that exerts a protective effect against colonization by pathogenic microbes. Due to this ability, probiotics and strains of *Lactobacillus rhamnosus*, *L. fermentum*, *L. reuteri* and various species of *Bifidobacterium* in particular proved to be useful in prophylaxis and treatment of infections in urogenital tract.

Mersacidin has been shown to be very effective in treating systemic staphylococcal infections and in eliminating nasal carriage of *Staphylococcus aureus* in a mouse rhinitis model, whereas cinnamycin exerts an inhibitory effect on phospholipase A2,

the enzyme active in synthesis of prostaglandins and leukotrienes in the human immune system. Its action takes place by the sequestration of its substrate, phosphatidylethanolamine. Due to this activity, cinnamycin may prove to have a useful application as an anti-inflammatory and antiallergic drug.

Microcins produced by various *E. coli* strains play a significant role in preventing chicken infections with *Salmonella* bacteria since microcins are capable of inhibiting growth of pathogenic *Salmonella* strains. Colicins and microcins are also used in infections with *E. coli* O157:H7. Microcins and colicins manifest their activity against strains producing shiga toxin and also against other *E. coli* strains of serotype O. The use of colicin- and microcin-producing bacteria as probiotics may markedly reduce pathogen levels in cattle alimentary tract and in this way prevent against infection with pathogenic strains. Potential medical application of selected bacteriocins is presented in Table 2.

Application of Bacteriocins in Food Preservation

In recent years, high interest has been shown regarding the potential for extending food durability using compounds produced by microbes, including bacteriocins. The substances exhibit a number of attractive properties: They are tasteless, they manifest no odor or color, and they easily penetrate into structure of food products. In contrast to chemical preserving agents, they are fully safe for human body. However, before bacteriocins can play a role of biopreserving agents used at an industrial scale, detailed investigations have to be completed on the compounds and they have to be legally accepted as food supplements.

Three typical applications of bacteriocins for the biopreservation of food include

(1) the addition of purified bacteriocins to food products;
(2) the inoculation of a food product with LAB, which will manufacture bacteriocin in the product itself;
(3) the use of an ingredient in food processing that has been previously fermented with a bacteriocin-producing bacterial strains.

Since bacteriocins are isolated from foods such as meat and dairy products, which normally contain LAB, they have unknowingly been consumed for centuries. LAB include Gram-positive cocci and rods belonging to genera of *Lactobacillus*, *Lactococcus*, *Bifidobacterium*, *Streptococcus*, *Leuconostoc*, *Oenococcus*, *Pediococcus*, *Carnobacterium*, *Enterococcus*, *Tetragenococcus*, *Vagococcus*, *and Weissella*. LAB play a defining role in the preservation and microbial safety of fermented foods, thus promoting the microbial stability of the final products of fermentation. Protection of foods is due to the production of organic acids (e.g., lactic acid and acetic acid), carbon dioxide, ethanol, hydrogen peroxide, and diacetyl; antifungal compounds such as fatty acids and phenyllactic acid; bacteriocins; antibiotics such as reutericyclin; and aroma compounds. LAB are broadly used for the production of fermented food and

dairy products, such as milk, kefirs, yogurts, and cheeses, yielding a specific taste and aroma to the products. Considering the typical association of LAB with food fermentation and also long tradition as food-grade bacteria, LAB have been 'generally recognized as safe.' Due to production of bacteriocins, they protect food, exerting an inhibitory effect on other microorganisms, including pathogenic microbes.

In food preservation, also microcins and colicins can be used. Microcins produced by various strains of *E. coli* play a significant role in the prevention against infections with *Salmonella* in chicken. Moreover, *E. coli* cells are capable of surviving and produce microcins in condition of alimentary product deficits, in acidic environment, and in the presence of bile and proteolytic enzymes. Colicins and microcins can be used also in combating infections with the enterohemorrhagic strain of *E. coli* O157:H7, the reservoir of which includes cattle. The strain produces shiga toxin, particularly dangerous for children. In cases of this strain, antibiotic therapy induces an even more intense secretion of shiga toxin, in this way increasing bacterial virulence. Microcins and colicins manifest their activity against strains producing shiga toxin and against other *E. coli* strains of O serotype, linked with human diseases. Therefore, the addition of colicin- and microcin-producing bacterial cultures as probiotics may significantly reduce levels of pathogens in alimentary tract of the cattle and in this way may prevent against infections with strains pathogenic in humans.

Another significant pathogen that can contaminate food is *Listeria monocytogenes*. Activity against *L. monocytogenes* is manifested by, for example, *L. lactis* DPC4275 strain, producing lactacin 3147, used in the production of a mold cheese. The development of *L. monocytogenes* bacteria is effectively inhibited also by nisin in combination with other antibacterial substances, for example, with pediocin, or in combination with appropriate processing technologies.

Nisin is the most known and commercially used bacteriocin. It is produced by *Lactococcus lactis* and belongs to the group of lantibiotics A, manifesting an elongated shape and affecting sensitive cells by permeabilization of their cytoplasmic membrane. Its activity encompasses a wide range of strains, such as *Lactococcus*, *Enterococcus*, *Staphylococcus*, *Micrococcus*, *Pediococcus*, *Lactobacillus*, *Listeria*, and *Mycobacterium*, as well as spores and vegetative forms of *Bacillus* and *Clostridium*. Ingested nisin is inactivated by trypsin and pancreatin and will have no effect on the gut microflora. In the absence of other preservation methods, nisin does not inhibit Gram-negative bacteria, yeasts, or molds. Consequently, nisin is often used in combination with other synergistic preservation methods (known as hurdle technology), such as low pH and high salt concentrations. Nisin has a double mode of antimicrobial action, binding to lipid II and subsequent inhibition of cell wall synthesis and forming pores in the cytoplasmic membrane. Activity of lysine can be altered under effect of physiological conditions, such as pH, ionic strength, temperature, and growth phase of target cells. Upon exposure to nisin, sensitive cells manifested disturbances in synthesis of DNA, RNA, proteins, and polysaccharides.

Important considerations for the use of nisin as a food preservative are its solubility and stability. Nisin is most stable in acid conditions and is soluble in aqueous environments. A solubility of 12% at pH 2.5 has been reported, decreasing to 4% at pH 5.0. Solubility at neutral pH is very low. It was found to be completely stable on heating to 115.6 °C when the pH value was 2.0 but lost 40% of activity at pH 5.0 and more than 90% at pH 6.8. Large protein molecules, for example, milk proteins, provide a protective effect for nisin when heated. Nisin is insensitive to food pasteurization or tyndallization, which markedly increases sensitivity of bacterial spores to nisin action. As a preservation agent, it is used mainly in products such as the following:

- Maturing cheeses, in which nisin prevents against growth of spores produced by *Clostridium tyrobutyricum*.
- Milk, particularly due to prevention against growth of thermophile bacteria spores, which are able to survive a prolonged pasteurization.
- Canned food, in which lysine kills first of all spores formed by thermophile bacteria of *Bacillus stearothermophilus* and *Clostridium thermosaccharolyticum* species.
- Meat, in the case of which nisin allows to reduce contents of nitrates. In addition, the application of nisin in combination with other antibacterial agents, such as pediocin, or with appropriate processing technologies effectively inhibits the development of bacteria of *Listeria monocytogenes* species. Supplementation with nisin allows also to control processes of alcohol fermentation and to reduce infections with lactic fermentation bacteria, such as *Lactobacillus* and *Pediococcus*. Current application of nisin in food preservation is presented in **Table 3**.

Commercial nisin preparations are made by fermentation of enzymatically digested skimmed milk with added yeast extract by nisin-producing strains of *L. lactis* subsp. lactis. The fermentation is maintained at pH 6–7 by the addition of alkali. Synthesis of nisin starts in the early exponential phase of growth of the bacterium, reaches maximum toward the end of this phase, and ceases when entering the stationary phase. In order to achieve prolonged production, continuous cultures are used. The nisin is concentrated either by a foam extraction or by a membrane filtration process.

Nisin is approved for use in over 40 countries and has been in use as a food preservative for over 50 years. For many years, the most commercially available form of nisin for food preservative uses involved Nisaplin™ (Danisco, DuPont), which contains 2.5% nisin active ingredient, 77.5% NaCl (salt), and nonfat dry milk comprising 12% protein and 6% carbohydrate. Nisin (E 234) is authorized for food preservation in the European Union by Directive 95/2/EC on food additives other than colors and sweeteners. Nisin is currently permitted in semolina and tapioca puddings and similar products (3 mg kg^{-1}), ripened and processed cheese (12.5 mg kg^{-1}), and mascarpone cheese (10 mg kg^{-1}). Specifications for nisin are laid down in Directive 96/77/EC. Studies showed that nisin is safe for human consumption at an acceptable daily intake (ADI) of 2.9 mg/person/day. The panel on food additives, flavorings, processing aids, and materials in contact with food (AFC Panel) issued an opinion on 26 January 2006, on the use of nisin as a food additive, which confirmed the ADI of 0.13 mg kg^{-1} body weight established by the Scientific Committee on Food in 1990. The Joint Expert Committee on Food Additives of the UN Food and Agriculture Organization and the World Health Organization recommended daily intake limits of 60 mg of pure nisin for a 70 kg person. However,

Table 3 Current application of nisin in food preservation

Food type	*Typical target organisms*	*Level of nisin (mg kg^{-1} or mg l^{-1})*
Dairy products (milk and cheese)	*Clostridium* spp. *Bacillus* spp. *Listeria monocytogenes*	0.25–15
Meat (ham, pork, beef, and chicken)	*Salmonella* Typhimurium *Escherichia coli* O157:H7 *Brochothrix thermosphacta* *L. monocytogenes* Lactic acid bacteria	1–25
Seafood (fishes, crabs, and lobsters)	*L. monocytogenes* *C. botulinum*	1–25
Pasteurized soups	*B. cereus* *C. pasteurianum*	2.5–6.25
Canned foods	*C. botulinum* *C. thermosaccharolyticum*	2.5–5
Dipping sauces and salad dressings	Lactic acid bacteria	1.25–6.25
Beer, wine, alcohol	Lactic acid bacteria	0.25–37.5

Cleveland, J., Montville, T. J., Nes, I. F., Chikindas, M. L. (2001). Bacteriocins: safe, natural antimicrobials for food preservation. *International Journal of Food Microbiology* 71, 1–20; Delves-Broughton, J. (2005). Nisin as a food preservative. *Food Australia* 57 (12), 525–527; Jones, E., Salin, V., Williams, G. W. (2005). Nisin and the market for commercial bacteriocins. TAMRC Consumer and Product Research Report No. CP-01-05, July 2005.

there is no maximum limit to the use of nisin in processed cheese in Australia, France, or Great Britain. In the United States, the maximum dose limits for use are 200 mg kg^{-1} in canned and plant protein foods and 500 mg kg^{-1} in dairy and meat products; the more typical dose is 100–200 mg kg^{-1}. In Australia and New Zealand, nisin is allowed in cream products at a maximum of 10 mg kg^{-1}; in crumpets, flapjacks, and pikelets (hot plate flour products) at a maximum of 250 mg kg^{-1}; and in cheese and cheese products, dairy desserts, oil emulsions (<80% oil), tomato products, liquid egg products, beer and related products, dips, sauces, mayonnaises, and salad dressings at levels compliant with good manufacturing practice.

Aside from nisin, technological significance is manifested also by pediocin, bavarian, piscicolin, jensenin, curvaticin, lacticin, and sacacin. It is regarded safe to use in food products of bacteriocins synthesized by strains of lactic fermentation bacteria such as *Lactococcus* sp., *Lactobacillus* sp., *Pediococcus* sp., *Carnobacterium* sp., and *Leuconostoc* sp. An increasingly significant commercial importance is manifested also by another bacteriocin, pediocin PA-1, which can be purchased for use as food additive as 'ALTA 2341.'

Numerous studies are devoted also toward the application of bacteriocins as antibacterial agents in food packs. A nisin-coated low-density polyethylene foil was found to inhibit growth of *Micrococcus luteus* ATTC 1240 in raw and pasteurized milk, while cellulose and polyethylene–polyamide bags containing nisin and lacticin 3147 were found to reduce the development of LAB, *Listeria innocua* and *Staphylococcus aureus* in sliced cheese and ham. The studies involved also food packs based on paper, cardboard, and edible covers.

Conclusions

Bacteriocins as peptides of antibacterial properties manifest high significance for preservation of homeostasis between bacteria. They find application in food industry and in medicine. Bacteriocins produced by LAB have been recognized to be fully safe for humans. Nisin is commercially the most important bacteriocin used in food preservation. At present, bacteriocins and probiotic preparations provide an alternative for antibiotics, used as a supplementation in human food and animal feeding.

Introduction

Among the tropical fruit crops that are consumed at large, bananas and plantains stand foremost not only because of the quantity produced but also in terms of serving the calorific needs of millions of people especially across Africa and Asia. The term 'bananas' is used to broadly denote the dessert forms and certain cooking types, while 'plantains' represent a group of starchy bananas that are often cooked, fried, or processed. Besides fruits, every other part of the plant has been known to possess commercial or medicinal value, and hence in Sanskrit language, it is described as 'Kalpatharu' meaning 'virtuous plant.' In India, it not only is a food crop but also is completely associated and forms a part in many religious functions and social ceremonies.

Origin and Domestication

Bananas and plantains have originated mainly from Southeast Asian regions with predominant diversity spread across Malaysia, Indonesia, and India and with secondary centers of diversity in West and Central Africa (plantain subgroup) and the highlands (Lujugira subgroup) of East Africa. Archaeological and phytolithic evidences suggest early domestication of wild *Musa* sp. probably for its fibers in Papua New Guinea about 7000 years ago. Over the past several millennia, anthropic migrations, natural mutations, and human selection have favored the banana to be one of the most cultivated and favored fruits across the tropics and subtropics of the world.

Domesticated over thousands of years, most of the present-day seedless (parthenocarpic) cultivated edible forms have arisen because of the contribution from two major wild progenitor diploid seeded species *Musa acuminata* and *Musa balbisiana* that provided the A and B genomes. Cultivar names are often described to denote the ploidy and genomic status. For example, *Musa* 'French plantain' AAB indicates that it is a triploid with a double genomic constitution from *Musa acuminata* and one set of genomic contribution from *M. balbisiana*. Recent cytological techniques, viz., genomic *in situ* hybridization and fluorescence *in situ* hybridization coupled with molecular markers, and quantification of nuclear DNA content using flow cytometry, have paved the way for establishing the ploidy status, parental lineage, and genomic nature of varieties with a high degree of certainty. Recent molecular findings also suggest the contribution of *Musa schizocarpa* (S genome) and *Musa textilis* (T genome) in the evolution of certain varieties.

Botany

Botanically, the bananas belong to the monocotyledonous family Musaceae (Zingiberales) under the revised section *Musa* and with the genus *Musa* consisting 33 species, while some more are believed yet to be discovered from wild forest regions spread across continental Asia. The plants are tall and herbaceous, and the true banana stem is an underground 'corm' from which the leaves are pushed up and the basal leaf sheaths encircle one over the other to form the aboveground 'pseudostem.' The leaves are simple, large, and arranged in circular phyllotaxy. The inflorescence shoots up through the central channel of the pseudostem. The root system is adventitious arising from the corm, and most of the roots are present within a depth of 45 cm beneath the soil. The inflorescence is borne on a long peduncled complex spadix shooting through the pseudostem at the terminal region having an overlapping spathe or bracts in succession, each of which subtends biseriately arranged cymose flower cluster. With the onset of anthesis, the bract subtending the flowers lifts up exposing the flowers. The flowers are zygomorphic, morphologically bisexual, but functionally unisexual, with the basal series functioning as female followed by neuter flowers and the distal ones or terminal portion bearing male forms. Perianth is made of six tepals of which one inner tepal is free while the others connate together. Androecium is made of five fertile stamens and a staminode positioned opposite the free tepal. The gynoecium consists of a single-compound pistil of three carpels, a single style, and an inferior ovary with three locules, with ovules in axile placentation. Abortion of ovules occurs commonly in cultivated varieties during fruit development leading to parthenocarpy. The fruit is a berry, with exocarp (peel) that loosens away from the flesh upon ripening.

Cultivars

Majority of the cultivated varieties are triploids while some are diploids (e.g., 'Ney Poovan' (AB), 'Matti' (AA), and 'Surya Kadali' (AA)). Several synthetically bred tetraploids (e.g., FHIA varieties) are also presently cultivated but in a very limited scale. While there are thousands of varieties available, not all of them are commercially exploited for catering to the larger market or export trade, but are still nurtured in backyards and tribal villages for their distinct appeal, taste, or potential food and nonfood or medicinal uses in many parts of Asia and Africa. Regional preferences and adaptability determine the varieties that are commercially exploited, and hence, 'polyclonal' system of cultivation is prevalent in many parts of Asia, as against the monoculture of Cavendish or plantain cultivars exclusively as plantations in many nations for export trade and domestic consumption. Some of the important cultivars commercially grown are listed in Table 1.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00054-4

Table 1 Major cultivars of banana and plantains

Cultivar groups and genomic status	*Usage and regions of cultivation*
'Pisang Mas' ('Sucrier'), 'Pisang Ambon Putih' (AA genome)	Mainly for dessert Malaysia, Indonesia
'Ney Poovan' and 'Kunnan' (AB genome)	Dessert India
'Cavendish' subgroup (AAA genome)	Dessert: 'Giant Cavendish' ('Mons Mori'), 'Dwarf Cavendish,' 'Williams' and 'Grand Naine,' 'Robusta,' 'Poyo,' 'Lacatan' In many countries
Red group (AAA genome)	'Red Banana,' 'Green Red'
East African Highland banana (AAA genome)	Cooking and beer: 'Lujugira' Acidic dessert: 'Yangambi Km 5'
'Gros Michel subgroup' (AAA genome)	Dessert: 'Gros Michel,' 'Highgate,' and 'Cocos' (both mutants of 'Gros Michel') In many countries
'Iholena' subgroup (AAB genome)	Cooking Pacific region
'Maoli-Popoulu' subgroup (AAB genome)	Cooking Pacific
'Mysore' subgroup (AAB genome)	Dessert: 'Mysore' ('Poovan') India, Malaysia, Thailand, Indonesia
Plantain subgroup (AAB genome)	Dessert, cooking, processing: 'French plantain'('Nendran'), 'Horn plantain,' 'False Horn plantain' Predominantly in Africa, in India, and in many other countries
'Pome' subgroup (AAB genome)	Dessert: Hill banana, 'Lady Finger,' 'Prata Ana,' South America, Asia, Australia
Silk subgroup (AAB genome)	Dessert: 'Rasthali,' 'Martaman' India, Bangladesh, South America, Asia, Australia
'Pisang Awak' (ABB genome)	Dessert: 'Karpooravalli' Malaysia, Indonesia, India
'Bluggoe' (ABB genome)	Cooking: 'Monthan', 'Ashy Monthan' Malaysia, Indonesia, India, and other Southeast Asian regions
'Saba' (ABB genome)	Cooking

Table 2 Status of banana production across the world

Geographic region	*Area (ha)*	*Production (tons)*
Africa	1 493 224	15 863 068
America	1 223 055	27 111 707
Asia	2 130 692	57 094 628
Europe	10 465	399 940
Oceania	95 879	1 523 400
Total	4 953 315	101 992 743

Source: FAOSTAT 2014: http://faostat3.fao.org/browse/Q/QC/E

Status of Production

During 2012, according to the estimates of Food and Agriculture Organization, banana cultivation was spread in more than 130 countries across the world in about 4.95 million ha with an overall production of 101.99 million metric tons. More than 50% of the production areas are in India, Brazil, the Philippines, the United Republic of Tanzania, and China. About 60% of African production occurs in Uganda and its neighboring countries, viz., Tanzania, Cameroon, Rwanda, Kenya, Côte d'Ivoire, Congo, and Burundi. The distribution of banana production across the different geographic regions is furnished in Table 2.

Nearly 84% of the global produce is utilized for domestic consumption, and the volume of global gross banana exports is estimated to be 16.5 million tons in 2012. Latin America and the Caribbean countries apart from Ecuador accounted for nearly 79% of the total exports. The contribution from Asia was about 17% with major contribution from the Philippines, while Africa contributed to about 3.66% of the global exports. The major countries that export bananas are Costa Rica, Ecuador, Mexico, Columbia, Honduras, Côte d'Ivoire, Cameroon, and the Philippines. The major importers are the United States (27%), the European Union (27%), Russia (8%), and Japan (7%).

Consumption and Economic Uses

Bananas and plantains are ideally suited for many systems of cultivation, be it large extensive corporate farms covering thousands of hectares or small holder farms with resource poor owners or as a backyard crop in urban settings and are part of many intercropping systems. In many mixed farming systems and multitier system of cultivation, bananas are grown along with coffee, pepper, and oranges in parts of India providing necessary shade to the crops and additional income to the growers.

While dessert bananas are sweet tasting and eaten raw, plantains and cooking banana pulp are boiled, fried, boiled and pounded, roasted, and consumed with cereals, other vegetables, and miscellaneous food complements in many West and Central African countries. Plantains are a major part of their diet for more than 70 million people in West and Central Africa, providing each with at least 200 cal a day. In Uganda, Burundi, and Rwanda, banana per capita

consumption is estimated to be as high as 250–400 kg per year. There is also a specialty group of bananas called as 'beer bananas' from which the juice extracted from the ripe fruits is fermented to produce low-alcoholic drinks in parts of Africa.

Similarly, in parts of Asia, several starchy cooking bananas (ABB) apart from plantains serve as complimenting culinary delight to meals after boiling or roasting. Some of the varieties conserved by tribal groups of Western Ghats of India and northeastern states serve as energetic weaning food. 'Matooke,' an East African Highland cooking banana, is known for staple food preparation by the people in the Great Lakes region especially Uganda. They are harvested from three-quarters to full maturity, peeled, and boiled or steamed in banana leaves for consumption. Banana flour and powder made from green mature bananas are often added as ingredient in bread preparation, in pastries, or as thickening of sauces and soups.

Nutritional Constituents, Bioavailability, and Health Benefits

As an easily available and consumable form, banana fruits are appreciated for their high calorific and mineral contents. The nutritional information from USDA database representing a medium-sized banana is furnished in Table 3.

Carbohydrates and Calorific Value

Bananas and plantains are rich in carbohydrate and poor in fat content and hence widely consumed as low-fat diets. Processed bananas such as chips roasted in edible oil enhance its acceptance and energy value. The large amounts of starch present in the unripe fruits are converted to sugars upon ripening and contribute to the sweetness. The carbohydrates are made of predominantly glucose, fructose, and sucrose. There are also a portion of carbohydrates, which are known as resistant starch and nonstarch polysaccharides, which have low glycemic index or low digestibility.

Table 3 Proximate composition of banana fruit (100 g)

Contents	*Availability*
Water	74.91 g
Energy	89 kcal
Protein	1.09 g
Total fat	0.33 g
Carbohydrate	22.84 g
Total dietary fiber	2.60 g

Proteins and Fats

Bananas are rich neither in proteins nor in fats as evidenced by their very constitutive presence. While there is a slight increase in protein concentration from unripe to ripe stage, the levels of lipids remain almost constant during ripening. The lipid present in the peel is rich in polyunsaturated fatty acids, particularly linoleic acid and linolenic acid. Protein bioavailability is limited in raw 'matooke,' and hence, cooked and extruded matooke flours are suggested to enhance energy efficiency and, for serving with proteinaceous food, to improve the nutritional needs of malnourished children.

Vitamins

The pulp is rich in vitamins A, B, and C. Dopamine and vitamin C contents in bananas act as antioxidants. Among the vitamins, the presence of high amounts of carotenes in Melanesian cultivars is noteworthy (0.20–28 nmol g^{-1} banana). 'Uht en Yap' has been reported to contain 6110 μg of α-carotene/100 g, as compared to 26 μg in Cavendish. Some of the Micronesian varieties having high carotene have the potential to serve as genetic resources for future breeding efforts to improve nutritional qualities of banana. Considerable amounts of the resistant starch present in bananas may limit the bioavailability of carotenoids, but studies have revealed that thermal processing improves the retinol bioefficacy of bananas. The lutein content (carotenoid) levels are more in ripened fruit and lutein helps as an antioxidant. The orange yellow or orange pulp color may serve as an indicator for carotene content.

Minerals

Bananas are known for its high potassium content in the pulp. Besides magnesium, calcium, and phosphorus are also present. Ripe fruits of *Musa* 'Bhimkol' occurring in northeastern India could meet 100% RDA of potassium, zinc, manganese, and selenium and several essential amino acids with 100 g of fresh pulp for a six-month-old infant.

Organic Acids

Citric, malic, and oxalic acids are the major organic acids in banana, and their levels normally increase during ripening. Ascorbic acid, β-carotene, citric acid, and malic acid present in ripe fruits may contribute to the flavor of banana-based fruit juices and other finished products.

Flavonoids and Other Bioactive Compounds

Several bioactive amines such as dopamine, noradrenaline, octopamine, histamine, 2-phenylethylamine, and tyramine have been reported in banana. The pulp of banana also contains many flavonoids. Leucocyanidin present in unripe banana has shown protective effect against aspirin-induced erosions. Gallocatechin, epicatechin, and condensed tannins present in banana pulp albeit in trace quantities may serve as antioxidants. Flavonoids extracted from unripe fruits have been attributed with significant hypolipidemic activities.

Health Benefits of Banana

The information on beneficial aspects on health by bananas and plantains is provided here to briefly narrate the tested and attributed benefits of banana and its products. Bananas are the cheapest and easily consumable source of carbohydrates, minerals, and vitamins and known to boost health in many ways. Bananas can serve the dietary needs substantially at any life stage, be it young active children or toddlers, young adults, adults, pregnant mothers, lactating mothers, middle-aged population, or the very aged people. Almost all of the parts of the banana plant are known to influence health. The potential of bananas as emollient, demulcent, and antiscorbutic has been known for long. The fruits, peel, leaves, roots, and pseudostem of banana have been also described to have antiulcerogenic, antioxidant, antimicrobial, antidiabetic, antihyperglycemic, and hypoglycemic properties.

Reduction on serum glucose levels, improved insulin secretion and glycogen storage, and inhibition of enzyme activity related to glucose absorption have been experimentally proved to corroborate the beneficial effects on the regulation of glucose homeostasis by banana leaves. Flowers are astringent and are used in dysentery, menorrhagia, and diabetes; green bananas are antidiarrheal and used as a curative for intestinal disorders. Root is antibilious and anthelmintic in folk medicines; young leaves are used to cover burns on the skin as cool compress; the astringent ashes of the unripe peel and of the leaves have antidiarrheal and antidysenteric properties. Banana stem is employed as diuretic and helps detoxify the body. It is commonly cooked and eaten to prevent or treat kidney stones possibly by regulating calcium uptake by the presence of potassium. Stem juice of fruited plant is used for treating diarrhea, dysentery, cholera, otalgia, and hemoptysis. The plant is also used in inflammation, pain, and snakebite.

The high calorific value of the fruit and the mineral nutrients make it a favorite fruit among sports personnel especially athletes and tennis players to maintain fluid balance and avoid muscle cramps. The low-salt content and high potassium presence help to avoid high blood pressure and improve the function of the heart muscles. Banana-based energizing drinks and dried banana bars for athletes are now available in the market.

Consumption of fresh banana helps to neutralize excessive acidity in the stomach and is a boon for ulcer patients. Vitamin B_6 present in banana influences the production of neurotransmitters including serotonin and the production of hemoglobin and insulin. Serotonin is implicated with mood elevation and a general sense of well-being. It also helps decrease homocystine (a causative factor in coronary artery disease and stroke episodes) levels within the body. Banana contains small quantities of sitosterol, campesterol, and stigmasterol, which are structurally similar to cholesterol and hence block the absorption of dietary cholesterol and reduce blood cholesterol levels. Further, along with ascorbic acid, it also serves to boost general immunity. The high pectin content in the fruit may help to absorb more water and assist in bowel movement. Apart from apples and oranges, banana fruits have been ascribed to have the potential to protect neurons against oxidative stress-induced neurotoxicity and in combating onset of neurodegenerative Alzheimer's disease.

Banana flour made from green bananas is an attractive alternative to wheat flour especially for those who suffer from celiac disease. Green banana flour is rich in type 2 residual starch, which is not digested in the small intestine but is acted upon by bacteria in the colon resulting in the breakdown of products into short-chain fatty acids and contributing to lowering colon inflammation and factors associated with colon cancer. The dietary fiber present in banana could favorably affect the intestinal health by contributing to increased fecal bulk, shortened colonic transit time, changes in the composition of the gut microbial population, lowered gastrointestinal pH, and changed bile acid profiles. In a recent study taken up at the University of Michigan Medical School, a type of lectin isolated from banana known as BanLec has been reported to be potentially active against HIV by binding naturally to the sugar-rich envelope that encases the HIV virus and blocking its entry into the body.

Allergy to Banana

A very low fraction of the population has been diagnosed with allergic reactions to banana. The allergic symptoms, such as stomach cramps, diarrhea, vomiting, runny nose, watery eyes, headaches, itching, sneezing, and wheezing, are displayed. Individuals allergic to chitinase also are very often reported to be allergic to bananas. The banana allergy is known to be a part of the latex-fruit allergy syndrome. Hypersensitivity to bananas is considered a type 1 allergy with very quick reaction within minutes after exposure to specific allergen. In severe allergic reaction, it may lead to anaphylaxis. Consumption of bananas is also not advisable with alcohol as it may aggravate migraine headache.

Cultivation Aspects

Bananas and plantains are vegetatively propagated from corms with a portion of the stem of the side suckers having sword-shaped narrow leaves. Large-scale production of Cavendish and to a certain extent plantains is now facilitated by tissue culture plants initiated from virus- and disease-free high-yielding mother plants. The plantation density generally varies between 1500 and 2500 plants/ha, and in certain intensive systems, even up to 5000 plants/ha are accommodated. Banana requires more of nitrogen and potassium than phosphorus apart from micronutrients. The dosage rates may vary depending on the cultivar and location. Fertilizer application is carried out in such a way to replenish the soil nutrient levels removed during the growth and to optimally maintain the

physiological health of the plant. Critical leaf nutrient norms for different varieties in different locations are available. The critical content range for leaf N may vary from 1.67% to 3.43%, phosphorus from 0.12% to 0.20%, potassium from 2.20 to 4.40, calcium from 0.40 to 1.40, and magnesium from 0.3% to 0.6%. Irrigation levels are decided by soil water potential and evapotranspiration rates. Drip fertigation systems are advantageously adopted in banana production systems to schedule the nutrient and water requirements depending on the crop stage so as to maximize yield and quality of the produce. Rain-fed production system is in vogue where the rainfall is well distributed throughout the year.

Bananas are also grown in green houses in Israel, Turkey, Morocco, and the Canary Islands. 'Grand Naine' and 'Dwarf Cavendish' are largely grown inside green houses. Periodical leaf removal is necessary to overcome excessive shade in green houses. Removal of side suckers until the plant shoots the inflorescence, periodical removal of dried leaf sheath, and removal of a portion of the inflorescence after last hand opening on the inflorescence are common practices followed. As banana plants are easily prone to wind injury, propping using bamboo or casuarina poles or by providing support with polyester or nylon ropes is important to avoid lodging. Periodical earthing up and weed management during the early phase of the crop until canopy coverage and mulching along the interspaces ensure efficient nutrient and water utilization. Bunch covering using polythene or polypropylene sleeves with 2–4% ventilation is regularly employed to protect the developing banana fingers against cold, bruise injury, and insect damage so as to obtain 'blemishless' fruits.

Under ideal growing and disease-free conditions, banana plantations are ratooned by allowing one of the suckers to follow the main plant for yielding and six to eight crop cycles are possible in such commercial plantings and with spatial arrangements that facilitate mechanization. However, the incidence of fusarium wilt or nematodes may force the grower to plant only a single cycle of crop production. Several pests and diseases affect banana production. Among the diseases, black leaf streak disease or black sigatoka (*Mycosphaerella fijiensis*), yellow sigatoka (*M. musicola*), fusarium wilt (*Fusarium oxysporum* f.sp. *cubense*), bacterial head rot (*Erwinia carotovora*), bacterial wilt (*Xanthomonas campestris*), Moko wilt (*Ralstonia solanacearum*), and viral diseases such as banana bunchy top virus (BBTV), banana streak virus, banana bract mosaic virus, and infectious chlorosis caused by cucumber mosaic virus are important and require timely attention. Among the major pests of banana, corm weevil (*Cosmopolites sordidus*), pseudostem borer (*Odoiporus longicollis*), and banana Aphid (*Pentalonia nigronervosa*) – a known vector for the transmission of the dreaded BBTV – pose threat to banana production. Different nematodes such as burrowing nematode (*Radopholus similis*), root lesion nematode (*Pratylenchus coffeae*), root-knot nematode (*Meloidogyne incognita*), and spiral nematode (*Helicotylenchus multicinctus*) can cause considerable yield loss if not properly managed.

Integrated production practices involving the use of organics; the addition of biofertilizers such as arbuscular mycorrhizae, *Azotobacter*, phosphobacteria, and biocontrol agents such as *Pseudomonas fluorescens*; crop rotations; cover cropping with legumes and sun hemp; and the use of nematode deterrent crops such as marigold and coriander are all currently recommended to maintain soil and plant health status. Organic production of bananas are followed by adopting internationally acceptable compliant norms with due certification from organizations authorized in each country. Bunches are harvested at 70–75% maturity (three-quarters round stage of fingers) for export market and at 85–90% maturity (near-round stage) for local trade. Under proper cultural conditions, a yield level of 80–100 t ha^{-1} from 'Grand Naine' is achievable. Productivity of cooking bananas and plantain may range between 40 and 60 t ha^{-1}.

Banana Processing and Processed Products

Although the majority of the produce is consumed fresh, the scope for processing of bananas and plantains is huge especially to reduce the postharvest losses or to meet the export standards when the produce fails. The extent of postharvest losses is reported to be in the tune of 30–40% in different countries. Several preharvest factors such as nutrient deficiencies and incidence of diseases like black and yellow Sigatoka in the main field (*Mycosphaerella* sp.) and postharvest factors such as improper harvesting methods, poor handling, packaging and transport methods, storage temperature and anthracnose incidence during storage, poor marketing facilities, unorganized marketing structure, and lack of market intelligence contribute to severe postharvest losses. Given the total volume of 101.99 million tons of production across the globe at present, even if a moderate postharvest loss of 15% is considered, then the postharvest losses accounts to nearly 15.3 million tons, which is nearly equal to the volume of bananas produced by the African countries. Processing methods offer the scope for waste reduction and waste utilization.

There are several processed banana products that are being consumed and traded all over the world. Apart from traditional uses for food preparation in parts of Asia and Africa, banana 'figs' produced by sun-drying of ripe bananas, banana powder, banana puree or mashed bananas, banana flakes or chips or crisp fries with edible oils, banana-based alcoholic and non-alcoholic beverages, etc., are some of the food products processed from bananas. There is a growing demand for processed and semiprocessed food, and even the large banana exporters have now diversified into this growing market. The guidelines and procedures used for processing of bananas are outlined here. The quality and outcome of the product so processed depend on the raw produce and varieties involved and may require adjustment of processing parameters.

Banana Chips or Banana Crisps

Banana chips or crisps are processed primarily from plantains. It is also possible to utilize the cooking-type cultivars, viz., 'Bluggoe' ('Saba' and 'Monthan'). In Cameroon, 'Popoulo', 'Pelipita', and plantains, viz., 'French Clair', 'Bâtard', and 'Big Ebanga', are used for the preparation of crisps. Banana chips could play an important role in intervention programs to combat micronutrient deficiencies by virtue of their iron, zinc, and total carotenoid contents.

The process generally includes deep-frying of thin raw banana slices of about 1–2 mm thickness in suitable cooking medium and salting them. Slicing can be done so as to have required shapes such as wholes, quarters, long cut or slivers, and fine

brokens. Blanching of bananas prior to cooking at a temperature range of 65–70 °C for 20–25 min before peeling, slicing, and frying can help to obtain crispier banana chips. The maturity stage is important to obtain properly processed banana crisps as browning occurs if the sugar content is higher in the pulp.

The fruits are harvested at unripe but optimal maturity stage for frying. In many parts of India, coconut oil is the most preferred medium, while in other countries, cottonseed oil or corn oil is used. Palm oil is also used for the preparation of banana crisps, but it has been reported that trans-esterified palm stearin and palm kernel olein (1:1 by weight) blend was highly susceptible to oxidative deterioration during deep-fat frying. Sweetened banana crisps with sugar or honey coatings by osmotic dehydration, spice powder coatings along with mint, and tomato flavorings are other forms of banana crisps that have market value.

Machineries are now available for mechanical slicing of fingers in large volumes for industrial processing. A frying temperature of about 160–170 °C for about 3–3½ min with proper shaking of cooking medium to disperse the heat evenly to the slices is recommended depending on the cultivars. Deep-fat frying at about 180 °C for a shorter time is more effective in preserving carotenoids, ascorbic acid, and potassium content in fruits than extended frying at low temperature. The fried banana chips are then air-dried at room temperature (27–29 °C) or cabinet-dried (60 °C).

Hydrocolloid treatment with 1% pectin has been found to reduce the oil absorption during processing and hence recommended for the preparation of low-fat crisps. High-temperature and high-sugar content in the slice can result in browning by caramelization. The addition of antioxidants like propylene glycol, propyl gallate, and citric acid has been recommended for reducing the rancidity during storage.

The processed crisps can be packed in polythene pouches or aluminum foils. Moisture-resistant laminated aluminum foil packaging is more preferable than polypropylene or polythene packaging as it preserves the crispiness of chips better with low rancid odor over time.

Crisp banana chips can also be produced by using a combination of foaming of banana puree and drying temperature of 80 °C at superficial air velocity of 0.5 m s^{-1}. Foaming agents such as egg albumin and a modified soybean protein and soy protein isolate have been tried.

Banana Flakes

Banana flakes are made by feeding the puree directly to the large chrome-plated drum dryers. As the drum turns, with water evaporation, a film of dried material gets formed on the drum surface. The dry film is then removed as a continuous sheet by employing carefully adjusted knives and transported to an air-conditioned room where it is broken into flakes, sifted, and packaged in bag-in-box containers.

Banana Puree

Banana puree is the processed pulp obtained after peeling and is used in baking, dairy, beverages, mixed fruit smoothie, and baby food products. For industrial processing, after harvesting at optimal maturity, the fruits are graded, are taken to ripening chambers, and are artificially ripened. The fruits are then spray-washed and cleaned, peeled, and fed into a hopper and pump system that forces the fruit pulp through a plate with ¼ inch holes and duplex filter into a vacuum deaerator where removal of air helps prevent discoloration of the pulp. To improve the viscosity of puree, mixtures of pure enzymes such as pectinase, cellulase, and hemicellulase can be added. Acidification of pulp with ascorbic acid or citric acid can reduce enzymatic browning. The puree was then pumped through a series of rotators (scrape heat exchangers) for flash pasteurization (71.5–74 °C for 15–30 s) and immediately cooled. The sterilized puree is then packed aseptically into steam-sterilized can or fiberboard cartons, each lined with a laminated plastic bag under high-pressure steam atmosphere. The processed puree has a storage life of 12–15 months.

Frozen banana pulp can also be obtained by extrusion process after rapid heating the pulp quickly to 120 °C and cooling to 2–3 °C, filling, and quick freezing (−20 °C). Pretreatments of plantain by blanching in hot water, steam, microwave treatment, or calcium chloride modifies the texture and the organoleptic characteristics. Calcium chloride and microwave pretreatments have been found to harden the frozen banana pulp.

Banana Powder

Banana powder is used chiefly in the baking industry for the preparation and fillings for cakes and biscuits. Banana flour, from both green and ripe fruits, enriched with sugar, powdered milk, minerals, and vitamins, is widely used in baby foods. Banana powder contains considerable amounts of resistant starch type 2 (RS2 16–18%), which is not digested by amylase and thereby can help to reduce glucose availability to the bloodstream in diabetics. Besides, the products of the *in vitro* fermentation of RS2 have been known to have the capability to inhibit the initiation and promotion stage in colon carcinogenesis.

For small-scale processing into flour, unripe green bananas (cooking banana or plantain) are peeled, sliced, and chopped into pieces about 5–10 mm thickness and dried by spreading them on a surface of mats or cement floors for drying. The slices can be also placed in a 0.2% solution of sodium metabisulfite (w/v) for about 5 min to prevent browning and then dried in an electrical drier at 60 °C for about 12 h. The dried slices are stored and converted to flour only when needed as the hygroscopic flour tends to absorb moisture and rapidly lose its flavor.

Dark-colored, gelatinized flour resulted when the temperature is raised above 75 °C, as a result of reaction between reducing sugars and amino acids. Changes in particle properties (moisture content and particle size) and storage conditions may influence the flowability of the powder.

Solar driers, industrial-scale cabinet driers, or tunnel are used for processing large volumes. A typical spray dryer can produce 70 kg powder per hour to give yields of 8–11% of the fresh fruit, while drum-drying gives a final yield of about 13% of the fresh fruit. In the latter method, the moisture content is reduced to 8–12% and then further decreased to 2% by drying in a tunnel or cabinet dryer at 60 °C.

Foam mat-drying method is done by foaming fresh banana pulp with the addition of soy protein (10 g/100 g) to induce foaming. A 1% or 2% sodium metabisulfite solution is added to improve the color of the final product. The puree can be

whipped for 12–15 min and the foam mats can be quick-dried using cross flow cabinet driers or by forced air circulation. The dried brittle slices or foam mats are then pounded to produce the banana flour.

Freeze-dried banana powder has been reported to retain maximum 3-methylbutanoic acid 3-methylbutyl ester, 3-methylbutyl acetate, and butanoic acid 3-methylbutyl ester that are responsible for the fruity aroma eugenol and elemicin that give the product its typical mellow aromas, as compared to vacuum-belt and air-drying.

Banana Juice

The pulpy nature of banana does not enable juice production simply by means of pressing the juicy fruits such as oranges. Clear juice (75–80% of pulp weight and a TSS content of 23–26° Brix depending on the variety) can be extracted by mechanical press and through pectolytic enzyme clarification. Pretreatment with cellulase 0.06% and pectinase 0.05% at 45 °C for 2 h resulted in 73% clear juice yield. High-tannin contents, polyphenol, and phenols and peroxidase activities cause browning of juice during processing. The clarified juice could be dispensed into cordials ready-to-serve and blended beverages by adjusting TSS to 18–20° Brix and acidity to 0.3% with sugar, citric acid, and water. After chilling, it forms an excellent thirst-quenching and nutritious drink. Preservatives like sodium benzoate, sodium nitrite, nitrates, sulfur dioxide, carbon dioxide, copper carbonate, and benzoic acid may be needed to extend the shelf life of fresh juice. Processed juice may be packed in aseptic conditions in cans or protective packages.

Banana essence, a clear, colorless liquid that has an agreeable concentrated aroma can be also extracted from ripe fruit for use in desserts, juices, and drinks.

Banana Figs or Dehydrated Banana

Banana figs are dried or dehydrated banana made from fully ripe fruits with sticky fig-like consistency and very sweet taste. Varieties with high total soluble solid content are highly suitable for making figs. The banana slices can be dried after following 60 min immersion in osmotic solution having sugar concentration of 65–70° Brix and heating to a temperature of 60 °C to produce stable dried plantain product. Drying at a temperature range of 60 or 70 °C with an airflow of 1.5 m s enabled rapid drying. Osmotic dehydration of 'Karpuravalli' ('Pisang Awak') banana in 60–70% sugar syrup for 12 h followed by drying in hot air oven at 50 °C gave high-quality figs with excellent color and taste. Wrapping the figs in cellophane paper and packaging in polymeric containers can give an extended storage life of 6 months under ambient conditions.

Canned Slices

Banana slices from early stage of ripening can be stored in syrup (25° Brix) at a pH of about 4.2. These sliced ripe bananas preserved in cans with syrup are used for desserts and fruit salads. Calcium chloride (0.2%) or calcium lactate (0.5%) can act as firming agent. The slices prepared from plantains can be cooked in 40° Brix syrup until the concentration becomes 55–60° Brix. The product may be hermetically packed in cans or in heat-resistant plastic pouches and quick frozen at −23 °C and stored in cold. The cold-stored plantain slices are heated in boiling water for about 15 min before serving.

Fermented Banana Products: Banana Beer, Wine and Ethanol, and Vinegar

In Central and East Africa (Burundi, Kenya, Rwanda, Tanzania, Uganda, and Zaire), the juice from the ripe fruit of varieties known as 'beer bananas' (*Mbidde* clone) is also processed by fermentation to produce a low-alcohol content beverage that is rich in vitamin B. The strained banana juice is fermented using ground roasted sorghum or maize as a source of wild yeast, for a few days after which the 'beer' is consumed within a few days due to poor shelf life. In Uganda, the distilled beer known as 'Waragi' is brewed both commercially and on small-scale home preparation.

Wine can be also made from bananas by mixing water to mashed pulp by 10% and after adjusting the TSS to 26° Brix, followed by sterilization and allowing for fermentation with wine yeast, *Saccharomyces cerevisiae* var. *ellipsoideus* at 24–26 °C for 7 days with intermittent aeration. Pretreatment with pectinase and α-amylase to hydrolyze pectin and starch can help to achieve higher-sugar levels in juice for fermentation. The fermented juice is then filtered and kept under anaerobic condition with water seal for secondary fermentation. After 2 weeks, the secondary fermentation can be stopped and the wine can be racked or centrifuged, bottled, and pasteurized at 50 °C for 20 min. Pasteurization of the banana-based alcoholic beverages increases the ester and alcohol contents. The pasteurized wine upon aging will have a characteristic flavor and aroma.

Banana peel can be also subjected to steaming under pressure coupled with enzymatic action of a cellulase following which fermentation using *Saccharomyces cerevisiae* var. *ellipsoideus*, and distillation can be carried out for the production of alcohol. About 150–200 ml l^{-1} of alcohol can be obtained.

The rejects and overripe banana pulp can be crushed with equal volume of water, and the clear juice obtained after enzymatic softening with 'pectinase' is fermented using a strain of *Saccharomyces cerevisiae* var. *ellipsoideus* and later by acetic acid bacteria for making vinegar containing 5–6% acetic acid.

Banana Jam and Ketchup and Other Food Products

The ripe banana pulp of many varieties can be cooked with equal quantity of sugar along with pectin and acid in the right proportions until it gives a good set to produce jam. Banana pulp can also be mixed with pulp of other fruits to process blended fruit jam. Banana ketchup is made from unripe fruits of cooking varieties. The process involves blanching, peeling, mashing, and cooking with salt, sugar, onion powder, and spices. In the Philippines, banana ketchup serves as substitute for tomato ketchup and has export demand in Asian and European markets too.

The technology for several other value-added products based on banana flour such as biscuits, papads, health drink, baby food, sweet chutney, and cakes has been developed. Banana flour in different proportions have been mixed with

other flours such as cassava flour, wheat flour, and pulses, to produce nutritious foods that can serve to prepare bread, baked products, sweets, savories, and baby foods. Using banana flowers, pickles can be made. The inner core of banana stem can be also steam-cooked and used for the preparation of food.

Bananas as Animal Feed

Green stems, corm, and sun-dried ripe banana peels provide feed for cattle and sheep. Ripe banana rejects, supplemented with protein, vitamins, and minerals, are also used as animal feed. The peels and corm are also directly fed to large animals in several parts of the world.

Nonfood Uses of Banana

Peeled leaf sheaths are used fresh or after drying as packaging material for flowers, betel leaves, fruits, and similar other items in parts of Asia and for lining cooking pits and for wrapping food for cooking or storage in parts of Africa. The leaves of the 'Fehi' banana are used for thatching, packing, and cigarette wrappers.

The pseudostem of banana plant is stripped into shreds, dried, and used for tying packages and making flower garland in southern India. Banana leaves serve as environmentally friendly disposable plates for serving meals in southern parts of India. While some of the banana and plantain varieties have been exploited for fiber extraction from pseudostem besides for fruits, the *Musa* species such as *M. textilis* is exclusively suited for fiber extraction. Banana fiber is extracted from dried petioles and pseudostem of plant is used extensively in the manufacture of papers. The pseudostem fiber has numerous other uses including textile manufacture, making ropes, strings, threads, and for the production of handicraft as baskets, toys, table mats, wall hangings, and lamp shades. Conventionally, in West Africa, fibers from the pseudostem were used in fishing lines.

In the Philippines, it is woven and used in textiles and forms the principal ingredient of special fabric in the Philippines. Efforts are also being made to produce nonwoven fabric from banana fibers. They have several uses like making bags, pots, and vases. Mechanical decorticators for efficient extraction of fiber from banana pseudostem are available now, which are employed by many small-scale entrepreneurs to produce banana fiber.

Future Outlook

Rapid strides being made in science and technology have paved the way to improve delivery of nutritional and health principles through food commodities. Improving postharvest shelf life, improving resistance to pests and diseases, enhancing carotene content in bananas, and the use of bananas as edible vaccines are being targeted through genetic transformation approaches. Newer processing and packaging technologies that are being developed to combine efficiency with preservation of nutrition will help enhance the product diversification and value of processed banana products. Being market-driven globally and managed by large-scale corporate sectors and with ever-persisting demand, banana has a stable future and lucrative market. However, threats due to biological factors such as pests and diseases and abiotic stress factors such as higher-temperature regimes, drought, and salinity that pose severe challenge to this easily available and affordable food crop need to be addressed more urgently. Developing and establishing efficient supply chain management system in developing countries are other important aspects to be focused further.

Background

Barley, *Hordeum vulgare* L., is an ancient grain with cultivation dating back to 8000 BC in the Fertile Crescent and North Africa in the Middle East. Throughout history, barley has been recognized as a versatile grain that can be cultivated in extreme environments such as the dry lands of North Africa and the high altitude and mountains of Tibet and other areas in Asia. Barley was mainly used as a nourishing human food, but in the nineteenth and twentieth centuries, it evolved largely into an animal feed and malting and brewing grain in most parts of the developed world. These uses drastically reduced barley human consumption, due in part to improved conditions of wheat production, along with the increase use of rice and maize in the human diet. Yet, barley is still considered a staple food in some parts of the world including Asia, the Middle East, North Africa, and Eastern Europe. More importantly, there is increased interest in barley and barley foods as a healthy alternative to refined grains and as a functional food ingredient. This is evident in the recent food health claims from the USFDA (2006), EU EFSA (2011), and Health Canada (2012), linking the consumption of barley with reduced risk of developing coronary heart disease and an ability to reduce the rise in blood glucose after a meal.

Production and Consumption

Barley is an important crop ranking fifth among all crops in dry matter (dm) production in the world. The top five barley producers are the Russian Federation, France, Germany, Ukraine, and Canada. Today, approximately 65% of barley crop is being utilized as animal feed, ≈30% for malting and brewing, and only 2–3% for human consumption. However, trends of breeding selective barley cultivars for human use and food industry are on the rise.

Despite the lack of barley consumption in most developed societies with the exception of Scandinavia and some parts of Eastern Europe, barley is still a stable food in many developing countries.

In Tibet, barley provides 80% of the calories in the diet of rural Tibetans; in Morocco, the average person consumed 68.3 kg of barley a year in 1986. In contrast, the 2009 FAO data show a significant reduction in barley consumption in Morocco to approximately 28 kg/person/year. This is thought to be due to lack of initiatives in barley research and food industry interest in barley. Yet, most individuals in North America and Europe consume on average less than 1 kg/person/year. The development of barley-based food ingredients and products is crucial to boost the consumption of barley.

Barley Cultivars

Barley may be one of the most widely adaptable grains allowing it to be cultivated in contrasting climates and various locations worldwide; it is a genetically diverse grain. This genetic diversity allows barley to be classified as either spring or winter type. Barley is further categorized as either two-row or six-row and hulled or hull-less (naked). Two-row barley has two rows of seeds on each spike, and six-row has six rows of seeds on each spike. Hulled and hull-less barley are distinguished by the presence or absence of a hull tightly wrapping the grain. Any of these types can be further classified into either malting or feed barley depending on the end use of the grain.

Kernels from two-row barley are generally larger and more uniform in size than those from six-row barley due to the crowding of spikelets on the spike in the latter. Hull-less barley is free-threshing or naked grains. According to the grain chemical composition, barley grains are further classified as normal (20–30% amylose), waxy (0–5% amylose), high-amylose starch type (>45% amylose), high-lysine, and high-β-glucan (βG). The mature barley grain also known as kernel or caryopsis is composed of the hulls (for hulled barley), pericarp, seed coat or testa, germ, and starchy endosperm. These parts of the kernel contain both similar and different nutrients in variable amounts. Therefore, when considering barley grains as a functional food or food product, knowledge of these differences would help in using them to add nutritional value and quality to barley-based products.

Chemical Composition

Barley cultivars can vary widely in their chemical composition due to differences in genotype, growing environment, and the interaction between these factors. Normal barley generally consists of approximately 60–70% starch per dm, making starch the most abundant constituent in barley found mostly in the endosperm (Table 1). The next chief constituents are total fiber ranging from 11% to 34% and protein 10–20%; of total fiber, 3–20% is soluble dietary fiber with 5–10% βG depending on the cultivar. Other constituents include 2–3% free lipids and 1.5–2.5% minerals. Barley also contains a myriad of other components including a number of antioxidants, phenolic and bioactive compounds of which preliminary research suggests a significant role for some of these compounds in the health benefits attributed to consuming barley. For example, phenolic acids are linked with barley's ability to inhibit human LDL cholesterol and to scavenge free radicals.

Available Carbohydrates

In general, barley is predominantly composed of glycemic carbohydrates and dietary fiber. There is a small concentration

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00055-6

Table 1 Water, energy, macronutrients, and fiber contents of barley per 100 g

	Pearl barley, uncooked	*Pearl barley, boiled*
Water (g)	10.6	69.6
Energy (kJ)	1535	510
Energy (kcal)	360	120
Carbohydrates (g)	83.6	27.6

of low-molecular-weight (MW) carbohydrates, which must be included with starch, the predominant constituent, when calculating the composition of glycemic carbohydrates in barley. Barley has a small percentage of simple sugars like glucose, fructose, sucrose, and maltose (range of 0.03–0.83% dB). Starch is the predominant glycemic carbohydrate in barley; in normal barley, starch consists of amylose and amylopectin polymers. Amylose is an essentially linear molecule consisting of glucose monomers joined by α-1–4 bonds. In contrast, amylopectin is a branched α-1–4- and α-1–6-linked molecules. The content of amylose in barley depends on the barley type with normal barley starch consisting of approximately 1:3 ratio of amylose to amylopectin, while waxy barley can range from 0% to 5% amylose of total starch.

Resistant starch (RS) in barley is of the type that is physically inaccessible starch or type I, most seen in whole grains. In cereal grains and their products, the RS proportion of starch is relatively small, typically 0–5% of starch; raw barley contains less than 1% RS. The amount of RS is influenced by factors like the amount of starch present, food processing, cooking, and storage conditions. The concentration of RS in barley can be increased through processing methods such as extrusion cooking and pelleting of barley products.

Fiber

In barley, fiber represents the second major constituent of the grain after starch, but unlike starch, fiber is found throughout the kernel. Fiber can be classified into soluble and insoluble forms. The content of total fiber in barley ranges from 11% to 34%, of which 3–20% is soluble dietary fiber mostly in the form of βG.

β-Glucan

βGs are soluble fiber found in many cereal grains; they are large linear polysaccharides of glucose monomers. Specifically, the mixed linkage (1–3, 1–4)-β-D-glucans are linear homopolymers of D-glucopyranosyl residues. Barley is considered to be the richest source of βGs that account for approximately 75% of the total cell wall polysaccharides in the endosperm cell walls; the rest consists of arabinoxylans, cellulose, glucomannans, and proteins. The recent focus and renewed interest in barley as a human food are largely due to the health benefits attributed to βG. The βG content of barley can range from approximately 2% to 11%, which is generally higher than oats (2.2–7.8%) and wheat (0.4–1.4%).

The health benefits associated with consuming βG-rich foods include lowering blood glucose, insulin, and blood lipids, in particular serum total and LDL cholesterol. Some of these effects have been shown to depend on the capacity of βG to increase the viscosity (defined as a measure of resistance to flow) of intestinal contents, which in turn depends on βG physicochemical characteristics such as MW and solubility.

Physicochemical Characteristics of βG

The physicochemical properties of βG in barley have been suggested to have a key role in affecting postprandial responses in humans. The number of parameters includes the following: MW, solubility, viscosity, microstructure, particle size, chain length, and concentration of βG among other parameters. The physicochemical properties denote an interaction between the physical properties (e.g., structure and MW) and the chemical properties (viscosity and chain length) and their impact on physiological activity *in vivo*.

Data in the literature indicate a strong correlation and interdependence between these factors and glycemic response. In particular, viscosity and MW are thought to have a superior role, and they are mutually associated with the physiological effectiveness of βG. Viscosity is defined as the resistance of a solution to flow, and MW is a measure of the size and weight of the polysaccharides in βG.

Barley Processing and Cooking

The physical and chemical characteristics of barley are important factors to be considered to reinstate barley as a human food. These characteristics are affected by processing, a necessary step in preparing barley for human consumption. The most common barley processing method is pearling, a common commercial process whereby the husk and outer layers of barley grains are removed by friction and abrasion. There has been a general preference, by consumers and food manufacturers alike, for a bright white color of pearled barley and milled barley flours. Yet, in recent years, the increased awareness of whole grains and their products such as whole-grain flour by consumers has diminished the demand for white food products such as white bread and pasta.

Since most barley cultivars are hulled, removing the hulls or dehulling is necessary. Pearling is considered one of the oldest practices used in the processing of barley. This process of abrasion of the barley kernel involves the successive removal of grain tissue starting with the outer layers of barley and working inward. Dehulling by pearling still renders the barley grain a whole grain, because the germ, endosperm, and bran layers are still intact. Depending on the amount of materials removed, the rate of pearling, which is dictated by cultural preferences, can produce barley cultivars labeled as whole grain (only the husk was removed), pot (dehulled and further removal of pericarp), and white-pearled (all the bran and most of the germ and crease removed). Varying the degree of pearling time results in significant alterations in the chemical

and nutritional compositions of barley. These changes include decreasing total fiber but not soluble fiber and increasing concentration of starch and βG; this can be done without significant effects on the endosperm but only up to a pearling degree of 15%. Pearling is considered a beneficial method of creating barley fractions with specific characteristics (i.e., high/low starch and high βG) for different end uses such as the addition of smaller amounts of barley to foods or incorporation of barley as a functional food ingredient.

Barley can also be milled using a roller mill to produce barley flour and bran; this is considered an uncommon practice and needs to be further explored. It is generally assumed that barley bran consists of the testa, pericarp, germ, aleurone, and the subaleurone layers; however, since barley is pearled before milling, the bran and flour composition may differ depending on the degree of pearling. Abrasion milling and sieving is another form of barley milling, which involves the milling of dehulled or hull-less barley by an abrasion mill and sieving the ground material through a series of sieves with an option of different sizes for the openings.

Extrusion cooking is a popular industrial technique for the production of breakfast cereals, breads, pasta, and cooked flour. This process employs simultaneous actions of temperature, pressure, and shear at different levels of intensity. Other forms of cooking include hydrothermal treatments. These processing methods are thought to aim principally on enhancing the nutritional value of barley and creating longer shelf life and convenient barley-based products. Nonetheless, their impact on the metabolic effect of barley in humans is not known.

Processing and cooking cause major changes in the architecture of the grain, mostly in the cell wall matrix. Exposing starch-rich foods to boiled water can result in significant changes to starch properties. Starch can go through transformations that can affect its digestibility such as gelatinization. Gelatinization occurs when starch is heated in water; it is the disruption of molecular structures within the starch granule. This leads to swelling in the granules due to increased water absorption that coincides with leaching of material from the starch granules, mostly amylose. Changes can also occur to the particle size due to either pearling, milling, or cooking, thereby reducing the particle size. This leads to more exposure per surface area to digestive enzymes and consequently accelerates starch hydrolysis and the digestion and absorption processes.

Barley Food Products

Barley product development and improvement in food processing methods received little attention over the last few decades, unlike wheat, for example. Quality standards of barley for food use have not been well established, making it challenging for food industry to select raw materials suitable for barley food product development. Yet, there have been a number of initiatives to breed selective barley cultivars for human consumption and product development. These specialty cultivars, mostly naked cultivars, contain higher βG, indigestible carbohydrate content, and protein quality.

Hull-less or naked barley holds a greater potential for food product development than hulled barley and oats. This is due to superior dietary quality and less processing required. Hull-less barley cultivars require minimal processing leaving the bran layer intact unlike hulled cultivars, which may lose a number of nutritious layers during pearling. There are a number of challenges that face barley food producers such as βG, which has an unfavorable effect on certain baked products leading to low volume and increased water retention. Barley also lacks in the protein gluten, unlike wheat; thus, it does not maintain certain characteristics of bread made from wheat flour. Nonetheless, there are several uses of barley in food products including flat bread, muffins, pastas, noodles, pearled barley, and rice extenders, notwithstanding future novel product development especially those from selectively bred cultivars.

Health Benefits of Barley

The renewed interest in barley comes from its ability to produce favorable effects on two main disease risk factors: postprandial glycemic responses and blood lipids. Barley has also been suggested to help in weight management by increasing satiety due to its low glycemic index and high content of viscous fiber, but the evidence in this area is inconclusive.

Barley and Blood Lipids

Reducing serum LDL cholesterol concentrations has been shown to reduce the risk of coronary artery disease. There is solid evidence in the literature to suggest that whole grains high in viscous soluble fiber such as barley are more effective in lowering blood lipids than other grains such as wheat or rice. The suggested mechanisms of cholesterol lowering after consuming a soluble fiber-rich diet include delayed intestinal absorption of lipids and inhibition of absorption and reabsorption of cholesterol and bile acids alongside an increased excretion of bile acids. These effects are thought to be induced by βG's ability to increase the viscosity of the intestinal contents. Other factors may also be responsible such as the reduced impact of barley on postprandial glucose and inflammatory responses and the fermentation of soluble fiber in the colon, resulting in production of short-chain fatty acids, which inhibit cholesterol biosynthesis. Barley is also a rich source of tocols, such as tocopherols and tocotrienols, which have been shown to have favorable effects on LDL oxidation via their antioxidant action. The ability of barley and βG food products in lowering blood cholesterol is well established, but research investigating other disease end points and metabolic markers such as glycemia, hypertension, inflammation, and satiety is progressing slowly. More importantly, most of the interventions are done in harshly processed barley and barley-enriched food products or in extracted βG with a few using intact whole-grain barley kernels.

Barley and Glycemia

Global data show an unabating upward trajectory in diabetes rates with 366 million people suffering from diabetes in 2011–2012 worldwide. Type 2 diabetes (T2D) is characterized by insulin resistance and reduced insulin secretion. Therefore, food products that decrease plasma glucose and insulin

demands may plausibly reduce the risk of developing T2D. Data also show that elevated blood glucose concentrations produce undesirable consequences on health, an occurrence known as hyperglycemia. Postprandial hyperglycemia is characterized by high blood glucose concentrations post meal, which is a strong predictor for developing T2D. Hyperglycemia and constant fluctuations in blood glucose have been further associated with increasing oxidative stress, protein glycylation, and inflammatory responses, all of which are risk factors for a number of chronic illness that share a common underlying pathophysiological mechanism.

Barley and barley food products have been shown to produce favorable effects on glycemia. The mechanisms responsible for these effects have been suggested to be related to the ability of barley βG in its original state, which possesses a very high MW that exhibits high viscosity at a low concentration. Consuming βG-rich barley can increase the viscosity of the meal bolus in the stomach, reducing the mixing of food with digestive enzymes and delaying gastric emptying. Increasing the viscosity has also been shown to retard the absorption of glucose and slow the rate of starch digestion in *in vitro* digestion model studies. There is solid evidence that the main factor responsible for the low glycemic response to barley foods is related to the viscosity of βG, but other factors such as barley's bioactive compounds may play a significant role.

Other Health Benefits

Barley consumption has been associated with improved bowel function and improved colonic integrity. These benefits in bowel function were evident by improvements in short-chain fatty acid production, especially butyrate and propionate, and in other biomarkers of bowel health such as fecal weight.

Other health benefits include weight management via glucose regulation and increased satiety. Barley consumed as an evening meal was found to regulate postprandial glucose; increase the release of GLP-1, a hormone associated with satiety and glucose homeostasis; reduce later energy intake the following day; and reduce hunger over two subsequent meals, a phenomenon known as second-meal effect. However, evidence from acute studies is not conclusive and other studies did not show similar findings. Research in barley's potential in weight management and/or reduction is still progressing.

Introduction

The word 'beef' is derived from the Latin terminology '*bos*,' and early English speakers referred to cattle and their meat by the Anglo-Saxon term '*cu*' (a term that later converted to 'cow'). In 1066, Norman French-conquered England showed no interest in the usage of ancestral Anglo-Saxon expressions and introduced the Latin-derived terminologies like '*boeuf*' (commonly referred to as meat of cattle). However, the contrast in terminologies becomes evident in Britain and the etymological journey through several years found to be in the English language for centuries as 'beef.' Generally, beef is the gastronomic name for meat obtained from bovines and can be harvested from cows, bulls, heifers, and/or steers. In general, the beef production system can be categorized based on the source, namely, beef from beef breed, beef from dairy production, or a combination of both. The beef production system also varies depending on the farming structure, resources, feeding system, etc. In terms of beef production, the United States produces nearly about 19% of the world's beef, followed by Brazil (17%), the European Union (13%), China (13%), and India (7%).

Consistent and high-quality beef is one of the most important requirements of the meat industry in order to maintain and expand markets. Like any other meat, beef quality and freshness is often perceived as the most helpful indicator in assessing safety at retail level. The two most important intrinsic beef quality attributes are flavor and tenderness in nearly all beef-consuming countries. Juiciness, color, and texture are the next important, followed by marbling and water holding capacity. Marbling has a favorable effect on juiciness and beef flavor. Both intrinsic (color and leanness) and extrinsic (country of origin and place of purchase) attributes are beneficial for predicting meat quality. The consumer perception of beef eating quality is complex, so does the measurement of quality indexes. The measurement of beef quality attributes is a complex task with high economic impact. There are many tests for quality attributes (tenderness, color, flavor, and water holding capacity) that can be applied to a piece of meat only after it leaves the beef plant. These conventional methods are destructive and time-consuming. Beef processors are constantly looking for alternative noninvasive techniques such as real-time ultrasound, x-ray computed tomography (CT), and magnetic resonance imaging (MRI). The beef eating and technological qualities are affected by several factors including breed, feed system, genotype, preslaughter handling, and slaughter technique employed.

Beef Primary Production

Cattle farming around the world started over 6000 years ago, supplying both meat and milk. Nowadays, cattle rearing for beef production has become more specialized, which varies from country to country. The beef production system can be classified as intensive, extensive, or semi-intensive production system. The intensive system involves cattle confinement with a regular supply of feed; extensive system involves movement of cattle in open area for feed (grazing), whereas semi-intensive involves any combination of both the intensive and extensive system. For example, to produce 1 kg of beef carcass, an intensive indoor dairy bull system would require 16.5 m^2 compared with 42.9 m^2 for an extensive beef breed farming system. Researchers have shown that high-forage systems as opposed to concentrate systems can provide beneficial effects in terms of nutritional profile, meat quality, stability, and sensory characteristics. Moreover, the consumer perceives that the grass-fed beef tastes better, enabling the character of the meat to develop in a natural environment. The environmental impact of three beef production systems, namely, (i) conventional (finished in feedlots with growth-enhancing technology), (ii) natural (finished in feedlots with no growth-enhancing technology), and (iii) grass-fed (forage-fed with no growth-enhancing technology), is shown in Figure 1. A study shows that all beef production systems are potentially sustainable with different environmental impacts; the grass-fed system has the highest carbon footprint per unit beef, followed by the natural and conventional feeding systems.

The beef consumed around the world comes from two main types of enterprises including (i) dairy herds where cattle are milked and meat is a coproduct of milk production and (ii) single-suckler herds where specialized beef breeds are reared for beef production. Significant effort has been made over the past couple of decades to beef breeds for the improved meat production and nutritional profile of meat. The improvement in animal breeding, selection of breeds, and genetic lines within breeds have resulted in an overall leaner beef product. The selection of beef breeds is important for the lipid profile of meat along with genotype, sex, age, nutrition, and management. There are various functional traits that are important for beef production, for example, body size, age at puberty, hot-climate adaptability, fleshing ability, muscle expression, cutability, and marbling. Table 1 shows some common beef breeds of commercial importance with their functional traits.

Beef Secondary Production

Preslaughter Activities

The preslaughter activities of cattle involve a number of critical points that include loading of animals at the farm, transportation from farm to abattoir, unloading of animals at the abattoir, restraining, and handling followed by

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00056-8

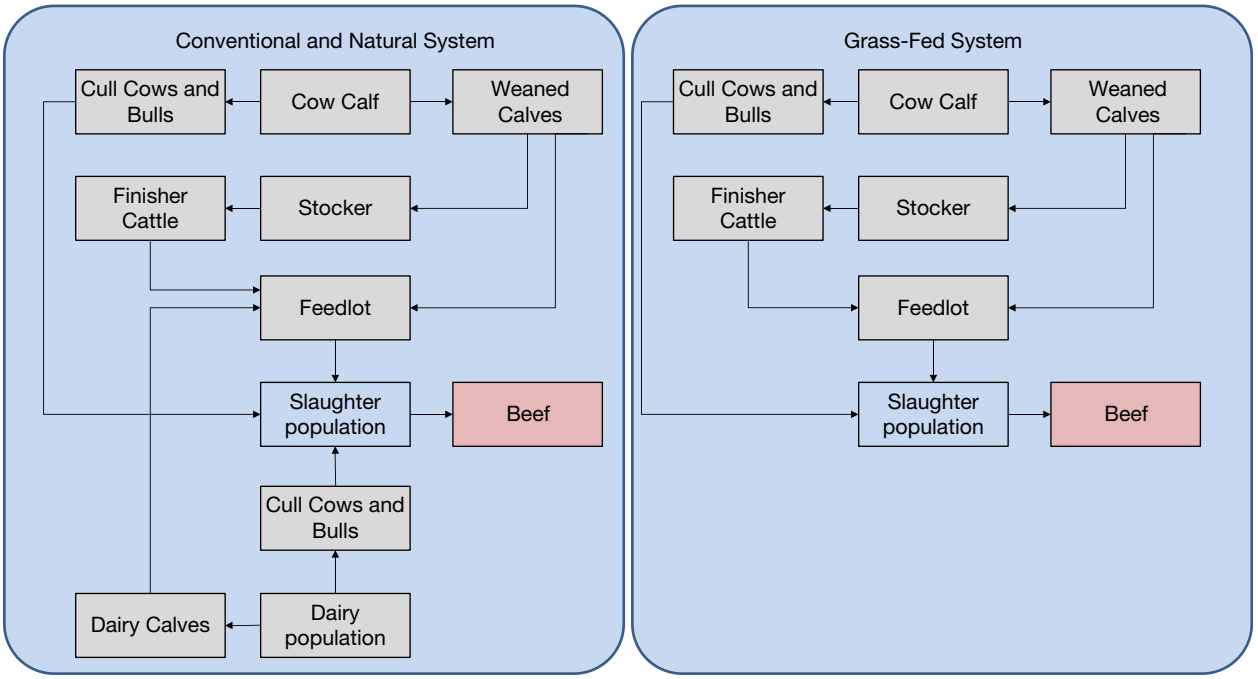

Figure 1 Schematic representation of the beef production systems. Adapted from Capper, J. L. (2012). Is the grass always greener? Comparing the environmental impact of conventional, natural and grass-fed beef production systems. *Animals 2*(2), 127–143.

slaughter. Transportation and loading/unloading are among the main activities that can cause physiological (change in the environment, breakdown of social grouping, and mixing) or physical stress (vibrations, changes in acceleration, confinement, noise, and crowding) in cattle. The transport and handling of cattle can have major implications on animal welfare and meat quality. Feed withdrawal during transportation or fasting during transportation can result in weight loss and also affect the meat quality of the animals that are transported to slaughter.

Recommendations related to the transportation of cattle vary from country to country. For example, in Europe, it is recommended to minimize the duration of transport periods without feed, whereas in New Zealand, livestock should be fasted for 4–6 h prior to a journey to reduce fecal output, facilitating a more comfortable journey. Cattle waiting for slaughter can be stressed and may lead to preslaughter depletion of glycogen in muscles because of many factors, leading to an increase in pH, which is not always ideal for the conversion of muscle to meat. Long-term preslaughter stress including fighting, cold weather, fasting, and transit, which occurs 12–48 h prior to slaughter, depletes muscle glycogen, resulting in meat that has a higher pH and darker color and is drier. The depletion of glycogen in muscles as a result of stress is related to a rapid release of the hormone catecholamines. Short-term acute stress, including excitement or fighting immediately prior to slaughter, produced lactic acid from the breakdown of glycogen. This results in meat that has a lower pH, lighter color, and reduced water binding capacity and is possibly tougher. The management of preslaughter activities is critical in designing effective animal welfare and in improving the quality of meat.

Slaughter

Beef processing begins with the slaughter of the cattle in slaughterhouses or abattoirs, involving several critical processes that lead to the production of fresh meat in the form of quarters. The healthy animal is generally off feed 24 h prior to slaughter with access to water. The age of healthy animals for slaughter varies depending on several factors including breed and feeding regime. The highest quality meat comes from cattle under the age of 36 months, and in some cases, calves are best slaughtered between 3 and 16 weeks of age. The basic commercial processes for live cattle that take place in the abattoir or slaughterhouse are generally uniform across the meat industry. The common processes include stunning, bleeding, hide or skin removal or treatment, evisceration, carcass dressing, and washing, followed by chilling of carcasses as shown in Figure 2. Cattle receiving is the first step with an objective to prepare the animal for slaughtering; the animal's sex, breed, ID number, and live weight are recorded at this stage. Visual screening and antemortem inspections are carried out to identify clinical signs of disease or other abnormalities. Diseased animals that are not fit for human consumption are condemned and are disposed appropriately. Cattle cleared by the inspector for the subsequent production process are presented for stunning. The objective of stunning is to make the animal unconscious before decapitation for animal welfare purposes. Commercially, cattle stunning can be achieved by either mechanical or electrical method as shown in Figure 3. To minimize stress, the animal is restrained using a center track, V-track restrainer, knocking box, or chute. This avoids animal movement and the animal can be positioned for appropriate stunning process. After the stunning process, the animals are shackled to the left hind foot

Table 1 Beef breeds of commercial importance

Breed	*Origin*	*Characteristics*
Angus	The United Kingdom	High growth and size; medium milking potential; early age at puberty; low hot-climate adaptability; high fleshing ability; low cutability[a] and high marbling[b]
Hereford	The United Kingdom	High growth and size; low milking potential; medium age at puberty; low hot-climate adaptability; high fleshing ability; low cutability and medium marbling
Red Angus	The United Kingdom	High growth and size; medium milking potential; early age at puberty; low hot-climate adaptability; high fleshing ability; low cutability and high marbling
Shorthorn	The United Kingdom	High growth and size; medium milking potential; early age at puberty; low hot-climate adaptability; high fleshing ability; low cutability and high marbling
Charolais	France	Very high growth and size; low milking potential; low age at puberty; low hot-climate adaptability; medium fleshing ability; very high cutability and low marbling
Chianina	Italy	Very high growth and size; very low milking potential; low age at puberty; medium hot-climate adaptability; low fleshing ability; very high cutability and low marbling
Limousin	France	High growth and size; very low milking potential; low age at puberty; low hot-climate adaptability; medium fleshing ability; very high cutability and very low marbling
Salers	France	High growth and size; medium milking potential; medium age at puberty; low hot-climate adaptability; medium fleshing ability; high cutability and low marbling
Simmental	Austria	Very high growth and size; high milking potential; medium age at puberty; low hot-climate adaptability; medium fleshing ability; high cutability and low marbling
Brahman	India/the United States	High growth and size; high milking potential; very low age at puberty; very high hot-climate adaptability; high fleshing ability; medium cutability and low marbling
Beefmaster	The United States	High growth and size; medium milking potential; medium age at puberty; high hot-climate adaptability; high fleshing ability; medium cutability and low marbling
Braford	The United States	Medium growth and size; medium milking potential; medium age at puberty; high hot-climate adaptability; high fleshing ability; medium cutability and low marbling
Brangus	The United States	High growth and size; medium milking potential; medium age at puberty; high hot-climate adaptability; high fleshing ability; medium cutability and medium marbling
Red Brangus	The United States	Medium growth and size; medium milking potential; medium age at puberty; high hot-climate adaptability; high fleshing ability; medium cutability and medium marbling
Santa Gertrudis	The United States	High growth and size; medium milking potential; medium age at puberty; high hot-climate adaptability; high fleshing ability; medium cutability and low marbling
Simbrah	The United States	High growth and size; medium milking potential; medium age at puberty; high hot-climate adaptability; medium fleshing ability; medium cutability and low marbling

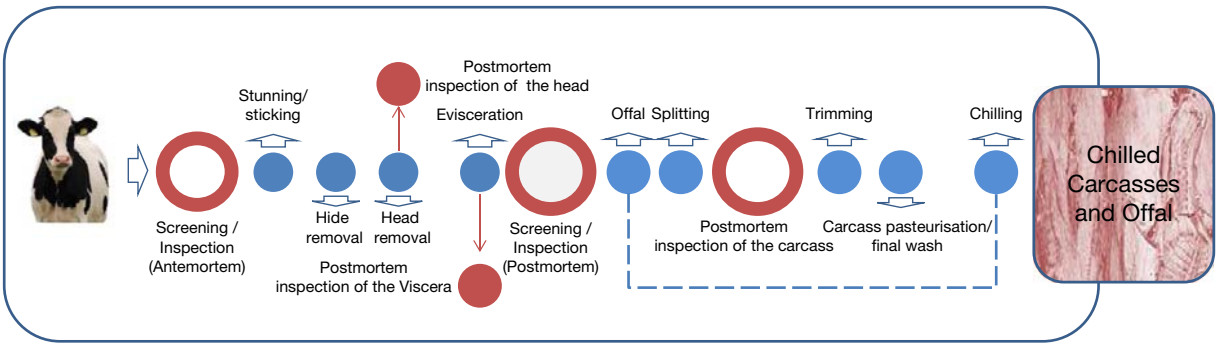

Figure 2 Beef slaughtering process.

when they are in the restrainer. The shackle generally comprises a heavy-duty chain attached to a roller trolley that can move freely on rails. Sticking/bleeding is carried out as quickly as possible after stunning of the animals. The standard method for cattle bleeding is to open the hide at the neck between the brisket and jaw through a longitudinal cut using a clean, sterilized knife, leading to a rapid discharge of blood. Cattle are allowed to bleed for several minutes and blood is collected. Approximately, blood accounts for 3–4% of the animal's live weight. The collected blood may be discarded or processed for various purposes including the use as a human food, feed, or fertilizer.

Hide/fleece washing or dehairing is one of the critical steps in the slaughterhouse immediately after bleeding to reduce the presence of pathogenic microorganisms. Chemical disinfectants can be used to clean hides before hide removal with an

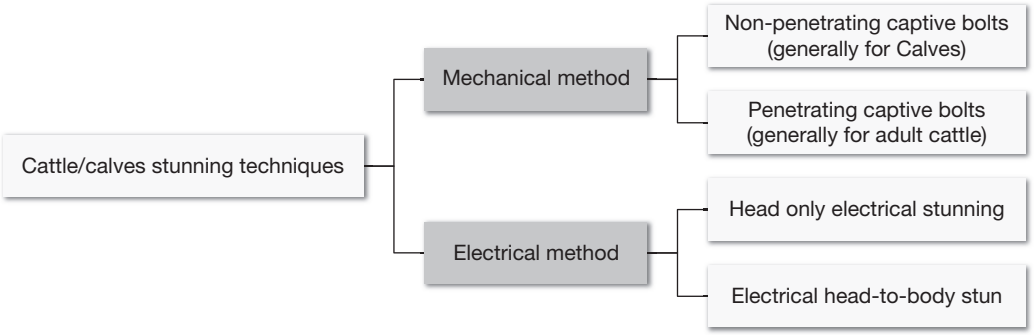

Figure 3 Cattle stunning techniques employed commercially.

aim to reduce microbial load and contaminants. Chemicals including sodium hydroxide, trisodium phosphate, acidified chlorine (sodium hypochlorite with acetic acid), and phosphoric acid have been investigated to date. However, the use of chemicals for hide washing varies from country to country. In the United States, the chemical dehairing process is carried out to remove hair, mud, manure, and other external contaminants from cattle before hides are removed, which should decrease the risk of transferring pathogens, namely, *Escherichia coli* O157:H7 and *Listeria monocytogenes*, to surfaces of beef carcasses. Hide removal, evisceration, carcass washing, and subsequent chilling are critical during beef slaughter and dressing from both meat safety and quality. Manual or mechanical hide removal techniques are generally adopted depending on the size and operational capacity of the slaughterhouse. Extreme care and hygienic conditions are required to avoid carcass contamination and to obtain success, which largely depends on the personnel conducting the activities. Several physical, chemical, or biological interventions have been proposed for carcass washing before the carcass chilling process. The chemicals or disinfectants employed for carcass decontamination include organic acids (acetic acid and lactic acid), sodium hypochlorite, chlorine and chlorine dioxide, trisodium phosphate, hydrogen peroxide, sodium hydroxide, ozone, sodium bisulfate, sodium chloride, acidified sodium chlorite, nisin, potassium sorbate, cetylpyridinium chloride, and activated lactoferrin. However, all of the aforementioned chemical disinfectants are not allowed for carcass washing due to variation in regulations around the world. For example, organic acids such as lactic acid and acetic acid are the most frequently used chemical interventions in commercial plants for beef dressing in countries like the United States, Canada, and Australia. Lactic acid treatment is allowed in the EU, whereas the use of organic acid is not permitted in Japan. Various physical interventions including the use of steam or hot water alone or in combination with organic acid has been proposed for effective removal of pathogenic and spoilage microorganisms. Chemical, physical, or biological disinfectants can be applied at various levels for the treatment of beef hides, carcasses, cuts, and/or trimmings in a variety of applications, namely, (i) spray washing hides prior to hide removal; (ii) spray washing or misting skinned animal preevisceration or postevisceration carcasses, either whole or split prechill; and (iii) misting carcasses, either whole or split, during chilling. Under commercial conditions, the use of multiple sequential interventions at various stages during slaughter should be considered in order to enhance the microbiological safety and shelf life of carcasses. The chilling process of carcasses is the most important step in cold chain for improving the quality, safety, and shelf life of beef meat. Various methods are employed for carcass chilling depending on the capacity and refrigeration facilities available. Refrigeration conditions under which the initial meat chilling takes place have an influence on key quality parameters including color, tenderness, weight loss, and shelf life. For example, studies show that initial chilling of carcasses at 6 °C can decrease in tenderness compared with 8 or 10 °C. Carcass cutting and boning often take place after chilling, since a carcass is easier to handle and cut when it is chilled. However, in some countries, the removal of bones as they come out of the slaughter floor and carcasses at a temperature of more than 20 °C is commonly known as hot boning. Hot boning involves the removal of muscles or cuts before the onset of rigor mortis. In the EU, there are separate requirements for hot-boned and warm-boned meat, whereas there is no distinction in Australia. There are advantages and disadvantages associated with cold boning (removal of bones from chilled carcasses) or hot boning. In general, a higher yield is obtained via hot boning compared with cold boning. This is in part due to elimination of the weight loss that normally occurs during chilling. At various stages of beef processing, diverse edible and inedible by-products are generated, which includes the head, bones, hairs, fat, and other offal. Edible offal for human consumption, including the heart, liver, kidney, tongue, and sweetbread, are either processed at abattoirs or sent to other facilities for subsequent processing. Other by-products are processed for other agri-food applications including pet food or suitably discarded depending on the regulatory regime. In the EU, because of bovine spongiform encephalopathy, the use of dead carcasses for animal feed is prohibited. The cattle slaughtering process and subsequent processing have significant effects on the shelf life, meat quality, and safety profile of carcasses.

Carcass Grading and Evaluation

Beef carcass evaluation is generally the basis for judging the commercial value of the livestock and is consequently one of the most common quality control tests carried out in the meat industry. Carcass quality attributes include tenderness, cut size, fat cover, marbling, meat, and fat color, whereas composition attributes include salable meat yield and proportions of fat,

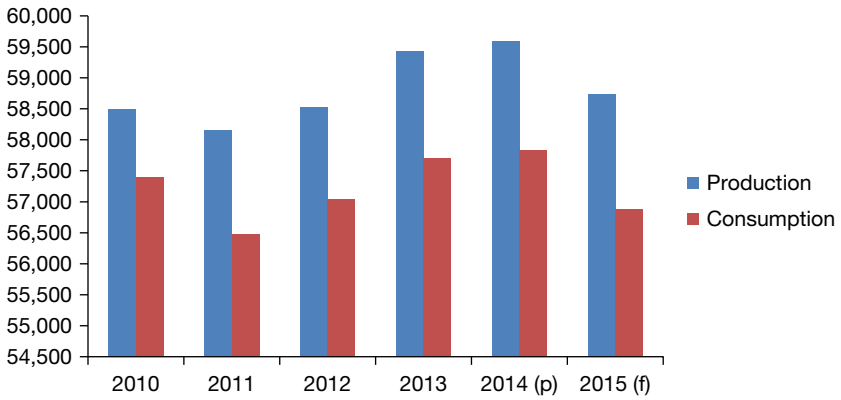

Figure 4 Beef and calf production and consumption trend (1000 tons carcass weight equivalent) (p: projected and f: future). Source: USDA.

lean, and bone. Carcass evaluation is a way to describe the quality of livestock in terms of their suitability and commercial value for various end usage including retail cut and processed meat. A number of approaches are available for the prediction of carcass composition and quality, which may also allow the grading of carcass into various categories. For example, in the United States, the beef carcass is evaluated based on the established Standards for Grades of Slaughter Cattle and Standards for Grades of Carcass Beef. According to this, quality grades are determined by marbling and overall maturity. There are eight quality grade designations: Prime, Choice, Select, Standard, Commercial, Utility, Cutter, and Canner. Prime, Choice, Select, and Standard are classified as young beef (maturity levels A and B) and must be <42 months of age, physiologically. Commercial, Utility, Cutter, and Canner are cow grades from carcasses >42 months of skeletal maturity. Similarly, In the European Union, adult bovine carcasses are classified according to the EUROP grid system, which is based on visual assessment scores according to the defined standards implemented by the European Community Regulations 1208/81 and 1026/91. The EUROP classification scheme includes carcass conformation scores on a 15-point scale with 5 main classes, E (excellent conformation), U, R, O, and P (poor conformation), and 10 subclasses and five main fatness scores (1 (low fatness), 2, 3, 4, and 5 (excessive fatness)) also with 10 subclasses. Mostly, carcass evaluation is done manually by trained graders using photographic references. Various carcass classification schemes adopted worldwide have been criticized due to the subjective nature of the process with a high degree of inconsistencies in such manual grade assessment. With growing concern of qualitative value of carcass and the possibility to improve the consistency of assessment, instrumented carcass evaluation techniques including ultrasound, x-ray CT, nuclear MRI, total body electrical conductivity, and video image analysis (VIA) are gaining importance in the meat industry.

Consumption Pattern

There has been an increasing pressure on the livestock sector including beef to meet the growing demand for high-value animal protein for the ever-increasing population, rising incomes, and urbanization. Beef is the third most widely consumed meat accounting for about 25% of world meat production. Historically, beef consumption is linked to Western culture and is now becoming popular and more affordable in Southeast Asia and Brazil due to an increase in disposable income and changes in society. There is a strong positive relationship between the level of income and the consumption of animal protein. A study observed that beef consumption is associated with an income compared with other meats. Consumers with medium and high income are target for premium beef. Moreover, meat consumption from ruminants has become a status symbol of the growing affluence of the new consumer societies. Cultural and religious factors have also erected in the way of wider diffusion of beef consumption in some countries such as in India. The global beef production and consumption trend is shown in Figure 4. In general, the consumption of beef is heavily and disproportionately concentrated in the industrial countries with an average per capita consumption of beef remained fairly constant in the range of 6.5–6.7 kg per capita. Argentina is the largest consumer of beef accounting for 40 kg per capita, followed by Brazil (25.4 kg per capita) and the United States (23 kg per capita), whereas in the EU (28 countries), the consumption of beef and calves is 10.9 kg per capita based on kilograms of retail weight per capita (carcass weight to retail weight conversion factor is 0.7 for beef and calves). The consumption pattern of beef and calves is projected to remain constant until 2030 years.

Retail Beef Cuts and Products

Various types of fresh beef cuts and beef-based meat products with varying sizes, shapes, tastes, textures, and colors are often visible at butcher shops or retail shops. The full range includes fresh beef, primal or nonprimal cuts, sausages, steaks, burgers, patties, mince, ground beef, charqui, jerky, and other ready-to-eat beef products. The fresh beef cuts may differ from country to country; however, there are eight well-recognized primal beef cuts. Each primal cut is then reduced into subprimal cuts (Figure 5). Individual portions derived from subprimal cuts are referred to as fabricated cuts. The primal cuts of beef are the following:

Chuck: The primal chuck is the animal's shoulder. Since this is a well-used muscle, the chuck contains a high amount of connective tissue and is very tough. It is further cut into subprimal roasts and steaks: blade steak, chuck short ribs, cross-rib pot roast, flat iron steak, ground chuck for hamburgers, and stew meat.

Brisket: The beef brisket is a very tough, course-textured muscle and contains a substantial percentage of fat. It is

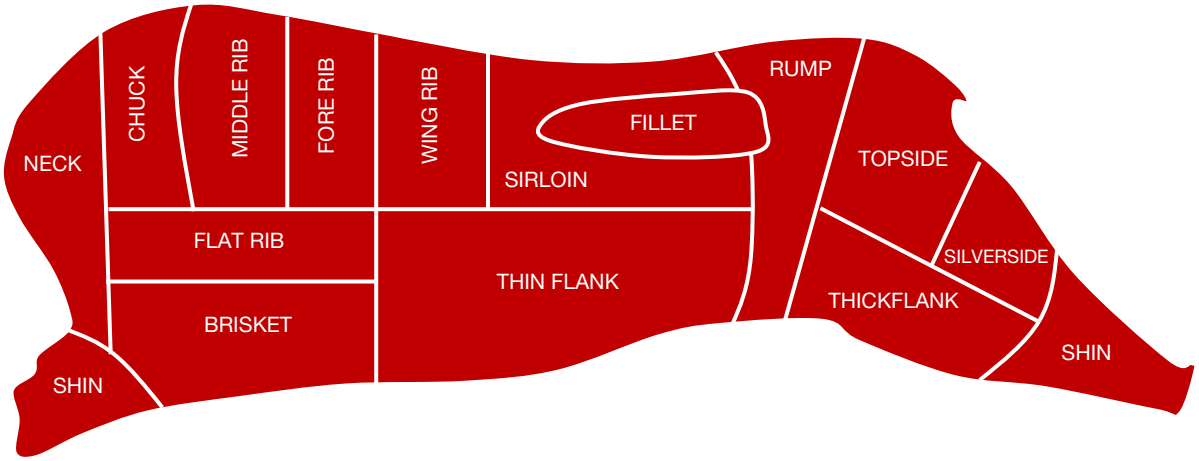

Figure 5 Major cuts of beef.

typically cut into smaller portions that are pickled to produce corned beef brisket or cured to make pastrami.

Shank: Beef foreshank is very flavorful and high in collagen. Typically, it is used in foodservice for making soups and stocks. In retail markets, it is ground for low-fat ground beef.

Rib: It consists of the ribs and a portion of the backbone. The center muscle portion of the rib is quite tender. It also contains large amounts of marbling and produces rich, full-flavored roasts and steaks. It is further cut into subprimal beef short ribs, boneless rib eye roast, rib eye steaks, and roast prime rib of beef.

Short Plate: The short plate contains rib bones and is located directly below the primal rib. It is cut into subprimal short ribs and skirt steaks.

Loin: The loin is located behind the primal rib and produces the most prized cuts of meat. It is further cut into subprimal fillet mignon, porterhouse, T-bone, sirloin butt roast, sirloin steak, and strip steak.

Flank: The flank is located directly beneath the loin. The flank contains no bones, is very tough, but is very flavorful. It is further cut into subprimal flank steak and London broil.

Round: The primal round is the hind leg of the animal and contains the round, shank, and tail bones and aitchbone. It is cut into subprimal round roasts and round steaks.

Nutritional Quality of Beef

Beef, like all meats, is an excellent source of protein. The beef protein is a high-quality, complete protein, meaning it contains all the amino acids necessary to be readily utilized by the body. Beef is a rich source of many minerals including zinc, iron, selenium, phosphorus, magnesium, potassium, and copper. The minerals found in beef are more bioavailable than those from the vegetable sources. Beef is also rich in many vitamins including vitamins B_{12} and B_6, riboflavin, thiamine, and pantothenic acid. Additionally, meat provides a number of saturated and unsaturated fats that are an important source of energy and facilitate the absorption of fat-soluble vitamins including A, D, E, and K. Approximately 50% of beef fat is saturated and the majority of the saturated fatty acids are palmitic acid (16:0) and stearic acid (18:0). The polyunsaturated fatty acid (PUFA) content of beef meat ranges from 11% to 29% of total fatty acids. Table 2 shows the general composition of grass-fed beef. In addition to the traditional essential nutrients,

beef meat is a potential source of a number of bioactive substances that have been studied for their potential beneficial effects. These meat-based bioactives include taurine, creatine, conjugated linoleic acid (CLA), carnitine, and several endogenous compounds (including ubiquinone, glutathione, lipoic acid, spermine, carnosine, and anserine).

Health Effects

Traditionally, beef is being considered as a highly valued, nutritious food and associated with good health and prosperity. With the growing health awareness and concern, this healthy image for beef meat has gradually been eroded in the last few decades. Health professionals recommend to reduce the overall consumption of fats, and the diet–heart (lipid) hypothesis focused attention on the saturated fat contributed from meat. A number of epidemiological studies have proposed an association of red meat consumption with the development of cardiovascular disease and colon cancer. Therefore, different strategies are being developed, aiming to reduce the intramuscular fat level. These approaches include selective breeding and feeding practices designed to increase the carcass lean-to-fat ratio, improved official carcass classification systems designed to favor leaner production, and modern butchery techniques (seaming out whole muscles and trimming away all intramuscular fat). Research over the past few decades suggests that grass-only diets can significantly alter the fatty acid composition and improve the overall antioxidant content of beef. Grass feeding improves the quality of beef and makes the beef richer in omega-3 fats, vitamin E, beta-carotene, and CLA. There is tremendous potential to enhance the health benefits of beef by the production of high-quality beef from better-bred animals with superior genetics and improved nutritional profile via better feed management.

Beer: Fermentation

S Livens, British Beer and Pub Association, London, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

For much of history, alcoholic beverage production has broadly been the result of 'one-pot cooking', with the final beverage being produced and consumed as a porridge-like 'mash.' Indeed, throughout the world, there are many countries that still produce alcoholic beverages in this way, and photographs of those drinking the fermented liquid through long 'straws' are recognizable from those Egyptian carvings that represent some of our earliest pictographic representations of the brewing process.

There has also been a fair amount of mysticism surrounding the brewing process. In medieval England, the foaming balm at the surface of fermenting vessels was referred to as 'Goddisgoode' and it was widely understood that this foam could be used to restart new fermentations. Words used to describe 'yeast' were based on characteristics that today we associate with the action of yeast during fermentation. Old English words for yeast include *gyst* or *gist*, which share similarities with the Germanic *gischt* meaning 'foam'; even older than this however, the ancient Greek *zestós* and Sanskrit *yásati* are both derived from words that translate as 'boiling.'

Today, our understanding of brewing is far more distinct and simplistically can be separated into four defined stages that each contribute in some way to the necessary characteristics that describe a particular style of beer:

- Brewhouse and wort production
- Fermentation
- Conditioning and maturation
- Packaging

The production of wort, which has already been described within the preceding article, will certainly contribute to the characteristics of a given beer style. However, it is fermentation that establishes the broader platform from which beer will ultimately emerge. Key to alcoholic fermentation is the nutritional composition of wort and the presence of fermentable sugars, which will support the growth and fermentative capabilities of brewing yeast, resulting in the production of alcohol, carbon dioxide, and various flavor-active components that are characteristic of yeast and this stage of production. In addition, yeast will also greatly influence the progress and outcome of the fermentation process. Therefore, for our understanding of fermentation and this stage of beer production, we must consider both yeast and the fermentative process.

Yeast

While yeast is the engine that drives fermentation, it was not until the nineteenth century that we began to fully recognize and even understand yeast as a biological entity. However, while the first classification of yeast as *Saccharomyces*, from the Latin meaning 'sugar fungus,' was applied by the German chemist Meyen, it is the brewing scientist Emil Christian Hansen who made one of the most significant early contributions to our knowledge of brewing yeast.

Hansen studied yeast performance in both ale and lager fermentations while working at the Carlsberg Brewery. His observations noted that whereas a sediment formed at the surface of the warmer, faster ale fermentations, for lager fermentations, which were colder and slower, the same sediment formed instead at the base of the fermentation vessel. Upon further observation, Hansen was able to isolate viable yeast cells from both sets of sediment that, upon repitching, individually demonstrated the same sedimentary characteristics. Hansen had thus successfully demonstrated fundamental differences in the production processes for ale and lager and had independently cultured two separate production yeast strains.

Hansen named the separate isolates *Saccharomyces cerevisiae* (ale yeast) and *Saccharomyces carlsbergensis* (lager yeast), and his work delivered important advantages to the brewing process. The concept of strain purity and an ability to store and propagate yeast as a pure culture introduced improvements to overall beer quality and consistency. However, Hansen's observations further provided new drivers for the manipulation of the fermentation process and, in particular, methods for the recovery of yeast and the importance of temperature in defining fermentation type and for controlling yeast performance.

Yeast Taxonomy

Taxonomy, and particularly in relation to those yeasts responsible for the fermentation of alcoholic beverages, has remained something of a moving feast. Various methods have been employed over the years to separate and define different yeast species. These have been primarily based on simple, observable morphological and physiological differences before becoming based on differences in the fermentation profiles of different carbohydrates and then, finally, in more recent times, based on differences at the molecular genetic level. The kaleidoscopic approaches to taxonomic categorization over the years have led to considerable debate over the identification of microorganisms, including yeast. However, we are now left with a vastly reduced list of strain variants with many previously uniquely defined strains now belonging to the same *S. cerevisiae* group. It is perhaps the almost continual reclassification of lager yeast since the 1970s that has led to the most confusion for brewing scientists. Not least because the ancestry of this 'chimeric' yeast strain, until recently at least, seems to have been well hidden.

Lager Yeast

Early reclassification of the lager yeast *S. carlsbergensis* in the 1970s by Lodder resulted in the new classification of lager production strains as *Saccharomyces uvarum*. Morphologically

and physiologically distinct from *S. cerevisiae*, *S. uvarum* was also reclassified due to its ability to metabolize the sugar melibiose, whereas *S. cerevisiae* cannot. However, in the 1990s, the classification of brewing yeast was once more thrown into confusion when *S. uvarum* was once again reclassified as *S. cerevisiae* before becoming *S. cerevisiae* var. *carlsbergensis* and, then finally, under the name that is today considered to be taxonomically correct – *Saccharomyces pastorianus*.

DNA sequencing has shown that whereas ale yeast is distinct as a species, lager yeast was formed as a hybrid from *S. cerevisiae* and at least one other yeast that has itself only recently been identified. *Saccharomyces eubayanus* was isolated and identified by Liebkind from the forests of Patagonia. Whereas *S. eubayanus* is itself shown to be district from any other yeast strain known today, sequencing of its genome has revealed a 99.5% homology with those areas of the *S. pastorianus* genome that are not related to *S. cerevisiae*. In particular, it is this region that is responsible for the cold tolerance associated with lager yeast and that is also a defining characteristic of *S. eubayanus*.

While admittedly a pun, this simplistic description merely skims the surface of the complexities behind the classification of brewing yeast over the years! It may even be suggested that characterization be based on phenotypic differences given that there is a considerable apparent variation in the flavor profiles of beers produced using the same 'strain' of yeast in addition to differences in yeast performance under different production conditions.

However, notwithstanding these issues and to avoid any further confusion, for the remainder of this article, the terms 'ale yeast' and 'lager yeast' will be used, and on this basis, we can list their principal differences as follows:

Ale yeast	*Lager yeast*
Top fermenting	Bottom fermenting
Optimum fermentation temperature 18–22 °C	Optimum fermentation temperature 7–15 °C
Cannot metabolize melibiose	Can utilize melibiose

Fermentation

There are many different configurations of fermentation vessel and in particular for those used to produce ale. Whether based on construction materials, shape, or indeed the more complex arrangements of vessels and elements as illustrated by the Yorkshire Square or the barrel-based Burton Union system, the common driver for such differing approaches was broadly based on yeast strain.

While changes in vessel shape were undoubtedly more significant following Hansen's characterization of yeast strains, a more contemporary shift towards the requirement for higher-capacity production has also contributed to the basic high- and low-aspect-ratio designs (see succeeding text) most frequently associated with the modern industry.

More recently, however, vessel design is returning to a more ubiquitous format and, in particular, with the realization that some ale yeast strains can show adaptive abilities towards vessel geometry such that those strains once considered as more typical of top fermentation, within reason, can be used in cylindroconical vessels as bottom-fermenting strains.

Certainly, vessel design will impact on the biological and biochemical processes that define fermentation and will therefore have a significant impact on its progress and outcome. Ultimately, all vessels must be 'fit for purpose' and in this way must satisfy a number of fundamental criteria:

- Filling and emptying of the vessel must be achieved as quickly as possible and in such a way as to reduce losses/maximize output.
- The chosen design must ensure efficient and thorough mixing during fermentation.
- Appropriate separation and collection of yeast.
- Efficient and precise control of fermentation conditions.
- Vessel durability, cleanability, and hygiene.

Vessel Construction

There are a number of principal factors that must be considered in the design and construction of fermentation vessels. To begin with, the material used to construct the vessel is important not only for vessel strength and durability but also in terms of issues such as food safety, hygiene, and cleanability.

Cost must not be ignored as a consideration, in terms of both the cost of the base material and the ease with which different materials can be worked on. The construction of early, more 'traditional' fermentation vessels was inevitably based on the availability of local materials. In most cases, this is likely to have been wood or stone; however, a variety of other materials might also be used, including slate and metal.

The final choice of material will also be dictated by the size of the fermentation vessel since the volumes of liquid involved and the extent of CO_2 evolution during active fermentation will exert considerable pressure on the vessel. Therefore, larger vessels will need to be built from more resilient materials, capable of withstanding such rigors, as well to enable sufficient process control and, in particular for lager production, the need for efficient temperature control, which is generally dependent on the thermal conductivity of the material in question.

In some cases, lining of vessels may be necessary to protect the fermenting liquid from toxic or tainting compounds leeching from the construction material. Materials traditionally used for vessel linings are metals such as aluminum or copper; however, glass and composite materials such as epoxy resins and plastics have been used. Vessel linings can protect against microbial contamination and improve the cleanability of the vessel and, in the case of materials that are prone to wear and corrosion, may also increase the life of the vessel. Lining a vessel can also improve rigidity and strength and may offer improved temperature control.

Vessel Geometry

Today, the most common material for construction is undoubtedly stainless steel that, while perhaps not the cheapest of materials, is inert and does not require lining, is extremely durable, and provides excellent thermal conductivity. In this instance, vessel shape becomes a principal concern

for new fermenter design. This will also largely be influenced by the type of beer being produced and in general terms may be described by two distinct geometries.

Low-aspect-ratio design

Vessels used to produce ale are relatively short and either round or square with an open top and a flat bottom. This low-aspect-ratio shape suits the dynamics of top-fermenting yeast, which generally ferment faster than bottom-fermenting lager strains. Ale yeast not only produces considerable amounts of CO_2 during the active fermentation but also is more flocculent. The flocs, or clumps, of yeast entrap rising CO_2 bubbles and are then driven to the surface of the fermenting liquid where the yeast collects and from where it will need to be harvested or 'skimmed' ready for repitching into subsequent fermentations.

High-aspect-ratio design

While lager fermentation vessels may have originally shared a similar design to the 'classic' ale fermenter, today, such vessels are considerably different in both shape and size. Vessel format and design have progressed through various iterations of cylindrical, enclosed, horizontal, and vertical vessel formats. Today's familiar cylindroconical fermentation vessel shape was patented in the 1940s by Nathan who was able to demonstrate considerable improvements in both the time and efficiency of lager fermentations using a high-aspect-ratio design. Nathan reduced overall fermentation time to a period of weeks rather than months based on this new design, which has since become the 'standard' format for fermentation vessel design with the main body of the vessel generally typified by an enclosed, tall, narrow cylinder attached to which is a conical base designed to more efficiently capture and separate yeast from the fermented wort at the end of the process.

Vessel Dynamics

Fermentation dynamics, including yeast performance, are greatly influenced by vessel geometry, which can be evidenced in the principle associated with vessel mixing. Whether in ale or lager fermenters, there is very little, if any, mechanical agitation of the vessel contents. In both cases, vessel mixing is intrinsically linked with the shape of the vessel and the evolution of CO_2 during active fermentation.

While gas evolution is greater in vessels with a low aspect ratio, it is not as vigorous as those with a high aspect ratio. In open, flat-bottom fermenters, CO_2 production will keep yeast suspended within the body of the fermenting wort until flocculation occurs. However, the conical base of cylindroconical vessels creates a concentrated column of rising gas towards the center of the vessel that carries yeast cells up through the body of the fermenting wort. Cooling systems built into the wall of the vessel cause the liquid away from the central rising column to be cooler than the liquid at the center. This changes the density of the wort and provides a region of reduced turbulence. Yeast that has been carried up within the central column is then able to sink back towards the base of the vessel. Finally, as the active fermentation comes to a close, CO_2 production becomes greatly reduced, and combined with vessel cooling, the flocculating yeast will then collect in the vessel cone.

The effects of different vessel geometries on yeast performance are most frequently seen in ale production where there are a number of peculiar formats that have evolved. Fermentation systems such as the Burton Union and Yorkshire Square, which in themselves are something of a rarity today, were designed in particular to accommodate highly flocculent yeast strains that are considerably more difficult to keep suspended during fermentation. Ultimately, this mirrors one of the more important aspects of vessel design that is the removal of yeast at the end of the fermentation process. Unfortunately, within the scope of this article, there is insufficient time to summarize the impact of all of the different possible configurations for vessel geometry on fermentation dynamics. Therefore, we will instead look at the primary differences between high- and low-aspect-ratio vessel geometries and how these impact on the management and recovery of yeast for subsequent fermentations.

Yeast Recovery: Ale Fermentations

One of the important aspects of fermenter design is the ease with which yeast is separated from the fermented wort. Ale yeasts are generally more flocculent than lager strains and, in this way, towards the end of fermentation, are driven to the surface of the fermenting liquid where they will then collect and remain. For this reason, low-aspect-ratio vessels are generally constructed with an open top that enables the easier recovery of yeast. Collection is usually undertaken using a vacuum-based, suction system; however, in its simplest format, this can be achieved using a 'parachute.' This is a metal funnel attached to a pipe that exits through a sealed port beneath the fermentation vessel. The parachute is lowered into the yeast head at the surface of the vessel to allow yeast to be transferred, by gravity, to a sanitized collection vessel situated beneath the fermenter.

Selective cropping is an important concept in brewing and allows for the collection of the yeast that is most optimal in terms of fermentative capacity. Yeast harvested from open fermenters is traditionally of a higher quality in respect of fermentation performance than that collected from lager fermentations. In top fermentations, the first visible yeast 'head' usually occurs quickly and will largely consist of significant amounts of wort solids or 'trub' as well as yeast that is damaged or atypical in terms of anticipated fermentation characteristics. This initial yeast crop is removed and discarded and a second 'head' will then subsequently form. This will contain a much higher concentration of healthier yeast cells and considerably less trub material and will be collected for pitching into subsequent fermentations. In some instances, a final, third crop may also occur. However, this yeast will once again generally be discarded on the principle that it will have flocculated late in the fermentation process and, in addition to exhibiting atypical or undesirable fermentation characteristics, will be less vital in terms of overall health.

The 'open' format of traditional ale fermenters permits easier collection of yeast for serial repitching; however, it also allows for greater risk from microbiological contamination, particularly earlier in the fermentation not only within the cooled or freshly pitched wort but also within the cropped yeast. Additionally, there is an increased likelihood of exposure

of pitching yeast to oxygen, which, if maintained during collection, may result in yeast remaining active during storage and therefore lead to a reduced fermentative capacity on repitching.

Yeast Recovery: Lager Fermentations

When compared with traditional open top fermenters, yeast removal from vessels with a high aspect ratio generally offers fewer options in terms of the actual physical removal of yeast. On this basis, the principle of harvesting yeast is arguably a simpler one and, in some cases, may also offer opportunities for automation, including active separation of the more viable portion of yeast within the cone. With such automated aids, it could be argued that the quality and health of the harvested yeast are at least equal to those taken from open top fermenters. However, there is cost involved in such advances that would favor larger brewers, and indeed, there remain some general caveats.

As for ale fermentations, there are distinct periods of sedimentation for lager yeast. However, in the latter case, the broad lack of opportunities to selectively harvest at different periods during fermentation means that all of the sedimented yeast will collect within the cone and, therefore, harvesting will need to be undertaken with some care.

At the end of fermentation, the yeast within the cone of a cylindroconical vessel can be viewed as being composed of three distinct 'bands.' Much like the first crop of an ale fermentation, the lowest band will be composed of yeast with atypical flocculation characteristics and, as well as containing a high proportion of wort solids, may also carry a greater risk of being contaminated with other microorganisms capable of spoilage. The outer band of yeast, while not carrying a significant amount of 'trub,' will similarly also contain yeast that exhibits atypical brewing characteristics. The central portion of the yeast cone however will generally contain the greatest concentration of healthy yeast cells, which will also exhibit those fermentative characteristics desired by the brewer.

Therefore, while yeast will usually be collected in one instance, harvesting must aim to collect the central portion within the cone and to discard the upper and lower bands. Traditionally, the simplest approach is to collect yeast based on visual prompts, whereby the central portion of the cone would usually present a consistency and 'creamy' color classically associated with healthy yeast. Unsurprisingly, this somewhat objective method is not an exact science and can result in the ongoing and increasing presence of wort solids and 'selecting' for particular undesirable characteristics in pitching yeast.

Today, there are some significant opportunities to improving the efficiency of cropping through the use of automated measurement solutions such as those produced by Aber Instruments Ltd (Aberystwyth, S. Wales). The ABER Yeast Monitor is an in-line device that will directly measure the viability of yeast cells as they are removed from the vessel and that can then specifically select for the healthiest and most viable portion of the crop.

Due to the longer fermentation times associated with lager fermentations, as well as the colder temperatures that are involved, it is more common to 'store' yeast within the cone of the fermentation vessel. In this way, new fermentations are then pitched 'cone to cone.' There are however similar concerns with this method as those associated with the storage of ale yeast, where ongoing fermentation within the cone itself, coupled with longer-term exposure to the greater hydrostatic pressures associated with high-aspect-ratio vessels, can lead to cell stress and damage.

Process of Fermentation

Laying aside the choice of fermenter and the impact of yeast strain on fermentation, the broader biochemistry associated with this process is common to all beer styles and, indeed, to the production of any fermented alcoholic beverage. For beer, this process is defined by the fermentation of wort sugars and the assimilation of other wort constituents with the resulting production of alcohol and CO_2 and a variety of other volatile substances associated with beer flavor. Successful fermentation is therefore highly dependent on the appropriate use of yeast, which must be healthy at pitch and introduced in sufficient quantity.

Yeast Health

In general, pitching yeast will have been harvested and, in particular for ale yeast, stored in special tanks prior to use. Both the extent and progress of previous fermentations and the storage process itself are vitally important for the ongoing health of pitching yeast. Ultimately, and even if the health of yeast is maintained to the greatest degree, there is the likelihood that a new production culture will need to be introduced periodically to ensure consistency of beer flavor and character and the efficiency and predictability of the fermentation process. Here, again, it is vitally important to ensure that the yeast undergoes as little stress as possible through the propagation process to ensure the continuity of the strain characteristics.

Replacing yeast cultures is generally more frequent for lager yeast than for ale. Lager yeast is usually replaced on an eight batch or 'generation' cycle, whereas for ales, this is more likely to be around twelve generations. In some cases, in particular, for the traditional British ale-producing breweries, the production culture may have been in use continually for hundreds of generations or more. While, genetically speaking, ongoing and uninterrupted use will likely lead to a more stable yeast, there will inevitably be some changes to both the flavor and fermentation characteristics associated with that strain. This then becomes a matter for the brewer to determine whether such changes are acceptable and remain within the overall character of the beer in question. However, if catastrophic events would lead to the loss of the production culture, while it is possible to recover or renew the strain, it is unlikely that the essential character of the beer would be preserved.

Maintaining yeast health prior to pitching is therefore a combined effort of ensuring consistent fermentation conditions, providing sufficient wort nutrients, and maintaining appropriate storage conditions over the shortest possible time.

Yeast Storage

At the end of fermentation, due to exhaustion of wort nutrients and sugars, yeast will have developed an internal store of glycogen as an energy reserve. Operationally speaking, it is

important to reduce the potential for yeast to utilize this energy reserve too early. In the case of ale yeast, this necessitates the removal of the culture from the fermented wort as quickly as possible while also looking to minimize contact with beer residue as well as exposure to oxygen or air.

In the case of lager yeast, reducing exposure to oxygen is less of an issue as the culture will generally be held within the cone of the fermentation vessel and that in itself should offer a largely anaerobic environment. However, in all cases, reducing temperature then becomes important in preventing further metabolic activity during storage where ongoing fermentation of residual sugars that are bound up within the yeast can result in significant damage to the health of the cell. Localized hot spots of activity within the bulk-stored yeast can lead to the production of alcohol, CO_2, and heat as a consequence of fermentation and will cause physical damage or weakening of the cells. Metabolically, the energy required for such activity will generally be provided by depletion of glycogen reserves, which are vital to yeast during the very early stages of fermentation.

For yeast held in temperature-controlled storage tanks, low-speed, mechanical agitators can be used to further reduce the likelihood of hot spots of fermentation. However, agitation may increase the potential for exposure to oxygen if this is not effectively excluded from the storage vessel. CO_2 or nitrogen top pressure can be applied; however, whereas this is an effective barrier to oxygen or air, the use of nitrogen in particular can induce a longer lag period in yeast upon repitching.

Yeast Pitching

Pitching of healthy yeast is vital to the progress of fermentation. In particular, at this stage are the quantity of yeast and the introduction of oxygen. Yeast pitching rates will generally fall between 10 million and 25 million yeast cells per milliliter. The final rate will be dependent on many factors including the style of beer, strain of yeast, anticipated patterns of flocculation, and wort strength. Much of this will rely on the experiences of the brewer and knowledge of the performance characteristics of the strain in question. However, over or under pitching can have serious consequences on the progress of the fermentation and will likely result in the inefficient and incomplete utilization of wort carbohydrates.

In particular, over pitching may result in an uncontrolled, 'runaway' fermentation whereby the utilization of sugars will occur at a faster rate than anticipated. The significant production of heat as a consequence of the rapid assimilation of wort sugars, in turn, promotes further rapid and uncontrolled fermentation where the supply of wort nutrients and carbohydrates is quickly exhausted and unable to further support the health of the culture.

Sufficient introduction of oxygen is also important at pitching. However, the quantity of oxygen that is required by yeast will be somewhat dependent on the strain. Brewing yeast cultures range in their demand for oxygen. If the strain in question has a high requirement, then oxygen will need to be delivered as pure oxygen. However, in the case of yeast with a lower demand, this can be achieved using filtered air that has an oxygen concentration just over 20%, providing a maximum of 8ppm oxygen in air-saturated wort.

Fermentation Characteristics

With the exception of time and temperature, the profile of fermentation is the same for ale or for lager and can be described in three distinct phases, borrowed from the classical microbiological model of cell growth:

1. Lag phase
2. Fermentation (growth) phase
3. Stationary phase

Lag phase

The temperature of the wort into which brewing yeast will be introduced will differ depending on yeast strain. For lager yeast, pitching is usually at between 7 and 15 °C, whereas for ales, this temperature is higher, between 18 and 22 °C. Pitching is followed by a period of apparent senescence; however, in reality, yeast is metabolically active as the cells transition through a period of 'acclimatization.'

Wort nutrients, including vitamins, minerals, and metals, are all important to overall yeast health and growth. During this period, dissolved oxygen will be assimilated for the production of sterols and fatty acids required to build and strengthen the cell membrane. Nitrogen is also a key requirement for yeast cell growth and metabolism and in the case of wort will be provided primarily via amino acids. These will be assimilated to build proteins required for cell health and a variety of cellular mechanisms including the production of enzymes needed for the utilization of wort sugars.

Fermentation or growth phase

This stage of the process will see the utilization of the bulk of the fermentable wort carbohydrates with the production of ethanol and CO_2. Many other positive flavor compounds (primarily higher alcohols and esters) derived from yeasts and commonly associated with beer are also produced at this stage.

The utilization of wort sugars will take place in the following order:

1. Sucrose (converted into glucose and fructose before metabolism)
2. Glucose
3. Fructose
4. Maltose
5. Maltotriose

At the start of the fermentation phase, yeast will preferentially utilize glucose before other sugars can be consumed. This period will also involve the production of new cell biomass since the excess of glucose provides sufficient energy for yeast to devote to cell growth and reproduction. However, as glucose is consumed and is no longer present in significant quantity, compared to the amount of yeast, cells switch to a fermentative metabolism whereby the remaining sugars are utilized with greater focus on the production of ethanol and CO_2.

There are a variety of both positive and negative contributors to flavor and aroma produced during the growth phase of fermentation. During cell growth, yeast produces a significant quantity of acetaldehyde, which will then be further converted to alcohol and CO_2. However, the production of compounds referred to as vicinal diketones can be more problematic. These

compounds, primarily diacetyl and 2,3-pentanedione, are a natural metabolite associated with yeast growth that can introduce unwanted flavors to finished beer if they are not removed sufficiently. This forms one of the most important functions of the early, postfermentative, maturation process whereby the concentrations of these compounds, in the presence of yeast, should be reduced to a level that is no longer flavor-active. For this reason, diacetyl reduction is a key indicator of fermentation process efficiency.

Positive flavor attributes associated with fermentation are generally associated with the formation of higher or fusel alcohols and esters. Fusel alcohols are produced initially and are closely associated with the quantity of amino acids in the wort. However, in addition to this, the choice of yeast strain and the temperature of fermentation will have a significant impact on their production. Linked with fusel alcohols is the production of esters. These are the most prevalent positive flavor contributor associated with yeast. There are over 100 different esters in beer with a broad range of characteristics but that typically are described as being fruity, solvent, and banana-like. Generally, esters are produced from the combination of a fusel alcohol and a fatty acid and are influenced by fermentation temperature and yeast strain. However, there are a variety of other effects that can influence the formation of esters, including the composition and strength of the wort, the geometry of the vessel, and the extent of vessel top pressure.

There are a number of factors that can be used to describe or monitor the progress of fermentation. Primarily, an increase in alcohol and CO_2 will be related to the decrease in wort gravity or strength, which simplistically is a measure of wort density and is then related to the concentration of wort carbohydrates. Similarly, yeast cell density within the fermenting wort can be measured as indicator of yeast growth and sedimentation. However, the growth of yeast will also impact on the pH of the wort. As the yeast assimilates wort minerals and nutrients and excretes metabolites such as organic acids, the pH of the wort by the end of fermentation falls to a level of around 4.5. This, along with the depletion of nutrients, presence of hop acids, and the lack of oxygen, is also responsible for the extent of microbiological stability that is associated with beer as a fermented alcoholic beverage.

Stationary phase

The fermentation process comes to an end as the concentration of wort nutrients becomes exhausted, and in particular, those compounds associated with metabolic function and cell membrane health become depleted. At this stage, there will invariably be a residual quantity of fermentable sugar remaining. However, cells will begin to reenter a period of senescence and will start to flocculate. This, along with a reduction in CO_2 production, promotes sedimentation of the yeast within the vessel, which signals the end of the fermentation process.

The end of fermentation is also the point at which those 'creative' processes associated with beer making are completed. In essence, all downstream processes from this stage are concerned with either the modification of flavors or characteristics already produced, typified by maturation or aging, or the preparation of the beer for the appropriate packaging format. There is however one further possible fermentation stage that can be undertaken, and this is associated with cask or bottle 'conditioning.' In this case, a quantity of fermentable extract is required, but rather than a full fermentation, the objective is generally a modest increase in alcohol concentration to enhance the presence of esters and higher alcohols and produce some additional CO_2, which is then used to naturally carbonate the packaged beer.

Introduction

Beer is a truly international drink, produced and marketed globally; it is the world's most widely consumed alcoholic drink and ranks third overall after water and tea. Alcohol (ethanol) is the most widely used psychoactive agent in the world, and its use is embedded in human culture. With the exception of Oceania and most of North America, tribal peoples from all major parts of the world knew how to make alcoholic drinks, and there have been very few, if any, societies whose people knew about alcohol and yet paid little attention to it.

Ancient people used indigenous plants as a source of fermentable material, and the 'first fermentations' were undoubtedly serendipitous. It is evident that man's early alcoholic drinks often used a mixture of fruit, grain, and honey as a base and were 'mixed' beverages – having affinities with wine, beer, and mead. It was some while before the individual categories of 'beer,' 'wine,' etc. emerged.

'Beer' may be simply described as "an alcoholic drink essentially made by fermenting sugar-rich extracts originating from a variety of plant starches." Today, most beer brewed is derived from cereal grains, which have been partially germinated (malted) – a process that leads to the release of fermentable sugars from starch. Thus, in its broadest sense, the term 'brewing' may be defined as "the combined processes preparing beverages from an infusion of sound grains that have undergone sprouting and the subsequent fermentation of the sugary solution (wort) thus produced by yeast." This results in a proportion of the fermentable carbohydrate being converted to ethanol and carbon dioxide. For reasons of space, most of this article concerns the history of 'European-style' beer, for it is this form that has become truly global.

The transition from nomadic hunter-gathering to a sedentary, crop-growing existence (the 'Neolithic Revolution') was a major step in the history of *Homo sapiens*, and early agriculturalists necessarily used whatever plants available to prepare mind-altering potions and drinks. Several reasons, including population density and climate change, have been forwarded to explain this change of lifestyle, but one school of thought attributes the transformation to the accidental discovery of the physiologically interesting beverages that resulted from fermented moist wheat and barley (i.e., 'beer'). The hunter-gatherers' precursor to beer was a gruel, or porridge, made simply by soaking grains in water.

In theory, any unspoiled grain could be employed provided that the seed had sufficient polysaccharide food reserve (endosperm). Cereal grains are the unique seedlike fruits (caryopses) produced by members of the grass family Poaceae (formerly Graminae). When raw, they present a relatively unattractive foodstuff. A combination of soaking in water or milling and mixing with water renders products that are far more palatable and digestible. Heating the grain/water mixture would have yielded a major improvement in digestibility and nutritional status – resulting from structural changes in starch and protein molecules. In particular, sugars would have been released. These, initially crude, processes have undoubtedly provided the basis for the malting, brewing, and baking industries that we know today.

For a variety of reasons, barley has evolved to become the grain of choice for the brewer, while wheat is preferred by the baker. The histories of beer and bread are intertwined, and some authorities have eloquently made the case for beer being considered as 'liquid bread.' In former times, cereals such as einkorn, emmer, spelt, oats, and rye have been used for brewing in Europe, while outside Europe, rice, millet, maize, and tuberous plants have been/are used.

With the brewing industry now dominated by a few multinational companies, it is difficult to envisage that, for most of its history, brewing was a domestic or, at best, a small-scale commercial enterprise, scarcely removed from its agrarian roots. Enough scientific and archaeological evidence now exists for us to believe that what we know as 'European-style beer' was first produced in the late fourth millennium BC by the Sumerians in southern Babylonia. The Sumerian civilization was located in Lower Mesopotamia – in the alluvial plain between the rivers Tigris and Euphrates – and it was one of the earliest of literate civilizations. Situated in the Fertile Crescent, one of the world's most important centers of cultural development, this region is one of the nuclei of early agriculture (Figure 1). Other centers almost certainly produced their own 'beer,' but we have little or no physical or textural evidence. What we do know is that barley was the ubiquitous cereal staple throughout the archaeological and cultural records of the earliest periods in both Egypt and Mesopotamia.

In brewing terms, the main species of relevance to the evolution of required Near Eastern founder crops are: wild einkorn (*Triticum boeticum*), wild emmer (*T. dicoccoides*) (both wheats), and wild barley (*Hordeum spontaneum*). Assuming that suitable grains evolved, other prerequisites for brewing include the facility to store grain, the ability to control fire, and the development of suitable (heatproof) containers – that is, ceramic technology (which first emerged in East Asia during the Late Pleistocene, ca. 18 000–10 000 BC).

Ancient Near East

The Neolithic Revolution in the lowlands of the Mesopotamian alluvial plain emerged around 7000 BC, but there is no conclusive archaeological evidence for the invention of beer brewing technology as early as this. Agriculture was so successfully organized in Sumer that grain surpluses were not uncommon, and it was to record such events, and subsequent transactions, that writing was developed. Sumerian culture saw the emergence of large cities and the stratification of society into different classes. Beer became one of the surplus

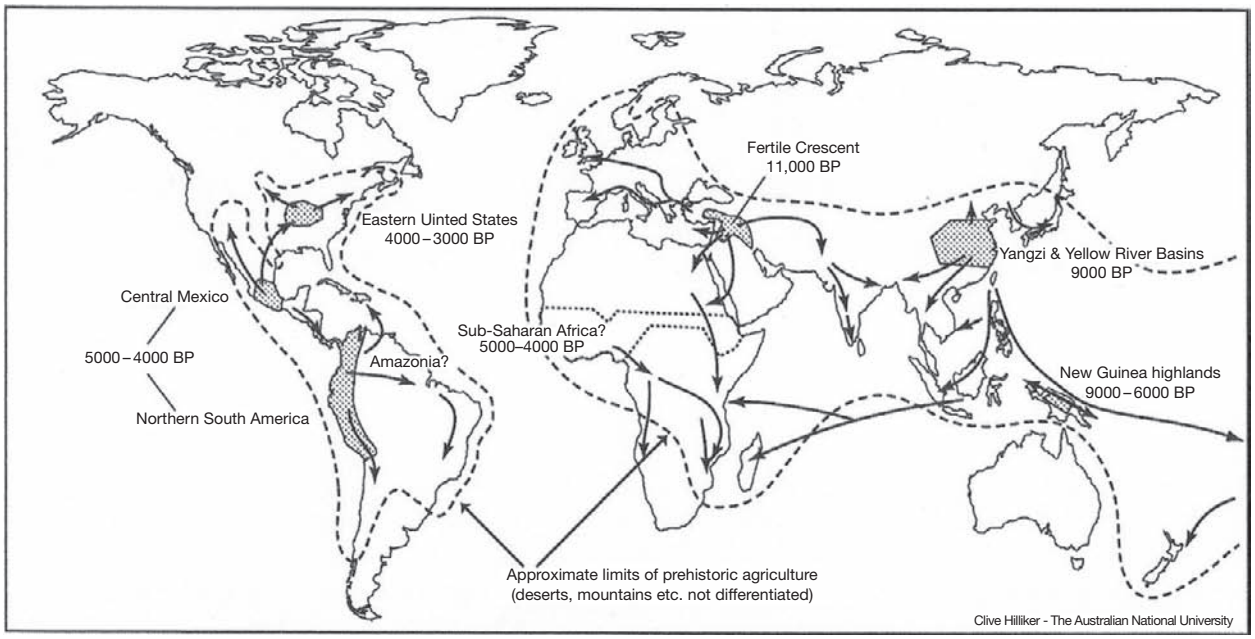

Figure 1 Areas where agriculture originated. Reproduced from Bellwood, P. (2005). *First farmers*: *the origins of agricultural societies*. Oxford: Blackwell, with permission.

products of this new society and brewing came under state control. As a result, the Sumerian bureaucracy of the time provided us with some of the earliest documentations of brewing beer. Proto-cuneiform texts, dating from around 3200–3000 BC, indicate that brewing was no longer a rural pastime, but was a central feature of the economy of Sumerian states. Hundreds of texts describe the administrative activities necessary for the production, distribution, and consumption of beer. Unfortunately, these texts tell us little about brewing technology (this knowledge was assumed!), but they do list raw materials, amounts and types of beer produced, and economic transactions.

Other literary documents yielding information about beer in ancient Mesopotamia can be found in the 'Code of Hammurabi,' which is considered to embody the world's earliest laws. King Hammurabi, who ruled Babylonia from ca. 1792 to 1750 BC, introduced a code of punishments dealing with all aspects of everyday life. Four of these relate to taverns and the distribution and price of beer.

In ancient Mesopotamia, brewers were so important that they were the only profession directly linked to a deity, the beer goddess Ninkasi. A cuneiform text discovered at the Sumerian city of Ur contained the 'Hymn to Ninkasi,' considered to be one of the oldest pieces of literature, and the script contains two Sumerian drinking songs dating from the eighteenth century BC. The first song outlines how Mesopotamian beer might have been brewed, while the second praises Ninkasi for providing beer drinkers with the opportunity to reach a 'blissful mood.'

When it became obvious that air was detrimental to these fermented brews, one saw the development of narrow-necked storage vessels common in archaeological sites in Mesopotamia. It is surmised that such vessels were designed to keep 'bad gasses' (air) out and 'good gasses' (carbon dioxide) in.

Figure 2 Shard of beer jug, ca. 3500–2900 BC from Godin Tepe. The grooves on the inner surface contain traces of 'beer stone.' Reproduced from Michel et al. (1992), with permission.

The first chemical evidence for beer comes from the site at Godin Tepe in the Zagros Mountains of what is now Iran. There is evidence that the neighboring Sumerians exploited this area for some of their essential commodities – and brought their beer-making knowledge with them. Numerous excavated samples of carbonized six-rowed barley have been recovered together with fragments of pottery jars with unique crisscross grooving on the inner surfaces (Figure 2). It is thought that

these grooves were designed to retain the sediment from the beer after storage. Chemical analysis of sediment found in the grooves indicated the presence of calcium oxalate, a major insoluble component of 'beer stone' (a scalelike deposit that accumulates in fermentation vessels and beer storage tanks). Oxalic acid is present in trace amounts in malt and combines during brewing with calcium ions to form the insoluble salt. Ancient jars known to have contained wine, cider, or mead do not show any evidence of calcium oxalate deposits.

Until recently, it has been widely accepted that brewing first commenced in the civilizations of Mesopotamia, but excavations at Göbekli Tepe in southeastern Turkey have indicated that brewing may be much more ancient. At the dawn of the Neolithic (Pre-Pottery Neolithic, i.e., some 6000 years older than Stonehenge, and seven millennia before the Great Pyramid of Giza was built), hunter-gatherers assembled at Göbekli Tepe and created a cultic center. The site ('Tepe' = mound), beset with dozens of massive stone pillars, was not used for habitation, but apparently for executing ancient rituals, many of which involved feasting. Even at this early stage in human history, there is evidence for plant domestication and for beer brewing, and if the latter is confirmed, this would represent the earliest known date for such activity.

From two ancient sites in what is now northern Syria, it is evident that ancient Near Eastern settlements differed in their beer production ethos; sometimes, every household in a settlement brewed, and sometimes, there were specialized (professional?) brewers capable of supplying numerous customers. The former situation is known to have applied to the Late Bronze Age site at Tell Bazi on the eastern bank of the Syrian Euphrates (some 60 Km south of the Turkish border), where seemingly every house contained remains of brewing pots. From excavations carried out at Tell Bazi, it has been possible to reconstruct their malting and brewing methods. Archaeological evidence from the site indicates that two-rowed barley (*Hordeum distichum* L.) was being widely used for malting and brewing, with the possibility that other grains were also used.

Conversely, at Tell Sabi Abyad in the Balikh Valley, 'a brewer' is specifically mentioned in the texts and so beer was centrally brewed and then distributed. A similar situation appertained for bread. Associated with brewing were several types of pottery jars and bowls. Beer brewed here was evidently not sieved or strained, as is suggested by the presence of several bronze filter straws that would have been used to keep large particulate matter out while drinking. Indeed, in a similar vein, the first visual evidence that we have relating to the actual drinking of beer comes from a sealing found at Tepe Gawra, in northern Iraq, dated ca. 4000 BC. The seal depicts two people with bent tubes drinking beer from a large jar (**Figure 3**).

The semimythical Hymn to Ninkasi (of which three copies exist, all written in the Old Babylonian period, ca. 1800 BC) gives us some information about brewing at this time. Most significant is the fact that *bappir* bread (a kind used for storage purposes – only eaten in times of food shortage) was a beer ingredient, as was malt. There is also mention of *bappir* dough being mixed with 'sweet aromatics' using a "big shovel... in a pit." From other sources, it seems as though bappir was always an ingredient of old Sumerian beer.

Ninkasi was head brewer of the great god En-lil and thus of all the gods. It was Ninkasi's responsibility to provide alcohol,

Figure 3 Clay sealing from Tepe Gawra, Zagros Mountains, northern Iraq, showing two people drinking through straws. Dated to 4000 BC. Reproduced from the University of Pennsylvania Museum of Archaeology and Anthropology, with permission.

especially beer, for the temples of the major religious center of Nippur (whose ruins lie ca. 180 km southwest of Baghdad). To the ancient Sumerians, Ninkasi was the personification of beer, and one translation of her name is 'lady who fills the mouth.'

A second seemingly invariable ingredient of beer, although not mentioned in the hymn, appears in protocuneiform documents of the Late Uruk period, and this is *munu* – an entity delivered in sacks, baskets, or vessels. Consensus among scholars is that this translates as malted barley. Emmer, an ancient wheat variety used in ancient Egyptian brewing, is commonly mentioned in ancient Near Eastern documents – but not as a beer ingredient.

A major feature of ancient Near Eastern civilizations was the formation of large conurbations, and it has been argued that beer played no small part in this process. As Alexander Joffe opined: "The appearance of beer has been regarded by some as an indicator of social complexity – the rather prosaic knowledge of brewing being regarded, in a sense following the Sumerian lead, as a sign of civilized behavior."

As urbanization occurred, it was imperative that risks associated with food procurement were minimized, and this was usually achieved through state control. In this respect, beer played an important role in securing the allegiance of the labor force engaged in food production. Also, increased population densities would invariably lead to the contamination of water supplies, and beer, being readily accessible, provided an

obvious alternative drink to water. It was also a cheap source of calories and dietary fiber and was, of course, a stimulant.

The fact that beer was a linchpin of Mesopotamian culture can be gleaned from the *Epic of Gilgamesh* (Gilgamesh was king of Uruk) where the wild, hirsute Enkidu was 'civilized' by a female who taught him to eat bread and drink beer.

Ancient Egypt

Evidence for the production and use of beer in ancient Egypt extends back to the Predynastic era (5500–3100 BC), with early twentieth-century discoveries of beer sediments from jars at Abadiyeh, a Predynastic cemetery on the east bank of the Nile, in Upper Egypt, and at Naqada, one of the largest Predynastic sites in Egypt (situated some 26 km. north of Luxor on the west bank of the Nile). The Predynastic site at Hierakonpolis contained numerous large, fixed vats, and this may represent the earliest known brewery site. Later, it seems as though brewing was mostly a domestic activity and was carried out in smaller, portable, pottery vessels. We also know from Early Dynastic (3100–2686 BC) written records that beer was very important at this time and was a well-established feature of the culture of that period. It is thus highly likely that Egyptian brewing had its antecedents in Predynastic times, and information from the Near East and the Middle East strongly indicates that humans knew how to make bread and brew beer in 6000 BC.

Classical Greek writers (erroneously) credited the Egyptians with having invented beer, and the geographer Strabo (ca. 63 BC to AD 21) commented that "Barley beer is a preparation peculiar to the Egyptians, it is common to many tribes, but the mode of preparing it differs in each." He also noted that it was one of the principal beverages of Alexandria. The Greek historian Diodorus Siculus, in his monumental work *Bibliotheca Historica*, mostly written between 60 and 30 BC, praised the quality of Egyptian barley beer, saying that "They make a drink of barley. . .for smell and sweetness of taste it is not much inferior to wine." Praise indeed from an oenophile. Diodorus Siculus also attributed the invention of beer to the god Dionysus, a god who was rather more associated with wine. To the Greeks, Dionysus was the equivalent of the Egyptian deity, Osiris, who the ancient Egyptians believed had invented beer. Osiris was one of their most important deities, whose principal associations were with fertility, death, and resurrection. Osiris was also credited with spreading beer into countries where the grape was unknown.

In ancient Egypt, beer was king. All sections of the community drank beer, from the pharaoh downward, and it was a product that was inextricably woven into the fabric of daily existence and was a feature of religious festivals and state occasions (when 'special' brews were produced). Beer was drunk daily as a highly refreshing and more reliably potable substitute for water, which in an urban context would become notoriously unhygienic. Beers brewed for everyday drinking would not be highly alcoholic and would have had a very short shelf life; this necessitated daily brewing and immediate consumption. Beer was especially important in regions where the vine would not grow, where it was considered, with bread, to be an indispensable staple. Generally speaking, grapes were much more expensive than grain in ancient Egypt, and so, wine was an expensive commodity.

The barley beer of Egypt was called 'zythos' by the classical writers, a name that refers to its propensity 'to foam.' It was Aristotle's student Theophrastus who first used the term 'zythos' to describe: "Those beverages, which were prepared, like those made of barley and wheat, of rotting fruits." The word has the same Greek derivations as the words 'leaven' and 'yeast.'

Emmer continued (up to the AD fourth century) to be the primary wheat in ancient Egypt long after it became superseded in the Near East. This preference for emmer over free-threshing wheats may have been due to some religious significance. By the New Kingdom period (1550–1069 BC), two types of barley – two-rowed (*H. distichum* L.) and six-rowed (*H. vulgare* L) and emmer (*Triticum dicoccum* Schübl.) – were being used for brewing. Apparently, barley was the predominant brewing cereal during the Old and Middle Kingdoms (2686–1650 BC) but was replaced by emmer by the New Kingdom. Flavorings, where used, consisted of figs, dates, honey, mandrake, lupine, and skirret; hops were not used.

Until the last couple of decades, it was believed that all brewing in ancient Egypt commenced by soaking partially baked barley/emmer bread in water and then allowing the resultant 'gruel' to ferment. This is exactly what happens when the ancient, wheat-based, drink 'bouza' is prepared. Bouza ('boozak' and 'boozeh') is an indigenous drink of Nubia and Sudan, which can now be found in Egypt and other parts of Africa, and is typically drunk by the working classes. It is opaque and can be consumed 'young' or 'old,' according to fermentation time. The latter is obviously more alcoholic (ca. 7% alcohol by volume (ABV)) and has greater nutritive value – with more amino acid and B-group vitamin content. Most bouza is consumed 'fizzy,' for it will still be fermenting. The beer can be partially clarified by passage through a cloth. The alchemist Zosimus of Panopolis gave us AD fourth-century accounts of the preparation of both zythos and bouza.

Work by Delwen Samuel over the turn of this century has shown that, certainly by the New Kingdom, the ancient Egyptians malted grain for brewing. Most work was carried out in the workmen's villages of Amarna and Deir el-Medina, where barley (mainly) and emmer were the brewing grains. A lack of other plant remains (not even dates) suggests that plant flavorings were not used at these sites and that the main body of the beer came from malt.

The importation of wine into Egypt by the Greeks during the Ptolemaic period saw brewing and selling beer become tightly regulated, and later, brewing became a state monopoly, with beer being taxed for the first time. Despite this, the drink was still being consumed during both secular and sacred rituals.

Prehistoric Northern Europe

Barley and wheat are not native to this region, and they were introduced from the Near East/Anatolia. The situation is further complicated by the fact that there is no 'single European Neolithic' per se, and the Mesolithic/Neolithic transition occurred during the sixth and fifth millennia BC. Processing

grains for brewing were vastly different from the Middle and Near East for soaked grains left out to dry merely rotted. Thus, heating (kilning) grain to dryness was a necessity.

Perhaps, the most convincing evidence of germinating and kilning malt comes from the Early Iron Age settlement (fifth to fourth century BC) of Eberdingen-Hochdorf, southwest Germany. This was a Celtic settlement that contained structures seemingly purposely designed for malting and drying grain; the main finds being of hulled barley and spelt (dinkel) (*Triticum spelta* L.).

Artifacts from the Neolithic Orcadian site at Skara Brae indicate that the conversion of barley into malt and ale was an important aspect of life, and evidence from various other Neolithic and Bronze Age sites in Scotland suggests the use of a mixed barley beverage, particularly in association with characteristic ceramic vessels. Most prominent were 'bell beakers' (Figure 4), part of a European culture (the 'Beaker people') that commenced at the end of the Neolithic (ca. 2900 BC) and ended in the early Bronze Age (ca. 1800 BC). Some authorities believe that these beakers were designed for consumption of alcoholic beverages, with beer and mead residues having been identified. The culture, with all its paraphernalia, certainly spread across Europe in the form of a cultural complex and marked a period of unprecedented cultural contact. Brewing knowledge is likely to have spread with the Beaker people.

Classical Antiquity to Medieval Europe

The ancient Greeks are often seen as having been oenophiles in the extreme, even though they were originally beer drinkers. The Minoans, the pre-Greek inhabitants of Crete, almost certainly made barley-based beverages. The Greek prejudice against beer arose from a cultural need to distinguish themselves from 'barbarians' (principally the Celts and the Germanic tribes); to the Greeks, wine was a 'pure, hot, manly drink,' while beer was 'corrupted, cold, and effeminate.' Aristotle declared that men who are drunk on wine fall down face foremost, while those intoxicated with barley beer lie outstretched on their backs! As a result of this attitude, roughly between the eighth century BC and the AD sixth century in Western Europe, wine is documented as the major (only?) alcoholic beverage consumed. This may be partly due to its adoption by 'elites' and/or its increasingly popular use in sacred contexts.

Figure 4 Bell beaker.

Greek prejudices against beer were assimilated by the Romans, but they had a need to meet the needs of their troops in regions of their empire where the grapevine would not flourish. In this context, the earliest written references to beer being brewed in the United Kingdom come from the Vindolanda tablets, dated to the AD first century. Vindolanda was an outpost just south of Hadrian's Wall, from which excavated tablets clearly indicate that beer (*cerveza*) was supplied to Roman soldiers. Also mentioned were 'a brewer' (*cervesarius*), malt, and a brewery. The recovery of malt in Roman contexts from various sites in their northern provinces firmly suggests that the Romans routinely consumed beer, but Roman writers such as Tacitus indicate that beer was the main drink of Celtic and Germanic tribes. Many Iron Age granaries have been found in Britain.

The Celts had been known from Central Europe since around 700 BC and gradually expanded into other parts of Europe. They possessed notable brewing expertise, as noted by Pliny the Elder, who affirmed that "the people of the Western world have also their intoxicating drinks made from corn steeped in water. . .The Spanish provinces have even taught us the fact that these liquors are capable of being kept till they have attained a considerable age." For the Celts, brewing was a domestic activity, typically carried out by women, and this theme was to be continued until brewing became industrialized. Beer at this time was mainly made from barley, although wheat and millet were also commonly used. In certain areas, where barley would not grow, rye and oats were used.

After the fall of the Roman Empire, our information about beer increases because sources increasingly come from northern Europe, where grapevines were more difficult to grow. One legacy left by the Romans was the notion that, in some Celtic tribes, at least, beer was the drink of 'common folk' and wine was for chieftains. Under Roman influence, many Celtic tribes turned to wine, but in regions free from Roman control, such as Ireland, Celtic beer culture survived.

In post-Roman Britain, the Anglo-Saxons were oceanic drinkers of beer (being drunk was considered honorable!), and the drink was certainly widespread during the early Middle Ages in northern Europe. 'Ale' was the most common drink in Wales at this time, but given their propensity for drinking it, there is no recorded evidence of brewing techniques, equipment, or sites from the Anglo-Saxons.

Beer is also widely mentioned widely in Norse literature; Viking beer consumption being sizeable enough for their great god Ódin to warn against drunkenness. They used various names for their beers, including *öl* (which equates to the Old English *ealu*) and *björr* (Old English *beor*), the latter probably containing honey as well. Beer drinking was especially important to Nordic seasonal religious festivals.

After 500 odd years of the Dark Ages in Europe, when there was apparently little innovation in brewing, beer became closely associated with religious establishments. Monasteries were probably the only institutions where beer was regularly brewed on anything like a commercial scale at this time; otherwise, brewing was mostly a household chore. During the Middle Ages (ca. AD 800–AD 1300), people were settling in larger communities, and technology from earlier periods had been fully assimilated, so brewing gradually moved away from the home and became a more commercial venture, certainly for some. The plans of St. Gall monastery in Switzerland, founded in the eighth century, include a kiln, malthouse, mill room, three brewhouses, and a storage facility. Three types of beer, varying in strength, were brewed: *prima melior*, intended for the monks and visiting VIP's; *secunda*, for the lay brothers; and *tertia*, for pilgrims, beggars, etc. These were probably produced by using three consecutive wort runoffs, of decreasing strength, from one mash – a technique that lasted several centuries.

Most importantly, monasteries were responsible for the introduction of hops (*Humulus lupulus* L.) into brewing. Prior to this, innumerable herbs were employed to flavor/stabilize beer; a herb mixture called 'gruit' was widely used. In AD 768, the Abbey of St Denis in Paris mentions 'humlonariae' (hop gardens?), probably the oldest mention of hops, but our first hop documentation in a brewing context arises from the Benedictine monastery in Corbie, near Amiens, where statutes of AD 822 refer to 'the gathering of hops.' A little later, hop cultivation (in 'humularia') is mentioned in documents from the Hochstift monastery, Freising, Bavaria. Early archaeobotanical evidence (ninth to tenth century) for hops was obtained from Haithabu, an important Viking trading station on the Schleswig coast, insinuating that the plant was being traded in Europe. Also notable in that context is the ninth-century 'Graveney boat,' a wooden cargo vessel replete with hops, stranded in the Thames estuary. The exact function of hops in brewing remained a mystery until Abbess Hildegard (1098–1179) of Rupertsberg, near Bingen, avowed: "its bitterness prevents some spoilage in drinks to which it has been added so that they last much longer."

From the early medieval period onward, hops (female flowers) were a common beer additive, especially in regions where sweet gale (*Myrica gale* L.), a major component of 'gruit,' did not grow. Sweet gale seems to have used for brewing in the centuries before and after the birth of Christ in its distribution areas and continued in this role until it was supplanted by *H. lupulus*. As hop usage spread, certain north European towns, such as Bremen and Hamburg, became famous for their beer, much of which was exported to Flanders and the Netherlands. Bremen beer is mentioned in Holland in 1252. Hamburg was to become 'the Hanseatic League's brewhouse,' and in 1369, the town had 457 hop-using breweries and was exporting enormous volumes of beer! All this was only possible because of the incorporation of the hop.

Soon, hop cultivation and use in the brewery spread northward, and Low Country beer arrived in the United Kingdom, being first recorded in Great Yarmouth, Norfolk, 1362/63 import tolls. Hopped beer import and brewing were controlled by mainland Europeans for some time, the English preferring to brew their unhopped 'ale,' and it was not until the early sixteenth century that hops were cultivated in the United Kingdom. In general, the introduction of hops met with resistance – but the agreeable flavor they imparted and their preservative properties meant that they became universally used in brewing. Brewers of unhopped beers relied upon high alcohol content to impart keeping quality, whereas hops also allowed the brewer to produce 'weaker,' stable beers and thus obtain more beer from his grain charge. Gradually, hopped 'beer' became prevalent in conurbations, while unhopped 'ale' survived in rural areas.

To obtain the bitterness from hops, boiling is necessary and this required special (expensive) equipment – the copper or kettle. Such an item would be beyond most domestic brewers, but affordable by commercial brewers – so, the overall pattern of brewing changed. Brewing became more regulated in cities and towns, and guilds emerged to guard the status of the brewer and the quality of beer. An early quality protection measure was the Bavarian 'commandment for purity' (*Reinheitsgebot*) of 1516, which decreed that only malt, hops, and water were to be used in brewing (yeast was added later).

Towards Industrialization

Beer consumption in Europe increased enormously during the fifteenth and sixteenth centuries, and commercial brewing became very profitable; and with profits came taxes. Both beer and its raw materials became taxable, the first beer-related tax in the United Kingdom (on malt) being raised by King James I in 1614. At this time, however, domestic brewing still accounted for around half of beer produced.

By the early 1700s, European cities and towns were expanding, and many urban breweries increased in size to accommodate population increase. The next major step would be brewing on an industrial scale; something spurred by the Industrial Revolution, the first phase of which began in the United Kingdom during the eighteenth century and then spread gradually throughout Europe. Even by the start of the eighteenth century, beer production in London was dominated by 'common brewers,' who supplied various outlets. 'Victualler brewers,' who brewed solely for their own inn or tavern, declined in number, and industrialization of brewing accelerated this decline.

For brewers, the harnessing of steam power was probably the singular most important aspect of the Industrial Revolution, and the first brewery steam engine (from Boulton & Watt) was installed in east London in 1777. By 1801, 14 steam engines were operational in London brewhouses, and the likes of Truman and Whitbread were able to expand dramatically and produce vast amounts of beer. Other factors that enabled brewers to expand were improved iron making and concrete making and improved transport links (canals and then railways). Unhopped ale virtually disappeared from Europe by the seventeenth century.

With industrial-scale brewing came the first 'industrial beer,' London Porter, about which much has been written. Suffice to say the drink probably arose as a response by London brewers to increased malt tax. By comparison to malt, hops were relatively cheap, so by using cheap brown malt and a very high hop rate, a dark, luscious, relatively weak beer with

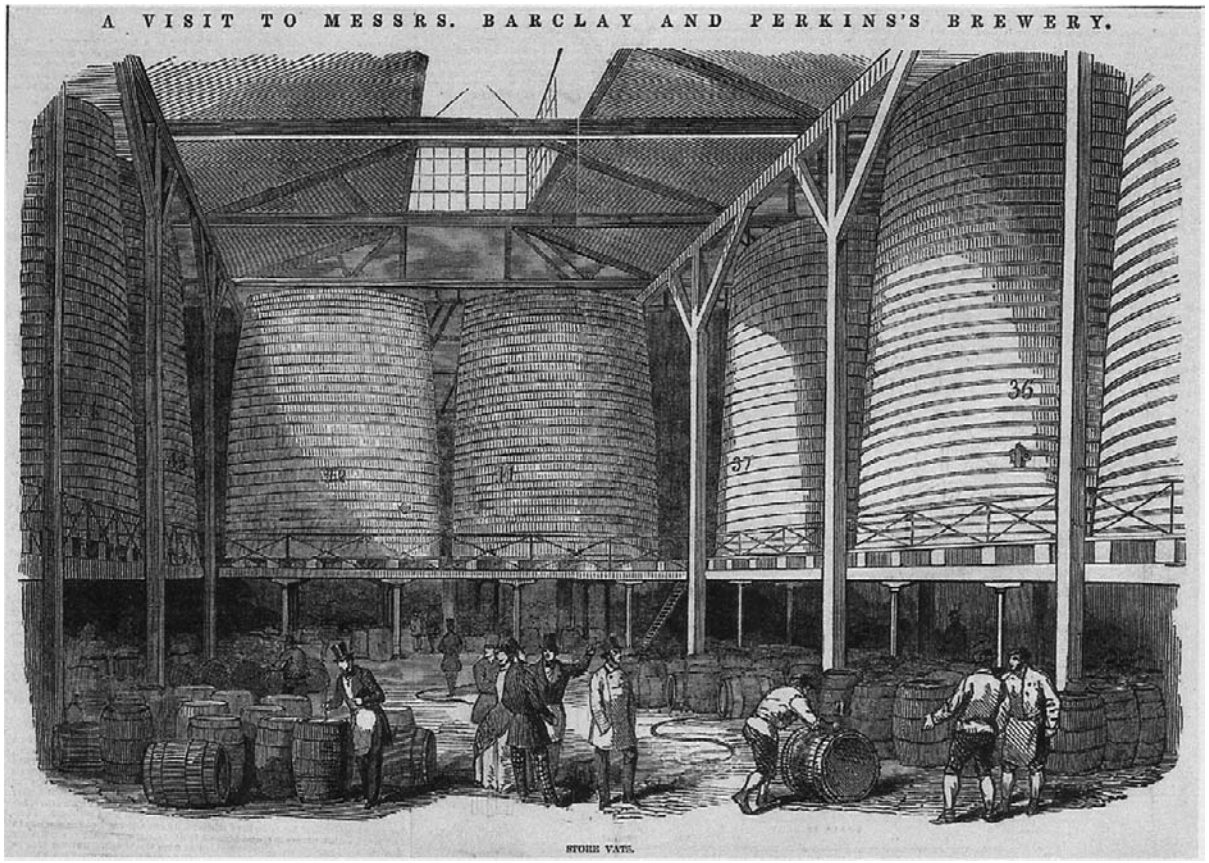

Figure 5 The great porter vats at the Brewery of Barclay, Perkins, and Co., London. Reproduced from 'Illustrated London News,' 6 February 1847.

excellent keeping qualities resulted, which sold to the working class at a competitive price. There was no need for prolonged storage, as was the case with most beers of the time, but its robust nature and low production cost meant that it could be brewed on a huge scale. Enormous wooden vessels (Figure 5) were constructed by some London brewers to accommodate demand – which peaked in the 1820s, London Porter being gradually usurped by mild beers and pale ales.

With large, semimechanized breweries and advancements in science, the late eighteenth century witnessed the first attempts to conduct accurate measurements during brewing. Pioneers were Michael Combrune (thermometry) and John Richardson (saccharometry), who brewed in London and Hull, respectively. Such innovations vastly improved beer quality.

British beers were top-fermented, but in parts of continental Europe, such as Bavaria, bottom fermentation was practiced, probably since the fifteenth century. Brewing here was impossible, even forbidden, during summer months, and beer brewed from October to March was stored for summer consumption. Bavarian monks used nearby caves as cool areas (in the absence of caves, ice (from frozen lakes, etc.) was used in brewery cellars) to store their beer, which proved to be bright, sparkling, and stable. Beer was (necessarily) fermented at low temperature with a low degree of attenuation, and this enabled viable yeast cells to survive after primary fermentation. This yeast continued to ferment slowly during cold storage, and these practices encouraged the cryophilic, bottom-fermenting yeast to evolve. Beers thus produced had a unique flavor profile and were termed 'lagers,' after the German verb 'lagern' ('to store'). These early, bottom-fermented beers bore little resemblance to today's lagers, and the now ubiquitous 'Pilsner' style emerged in 1842 when German brewer, Josef Groll, was appointed head brewer at the Civic Brewery in Plzen. Armed with Bavarian yeast, soft Bohemian water, and local, lightly cured malt, he produced a unique, pale, creamy beer that proved extremely popular and the template for around 95% of today's beer. The style was recreated in Germany, and 'lager yeast' was disseminated all over the globe, Germany becoming a major brewing nation.

Science Plays a Role

Scientific/technological developments at the end of the eighteenth century paved the way for further industrialization of brewing during the following century. Another feature of the nineteenth century in Europe was the gradual spread of bottom-fermented beers at the expense of their top-fermented sisters, the latter only really surviving in Belgium and the United Kingdom. An important innovation was the use of a Carl von Linde mechanical refrigeration machine in Munich's Spaten brewery in 1873. Beer could now be safely brewed all year round and stored with reduced risk of infection. Three years later, Pasteur published his *Études sur la Bière*, which dealt with

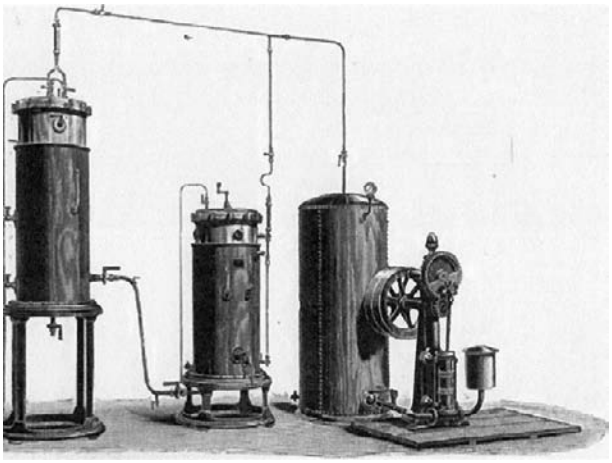

Figure 6 Emil Hansen (1842–1909) – his yeast culture equipment.

beer contamination, having previously proved beyond doubt that the single-celled yeast was the cause of fermentations.

From now on, chemistry and the 'new' science of biology were rigorously applied to brewing, and seminal work was conducted at dedicated laboratories. Most significant was the Carlsberg Laboratory in Copenhagen, where, in 1883, Emil Hansen isolated and propagated the first pure yeast strain (Figure 6). It was bottom fermenting, and he named it *Saccharomyces carlsbergensis*. Hansen's work transformed the way brewers worked and paved the way for our modern fermentation industries. Other fundamental work in the Danish laboratory was carried out by Winge (yeast genetics), Sørensen (pH scale), Kjeldahl (N determination), and Linderstrøm-Lang (protein chemistry).

At the start of the twentieth century, around 69% of all beer was being produced in Germany, the United Kingdom, and the United States, but all three of these countries were soon to see beer volumes fall dramatically, the United States because of prohibition and the other two due to World War I. In particular, the latter changed UK brewing forever – with a fall in beer strength and much more regulation. In Britain, there were 6447 commercial breweries in 1900, but between 1910 and 1920, nearly 1600 breweries disappeared, and, by the start of World War II, only ca. 1400 such enterprises remained. Post-1945, for economic reasons and the takeover mania exhibited by six or seven national brewers (called 'consolidation'!), by 1971, only 170 commercial brewing sites were operational in the United Kingdom, a new low. Inevitably, one of the main casualties of large-scale brewing and a contracting number of brewers was consumer choice.

Not by coincidence, 1971 saw the founding of the Campaign for Real Ale (CAMRA), a UK consumer group determined to improve consumer choice. The number of UK breweries declined slightly after CAMRA's inception, until the nadir was reached in the late 1970s, when some brewers, made redundant by brewery closures, began to start their own small concerns; the microbrewing revolution had started, and from 1980 onward, the brewery count has steadily increased, there now being around 1200. The ethos quickly spread to the United States ('craft beer'), and a similar thing is now happening in Europe and further afield.

Beer Types

There are basically two types of modern beer – 'live' and 'dead' – the difference being whether the product remains in contact with viable yeast or not. If live yeast is removed from beer, by filtration or pasteurization in the brewery, it is described as 'brewery-conditioned,' and no further conditioning will occur once in its container (keg, can, or bottle). In the United Kingdom in particular, beer is often left in contact with live yeast so that a slow secondary fermentation ('conditioning') can take place. This 'live' beer is usually placed in a cask, sometimes a bottle. CAMRA's remit was to save cask-conditioned ('real') beer. With brewery-conditioned beer, once yeast ('life') has been removed, oxygen must be kept at arm's length, and the beer is suffused with CO_2 or a mixture of CO_2/N_2; this enlivens the product.

Since ancient times, man has brewed a variety of beers, as witnessed by the 70 odd types described for Babylonia. The variety of flavoring plants used in brewing over the years coupled with the various sources of extract could have produced an unimaginably large variety of beers. Although today's raw materials are more standardized, it is still possible to brew a vast range of beers, as witnessed at the biennial World Beer Cup held in Denver, Colorado, in April 2014, where there were over 90 style categories for judging! These days, microbrewers tend to lead the way in beer-style innovation. Space permits me to mention only a few examples.

The modern difference between lager and ale is down to fermentation, and in the latter category, the old British distinctions give us 'milds' (light and dark), usually of low strength (<4% ABV) and 'bitters' (light amber–mid brown) (these include the categories 'ordinary' (the so-called 'session' beers, <4% ABV), 'best' (ca. 4.5% ABV), and 'special' (>5% ABV)). Most India Pale Ales (IPAs) fall into the 'ordinary' category – far weaker than their nineteenth-century counterparts. All but the milds are 'hop-driven' beers, and one may broadly categorize other styles as being: 'malt-driven' ('dunkel,' 'Düsseldorf altbier,' 'barley wine,' and 'Scottish ale'), 'roast malt-driven' ('porter' and 'stout'), 'smoky' ('Franconian rauchbier'), and 'fruity and spicy' ('hefeweizen' and 'saison').

Belgium's 'lambic beer' is the oldest surviving commercial brewing style and is a sour wheat (70% malted barley and 30% unmalted wheat) beer brewed in and around Brussels, traditionally between October and April. The essence of such beers is their complex fermentation that involves naturally occurring bacteria and yeasts (i.e., is spontaneous). Only aged (oxidized) hops are used and these are subjected to a lengthy boil. Lambics have unique aromas, and there are several styles: 'young' (ca. 1 year), 'old' (>3 years old), and Faro (sweetened 'old'). Gueuze is a blend of 'young' refermented with 'old.' All are slightly sour (lactic acid) with resinous and cheesy notes, while Kriek is made by steeping Scarbeek cherries in lambic for 6 months. Alcohol contents vary with type.

Another, lesser known, spontaneously fermented beer is 'sourish shchi,' an unhopped, unboiled Russian drink that has a grain bill of malted barley, wheat, rye, and buckwheat. Honey is also used. Yeasts and bacteria for fermentation come from raw materials and equipment. Highly popular in the eighteenth and nineteenth centuries, it survives today (2.0–2.5% ABV) as a sparkling drink, for it is given a secondary

Figure 7 Women chewing maize for 'chicha' production in the town of Arequipa, Peru. Reproduced from Marcoy (1873).

fermentation in champagne bottles. Unlike 'sourish shchi,' the mildly alcoholic (ca. 1.5% ABV), rye-based, Slavic beer 'kvass' is lowly carbonated. Made from malt and soaked rye bread, which is then subjected to alcoholic/lactic fermentation, the drink is healthy and nutritious. Kvass has a strong flavor and sour taste and is usually flavored with fruit and/or herbs.

'Steinbier' is another ancient style, going back to times when the wort boil was raised by repeatedly heating stones in a fire and placing them in the wort. As time progressed, wort would caramelize on the stone surface and impart a sweetish, smoky flavor.

'Weißbier,' the classical wheat beer of Bavaria, also known as 'Hefeweizen' ('yeast wheat') in bottle-condition form, is a turbid (unfiltered) drink made from grist that must contain at least 50% wheat malted wheat. This style probably has similarities with ancient Near Eastern beers. It is normally top-fermented (rare in Bavaria!) and is characterized by phenolic notes, due to the presence of 4-vinyl guaiacol. Special yeast strains are used.

'Kölsch' is a pale, top-fermented beer (ca. 4.5% ABV) brewed only in Köln and Bonn. After the 'ale' fermentation, it is matured at low temperature (3–5 °C). 'Altbier' is similarly brewed and matured; 'Chicha' is a pre-Colombian Andean drink, typically brewed by women and normally made from maize (*Zea mays* L.), although cassava and quinoa can be used. Today, the drink can still be purchased in 'chicharias' throughout Central and South America. The name is derived from *chichal*, which translates as 'with saliva' or 'to spit,' because the original way of breaking down maize starch was to chew the grain and expectorate it for brewing (**Figure 7**). No hops are used, and the beer usually has $<5\%$ ABV.

'Sahti,' a top-fermented, full-bodied, live, turbid Finnish beer (6–8% ABV), is a relic of an ancient farmhouse brewing tradition and is reckoned to be the sole surviving 'primitive' ('fossil') beer style in Western Europe. Grains used are malted barley (and, variously, wheat, oats, and rye), either in malted or unmalted form. ABV is in the 7–12% range. A less potent, partially fermented (sweet) form is also brewed, called 'naisten sahti' ('sahti for women').

In Africa, where the beer market is dominated by Nigeria and South Africa, malted barley and wheat are difficult to cultivate in many areas and are replaced by sorghum, maize, roots, tubers, and plantains. Beer produced from these sources is very different from 'European-style' beers, although sorghum is widely malted for brewing clear, lager-style beers. There is a plethora of African beers, best known being turbid 'kaffir' or 'Bantu' beer, which is known under various tribal names. An artisanal kaffir beer would be expected to contain 2.0–4.0% w/v ethanol, 0.3–0.6% acid (as lactic), and 4–10% solids. Drinking African beer, which is often turbid, was/is often a communal activity and involves drinking through straws (**Figure 8**).

Beer: Raw Materials and Wort Production

GG Stewart, G.G. Stewart Associates, Cardiff, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The purpose of beer brewing is to hydrolyze the starch from barley malt together with maize (corn), wheat (sometimes malted), rice, sorghum (malted and unmalted), unmalted barley, or sugar/syrups into a sugary nitrogenous, hopped fermentable liquid called wort and convert it into an alcoholic carbonated beverage by yeast. This article will consider the raw materials employed and the production and composition of the resulting wort: the chemistry, biochemistry, and microbiology of wort fermentation.

The wort production process is outlined in Figure 1. Malting and mashing (together with fermentation) are largely enzymatic processes. The principal brewing raw material, malt, contains extractable components (starch, proteins, etc.) and enzymes (amylases, proteases, etc.). However, malt is an expensive raw material. The purpose of malting and mashing is to hydrolyze the starch/protein sources into a sugary nitrogenous fermentable liquid called wort, which will be fermented by yeast into the alcoholic carbonated beverage called beer. Brewing was one of the earliest biological processes to be undertaken on a commercial scale, and it became one of the first processes to develop from a craft into a technology. Beer production is a unit process divided into five distinct, but related, interconnected stages – the first three units will be considered here with the next unit (fermentation). Packaging is a unit process with a distinct and related but separate objective:

- Malting is the germination of barley or other cereal and subsequent drying (or kilning) of it. Malt is produced in malting plants, which are usually these days, but not always, physically separate from breweries. The raw materials are specially selected brewing varieties suitable for malting. The objective of malting from a brewing (and distilling) perspective is to permit the development of enzymes that will hydrolyze proteins and starch during the later stages of germination and during mashing;
- Mashing involves the hydrolysis of proteins/peptides, starch, and other materials from the ground malted barley and unmalted cereals (adjuncts) by a spectrum of enzymes (details later) to produce a water-soluble largely fermentable extract, which can be separated from the insoluble material (called spent grains). This unboiled, unhopped, nonsterile liquid is called sweet wort.
- Sweet wort boiling with the inclusion of hops and/or hop extracts and sometimes sugar and/or syrups to produce the sterile medium called wort.
- Fermentation of oxygenated wort with yeast followed by maturation, dilution (if required) carbonation, and filtration.
- Packaging – used generally to mean kegging, bottling, and canning.

The principal raw materials employed in the brewing process are malted cereals (usually barley (Figure 2), but not always, sometimes wheat and sorghum), unmalted cereals (corn, wheat, rice, sorghum, oats, and barley), and sugar and syrups. Unmalted carbohydrate sources are termed adjuncts (also called a secondary brewing material). Other critical raw materials involved in wort production are hops and the often overlooked primary raw material (considered by some also to be a utility) – water. Some processing aids and additives take part in chemical reactions, for example, carrageen, silica gel, and polyvinylpolypyrrolidone. However, some of these reactions (not all) are more important later in the brewing process during maturation.

Malt and Malting

Wort is a hopped medium that will support yeast growth and fermentation with beer as the end product. It is important that beer is drinkable (beer is not usually supped, it is drunk!) and it exhibits a number of stability characteristics (flavor, physical, foam, and biological). Malt contributes a large number of materials to wort. The principal components of wort are free amino nitrogen (FAN) and fermentable sugars.

The word 'malt' is derived from the Anglo-Saxon 'mealt' and perhaps has the same root as 'melt', referring to grain softening. This occurs during germination or malled (mauled: broken or ground), as malts are milled before being used in brewing (and distilling). Malting is the limited germination of cereal grains – usually (but not always) barley. Sometimes, malt is used 'green' (undried not kilned). The use of the word 'green,' in this context, is obscure, but it may mean cereal color or it may be related to immature or green beer. Although malt made from barley (*Hordeum vulgare*) (Figure 2) is by far the most important, it is also made from wheat, rye, oats, triticale, maize (corn), sorghum, various millets, and rice.

Malting is perhaps the oldest biotechnology. The cultivation of barley and wheat probably began about 10 000 BC and wild grain must have been available earlier. Malting is the controlled germination of cereals, followed by termination of this natural process by the programmed application of heat to dry the grain (kilning). Additional heat is then applied to kiln the grain in order to maintain the enzyme activity and develop the required malt flavor and color. According to the Brewing and Malting Barley Research Institute (BMBRI) based in Winnipeg, Canada, the following barley characteristics are required in order to produce superior malting barley:

- Pure lot of an acceptable variety
- Germination of 96% grains or higher
- No evidence of preharvest germination
- Protein concentration of 11–12.5% on a dry weight basis
- Maximum moisture content of 13%
- Plump kernels of uniform size
- Free from disease, mycotoxins such as deoxynivalenol and chemical residues

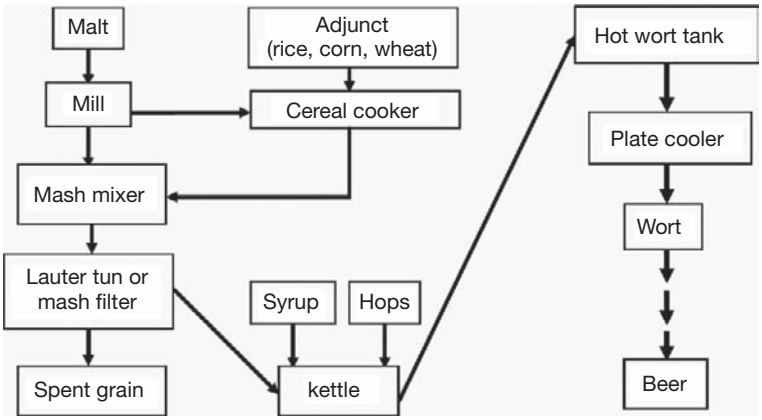

Figure 1 The wort production process.

Figure 2 Barley ears.

- Free from frost damage and weathering
- Less than 5% peeled or broken kernels
- Free of insects, ergot, treated seeds, grit, and odor

The malting process is a blend of pure and applied science involving plant and microbial biochemistry, physiology, chemistry, physics, and engineering. The stages of a typical malting process are depicted in Figure 3. However, there are a number of variations on the basic procedure. The procedure is based on the principle that barley, or another grain, must be converted into malt of the best achievable quality, economically, in the shortest feasible time with the best yield. The choice of malting procedure is guided by these considerations. As malting proceeds, the grain tissues undergo changes. The aleurone cells are partly depleted of their contents but are still metabolically active. The contents of the dead starchy

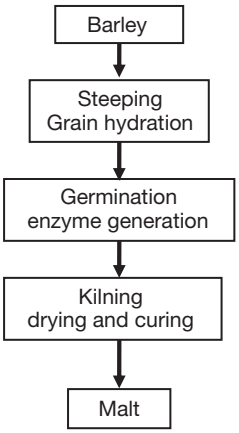

Figure 3 Typical barley malting process.

endosperm are partly degraded and depleted. The embryo metabolizes and grows, chiefly at the expense of hydrolysis products from the starchy endosperm. The hydrolytic and biosynthetic processes proceed simultaneously. There is a net breakdown of polymeric substances, such as starch, and a migration of substances from the aleurone layer and the endosperm to the embryo.

The changes that occur during malting are normally described in terms of physical modification of the grain and an alteration in conventional malt analysis (Table 1), on a biochemical basis. The gross changes are the net result of the degradation of reserve substances. This leads to the interconversion of substances in the living embryo and aleurone layer, the flow of substances to the embryo from the aleurone layer and starchy endosperm, the synthesis of new grain substances, and their incorporation into the raw, growing tissues (the acrospire and rootlets) of the embryo (Figure 4). Allowances must be made for malting losses – the losses of dry matter that occur during the conversion of grain into malt.

The chemical and biochemical changes that take place during malting are complex. They can only be understood by appreciating the range of reactions that occur during the overlapping processes of steeping, germination, and kilning and the effects of deculming and dressing (cleaning) the malt. During steeping, the grain is permitted to imbibe water in

Table 1 Typical barley malt analysis

Moisture (%)	3.8–4.2
Extract (%)	79.9–81.0
Wort color (SRM)	1.4–1.7
Diastatic power (ASBC)	120–145
α-Amylase (DM)	39–49
Malt protein (%)	10.8–12.3
Wort protein (%)	4.9–5.6
FAN (mg/l)	180–220
Wort viscosity (CP)	1.38–1.48
Wort β-glucan (mg l^{-1})	25–150
Friabilimeter value (%)	70–86
Wort fermentability (%)	78–82

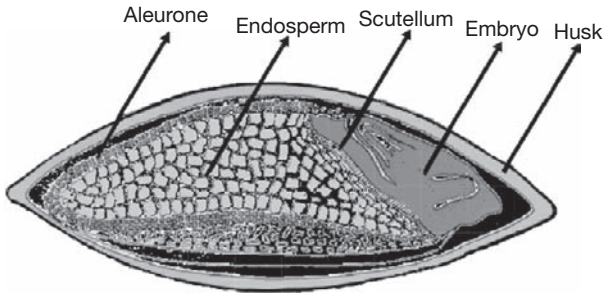

Figure 4 The barley grain.

order to increase the grain moisture from 12–14% to 42–48%. This occurs by immersing the grain in water or by spraying with water and usually a combination of both. The steep water becomes dirty and is replaced at least once in order to maintain the grain fresh. During steeping, the grain swells and softens, and the living tissues resume their metabolism, which had ceased during grain ripening and drying prior to harvesting and during storage awaiting malting. Sometimes, air is blown through the grain–water mixture, aeration, or the grain can be 'air-rested' – the water is drained away and air is sucked downward through the grain. When the grain has achieved the correct moisture content, the water is removed. Usually, this steeped grain is transferred to a germination vessel. In some malting plants, steeping and germination, and occasionally kilning, takes place in one container.

Each batch of grain being malted is referred to as a 'piece.' Following steeping, germination begins and the grain undergoes 'modification.' Modification is an imprecise term that signifies all the desirable changes (biochemical and chemical) that occur when grain is converted to malt. Modification continues during the initial stages of kilning. The three major aspects of modification are

- accumulation of hydrolytic enzymes;
- a variety of chemical reactions that occur in the grain;
- physical changes, which appear as weakening and softening in the grain.

Visible signs in the germination include the initial appearance of a white 'chit' at the end of the grain, followed by a tuft of rootlets or 'culms.' At the same time, the 'acrospire' (coleoptile or shoot) grows. It is covered by the husk in the barley but it grows freely in many other grains. The germinated grain is transferred to the kiln while it is still fresh (called green or undried but it is not really green colored). The moisture content of kilned barley malt is usually 4–4.5%.

Adjuncts

Adjuncts are alternative sources of fermentable extract and are used to replace a proportion of the malt. They may be used usually as less expensive sources of extract. Also, they are used to impart elements of beer product quality such as color, flavor, foam, and drinkability. Alternatively, adjuncts are important if there are taxation considerations that make reduced malt use in brewing financially advantageous, for example, the Japanese legislation that permitted the development of happoshu (containing 25% malt or less) and third category (containing no malt) beers. It should be noted that in Japan, taxation on beer is levied based on the percentage of malt used in the grist.

Although a wide range of brewing raw materials fall within the previously mentioned adjunct definition, attention here will be focussed on the use of adjuncts during three areas of the brewing process: (a) solid unmalted raw materials usually (but not always) processed in the brewhouse, (b) liquid adjuncts (syrups) usually added to the kettle (copper) and some specialty products used for priming beer at a later stage in the process, and (c) malted cereals other than barley, such as wheat and sorghum. Basically, adjuncts are considered to be nonmalted sources of fermentable sugars. Typically (with a few exceptions – discussed later), they contribute only extract, no enzyme activity, and little or no soluble nitrogen and are usually less expensive than malt. It is also considered that adjuncts do not contribute flavor to the finished product. However, this is not always the case. In general, barley tends to give beer a strong, harsh character (particularly stouts), whereas wheat imparts beers with dryness and a stable foam (good head retention). Rice and corn (maize) will give a characteristic light flavor to lager beers.

Starch consists of two types of polymer molecules – the linear amylose and the branched amylopectin. Depending on its source, starch generally contains 20–25% amylose and 75–80% amylopectin. Amylose and amylopectin are inherently incompatible molecules with amylose having a lower molecular weight with a relatively extended shape, whereas amylopectin comprises much larger but more compact molecules. Amylose molecules consist of largely simple unbranched chains with 500–20 000 α-(1→4)-D-glucose units depending on the plant source (very few α-1→6 branches may be found and they will have little influence on the molecule's overall behavior). Amylopectin is formed by nonrandom α-1→6 branching of the amylose-type α-(1→4)-D-glucose structure. The branching is determined by branching enzymes that leave each chain with up to 30 glucose residues. Each amylopectin molecule contains a million or so residues, about 5% of which form the branch points.

Syrups

The major liquid adjuncts used in brewing are glucose syrups, cane sugar syrups, invert sugar syrups (a mixture of glucose and

Table 2 Sugar spectra (%) of brewing worts

	Acid/enzyme syrups	*Enzyme/ enzyme syrups*	*VHMS*[a]	*All-malt wort*
Glucose	65	5	5	8
Maltose	10	55	70	54
Maltotriose	5	20	10	15
Dextrins	20	20	15	23

[a]VHMSs – very high-maltose syrups.

fructose), and syrups with a similar sugar spectrum to wort – details later. Glucose syrups have been available since the mid-1950s. Originally, they were produced by direct acid conversion of starch to a 64–68 DE range. (DE is 'dextrose equivalent' – it is a measure of the reducing power of the solution. For example, starch would have a DE of 0 and pure dextrose (glucose) of 100.) During the mid-1960s, new developments in enzyme technology led to acid/enzyme conversion and production of approximately 64 DE syrups. Table 2 shows the sugar (dextrin) profile of these syrups in comparison to a typical all-malt wort. The only similarity was the content of the higher saccharides or nonfermentables.

The use of liquid adjuncts continued during the 1980s but their use had shortfalls. The high level of glucose became a concern because they induced sluggish and 'hung' fermentations (also called the 'glucose effect'). All brewing raw materials need to be consistent including brewing syrups. However, acid and acid/enzyme syrups depend on the termination of the reaction by chemical or mechanical means when the desired end point is reached, and it is difficult to attain the proper production consistency by operator judgment required due to variables such as temperature, time, pH, and concentration of substrate. In addition, large volume users and breweries located a long distance from the suppliers factory experienced inconsistent syrup color when it is stored for lengthy periods at elevated temperatures. This is the sugar browning reaction particularly with high levels of glucose – this reaction is catalyzed by the presence of metal ions and proteins. This variable quality has forced the syrup manufacture to become more flexible, more competitive, and more adaptive to the wide differences when marketing on an international scale. Also, the use of acid and acid/enzyme syrups had a number of disadvantages such as elevated sulfite concentration, which can cause allergic reactions with some people. In addition, the manufacturing procedure involves exposure to low pH conditions followed by neutralizing with sodium hydroxide or another alkaline base, and as a consequence, elevated syrups and eventually beer sodium levels are frowned upon by the appropriate food and drug authorities. However, although acid/enzyme carbon-treated syrups possess disadvantages, they were acceptable and popular until the late 1980s when there was need for a change. Many changes have occurred in the brewing and wet-milling industries that have led to the development of a novel spectrum of liquid adjuncts. This development has been allied to the increase in adjunct levels in many beers (up to 50% of the wort content) particularly in North American and high-gravity brewing (details later in this article).

With the advent of new technology in enzyme liquefaction and multistage enzyme hydrolysis, production of corn syrups

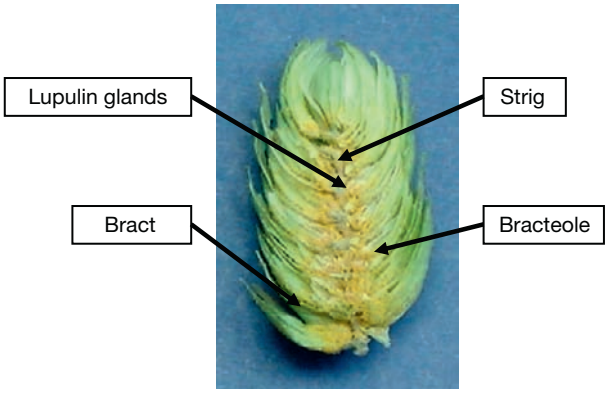

Figure 5 Cross section of a typical hop cone.

with virtually any carbohydrate profile is possible. Table 2 shows the sugar/carbohydrate profile of 'new-generation' very high-maltose syrup (VHMS)/corn (enzyme/enzyme) and its comparison to a typical all-malt wort. The profiles are very similar. This has permitted the brewer to introduce liquid adjuncts into the process without changing the wort sugar profile. Sensory evaluations of beers provided with HMS have revealed no significant differences from beers produced with acid/enzyme syrups. In addition, the sodium levels dropped by as much as 60% in comparison to beers produced with earlier-generation syrups. In the past decade, a further brewing syrup has been prepared. This is VHMS and contains 70% (w/v) maltose and low levels of glucose (Table 2). VHMS is used in high-gravity worts (>18°Plato) as part of a brewing capacity initiative, and the elevated maltose concentration will reduce ester levels in the HG produced beers.

Hops

Hops are the wort ingredient that provides beer with bitterness. It also increases the beer's biological stability, helps stabilize its foam, and greatly influences its taste and aroma. Hops are the flowers or 'cones' (Figure 5) of the plant *Humulus lupulus*. The lupulin glands in the cone contain the important flavoring compounds. The *Humulus* genus belongs to the family of the Cannabaceae, which includes Cannabis (hemp and marijuana) and Celtis (hackberry). Hops are native to the Northern Hemisphere in the temperate zones of Europe, western Asia, and North America and are thought (not proven) to have originated in China. They are now grown commercially in both hemispheres between approximately 30° and 52° latitudes. They are hardy plants that can survive cold winters with temperatures as low as −30 °C. The five recognized taxonomic varieties in the species *Humulus lupulus* are *H. lupulus* var. *lupulus*, European hops; *H. lupulus* var. *cordifolius*, Japanese hops; and *H. lupulus* var. *lupuloides*, *H. lupulus* var. *neomexicanus*, and *H. lupulus* var. *pubescens*, North American natives.

Hops come in two basic market classes, bittering and aroma hops, with a few hops being marketed as dual-purpose varieties. Bittering or kettle hops are added to the sweet wort near the beginning of the boil and aroma hops are added at any time from 30 min before the end of the boil to strike out. They can also be added to the whirlpool, or even later. The addition of

hops to fermented beer is called dry hopping. This practice adds highly volatile essential hop oils to the beer – oils that evaporate into the brew stack during the kettle boil and may even be purged out of the wort during fermentation. The intensity of hoppiness is a matter of beer style and brand. For instance, most American lagers contain minimal hop content and are refreshing to many consumers. At the same time, microbrewers (craft-brewed) add so much hop and produce a beer with almost a 'punishing' hop character. Such beers are growing in popularity, especially in North American bars, and are catching up with other beer cultures around the world but are not for everyone!

Alpha acids, also called humulones, are the sources of most bitterness in beer and make up about 3–4% of the cone's weight in aroma varieties. In superalpha bittering varieties – which are the most recent products of many breeding programs – alpha acids make up more than 20% of the cone's weight. During the wort boil, alpha acids are converted to water-soluble iso-alpha acids or isohumulones, the true bitter compounds in beer. This conversion or isomerization is one of the main objectives of wort boiling and the boiling time must usually be long enough (at least 45 min for most hop varieties) to allow isomerization to take place. The unit of measurement for hop bittering potential is the international bitterness unit (IBU).

Alpha acids are divided into three analogues – compounds of very similar structure – the desirable humulone and adhumulone and the undesirable cohumulone. Cohumulone may make up 15–50% of the hop's total alpha acid content – depending on the hop variety but will also greatly vary depending on variety. It can also vary from one growing year to the next with the same variety. High cohumulone levels in hops tend to result in lower beer foam stability, a harsher, often unpleasant bitterness, and poor aroma profiles. Hops are often marketed, in part, based on their cohumulone content.

Essential oils in hops are responsible for the distinct hop aroma. Some fresh hop varieties smell very 'citrusy' such as Cascade, which has a grapefruit–piney bouquet, whereas others have a more floral bouquet. The main essential oils in hops are humulene, which has a woody, balsamic aroma; caryophyllene, which has a black pepper spicy aroma; myrcene, which has a geranium-like floral aroma; and farnesene, which has a gardenia-like floral aroma. Of these, farnesene either is often completely absent or only occurs in miniscule quantities. Other essential oils, such as linalool with its citrus-like bergamot aroma, although present in only tiny amounts, may have a disproportionately large impact on the overall aroma of certain hop varieties. Approximately 300 compounds are likely contributors to hop aroma profiles. Some of these impart floral, fruity, and spicy notes, whereas others contribute off-aromas and can negatively impart beer aromatics.

There are a number of ways that hops can be introduced into the process:

- Traditionally, leaf hops are added to the boiling wort in the kettle (copper). Bittering hops are added early in the boil in order to extract maximum bitterness into the wort. Aroma hops are added later in the boil to ensure that aroma compounds are not lost through the kettle stack. At the end of boiling, the spent hops (with the bittering and aroma compounds extracted) are removed from the wort with a hop strainer (also called a hop back).
- Dry hopping is the addition of leaf hops to wort during fermentation conditioning or into the barrel in the cellar of a public house or bar. The purpose of dry hopping is to infuse beer with additional fresh hop flavor and aroma. Dry hopping is a cold infusion technique that both intensifies hop aromatics and also adds aromatics that are substantially different from those achieved by late hopping. The alpha acids responsible for hop bitterness are not isomerized and therefore remain insoluble during dry hopping, but testing trials have shown that the bitterness perception of beer can be enhanced by dry hopping, although international bitterness unit values essentially remain unchanged.
- Hop pellets are a form of processed whole hops whereby the dried cones are pulverized using a hammer mill and then extruded through a pelleting die to produce a densely packed pellet. Whereas the hop cone is a flowerlike structure (**Figure 5**) that is both bulky and delicate but not very practical in a brewery, pellets offer brewers a range of advantages over the use of whole hops. For example, whole hops are packed in large bales and require cooled hop storage facilities, whereas pellets are compact and are easy to store. However, while processing hop pellets is likely to break the hop cone's lupulin glands, pellets are much more sensitive to oxygen than whole hops. Consequently, hop pellets must be flushed with an inert gas and vacuum packed but can be stored at room temperature, if required.

Pelletized hops are available in two varieties – Type 90 and Type 45. T-90 pellets are produced from the entire hop flower, whereas T-45 pellets are produced after much of the vegetative matter has been removed from the flower, which concentrates the lupulin content in the pellets. An important brewhouse advantage of pellets compared to baled hops in automated brew systems is the suitability for automated hop dosing equipment. This is because pellets flow more consistently than loose hop flowers (leaf). Because of the overall advantages of pelletized hops, they are used by all sectors of the brewing industry, from the largest brewers to craft brewers including the smallest brewpubs. For example, in North America, pellets are favored over whole hops and hop extracts.

- Hop extracts are one of the many processed products currently available to modern breweries. Currently, over 50% of the hops used by the brewing industry are processed into extracts. Carbon dioxide is the primary solvent employed in the modern hop extraction process. Prior to CO_2, solvents such as ethanol, methanol, methylene chloride, and hexane were used. Ethanol extraction of hops is still practiced on a limited scale particularly by the German brewing industry. Hop extracts possess many advantages. When extracts are used in a brewhouse, it can yield more wort because the hop plant's cellulose has been removed, making wort separation less difficult relative to the use of whole hops or pellets. Also, extracts are concentrated and therefore reduce raw material shipping costs.
- Carbon dioxide hop extracts are often the starting material for a number of enhanced value purified hop extracts such as preisomerized extracts and other modified downstream products such as 'tetra.' These modified extracts have greater utilization properties and therefore higher efficiency when

dosed into beer postfermentation and are very popular with brewers of light (lite) lagers. Indeed, some modified hop extracts provide light stability preventing the light struck (skunky) flavor, and this allows beer to be packaged in clear or green bottles without changes in beer flavor. The use of hop extracts has both its proponents and detractors. Some malt brewers (not all) in the United States and Britain and elsewhere avoid hop extracts entirely, either for philosophical reasons or out of a belief that they are inherently inferior to leaf hops or pellets. Proponents, including some craft brewers, argue that hop extracts allow them to dose bitterness into their beers in a manner that might otherwise be impractical!

Water

Water is the principal ingredient in beer (and distilled beverages). It is both a raw material and a utility. Aside from water, the other major brewing raw materials are malt and unmalted cereals, hops, and caramel (and other coloring materials) together with processing aids and additions. Also, brewery (and distillery) utilities provide the means by which the process can operate. These utilities include the energy source (oil, gas, electricity, and steam) to drive the process, vital services including the supply of water and process gases (CO_2, nitrogen, and oxygen), and facilities for disposal of waste materials.

The ratio of water used as both a raw material and a utility to the volume of beer produced is very important. Over the past 20 years or so, the price of water in many countries has consistently exceeded inflation, and as a consequence, the ratio of water used to the volume of beer produced has decreased. Effluent treatment systems are required to minimize the impact of the process on the environment. With anaerobic treatment systems, it is possible to generate biogas that may be used to replace fossil fuels.

Historically, brewery sites (and distillery sites) were (and still are in many cases) linked to the availability of good water quality, hence the establishment of such brewing centers in Pilsen, Munich, Edinburgh, Burton-on-Trent, St. Louis, Mo., and London, Ontario, and distilling centers in Speyside in the Scottish Highlands. Nowadays, many breweries are situated closer to the consumer and near to the centers of population. However, the criteria for water availability and quality still apply. Water consumption varies markedly from brewery to brewery and is often, but mistakenly, considered as a resource available in limitless quantities at virtually no cost. The actual situation, especially for the more heavily industrial nations, is that water is becoming a limited resource at an ever-increasing price. These costs include the purchase of the water, treating the water en route to the brewery, and treating the resulting effluent.

A brewery has several options for its water supply:

- Groundwaters from wells
- Surface water from rivers, lakes, or streams
- Water from the public supply, which may be derived from either ground or surface sources but treated to comply with international standards

From a consistency point of view, groundwater from wells is preferred, though to keep the supply potable and free of contamination requires appropriate construction and regular maintenance. Surface water is preferred for distilling (especially Scotch whisky). Breweries today make extensive use of water supplied by public utilities or treat the water themselves. Generally, surface water is less microbiologically sound than water obtained from wells or public utilities. In summary, the choice of water supply depends on the availability and on the costs for treatment and quality control. It is often the case that supplies are drawn from multiple sources.

The food and beverage industry is required to use water of 'potable quality' as specified by either the World Health Organization or European Directives. Sometimes, additional quality parameters regarding hardness, alkalinity, and ion content are established by brewers (and distillers) in the interests of the beer (and whisky) character (Table 3).

Breweries often use several qualities of water although in some cases, the brewing, packaging, and general purpose water used is the same (Table 4).

Mashing and Boiling

The purposes of mashing are

- to extract starch, proteins, peptides, lipids, and other components from the malt and adjuncts;
- to render the extract fermentable by ensuring the necessary enzymatic hydrolysis of the previously mentioned components to sugars, amino acid, small peptides, etc.

Table 3 Typical analyses of water used in breweries and distilleries (mg l^{-1})

	Pilsen	*Munich*	*Burton-on-trent*	*Jura*

	Quality parameters
Brewing	Potability, hardness, alkalinity, carbon-filtered
Dilution	Potability, carbon-filtered, sterile, hardness, alkalinity, carbonated, reduced dissolved oxygen concentration (50 μg ml^{-1})
Packaging	Potability, hardness, corrosive properties (Langelier index)
General purpose	Potability
Boiler feed	Hardness, pH, silica

Prior to mashing, the malt is milled employing a variety of milling procedures. This is a physical process and beyond the scope of this article. The milled grain is wetted in order to stimulate enzyme activity, which will hydrolyze the starch into fermentable sugars, the proteins into amino acids and small peptides, and the lipids into free fatty acids and sterols. In order to achieve this complex hydrolysis procedure, the mash is subjected to a series of heating and rest periods at set temperatures in order to realize the optimum catalytic conditions with reference to the type of beer being produced. The infusion mashing program is extensively used and is shown in Figure 6. The initial temperature of 52 °C is employed to stimulate both protease and glucanase activities (often called the 'protein rest'), but the rate of activity of the two enzyme systems is unclear. After 15–20 min, the temperature is increased gradually to 65 °C. This temperature is the saccharification temperature and is optimal for both α and β amylase activities. Alpha-amylase is an endoamylase that hydrolyzes 1,4-α-glucosidic linkages in amylose (contains 1α4 linkages) and amylopectin (contains both 1α4 and 1α6 linkages) (Figure 7). This enzyme is virtually absent from mature barley unless it has pregerminated. However, considerable quantities are synthesized *de novo* in the embryo and aleurone layer and large proportions are generated into the starchy endosperm. Beta-amylase is an exoenzyme that catalyzes the hydrolysis of the 1α4 linkages penultimate to the nonreducing chain ends (Figure 7), releasing the disaccharide maltose (G2) and the trisaccharide maltotriose (G3) (Figure 8) and oligosaccharides (also called dextrins) shortened by the removal of two and three glucose residues. Unlike α-amylase, this enzyme is present in unmalted barley. During malting, the level of free β-amylase may initially fall during steeping, and subsequently, during germination, nearly all the β-amylase becomes free, and the bound form disappears. This enzyme will not attack 1α6 or 1α4 linkages immediately adjacent to them.

Another important enzyme during mashing is the debranching enzyme that hydrolyzes1α6 linkages in amylopectin, dextrins, and other oligosaccharides (Figure 7). This enzyme is also known as limit dextrinase and as pullulanase because of its ability to degrade a particular branched bacterial polysaccharide – pullulan. In malt, this enzyme occurs in both freely soluble and bound forms. There exists a heat-stable protein in barley that inhibits malt limit dextrinase. The degree of inhibition increases during malting. However, there is evidence that this enzyme is synthesized *de novo* in the barley aleurone layer during germination.

After approximately 30 min at 65 °C (saccharification rest) (Figure 6), the temperature is raised to 78 °C – mash-off temperature. The principle reason for this mash-off temperature is to inactivate most of the enzymes that were active in the mash. In addition, some final α-amylolysis will occur, whereas at this temperature, β-amylase will be rapidly inactivated. Also, at this temperature, the viscosity of the sweet wort (due to β-glucans and arabinoxylans) will be reduced, and many (not all) microorganisms that are contaminating the malt will be heat inactivated. This sweet wort is separated from the spent grains in a lauter tun or a mash filter.

The sweet wort is boiled in a kettle (also called a copper), usually for 30–60 min with 4–6% evaporation. Boiling is needed to isomerize the hop alpha acids (already discussed). Isomerized hop acids are bitter, whereas nonisomerized hop alpha acids are not. Boiling is also needed to strip out unwanted malt and hop volatiles, to denature proteins and coagulate proteins/polyphenols as hot break, and to establish the wort composition (details later) by terminating all enzymic and microbiological activity surviving the mashing process. As a consequence of boiling and evaporation, there will also be color development (melanoidin reactions) and wort gravity increase that need to be accommodated in order to achieve the finished target for a particular wort. Ideally, a kettle should be fitted with in-line probes in order to follow the isomerization of alpha acids, the disappearance to dimethyl sulfide, the coagulation of colloidal size particles (0.1–10 μm) to form hot break (30–70 μm), and the wort gravity. Currently, this on-line control is not practical, and the brewer has to rely on pragmatic experience to achieve these critical parameters. However, this on-line control cannot be too far in the future!

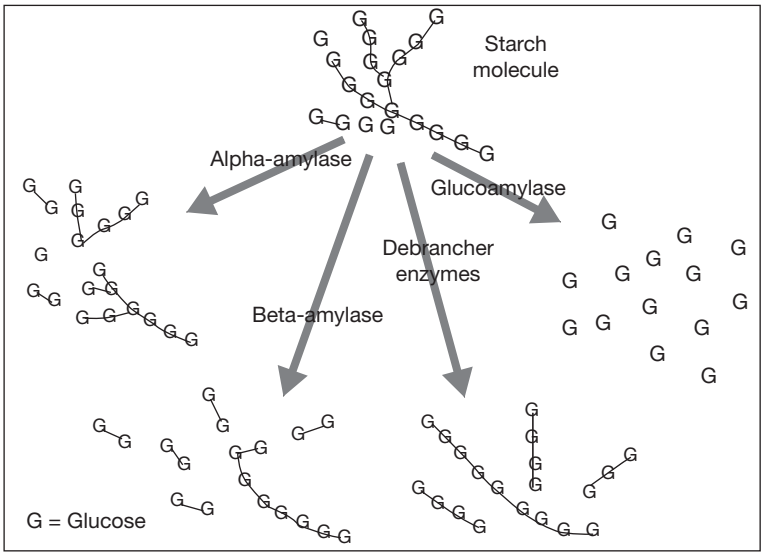

Figure 7 The enzymatic hydrolysis of starch.

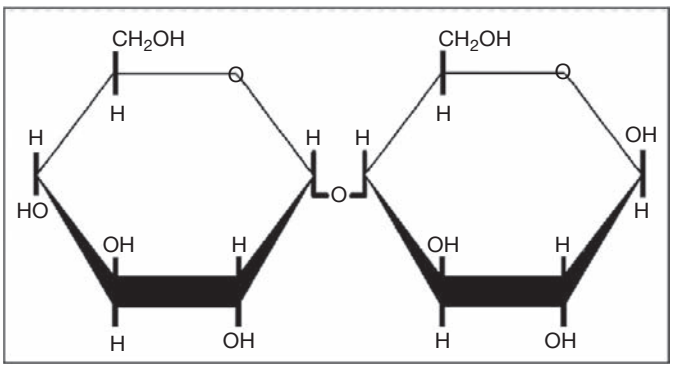
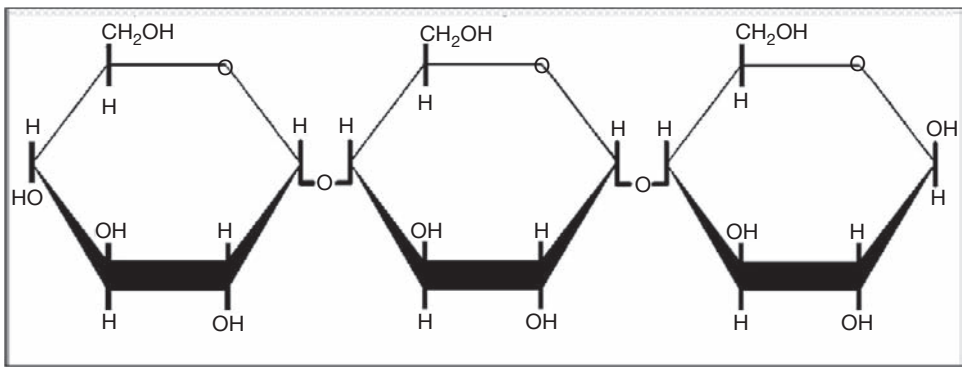


Maltose, molecular weight = 342



Maltotriose, molecular weight = 504

Figure 8 Structure of maltose and maltotriose.

Wort Composition

Wort contains the sugars sucrose, fructose, glucose, maltose, and maltotriose, together with dextrin material (Table 2). Also, wort contains a number of amino acids, all of which, with the exception of proline, are metabolized during fermentation. However, it should be reported briefly here that the objectives of wort fermentation are to consistently metabolize wort constituents into ethanol, carbon dioxide, and other fermentation products in order to produce beer with satisfactory quality and stability. Another objective is to produce yeast crops that can be confidently repitched into subsequent brews.

Aside from the actual composition of the wort, its concentration is also important. Traditionally, the wort concentration

(gravity) was 1030–1048 (∝7.5–12°Plato). This produces beers with alcohol concentrates between 3% and 5% (v/v) ethanol. However, beginning in the 1980s, high-gravity brewing (HGB) evolved. This is a procedure that employs wort at higher than normal concentration and, consequently, requires dilution with water (usually deoxygenated), at a later stage in processing. By reducing the amount of water employed in the brewhouse, increased production demands can be met without expanding existing brewing, fermenting, and storage facilities. Dilution with water can occur either entirely or in part at almost any stage in the process, including kettle (copper), strikeout, and prewort cooler; during or after fermentation; during maturation; and pre- and postbeer filter.

HGB has been progressively introduced into breweries around the world for the past half century.

There are a number of advantages and disadvantages to this process. The effects of HG wort on various aspects of fermentation will be discussed later. Other advantages can be summarized as follows:

- Increased brewing capacity – more efficient use of existing plant facilities.
- Reduced energy (heating, refrigeration, etc.), labor, cleaning, and effluent costs
- Improved beer physical and flavor stability.
- More alcohol per unit of fermentable extract because of reduced yeast growth and more of the wort sugars being converted to alcohol.
- HG worts may contain higher adjunct rates and different wort sugar spectra.
- Beer produced from HG are often rated smoother in taste.
- HG brewing offers greater flexibility in product type. From one 'mother' liquid, a number of products can be brewed as a result of dilution and/or use of malt and hop extracts and syrups.

The disadvantages of HG brewing can be summarized as follows:

- Due to the more concentrated mash (increased rate of carbohydrate to water), there is a decreased brewhouse material efficiency and reduced hop utilization.
- Decreased beer foam stability (head retention).
- Difficulties in achieving flavor match compared to equivalent lower-gravity beers.
- High-gravity worts can influence yeast performance with effects on fermentation and flocculation.

Berries and Related Fruits

P Padmanabhan, J Correa-Betanzo, and G Paliyath, University of Guelph, Guelph, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Botanically, berries are defined as a fleshy fruit that forms from the entire ovary that surrounds the seeds, and true berries include banana, grapes, and blueberries. In this article, the term 'berries' refers to the small, soft, edible, and colored fruits of the plants of the species *Vaccinium*, *Fragaria*, and *Rubus*. Berries have been emerging as important dietary components because of their numerous health benefits. The most popular and commonly consumed berries in North America include blackberries (*Rubus* spp.), red (*Rubus idaeus*) and black raspberries (*Rubus occidentalis*), blueberries (*Vaccinium corymbosum*), cranberries (*V. macrocarpon*), and strawberries (*Fragaria* × *ananassa*). Other berries including bilberries, lingonberries, goji berries (*Lycium barbarum*), and sea buckthorn (SBT; *Hippophae rhamnoides*) are also consumed to a limited extent. Additionally, several exotic berry fruits such as acai berries and honeysuckle (*Lonicera caerulea*) are also gaining importance. This article mainly focuses on the popular berries consumed in North America and those belonging to the genus *Rubus* and *Vaccinium* and some exotic berries including acai berries, honeysuckle, and SBT.

Berries of *Rubus*

Both raspberries and blackberries belong to the genus *Rubus*, which is a member of the Rosaceae family. This genus includes blackberries and raspberries. Blackberries, dewberries, raspberries, and their hybrids are collectively referred to as 'brambles.'

Blackberry (*Rubus* spp.)

Blackberries are grown worldwide, but they prefer regions with mild winters and long moderate summers. North America, Europe, Asia, South America, Central America, and Africa are the main areas of blackberry production. Blackberries are mostly consumed fresh, and also processed into ice cream, jam, marmalade, and other confectionaries. Blackberry fruit is an aggregate fruit consisting of a number of fleshy drupelets, each containing a single seed (pyrene) around the central torus or receptacle. There are three main types of blackberries cultivated based on cane architecture, classified as erect, semierect, and the trailing types. Trailing blackberries bear vigorous primocanes from a single crown that lie on the ground. Trailing blackberries are characterized by flavorful fruit with excellent aroma and with less seeds than other species. Semierect types are characterized by thornless, erect, large, and vigorous canes that grow from a crown and arch to the ground. Semierect and trailing types produce new primocanes only from buds on the crown and are biennial fruiting. Erect blackberries produce primocanes from buds at the crown or from buds on roots. Erect blackberries are characterized by plants that produce stiff, erect canes that are 1–4 m tall. Erect blackberries can be biennial or annual fruiting types. Boysenberry and loganberry are considered as trailing types due to their growth habit. They are highly productive and the berries are similar to the erect type. Blackberries are good sources of vitamins, minerals, and other bioactive compounds such as polyphenols. Glucose, fructose, and sucrose are the principal sugars of blackberries. Malic acid is the predominant organic acid in blackberry. Other acids including ascorbic acid and trace amounts of shikimic, fumaric, and succinic acid have also been detected. Organic acids help in stabilizing anthocyanins and ascorbic acid plays a role in extending the shelf life of berries. Blackberries are rich in polyphenolics such as anthocyanins, ellagitannins, flavonols, flavanols, procyanidins, and phenolic acids. According to various studies, phenolics in blackberries range from 114 to 1056 mg 100 g^{-1} FW.

Raspberry

Raspberries are closely related to blackberries. Raspberry cultivation started in Europe nearly 450 years ago. Russia, Europe, and the pacific coast of North America are the three major raspberry production regions. Raspberries are most productive in areas with mild winters and long, moderate summers. The major production areas of red raspberries in North America are the Pacific Northwest (Oregon, Washington, and British Columbia), California, and the eastern United States (New York, Michigan, Pennsylvania, and Ohio) and also in Mexico and Guatemala. The European red raspberry (*R. idaeus* subsp. *vulgatus* Arrhen.), the North American red raspberry (*R. idaeus* subsp. strigosus Michx.), and the black raspberry (*R. occidentalis* L.) are the most important commercially grown species. There are also yellow raspberries that are mutations of the red genotype and the purple ones are hybrids of the red and black genotypes. Red raspberries are the most widely grown while black raspberries are common only in some areas of the eastern United States. Red raspberries (*R. idaeus*) are widely consumed in fresh, frozen, or processed form, than black raspberries (*R. occidentalis*). Tayberry, loganberry, boysenberry, and youngberry are some important interspecific hybrids of blackberries.

Raspberry canes are biennial with the first year canes called primocanes and the second year canes called floricanes. Commercial red raspberries are either 'summer-bearing' (primocane-fruiting) or 'fall-bearing' (floricane-fruiting) types. Floricane-fruiting cultivars produce canes that are vegetative in the first year, and in the second year, they flower, fruit, and die. The primocane-fruiting raspberries produce canes that are vegetative in the first year, and in the second year, they flower, fruit, die, and are pruned out. Black raspberry cultivars are generally floricane-fruiting. Each raspberry flower has 60–160 ovaries,

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00060-X

and each ovary contains two ovules, clustered into an aggregate fruit. The fruit ripens about one month after pollination. Raspberry fruit is an aggregate of many individual drupelets. The cohesion of drupelets results from the entanglement of epidermal hairs on the sides and base of the drupelet. Fruit size considerably varies in raspberries ranging from 1 to 5 g. Fruit ripening occurs in three phases and each phase lasts for about 10–12 days. In the first phase, a period of rapid cell division follows pollination. In the later phase, there is a slowdown of cell division while the embryo develops and the seed coat hardens. In the final phase, very rapid growth occurs due to cell enlargement. Ethylene production peaks with ripening, while respiration decreases.

Raspberries are eaten fresh or processed. The major products of processing are individually quick frozen, block-frozen, puree-frozen, canned, juice, concentrate, and preserves. Red raspberries contain an array of health beneficial compounds including essential minerals, vitamins, fatty acids, dietary fiber, and polyphenolic compounds such as flavonoids, phenolic acids, lignans, and tannins. Typically, sugar constitutes 5–6% of ripe raspberry fruit. The main sugars are glucose, fructose, and small amounts of sucrose. Red raspberries are low in energy and a 100 g supplying only 52 kcal. The high fiber content (6.5 g per 100 g) and fructose content regulate blood sugar levels and provide a satiating effect. Soluble solid portion comprises about 9% of the fruit.

Berries of *Vaccinium* (Ericaceae)

Vaccinium is a large complex genus of about 150 species, and it comes under the family Ericaceae. The genus *Vaccinium* includes popular berry fruits such as blueberries, huckleberries, cranberries, lingonberries, and bilberries. The three major cultivated crops of this genus are blueberry, large cranberry, and lingonberry. The genus *Vaccinium* is often divided into several subgenera and sections. The large cranberry (*V. macrocarpon* Ait) belongs to section *Oxycoccus*; and the section *Cyanococcus* (cluster-fruited blueberries) include the highbush blueberry (*V. corymbosum* L.), rabbiteye blueberry (*V. ashei* Reade), and the lowbush blueberry (*V. angustifolium* Ait.). The other species include *V. myrtillus* L. (bilberry and whortleberry) in section Myrtillus, and *V. vitis-idaea* (section Vitis-idaea) are collected mostly from the wild.

Cranberry (*V. macrocarpon* Ait.)

V. macrocarpon Ait. is also known as the cranberry or the American cranberry. Red-fruited species of *Vaccinium* are called as cranberries in North America. Cranberries are commercially cultivated in the United States and Canada. Some production also occurs in Argentina, Chile, and the Netherlands. Cranberry is an evergreen woody perennial mat-forming shrub of about 7 ft with a creeping habit. Pink flowers are borne on young upright shoots. Flower buds form in late summer and open in midsummer of the following year. After pollination, flowers mature late in the autumn. At maturity, berries are bright red with a hard shiny skin. Usually, cranberries are harvested in September through the first part of November. Beds are flooded with 6–8 in of water above the vines, and a harvester is driven through the beds to remove the berries. Cranberries are cleaned, graded, and stored prior to packaging or processing. Cranberries can be stored for several months without any significant quality losses. Shelf life can be extended for several weeks by decreasing the storage temperature to 0 °C.

Cranberry pulp contains lignin, glucose, fructose, and sucrose. In ripe cranberries, acids form 2–3% (w/w), and citric acid forms the primary organic acid. Cranberry also contains several organic acids such as quinic, citric, malic, and benzoic acids. Due to its tartness, most cranberries are processed into products such as juice, sauce, jam, and dried cranberries. Usually, cranberry juice is blended with other fruit juices to reduce tartness. Cranberries are made into a compote or jelly known as cranberry sauce. Cranberries contain about 1.2% pectin. The edible portion of the cranberry is composed of 2.66% glucose, 0.74% fructose, and 0.14% sucrose. Cranberry pulp also contains lignin, glucose, arabinose, and xylose. The overall acid content of ripe cranberries ranges from 1% to 2%.

Blueberry

Blueberries are the most popular berries of the genus *Vaccinium* and subgenus *Cyanococcus*. There are different kinds of blueberries such as the wild-growing lowbush blueberries (*V. angustifolium*) and cultivated highbush blueberries. Cultivated blueberries consist of various species, for example, *V. corymbosum* L., *V. angustifolium* Ait., and *V. virgatum* Ait. The rabbiteye blueberry is *V. virgatum* (*V. ashei)* and also comes under the highbush category. The northern highbush blueberry is *V. corymbosum*. The highbush blueberry is a major crop cultivated in the United States, Canada, Europe, Australia, New Zealand, Chile, and Argentina. The rabbiteye blueberries are commercially produced in southeastern United States. The commercial production of lowbush blueberries is largely confined to Maine (the United States) and Quebec and the Maritime provinces in Canada.

Flowering occurs in early spring, and after pollination, blueberry fruit develops according to a double-sigmoid growth curve. Fruits are borne as racemes or corymbs and berry contains 1–50 seeds embedded in a fleshy and colorless mesocarp. Berries are covered by a waxy cuticle covering the epidermis. Fruit development can be divided into several phases of color development: immature green, translucent greenish white, greenish pink, blue-red, and blue. Fruits ripen in 40–60 days. Blueberries are consumed fresh as dessert fruit and also used for baking. Blueberries are also processed or preserved into jams, pies, syrups, juices, soft drinks, and wines. Most *Vaccinium* fruits for fresh markets are hand-harvested, and for processing, highbush and rabbiteye berries are mechanically harvested.

Blueberries contain 3.5% cellulose and 0.7% soluble pectin. More than 10% of fresh weight of the berry is composed of total sugars. Glucose and fructose constitutes the predominant reducing sugars in blueberries. The acid content of ripe blueberries ranges from 1% to 2% and citric acid forms the primary organic acid (1.2%) in blueberries. Blueberries contain high levels of the amino acid arginine. Blueberries contain 22.1 mg of vitamin C per 100 g FW.

Bilberry

V. myrtillus L. (bilberry, dwarf bilberry, whortleberry, etc.) is similar to the North American lowbush blueberries. The bilberry (*V. myrtillus* L.), a low-growing shrub, is a native of northern and Central Europe and is also found in parts of North America and Asia. It is a small perennial deciduous shrub with slender branches arising from a creeping rhizome. Leaves are bright green and the flowers are globular and waxy with pale green or pinkish petals. Berries are bluish black, globose with purple pigmented flesh and brownish red seeds, and occasionally covered with a gray bloom. Bilberry fruits occur singly in the axils of the lowermost leaves of the vegetative shoot. Bilberries are harvested from the wild in Finland and in other European countries. The berries are used to prepare pies, tarts, syrups, jellies, and wines. Bilberries have a long history of medicinal uses. Glutamic acid and valine are the predominant amino acids in bilberries. Flavonols (quercetin and catechin), ellagitannins, tannins, anthocyanins, and phenolic acids form the phenolic compounds in bilberries. The anthocyanin content in bilberries is relatively higher than the other types of berries including strawberry, cranberry, elderberry, sour cherry, and raspberry. The total anthocyanin content of bilberries ranges from 300 to 700 mg per 100 g FW.

Lingonberry

Lingonberry is popular in Europe and Newfoundland. Lingonberry (*V. vitis-idaea*) is a perennial evergreen shrub that prefers acidic soils and is distributed in circumboreal regions. Lingonberries (*V. vitis-idaea* L.) are predominantly collected from the wild, but this crop has been domesticated recently. They are cold hardy plants and cannot tolerate heat. Lingonberry is commercially cultivated in several locations across Europe, Scandinavia, and also recently in the United States. Major lingonberry-exporting countries are Sweden, Finland, and the Russian Federation. Lingonberries are tart but edible when cooked or processed. It is commonly used in juice, pie fillings, and jam. Lingonberries are abundant in anthocyanin glycosides. The principal amino acids in lingonberries are serine and γ-aminobutyric acid. Lingonberries also have significant levels of benzoic acid. Lingonberries have been used traditionally to treat inflammatory diseases, wounds, gastric disorders, and rheumatism.

Berry Bioactives and Composition

Besides supplying vitamins and minerals, berries are rich sources of several bioactive phytochemicals and antioxidants including phenolic compounds and triterpenoids. Nutritional composition of some selected berries is presented in Table 1. Berries vary greatly in their contents of phenolic compounds. They are crucial sources of phenolic compounds and are represented by flavonoids (flavonols, flavones, flavonones, flavanols, and isoflavonoids), stilbenes, tannins, and phenolic acids (derivatives of benzoic acid and cinnamic acid) in our diet. Studies have shown that varietal differences and differences in the ripeness of the fruit had an effect on the profile and concentrations of phenolic compounds. In the *Vaccinium* genus, the relative amounts of anthocyanins, flavonols, hydroxycinnamic acid derivatives, and proanthocyanidins varied between bilberry, cranberry, and lingonberry. Hydroxycinnamic acid derivatives predominate in blueberries and huckleberries.

Anthocyanins

Anthocyanins are subgroups of flavonoids constituting a large group of water-soluble pigments. They are abundant in berries with red, purple, or blue color. In berries, anthocyanins are composed of aglycones (anthocyanidins) and their glycosides. Anthocyanins function as an antioxidant and a modulator of signal transduction and gene expression. In general, these fruits and their products show strong anti-inflammatory activity. They occur as mono-, di-, or triglycosides, where glycosides are usually substituted at their C3 or less frequently at C5 or C7 positions. Anthocyanins are predominant in *Vaccinium* species, such as bilberry and cranberry, and also in black and red currants and gooseberries. A total of 13 anthocyanins have been detected in cranberry. Among 100 commonly consumed foods in the United States, cranberries are reported as the main source of peonidin. The predominant anthocyanins are the 3-*O*-galactosides and 3-*O*-arabinosides of cyanidin and peonidin. Cranberries have total anthocyanin content ranging from 25 to 100 mg per 100 g fruit.

Anthocyanin profile is quite diverse in blueberry with more than ten anthocyanins, while less diversity is found in chokeberry, strawberry, and raspberry fruits. The total anthocyanin content in blueberry fruit ranges from 85 to 270 mg per 100 g FW. Anthocyanins in blackberries are 3-glycosidic derivatives of cyanidin, delphinidin, malvidin, petunidin, and peonidin. Cyanidin-3-dioxaloylglucoside is unique to blackberries. Raspberries are also rich in cyanidin glycosides. Malvidin-3-galactoside has been found to be the most predominant anthocyanin component in blueberries. The prominent anthocyanins in cranberries are cyanidin-3-monogalactoside, peonidin-3-monogalactoside, cyanidin-3-monoarabinoside, and peonidin-3-monoarabinoside. Cowberries contain high amounts of cyanidin-3-galactoside, and bilberries contain high levels of hydrocinnamic acid and quercetin 3-glucoside, rhamnoside, and arabinoside.

Phenolic Acids

Phenolic acids are major components of berries. Phenolic acids are represented by cinnamic and benzoic acid derivatives. Benzoic acid derivatives include *p*-hydroxybenzoic acid, salicylic acid, gallic acid, and ellagic acid. The common cinnamic acid derivatives include *p*-coumaric acid, caffeic acid, and ferulic acid. Chokeberry is abundant in hydroxycinnamic acid derivatives represented mainly by chlorogenic acid and neochlorogenic acid. Ellagic acid and its conjugates form the majority of phenolic acids in red raspberries. The predominant phenolic acids in strawberries are *p*-hydroxybenzoic acid and *p*-coumaric acid. Among the berries, raspberries and strawberries contain the highest content of ellagitannins. Hydroxybenzoic acid is the most abundant phenolic acid in cranberry followed by hydroxycinnamic acid. Cranberry and blueberry are particularly rich in

Table 1 Nutritional composition of some selected berries (100 g fresh-weight edible portion)

ferulic acid, while bilberry contains *p*-coumaric acid and ferulic acid. Phenolic acids in blackberries are mainly hydroxycinnamic acid and hydroxybenzoic acid and the phenolic acid content range from 7 to 64 mg 100 g^{-1} FW.

Flavonols

Quercetins and kaempferols have been identified in raspberry. In strawberry, kaempferol was detected as the predominant flavonol followed by myricetin and quercetin. Oligomers and polymers represent 85% of the total flavonols and are known as condensed tannins or procyanidins. Flavonol profile of blackberry is quite complex due to the presence of nine quercetin and 3-kaempferol derivatives, as well as other quercetin-derived compounds. Flavonols occur in cranberry as monomers, oligomers, and polymers. The main flavonol compounds in cranberry are glycosides of quercetin, myricetin, and kaempferol. The predominant flavonol is quercetin 3-galactoside. Quercetin exists in many glycosidic forms, and the most abundant form is quercetin galactoside. Myricetin galactoside and arabinoside are also present as well. Cranberries contain substantial amounts of quercetin and its total flavonol content ranges from 20 to 30 mg per 100 g FW. Both blueberries and cranberries are also rich in proanthocyanidins (tannins). A number of studies demonstrate the anticancer potential of quercetin and its derivatives *in vitro* against cell lines derived from the breast, colon, pancreas, and white blood cells (leukemic). Its anticancer actions include the induction of apoptosis, inhibition of epidermal growth factor receptor expression and associated tyrosine kinase activity, reduced expression of ras protein in colon cancer cells, and increased expression of matrix metalloproteinases. Quercetin is a major contributor to cranberry's antitumor property.

Stilbenes

Stilbenes are phenolic compounds that occur in some berries. Resveratrol, pterostilbene, and piceatannol are found in berries including blueberry, cowberry, lingonberry, and acai berry. Resveratrol and its analogs have potent biological properties such as anti-inflammatory, antiaging, antiallergenic, anticarcinogenic, and antimutagenic activities. Studies suggest

that resveratrol can boost apoptosis of cancer cells by enhancing sensitivity to tumor necrosis factor alpha (TNF-α) and reducing NF-κB activation. Studies show that different blueberry varieties of *V. corymbosum*, *V. ashei*, and *V. angustifolium* contain up to 860 ng of resveratrol per gram dry weight of fruit. Cranberry fruit contain about 900 ng of resveratrol per gram dry weight of fruit. Pterostilbene and piceatannol are two analogs of resveratrol, and 100–420 ng per gram fruit was detected in rabbiteye (pterostilbene) and highbush blueberries (piceatannol). Both of these compounds have been shown to possess anticarcinogenic properties to a similar or superior level to resveratrol.

Bioavailability

Only a small portion of the polyphenols (0.5–1%) present in ingested food is actually absorbed. Bioavailability of polyphenolic compounds could be enhanced through biotransformation involving catabolic breakdown, methylation, deglycosylation, etc. According to various *in vitro* studies, phenolic compounds are transported across intestinal epithelium by sugar transporters as glycosides. Following absorption into epithelial cells, these glycosides are converted to aglycones through β-glucosidase-mediated hydrolysis. Aglycones can also be formed in the lumen through the action of membrane-bound lactase–phlorizin hydrolase, and aglycones produced in this way are absorbed passively through the epithelium as compared with conjugation in the ileal epithelium or the liver. Hepatic metabolites (methylated, sulfated, or glucuronidated conjugates) are returned via the enterohepatic circulation (in bile) to the gut lumen. The phenolic compounds that enter the colon consist largely of unabsorbed glycosides and conjugates that have been cycled through ileal and hepatic metabolism. Polyphenols that are associated with food matrix may become unavailable for absorption. These compounds are subjected to metabolism by the gut microbiota after reaching the cecum. For instance, flavonoids undergo ring fission, where the C-ring is degraded resulting in the formation of several phenolic acids.

Berries and Health Benefits

Berries are excellent sources of several antioxidant compounds such as flavonoids, phenolic acids, and vitamins C and E. The hypothesized health benefits related to berry consumption include their role in the prevention of inflammation, oxidative stress, cardiovascular disease (CVD), cancers, type 2 diabetes, obesity, and neurodegeneration.

Antioxidant Activity of Various Berry Compounds

Berries vary in their natural antioxidant capacity, and they owe their antioxidant capability mainly to the various phenolic compounds including tannins, phenolic acids, stilbenes, and flavonoids. The antioxidant compounds in berries exert their action through various mechanisms. Phenolic acids may inhibit the oxidation of vitamin C, carotenoids, and unsaturated fatty acids. Flavonoids can chelate metal, scavenge oxygen radical, and also inhibit lipid oxidation. Anthocyanins could also scavenge free radicals and inhibit the oxidation of human low density lipoproteins (LDL). Carotenoids are also scavengers of active oxygen species preventing the oxidation of LDL. Blueberries and cranberries are ranked among the fruits with high antioxidant capacity owing to the presence of substantial amounts of several phytochemicals such as phenolic compounds. The antioxidant capacity ranges from 13.9 to 45.9 μmol of Trolox equivalents per gram of fresh berry.

Cardiovascular Disease

Evidence from *in vitro* and animal studies suggests that berry bioactive components can influence parameters or factors associated with CVD risks. There is evidence that the addition of berries to the diet could positively affect risk factors for CVD by inhibiting inflammation and improving the plasma lipid profile and free radical scavenging. In a study conducted in middle-aged unmedicated subjects, long-term consumption of moderate amounts of mixed berries resulted in increased high-density lipoprotein cholesterol, decreased blood pressure (BP), and also induced favorable changes in platelet function, indicating that certain constituents of berries alone or in combination play a role in decreasing the CVD risk. Berry and grape consumption has also resulted in increased high density lipoprotein-C (HDL-C) levels and decreased LDL-C levels in healthy, at-risk, and diseased individuals. Some recent study also suggests that berry consumption may also improve insulin sensitivity. Berries have also been associated with the prevention of obesity through interference with lipid digestion and/or through the modulation of lipid metabolism. In dyslipidemic subjects, anthocyanin intake resulted in an increase in plasma HDL cholesterol and a decrease in LDL cholesterol concentrations.

Studies have shown that chokeberry improves blood circulation and can boost the body's immune system. Chokeberry fruit and its products have a protective effect against atherosclerosis, hypertension, and gastrointestinal tract infection. Improvement in vascular function has been reported following intake of pure anthocyanins and cranberry juice (4 weeks) in human subjects. Improvement in endothelium-dependent vasodilation and serum lipid profiles following berry anthocyanin intake was reported in individuals with elevated cholesterol. A decrease in BP has been reported after consumption (6–8 weeks) of mixed berries, anthocyanin-rich tea, and chokeberry and blueberry extracts by individuals with hypertension, myocardial infarction, and markers of metabolic syndrome. Lack of efficacy was noticed in healthy individuals, chronic smokers, dyslipidemic, and obese subjects who consumed blueberry and cranberry juice. Reduction in oxidative stress markers was noticed in overweight and obese children following a short-term blueberry consumption for 8 weeks. Elevated plasma antioxidant capacity was noticed in elderly women and middle-aged men after consumption of strawberry fruit and blueberry extracts. Oxidative DNA damage was significantly decreased in blood cells isolated from human subjects after the consumption of *Aronia*, blueberry, and boysenberry juice for 5 weeks. Bilberry extracts improved circulation in volunteers with a variety of circulatory problems.

Neuroprotective/Neurodegenerative Diseases and Aging

A combination of epidemiological and preclinical studies suggests that the consumption of berries and berry products may

be effective in reversing neurodegenerative symptoms and age-related declines. But a direct association between berry consumption and improvement in neurological health cannot be made at present. A number of observational and human interventional studies have indicated that regular intake of flavonoid-rich plant food and extracts induced improvements in cognitive functions. Evidence from *in vitro* studies also supported the possibility that polyphenolics in berries can beneficially remodel beta-amyloid aggregation *in vitro*. Blueberry consumption and strawberry consumption have been shown to improve memory in older adults.

Diabetes

Polyphenol-rich berry extracts showed α-amylase and α-glucosidase inhibition *in vitro*. Consumption of a berry puree (blueberry, strawberry, black currant, and cranberry) altered the glycemic responses in volunteers. SBT berry induced changes in postprandial glycemic and insulin responses after glucose intake in a human intervention study. Consumption of black currant juice with crowberry powder altered the glycemic and insulin responses of healthy subjects after sucrose-sweetened juice intake. These effects may originate from the inhibition of α-amylase and α-glucosidase activities.

Cancer

The antiproliferative and anti-inflammatory activities of strawberry, raspberry, blueberry, blackberry, and cranberry juices were evaluated against the human stomach, prostate, intestine, and breast cancer cell lines, and the strongest inhibition of cell growth was observed for the raspberry, lowbush blueberry, and cranberry juices. Reduction in the proliferation of the breast cancer (MCF-7) and colon cell lines (HT-29) was noticed on treatment with extracts from fruits and berries including blueberries, black chokeberries, black currant, and raspberries. The raspberry extracts also conferred significant effective protection to DNA damage induced by hydrogen peroxide in the colon cells. A recent study has shown that freeze-dried black raspberry extracts suppressed cell proliferation of human oral carcinoma cells without affecting their viability and also induced apoptosis. The chemoprotective effects of blackberry extracts were demonstrated in studies conducted in a human lung cancer line, A549 with blackberry extracts that inhibited tumor promoter-induced carcinogenesis and associated cell signaling. Cranberry extracts and cranberry press cake showed strong inhibition of the growth of human breast, prostate, skin, and brain cancer cells, which was attributed to its ability to initiate apoptosis and induce G1 phase arrest in the cell cycle. Bilberry extracts induced programmed cell death in human leukemia cells. *In vitro* digested raspberry extracts significantly decreased the population of HT-29 cells in the G1 phase of the cell cycle and showed that raspberry extracts can inhibit key stages in colorectal cancer development, namely, initiation, promotion, and invasiveness.

Different proanthocyanidin fractions from wild and cultivated blueberries also suppressed the proliferation of the androgen-sensitive (LNCaP) and androgen-insensitive prostate cancer cell lines (DU-145). Cranberry flavonoid fractions inhibited the proliferation of various cancer cell lines (androgen-dependent prostate, breast, skin, colon, lung, and brain cell lines) at varying levels. Esters of ursolic acid also inhibited the growth of several types of tumor cells *in vitro* including MCF-7 breast, HT-29 colon, DU-145 prostate, H460 lung, ME180 cervical, and K562 leukemia cell lines. Ursolic acid isolated from cranberry fruit also showed the inhibition of proliferation of HepG2 human liver cancer cells.

Another important anticancer therapeutic property of berries and berry components derives from their ability to inhibit angiogenesis. Studies conducted using extracts from strawberry, bilberry, wild berry, cranberry, elderberry, and raspberry seeds inhibited angiogenesis inhibiting TNF-α-induced vascular endothelial growth factor expression in human keratinocytes. Berries also impaired angiogenesis in human dermal microvascular endothelial cells. Seed flours from berries including black raspberry, red raspberry, blueberry, and cranberry also showed anticancer properties suggesting that berry seed flours have the potential for the development of products for cancer prevention and overall health.

Medicinal Properties of Berry Bioactives

Research has found that bilberry and its products improve the elasticity and permeability of the capillary vessels of the eyeball improving circulation. Cranberry juice has been effectively used for the prevention and treatment of urinary tract infection (UTI). The antibacterial activity of cranberry juice has been known for a long time. It was reported that proanthocyanidins isolated from cranberry fruit exhibited strong bacterial antiadhesion activity offering protection against UTI. Research has found that proanthocyanidins from cranberry are unique and compositionally different from proanthocyanidins from other fruits such as apple and grape. Cranberry juice and cranberry compounds were capable of exerting bacterial antiadhesion activities against *Helicobacter pylori* and oral bacteria including *Streptococcus mutans*. Blueberry compound also exhibited weak antiadhesion activity to *S. mutans*. Ellagitannin fractions from cloudberry and raspberry also demonstrated potent antibacterial activity against *S. aureus*. Recent studies have shown that pure phenolic acids such as hydroxycinnamic acid have bactericidal and bacteriostatic activity against several strains of *Listeria monocytogenes*. *In vitro* studies demonstrated that bilberry and lingonberry extracts containing high amounts of polyphenols exert protective effects against blue LED light-induced retinal photoreceptor cell damage mainly through inhibition of ROS production and activation of proapoptotic proteins.

Sea Buckthorn

SBT (*Hippophae rhamnoides*), a hardy deciduous shrub, belongs to the family Elaeagnaceae. It occurs as a native plant throughout temperate zones including China, Mongolia, Russia, and most parts of northern Europe. It includes several species and *H. rhamnoides* is the most important. In the recent past, it has attracted considerable research attention around the world mainly because of its high nutritional and medicinal value. SBT is a dioecious multibranched and spinescent shrub that grows to 3–4 m in height. Sea buckthorn berries are among the most nutrient-rich fruits in the plant kingdom. The female

plants produce spherical fruit or berries that turn yellow orange or red when ripe. The fruit has a single dark brown glossy ovoid seed surrounded by a soft fleshy outer tissue. Berries are about 3–8 mm in diameter. Berries consist of 68% pulp, seed (23%), and peel (7.75%). Berries are acidic and astringent and unpleasant to eat raw. Sea buckthorn fruit is composed of seed (23%), pulp (68%), and peel (7.75%). Berries are pressed to yield juice (60–85%). Juice is mixed with other sweet juices like apple or grape. Berries are processed into products such as beverages, squash, syrup, wine, beer, preserves, compote, jams, tea (leaves), and jellies. Astringency of fruit juice is minimized by blending with juice or pulp from other fruits in different ratios. Sea buckthorn berries are also included into pies, candies, and liquors. Sea buckthorn oil is also an ingredient in several cosmetic products such as shampoos, lotions, and creams. Juice, oil from pulp and seeds, cream, and pigments are the main commercially utilized sea buckthorn berry products. A yellow pigment can be extracted from sea buckthorn pulp or skin. This pigment contains flavonones, carotene, and vitamin E. Tea is made from the air-dried leaves of sea buckthorn containing many nutrients and bioactive compounds. Pulp oil is another bye product of sea buckthorn processing and is high in carotenoids, tocopherols, and sterols. It also contains the predominant fatty acid, palmitoleic acid.

Sea buckthorn berries are nutrient-dense and are rich in carbohydrates, proteins, fat-soluble vitamins, antioxidants (vitamins C and E, β-carotene, and lycopene), essential fatty acids, phytosterols, and flavonoids, in addition to minerals such as iron and calcium. Berries are exceptionally rich in vitamin C, and the vitamin C content of sea buckthorn has been found to be higher than strawberry, kiwifruit, orange, tomato, carrot and, hawthorn. Sea buckthorn is a rich source of natural flavonoids such as isorhamnetin, quercetin, and aglycones. Studies have shown that sea buckthorn flavonols when ingested with oatmeal porridge had no significant effect on the levels of oxidized LDL, C-reactive protein, homocysteine, and plasma antioxidant potential. Rapid absorption of flavonols was observed by the addition of a small quantity of sea buckthorn oil to the porridge and by doubling the dosage of flavonols in porridge. Extracts of sea buckthorn were also reported to inhibit the cell proliferation of Caco-2 cells and Hep 2 (liver) cancer cell lines *in vitro*. Clinical and human intervention studies investigating the therapeutic potential of sea buckthorn are inadequate. Majority of the medicinal applications of sea buckthorn products in humans are based on anecdotal evidence. SBT seed oil has been clinically used for the treatment of chronic cervicitis, ulcers, and ulcerative stomatitis. In another human intervention study, a significant decrease in waist circumference and vascular cell adhesion was reported in female volunteers fed with SBT berry oil. Further, positive effects of SBT in improving the liver function were noticed in a study conducted in cirrhotic patients indicating that SBT may help in preventing the progression of liver fibrosis.

Honeysuckle

Lonicera caerulea (blueberry honeysuckle) also known as blue honeysuckle, haskap, honeyberry, and edible honeysuckle is a medium-sized shrub with blue edible fruit. This species belonging to the family Caprifoliaceae is a native of the northern hemisphere. This plant species is commercially cultivated in Russia and Japan. Their flavor is described as similar to a combination of blueberries and raspberries. *Lonicera caerulea* plants grow to 0.8–3 m tall and can survive low temperatures without damage. Plants can bear fruits within 1 year of planting. Dark navy blue to purple-colored fruits are oval to long with blue waxy coating. A variety of beneficial compounds such as organic acids, flavonoids, iridoid glycosides, and saponins are present in this plant. Berries contain sugars, lipids, proteins, organic acids, and polyphenols. Honeysuckle fruits contain about 1.52% lipids. Ursolic acid and its derivative pomolic acid were reported in berries. Chlorogenic, caffeic, and ferulic acids form the main phenolic components in *Lonicera caerulea*. The prominent anthocyanins in *Lonicera caerulea* are the glucosides and rutinosides of cyanidin, peonidin, delphinidin, and pelargonidin. In Chinese medicine, the dried bud of this plant has been used for thousands of years for its antipyretic, antidote, and anti-inflammatory properties.

Acai Berries

Acai (*Euterpe oleracea* Mart.) is a palm tree indigenous to South America and grows widely in Brazil, Colombia, Surinam, and in the Amazonian floodplains. Acai palm, also known as the cabbage palm, bears small purple blackberry-like fruit. The state of Para in Brazil is the main producer of acai berry being responsible for 85% of the world production. Acai is a tall, slender multistemmed, and monoecious palm with pinnate leaves that can grow to about 80 ft. A mature tree has about 4–8 well-developed stems. The stem of the palm is smooth and gray in color. Acai palm is propagated by seeds and suckers. It grows well in organic acidic soil and highly warm and highly humid tropical conditions where temperature rarely drops below 10 °C. This palm is adapted to live in waterlogged and flooded areas by developing special root structures known as pneumatophores. Trees start bearing fruit at 3 years and become fully productive 3 years later. Berries can be harvested throughout the year, and higher yields are noticed during August to December. Acai berry is a small drupe and produced in branched panicles of 500–900 fruit. Fruit are spherical and green when young and unripe and turn dark purple on ripening. Fruits of some varieties remain green at maturity and are called white Acai. Fruit are one-seeded and each fruit has a core surrounded by thin stringy fibers covered by a greasy cuticle. The acai berry is about 1–2 cm in diameter and weighs about 0.8–2.3 g. About 80% of the fruit is seed. Seeds are 0.6–1 cm in diameter. The mesocarp of the berry is thin and pulpy surrounding the tough endocarp. The endocarp contains the seed and embryo as well. Depending on the maturity of fruit and the variety, the exocarp is either green or deep purple. The berries are described as having a nutty flavor with metallic taste and an oily texture.

Acai palm is a commercially valuable plant due to its multiple uses. Recently, acai and its products have gained great popularity as a superfood in the United States and North America. Various acai products are now available in the US market including fruit drinks, freeze-dried powder, powdered juice extracts in capsules, and energy bars and snacks. Local inhabitants use acai berry to prepare a thick dark purple juice

by macerating the ripe fruits. The main export product is a mixture of juice mixed with other fruits such as acerola (*Malpighia emarginata*) and guarana (*Paullinia cupana*).

Lipids comprise 50% of pulp and proteins account for about 10% of the dry matter. Extremely high antioxidant capacity was reported in acai pulp with respect to other anthocyanin-rich fruits and vegetables based on the oxygen radical absorbance capacity. The phytochemical profile of acai berries has been characterized. Berries contain a variety of bioactive phytocompounds such as anthocyanins, phenolic acids, proanthocyanidins, and other flavonoids. Cyanidin 3-rutinoside and cyanidin 3-glucoside are the major anthocyanin components. Additionally, lignins have also been identified. Cyanidin 3-glucoside content ranges from 11.1 to 227 mg per 100 g wt. The total anthocyanin content of acai frozen pulp ranges from 282 to 303 mg per 100 g. Low concentrations of resveratrol have also been detected.

Beverage: Health Effects

BM Popkin, University of North Carolina, Chapel Hill, NC, USA
V Malik and FB Hu, Harvard School of Public Health, Boston, MA, USA

© 2016 Elsevier Ltd. All rights reserved.

We have learned that we are what we drink more than what we eat. Over the past 60 years, the world has undergone a profound transformation, from drinking minimal calories from beverages to the consumption of hundreds of calories per day. More recently, we have learned that we compensate very little in our food intake when we consume additional calories as a beverage. A large literature that encompasses short-term to long-term feeding studies, longitudinal epidemiological studies, intervention studies, and randomized controlled trials has emerged. We know that the form of the beverage does not matter, as there appears to be little variance in compensation when the beverage is fat-, carbohydrate-, or protein-based. In this article, we review our knowledge about the health effects of caloric beverages. This is done in the context of our having drunk water for millennia and developing physiological systems finely attuned to water intake and seasonal hunger. We know a great deal about the relationship between beverage form and energy intake and the subsequent relationship with an array of cardiometabolic problems; however, we do not understand mechanisms underlying this well. The article also discusses additional health problems linked with excessive refined carbohydrate intake and excessive fructose intake. We then present some historical evidence on beverage consumption and discovery and review recent patterns and trends of beverage consumption.

One of the most important aspects of the entire literature of beverages and health is the dearth of research on water and health. We have developed physiological adaptations to protect us against dehydration. Although the bulk of our body is composed of water, we focus far more attention on reducing the intake of all caloric beverages than on understanding the strengths and importance of water.

One of the major dimensions of the sugar and beverages and health debasement reflects the fact that there is an innate human desire for sweetness. If sugar, high-fructose corn syrup (HFCS), and fructose were not sweet, there would be no debate because their consumption would be low. Sweet taste is present in newborns and increases in intensity throughout childhood. It may be that the 'craving' for sweets can even be enhanced by early exposure to intense sweeteners. The food industry has used sugar as a major sweetener for delivery for increasing the amounts of beverages and food over the past half century. The result has been that the consumption of sugar-sweetened beverages (SSBs) rose by a startling 38.5 gallons per person between 1950 and 2000 (from 10.8 gallons per person in 1950 to 49.3 gallons per person in 2000). We have seen small declines since then; however, the industry continues to find new ways to increase liquid sugar consumption by constantly adding new products, be they in fruit juice, energy drinks, vitamin waters, protein waters, sports drinks, and hundreds of new options. Thus, the question 'do current levels of sugar consumption pose a serious health risk to Americans?' seems in crying need of clarity.

Beverage Intake: Effects on Health

Ingestatory Behavior

There is a clear biological basis for reducing intake of sugary beverages, namely, the lack of compensation by reducing food intake when one consumes a caloric beverage. This is particularly true for SSBs but there is an emerging literature that suggests that 100% fruit juice has identical effects to SSBs on our health. There appears to be little reduction in food intake when caloric beverages are substituted for water and other low-nutritive sweetened or 'diet' beverages. This relationship between beverage intake and food intake occurs despite studies showing that individuals who consume caloric beverages feel they are sated. While they may feel more sated, they do not reduce their food intake. Consequently, individuals fed with water or noncaloric or low-calorie sweetened beverages consume reduced total energy intake when compared with those consuming caloric beverages. This relationship appears to hold as food and beverage form changes. That is, whether it is a carbohydrate-, fat-, or protein-based beverage (e.g., SSB, coconut milk, or cow's milk), the relationship holds. A more detailed examination shows that intake of calorically sweetened beverages does not reduce the intake of solid food by a corresponding amount.

The effects of consuming water with meals with various types of caloric and diet beverages (DBs) have been less studied. We undertook a systematic review of English language studies evaluating the impact on energy intake and/or weight status of not drinking water or drinking other beverages compared with water. Relevant clinical trials and epidemiological and intervention studies were collected, and findings across the literature were summarized. Using clinical trials, average differences in total energy intake at test meals (ΔTEI) were calculated across studies for several beverage categories compared to water. The literature for these comparisons is sparse and somewhat inconclusive. One of the most consistent sets of studies compared drinking SSBs with water among adults at a single meal. Total energy intakes were increased by 7.8% (ΔTEI range: −7.5 to 18.9) when SSBs were consumed. Studies comparing noncaloric sweetened beverages with water were also relatively consistent and found no impact on energy intake among adults (ΔTEI = − 1.3, range: −9 to13.8). A set of fewer studies showed that replacing water with milk and juice increased TEI by an estimated 14.9% (range: 10.9 to 23.9).

One-year-long intervention study also promoted water and removed from schools all caloric beverages. This study instituted both educational and environmental interventions to increase water intake in 17 German schools (15 control schools had no intervention). Teachers presented four empirically developed lessons about the body's water needs and the water cycle. Special filtered drinking fountains were installed, water bottles were distributed, and teachers were encouraged to

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00063-5

organize the filling of water bottles each morning. After 1 year, the children completed 24 h beverage intake recalls in class. Intervention schools had higher water intakes (1.1 glasses per day, $P<0.001$) and lower adjusted risk of overweight (OR = 0.69, 95% CI: 0.48–0.98).

Weight and Children: Trials

Over the past decade, the major addition to our literature on the impact of SSBs has been the effect of SSBs on child weight and risk of obesity. We have summarized research that was reported in detail elsewhere. A total of five studies including 2772 children and adolescents were included in our analysis of SSB trials and body weight. Based on these data, Malik, Pan, Willett, and Hu found a nonsignificant difference in the change in body mass index (BMI) from reducing SSB consumption (weighted mean difference (WMD) −0.17; 95% CI: −0.39, 0.05; $I^2=74.6\%$; P-heterogeneity = 0.003) in the random-effects model (Figure 1). Results from the fixed-effects model were statistically significant (−0.12; 95% CI: −0.22, −0.02). Different statistical models may explain these differences. Metaregressions for intervention modality (education or beverage substitution; $P=0.08$), duration ($P=0.18$), and age ($P=0.84$) were not statistically significant, although power to detect a difference was low with only five studies. When we stratified our analysis by intervention modality, they observed a significant weight reduction among the three studies that provided noncaloric beverages as substitutes for SSB: the summary estimate was (−0.34; 95% CI: −0.50, −0.18; $I^2=0\%$). In contrast, we did not find a significant intervention effect in the two studies that used focussed school-based education to discourage SSB consumption (0.01; 95% CI: −0.19, 0.20; $I^2=59.6\%$).

All studies except for the one by Sichieri et al. showed a beneficial effect or trend of interventions to reduce SSB intake on weight. The study by Sichieri et al. was a school-based intervention that used focussed education to discourage the consumption of carbonated SSBs, but according to the author, the students compensated by increasing their consumption of sugar-added juices and fruit drinks, which may explain the lack of findings. However, in a subgroup analysis, children who were overweight at baseline showed greater BMI reduction in the intervention group, which was statistically significant among girls. Similarly, Ebbeling, Ludwig, and their team, discussed in this same article, found more pronounced benefits of the intervention among adolescents who were overweight at baseline, and Ebbeling et al.'s study, which was conducted exclusively among overweight adolescents, showed the strongest intervention effect among studies included in our analysis. Combining Ebbeling et al. with the subgroup findings from Ebbeling et al., we observed an increased benefit of substituting noncaloric beverages for SSB on weight gain (−0.64; 95% CI: −1.07, −0.21), suggesting that this type of intervention may have greater impact on those who are overweight.

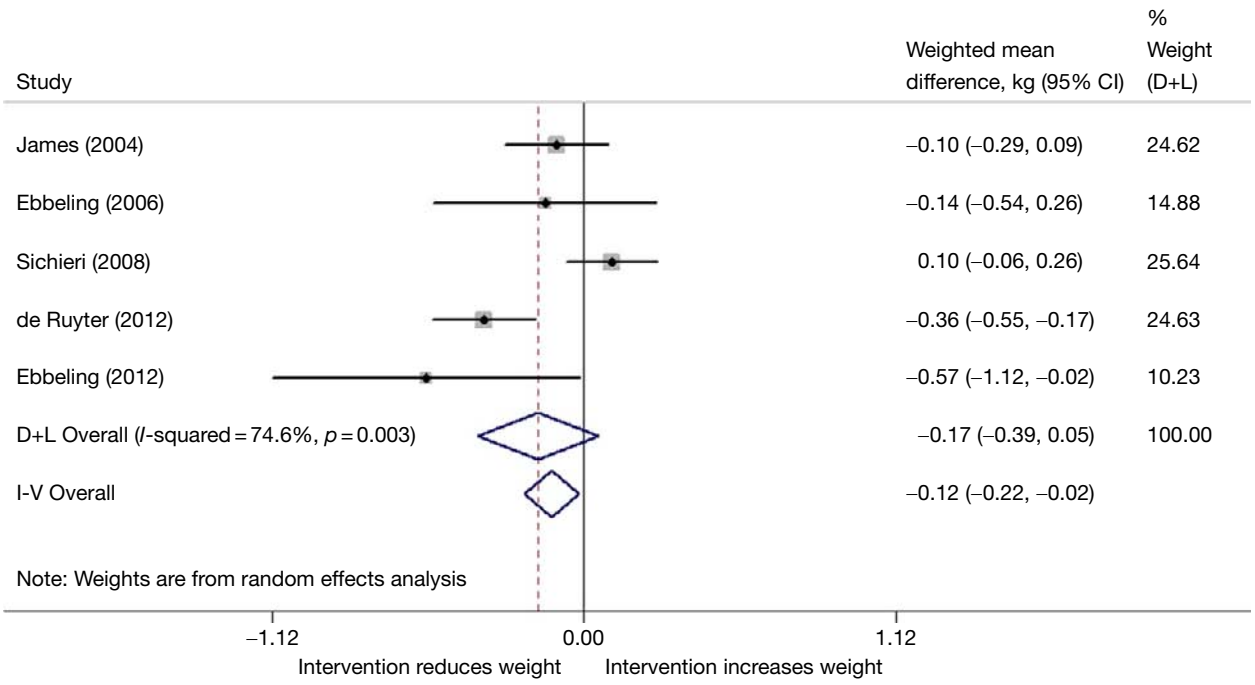

Figure 1 Weighted mean difference in BMI change (95% CI) between intervention and control regimens from RCTs in children. Interventions evaluated the effect of reducing SSB. Horizontal lines denote the 95% CIs; solid diamonds represent the point estimate of each study. The open diamond represents the pooled estimate of the intervention effect and the dashed line denotes the point estimate of the pooled result. Weights are from the random-effects analysis (D + L; DerSimonian and Laird). Pooled estimates from the random-effects analysis (D + L; DerSimonian and Laird) and fixed analysis (I-V; inverse-variance) are shown based on 5 RCTs ($n=2772$). *I*-squared value and *P*-value for heterogeneity are shown. Reproduced from Malik, V. S., Pan, A., Willett, W. C. and Hu, F. B. (2013). Sugar-sweetened beverages and weight gain in children and adults: a systematic review and meta-analysis. *American Journal of Clinical Nutrition* 98, 1084–1102.

There is also extensive epidemiological literature on child weight gain but minimal work on other outcomes. We did not review the epidemiological child weight gain literature here since the major RCTs for children – the two most recent NEJM ones – provide such convincing evidence. Based on the totality of the available evidence from prospective cohort studies, a one serving per day increase in SSB was associated with a 0.06 unit increase in BMI over a 1-year period among children and adolescents and an additional weight gain of 0.12–0.22 kg (~0.25–0.50 lb) over a 1-year period among adults. In children, it is difficult to gauge the impact of our findings, since weight gain in childhood varies as a function of age, maturation, and growth velocity.

Adult Weight

Prospective cohort studies

To our knowledge, the Malik, Pan, Willett, and Hu study noted in the preceding text was the first meta-analysis to evaluate prospective cohort studies of SSB and body weight in adults. This analysis of a 1-year change in weight (kg) in adults was based on seven studies, including eight comparisons and 170 141 men and women. We found that each serving per day increase in SSB was associated with an additional weight gain of 0.22 kg over 1 year (0.22; 95% CI: 0.09, 0.34; $I^2 = 70.2\%$; P-heterogeneity <0.001) from the random-effects model (Figure 2). Metaregressions for age at baseline ($P = 0.32$), duration ($P = 0.37$), use of FFQ to assess diet ($P = 0.26$), sample size ($P = 0.48$), and baseline weight status ($P = 0.10$) were not statistically significant. However, when they stratified the analysis by baseline weight status, they observed greater though nonsignificant weight gain in the two studies conducted among overweight populations (1.22 kg; 95% CI: −0.23, 2.68; $I^2 = 77.5\%$), compared with non-overweight populations (0.15; 95% CI: 0.06, 0.24; $I^2 = 50.3\%$).

Trials

A total of five studies including six comparisons with 292 men and women were included in our analysis of trials in adults. We found a significant difference in change in body weight (kg) between intervention and control regimens (WMD: 0.85; 95% CI: 0.50, 1.20; $I^2 = 0.0\%$; P-heterogeneity = 0.78) from the random-effects model. All studies observed significantly greater weight gain or trends toward greater weight gain in intervention compared to control regimens and there was no evidence of heterogeneity. When stratified by baseline weight status, they observed greater weight gain in intervention

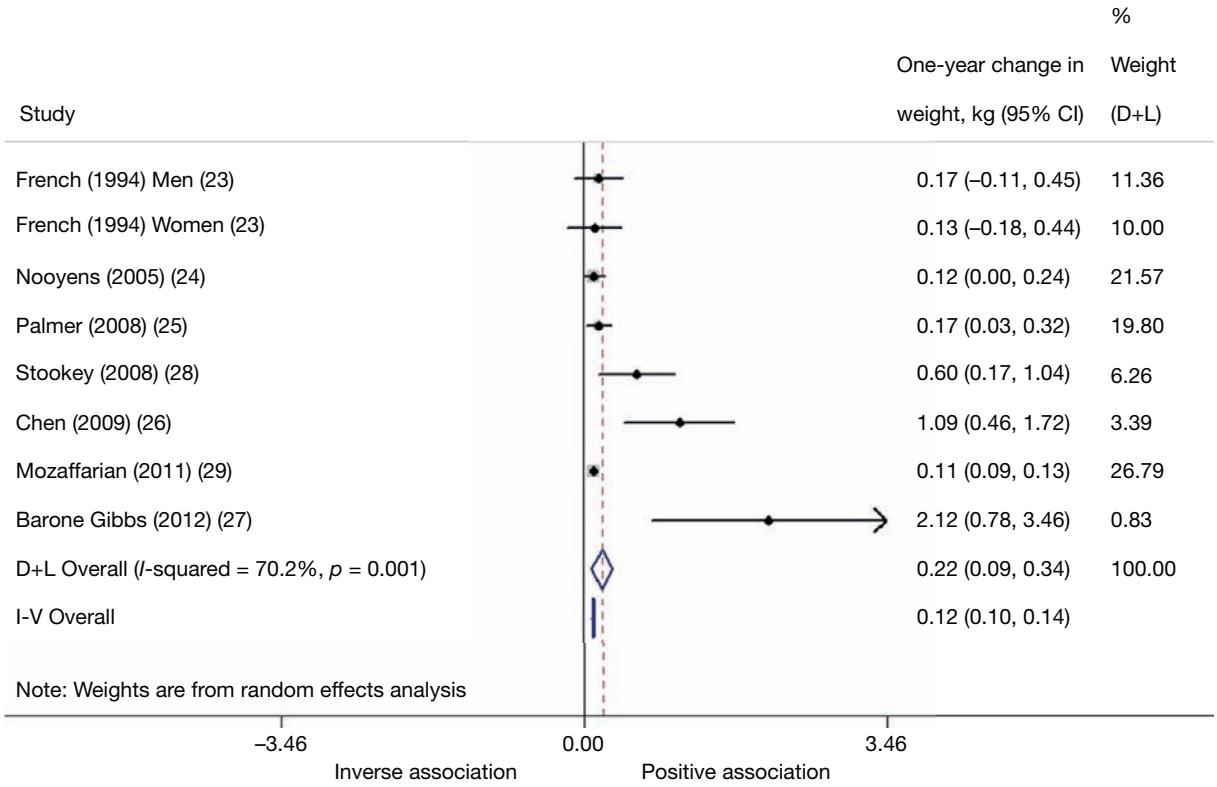

Figure 2 One-year change in weight (kg) per one serving per day increase in SSB, from prospective cohort studies in adults using a change versus change analysis strategy. Horizontal lines denote the 95% CIs; solid diamonds represent the point estimate of each study. The open diamond represents the pooled estimate and the dashed line denotes the point estimate of the pooled result. Weights are from the random-effects analysis (D + L; DerSimonian and Laird). Pooled estimates from the random-effects analysis (D + L; DerSimonian and Laird) and fixed analysis (I-V; inverse-variance) are shown based on seven cohort studies ($n = 174\,252$). *I*-squared value and *P*-value for heterogeneity are shown. Reproduced from Malik, V. S., Pan, A., Willett, W. C. and Hu, F. B. (2013). Sugar-sweetened beverages and weight gain in children and adults: a systematic review and meta-analysis. *American Journal of Clinical Nutrition* 98, 1084–1102.

compared to control regimens among the three studies conducted in non-overweight populations (WMD: 0.89; 95% CI: 0.52, 1.26; $I^2 = 0.0\%$), compared with the two studies conducted in overweight populations (WMD: 0.47; 95% CI: −0.70, 1.63; $I^2 = 0.0\%$). Adding the study by Raben et al. to the analysis, which was excluded because the intervention contained some foods in addition to beverages (~70% beverage and 30% food), increased the overall estimate but introduced some heterogeneity to the studies examined (WMD: 1.06; 95% CI: 0.54, 1.58; $I^2 = 46.3\%$; P-heterogeneity = 0.08).

Adult SSB and Type 2 Diabetes

A growing body of evidence clearly indicates that SSB consumption is associated with increased risk of diabetes through effects on adiposity and independently through other metabolic effects. These results come from our Malik et al. review. We conducted a meta-analysis of eight prospective cohort studies evaluating SSB intake and risk of diabetes. Based on 3,10,819 participants and 15,043 cases, individuals in the highest category of SSB intake (usually 1–2 servings per day) had a 26% (RR 1.26, 95% CI 1.12–1.41) greater risk of developing type 2 diabetes compared with those in the lowest category (none or <1 per month) (Figure 3). A one serving per day increase in SSB was associated with a 15% increased risk for diabetes (RR 1.15, 95% CI 1.11, 1.20). Similar to studies evaluating weight gain, results were generally more consistent among larger and longer studies that did not adjust for potential intermediates in the causal chain such as total energy intake and, in the case of diabetes, BMI (kg m^{-2}). In a study by Schulze et al. in more than 50 000 women with 8 years of follow-up, those that consumed ≥1 SSB per day had an 83% increased risk for diabetes, compared with those consuming <1 per month (p trend <0.001) after adjusting for a number of risk factors. After additional adjustment for BMI, the associated risk decreased to 41% (p trend <0.001), suggesting that BMI accounts for about half of the excess risk. Similar findings were recently reported in the Health Professionals Follow-up Study in over 40 000 men followed for 20 years where SSB was associated with a 24% (p trend <0.01) increased risk of diabetes comparing extreme categories after adjusting for risk factors including pre-enrollment weight change, dieting, total energy intake, and BMI. Although these studies adjusted for various dietary and lifestyle risk factors in their analyses, they are observational and confounding by unmeasured or imperfectly measured factors that may still be present, as SSB may be a marker for a globally unhealthy diet and lifestyle. Randomized controlled trials, on which policies and public health recommendations are often based, are not well suited to evaluate this question because they are greatly affected by intervention intensity and limited by compliance and duration for clinical end points. For these reasons, most interventions have evaluated biological markers of T2D risk or metabolic syndrome.

SSB and Cardiovascular Risk

A small number of prospective cohort studies have evaluated the risk of metabolic syndrome in relation to SSB consumption. Our recent meta-analysis pooled findings from three studies including 19,431 participants and 5803 cases of metabolic syndrome and observed an increased risk of about 20% comparing highest to lowest categories of intake. Two of these studies also looked at SSB consumption in relation to individual components of metabolic syndrome. Dhingra et al. found that individuals that consumed ≥1 SSB per day had a marginal

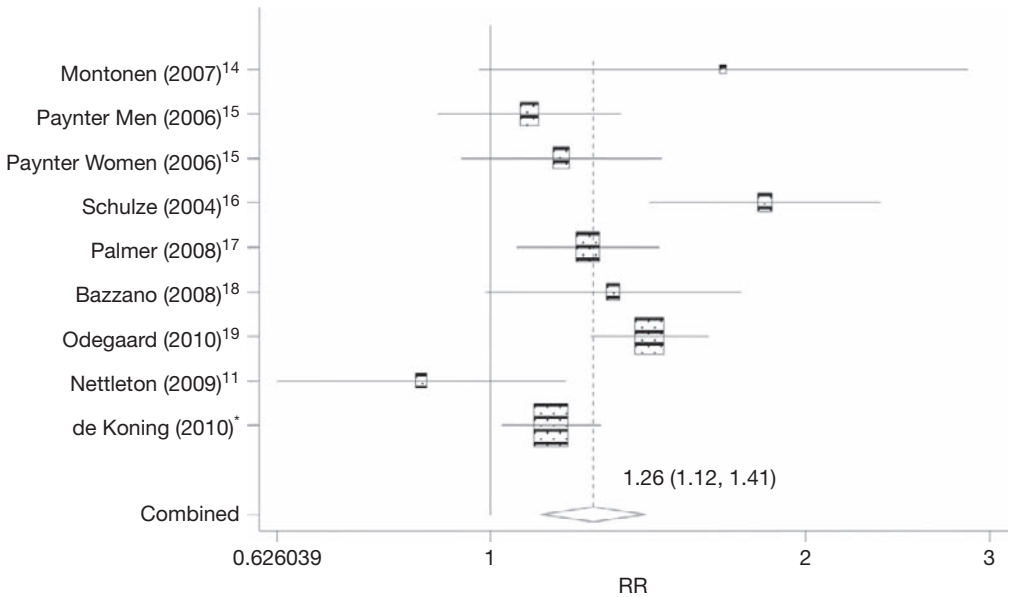

Figure 3 Forrest plot of studies evaluating SSB consumption and risk of type 2 diabetes, comparing extreme quantiles of intake. Random-effects estimate (DerSimonian and Laird method). *Information from personal communication. Reproduced from Malik, V. S., Popkin, B. M., Bray, G. A., Despres, J. P., Willett, W. C. and Hu, F. B. (2010). Sugar-sweetened beverages and risk of metabolic syndrome and type 2 diabetes: a meta-analysis. *Diabetes Care* 33(11), 2477–2483.

18% (RR 1.18, 95% CI 0.96, 1.44) greater risk of developing hypertension compared with nonconsumers after adjusting for baseline hypertension, age, sex, physical activity, smoking, intake of saturated fat, trans fat, fiber, magnesium, total energy, and glycemic index. Results from Nettleton et al. also found a marginal effect of SSBs on incident hypertension (RR 1.10, 95% CI 0.87, 1.39) comparing daily consumers with nonconsumers. These trends are supported by stronger associations in the NHS and NHS II cohorts where women that consumed $\geq$4 SSB per day had a 44% and 28% greater risk of developing hypertension, respectively, compared with infrequent consumers. Studies by Dhingra et al. and Nettleton et al. also found that daily SSB consumers had a marginally increased risk for developing hypertriglyceridemia compared with infrequent consumers after adjusting for risk factors (RR 1.25, 95% (CI 1.04, 1.51) and RR 1.24, 95% CI (0.98, 1.57), respectively). In these studies, daily SSB consumers also had an increased risk for low HDL cholesterol (RR 1.32, 95% CI (1.06, 1.64) and RR 1.24, 95% CI (0.95, 1.61), respectively). In the Coronary Artery Risk Development in Young Adults (CARDIA) study, higher SSB consumption across quartiles was associated with a number of adverse cardiometabolic outcomes: high waist circumference (RR: 1.09; 95% CI: 1.04, 1.14; p for trend, 0.001), high LDL cholesterol (RR: 1.18; 95% CI: 1.02, 1.35; p for trend = 0.018), high triglycerides (RR: 1.06; 95% CI: 1.01, 1.13; p for trend = 0.033), and hypertension (RR: 1.06; 95% CI: 1.01, 1.12; p for trend = 0.023).

Data from short-term trials also provide important evidence linking SSB with cardiovascular risk. Raben et al. found that a sucrose-rich diet consumed for 10 weeks resulted in significant elevations of postprandial glycemia, insulinemia, and lipidemia compared with a diet rich in artificial sweeteners in overweight healthy subjects. A randomized crossover trial among normal-weight healthy men found that after 3 weeks, SSBs consumed in small to moderate quantities (600 ml SSB per day containing 40–80 g of sugar) significantly impaired glucose and lipid metabolism and promoted inflammation. Specifically, LDL particle size was reduced for high-fructose and high-sucrose SSBs and a more atherogenic LDL subclass distribution was seen when fructose- and high-sucrose-containing SSBs were consumed. Fasting glucose and high-sensitivity C-reactive protein increased significantly after fructose, glucose, and sucrose intervention and leptin increased during interventions with SSBs containing glucose. A 10-week intervention comparing the effects of sucrose and artificially sweetened food/beverages on markers of inflammation found that serum levels of haptoglobin, transferrin, and CRP were elevated in the sucrose group compared with the sweetener group.

SSBs may affect the risk of coronary heart disease (CHD) in a relatively short time of just a few years through effects on inflammation that influence atherosclerosis, plaque stability, and thrombosis. Few studies have looked at the association between SSB consumption and clinical CHD. Among over 88 000 women in the NHS followed for 24 years, those that consumed $\geq$2 SSBs per day had a 35% (p trend 0.01) increased risk of CHD compared with infrequent consumers after adjusting for risk factors. Additional adjustment for mediating factors such as BMI, total energy, and incident diabetes attenuated the associations, but they remained statistically significant, suggesting that the effect of SSBs is not entirely mediated by these factors.

A recent meta-analysis of the effect of SSBs on blood pressure was published by Malik, Akram, Shetty, SS Malik, and Njike. All of the final studies reviewed showed a positive relation between SSB intake and hypertension with only 10 of the 12 achieving statistical significance. Their most conservative estimate showed that intake above 12 fl oz of SSB per day would increase the risk of hypertension by at least 6%.

Randomized controlled trials

To date, one well-executed randomized controlled trial has been completed. The CHOICE (Choosing Healthy Options Consciously Everyday) clinical trial focussed on the impact of shifting from normal caloric beverages to either water or DBs among adults involved in active weight loss. The hypothesis was that participants assigned to the beverage substitution groups would achieve greater weight loss at 6 months compared with control participants who made dietary changes of their choosing (DBs were greater than active choices (ACs), and water (WA) greater than AC). Secondary outcomes were to compare the noncaloric beverage groups to the control group on criterion measures of weight loss, waist circumference, blood pressure, glucose, and osmolality as a marker of hydration from 0 to 3 months and 0 to 6 months.

Despite similar or somewhat smaller weight losses, replacement WA showed statistically significant reductions in fasting glucose and improvement in hydration compared with control AC. DB also showed improvements on many of these parameters by 6 months but was not significantly different from AC. In the completer's analysis, the improvements in systolic and diastolic blood pressure in WA compared with AC reached statistical significance. This study showed that approximately a two-serving reduction in caloric beverages resulted in a 2 kg weight loss at 6 months across DB and WA.

In the intent-to-treat analysis, all groups significantly reduced weight and waist circumference and improved systolic blood pressure from 0 to 6 months. Average percentage weight losses ($\pm$SE) at 6 months were DB -2.54% (0.45), WA -2.03% (0.40), and AC -1.76% (0.35); there were no significant differences between groups. DB had greater odds of achieving a 5% weight loss at 6 months compared with AC (OR = 2.29, 95% CI: 1.05, -5.01; $p = 0.04$); WA showed a significant reduction in fasting glucose at 6 months ($p = 0.19$) and improved hydration at 3 ($p = 0.0017$) and 6 ($p = 0.049$) months compared with AC. In a combined analysis, participants assigned to replace beverages were two times more likely to have achieved a 5% weight loss (OR = 2.07, 95% CI: 1.02, -4.22; $p = 0.04$) compared to AC.

The strength of this study is that it is the first randomized controlled trial in adults examining a simple strategy for calorie reduction and weight control, with participants masked to the study purpose, including over 50% racial and ethnic minorities, strong retention rates, 24 h dietary recalls, provision of beverages, an attention control group, and objective weight and physiological outcome measures.

On a population level, the replacement of caloric beverages with noncaloric alternatives could be an important public health message. This strategy also has implications for health care settings, as assessing SSB intake is feasible and the

prescriptive recommendation to replace caloric beverages with noncaloric alternatives is simple and straightforward. Replacing SSB with either DBs or water appears warranted based on these findings.

Does the Type of Caloric Sweetener Matter? Is HFCS the Culprit?

Fructose comes from many sources; however, it first came to fame as a component of HFCS. We now understand that the source of the fructose does not matter and that fructose contained in any sugar (e.g., cane or beet sugar, fruit juice concentrate, honey, and corn syrup) is equally harmful. At one point, there was extensive concern that HFCS might have posed a major impact on health. Bray et al. hypothesized that the large shift toward the use of HFCS coupled with unique metabolic properties of fructose posed a major problem.

Subsequent research has provided clear evidence that all sugars are equal in their impact on cardiometabolic health; nevertheless, the fructose component of sugars such as sucrose and syrup HFCS might lead to additional cardiometabolic risks. These range from gout, linked with the high concentration of uric acid, to many other cardiometabolic complications, particularly related to renal function.

What about Noncaloric Sweeteners?

An increasing component of the beverage market, particularly in high- and middle-income countries, consists of beverages with either noncaloric sweeteners (NCSs) or a combination of caloric sweeteners and NCS. There is minimal evidence that NCS poses any toxicological effect on health. However, there is a large set of epidemiological studies suggesting that the consumption of beverages with NCS is linked with increased cardiometabolic risks including diabetes, metabolic syndrome, and obesity.

Two recent studies question this relationship. A new study by de Koning and colleagues found that an observed association between intake of beverages with NCS and increased risk of T2DM is attenuated and no longer statistically significant following multivariate adjustment for detailed measures of family history, previous weight change, dieting, Healthy Eating Index score, and total energy intake (top bottom quartile of intake: HR (95% CI): 1.09 (0.98, 1.21), p for trend = 0.13). Although de Koning et al. addressed possible confounding by diet more completely than other studies have, their results still could have missed important interactions between dietary pattern and DB consumption.

A second publication went a step further. Using CARDIA longitudinal data, Duffey et al. found that people who consumed DBs tended to be less healthy compared to people who did not consume them. However, there was an important interaction with diet. People who were healthiest tended to be those who ate a 'prudent' or healthy diet (with more fruit, whole grains, nuts, and milk) and did not consume DBs. They had a lower risk of high waist circumference, high triglyceride levels, and metabolic syndrome. But the second healthiest group was those individuals with a prudent diet who also consumed DBs. In contrast, individuals who consumed the 'Western' diet, which had higher amounts of fast food, meat and poultry, pizza, and snacks, had increased risk of heart disease regardless of whether or not they drank DBs.

A recently published study illustrates the complex issues we face related to the use of NCS in beverages and foods. Piernas et al. compared dietary patterns of those in the previously mentioned CHOICE trial. The DB group showed statistically significant decreases in most caloric beverages and specifically reduced more dessert consumption over the study period. The DB group showed statistically significant decreases in most caloric beverages and specifically reduced more on desserts over the study period. This is a small study not powered to examine this topic, but it is suggestive of a potentially important issue.

Mechanisms, History: When Did Caloric Beverages Enter the Human Food System?

We have no clear known mechanisms that explain why when we consume beverages it does not affect our food intake; however, we speculate on this mechanism. It is well known that humans will die within 3–7 days if they do not consume water. Water comprises 75% of the body weight in infants to 55% in the elderly and is essential for cellular homeostasis and life. From the time that primeval species ventured from the oceans to live on land, a major key to survival has been the prevention of dehydration. The critical adaptations cross an array of species, including *Homo sapiens*. To prevent dehydration, reptiles, birds, vertebrates, and all land animals have evolved an exquisitely sensitive network of physiological controls to maintain body water and fluid intake by thirst. Humans may drink for various reasons, particularly for hedonic ones, but most drinking is due to water deficiency, which triggers the so-called regulatory or physiological thirst. We understand from extensive research on the topic that the hydration system of a human is finely tuned to protect us. What is not clear is how this thirst mechanism is different from the hunger or feeding mechanism. We know that humans will die if they do not eat over a 1- to 2-month period depending on their initial weight so there appear to be some evolutionary reasons behind the lack of compensation in food intake when they drink water or caloric beverages.

A consideration of our evolutionary history may help to explain our poor compensatory response to calories from fluids. Elsewhere, we have reviewed the history of eight important beverages: milk, beer, wine, tea, coffee, distilled alcoholic beverages, juice, and soft drinks. Humans may lack a physiological basis for processing carbohydrate or alcoholic calories in beverages because only breast milk and water were available for the vast majority of our evolutionary history. Alternatives to those two beverages appeared in the human diet no more than 11 000 years ago, but *Homo sapiens* evolved over a 100 000- to 200 000-year period. Second, carbohydrate- and alcohol-containing beverages may produce an incomplete satiation sequence that prevents becoming satiated on these beverages.

Current Patterns and Trends of Beverage Intake

Global Aggregate Trends

Across the globe, there is evidence of increasing a shift toward increased consumption of SSBs and more recently also

increased intake of NCS beverages. A recent study examined patterns of carbonated soft drink availability using the two largest and most influential producers of sweetened beverages, The Coca-Cola Company and PepsiCo, who together control 34% of the global soft drink market, examining their product portfolios globally and in three critical markets (the United States, Brazil, and China) from 2000 to 2010. This study used Euromonitor International's definition of 'soft drink,' which includes the aggregation of (i) carbonates/carbonated soft drinks, (ii) fruit/vegetable juice, (iii) bottled water, (iv) functional drinks, (v) concentrates, (vi) ready-to-drink tea, (vii) ready-to-drink coffee, and (viii) Asian specialty drinks. Thus, although the term 'soft drink' may refer specifically to carbonated soft drinks in everyday use, the 34% market share takes into account other beverage categories, with carbonated soft drinks considered a subset of soft drinks overall.

On a global basis, total revenues and energy per capita sold increased from 2000 to 2010, yet the average energy density (kilojoules per 100 ml) sold declined slightly, suggesting a shift to lower-calorie products. Per capita volume sales showed similar worldwide trends during the past decade, with modest increases in sales of carbonated soft drinks alongside marked increases in bottled water, fruit/vegetable juice, and sports and energy drinks.

What is most interesting is the differential trends in the United States versus the developing markets of Brazil and China. Despite the global increase in energy and volume sold per capita by Coca-Cola and PepsiCo from 2000 to 2010, there is a clear decrease in energy and volume sold per capita in the United States over the same time period because of a shift toward reduced kilocalories per milliliter of sales. In contrast, the opposite was true in Brazil and China, with total per capita energy increasing greatly in China and to a lesser extent in Brazil. Daily energy per capita sold by Coca-Cola increased by 41% in Brazil between 2000 and 2010, while daily energy per capita sold by PepsiCo rose by 168%, largely because of increases in energy from carbonated soft drinks. Likewise, in China, daily energy per capita sold by Coca-Cola increased by 215% between 2000 and 2010, while daily energy per capita sold by PepsiCo rose by 147%, also driven by carbonated soft drinks. Energy from carbonated soft drinks alone sold by both Coca-Cola and PepsiCo experienced an even stronger upward growth trend in China between 2000 and 2010. Figure 4 shows the global increases in this one component of soft drink sales from these two companies. The remarkable increases in Brazilian and Chinese sales per capita are presented in Figure 5.

A major objective of the global beverage companies has been to increase sales of water and beverages with NCS and to reduce their total sale of calories. Figure 6 highlights the much lower in average energy density of carbonated soft drinks sold by Coca-Cola and PepsiCo in the United States versus globally and in Brazil and China, as well as the reduction ounce of in average energy density of carbonated soft drinks for both companies. In contrast, the energy density of carbonated soft drinks has not changed in China while there is a slight reduction by PepsiCo in Brazil. Caution is warranted in interpreting Figure 3. First, Coca-Cola and PepsiCo represent only the two largest companies, but in each local market, there are many other companies, few of which have the capacity to promote sales of nonnutritively sweetened beverages like these two companies do. Second, Figures 1 and 2 show overall caloric beverage sales increases represent potentially important current risks to energy imbalance and weight gain.

Discussion and the Future

An expanding literature suggests that caloric beverage intake is linked with obesity and excessive weight gain and increased risk of diabetes and cardiovascular disease. One of the clearest causal linkages between our food supply and excessive weight gain and an array of cardiometabolic problems is the excessive intake of the array of SSBs. Our concern is echoed by experts in the heart, cancer, diabetes, and many other fields as well as in much public debate. Nevertheless, the sugar and beverage sectors represent two of the more powerful of interests in our society, dwarfing the tobacco sector. Country after country is attempting to limit the consumption of SSBs and other caloric beverages, and in many cases, they are succeeding as is seen by the recent 10% SSB tax in Mexico and in equally complex attempts that have yet to succeed in many other countries.

Beverage: Patterns of Consumption

A Drewnowski, University of Washington, Seattle, WA, USA
CD Rehm, Tufts University, Boston, MA, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Beverages contribute more to hydration than they do to energy intakes. Based on the national food consumption data for the United States, drinking water and caloric and noncaloric beverages accounted for up to 75% of total water intake with the remaining 25% provided by moisture in foods. In contrast, solid foods provide as much as 81.3% of daily calories for people aged over 4 years, whereas caloric beverages provide only 18.7%. Beverages consumed in the United States include drinking water, milk, juices, sodas (carbonated) and fruit-flavored drinks, and coffee and tea.

The nutrient density of beverages has been expressed in nutrients per calorie and nutrients per serving. While drinking water, tap and bottled, contains no calories and no nutrients, other beverages are important dietary sources of vitamin C, potassium, calcium, and other vitamins and minerals. Although sweetened beverages are the biggest source of added sugars, they are not the largest source of dietary calories. Added sugars account for about 13–18% of total daily calories in the American diet, depending on age. On the average, sugar-sweetened beverages (SSBs) account for about 40% of added sugars. Thus, the mean contribution of SSBs to total daily calories in the United States has been estimated at 6–7%.

Consumption patterns of different beverages vary sharply by age. Young children are more likely to drink milk, whereas older adults are more likely to drink coffee. Consumption of both citrus juices and sodas peaks in adolescence before declining in adult life. Consumption patterns can also vary by socioeconomic status (SES). In the United States, consumption of tap water, bottled water, skimmed milk, and diet soft drinks has been linked to higher education and higher incomes. In contrast, the regular consumption of soda and whole milk is linked to lower SES.

Most data on beverage consumption patterns and consumption trends in the United States come from federal agencies. The ongoing National Health and Nutrition Examination Survey (NHANES), conducted by the National Center for Health Statistics, is the primary source of beverage consumption data, based on 1- or 2-day food recall. NHANES data are based on a representative sample of the United States population, spanning different demographics and age groups. The US Department of Agriculture (USDA) maintains national food availability data, which is useful for tracking long-term time trends by beverage category.

Classification of Beverages

All foods and beverages listed as consumed by NHANES participants are included in the USDA Food and Nutrient Database for Dietary Studies (FNDDS) that is available online (http://www.ars.usda.gov/News/docs.htm?docid=12089). The 'What We Eat in America' surveys classify beverages as milk and milk beverages, citrus juices, apple juices (including fruit juice blends), other noncitrus juices, soda (regular and diet), fruit drinks (regular and diet), sports and energy drinks (regular and diet), vegetable juice, water (bottled and tap), flavored and enhanced water, alcoholic beverages, coffee, tea, and meal replacement beverages. This aggregation scheme for beverages is shown in Table 1.

Energy and nutrient characteristics of selected beverages are summarized in Table 2. First, the water content of beverages is high (~90%) and their energy density is low, generally < 50 kcal per 100. Whereas 100% juices and milk contain naturally occurring sugars, sugar is added to SSBs, typically 10 g per 100 g. These amounts correspond to the optimum human pleasure response to sweet solutions. The added sugar can be sucrose (cane or beet sugar) or corn-derived high-fructose corn syrup.

Nutrient density of individual beverages needs to be calculated using a nutrient profiling model. Nutrient profiling is a technique used to rank or rate beverages and foods according to their nutrient composition per reference amount: generally 100 kcal, 100 g or per serving. Profiling models can be based on human nutrient requirements (protein, vitamins, and minerals), on nutrients of public health concern (e.g., added sugars), or a combination of both. Shown in Table 2 are ratings for individual beverages based on the published and validated nutrient-rich food (NRF) index.

The NRF scoring system was designed to be consistent with the Food and Drug Administration (FDA)-regulated Nutrition Facts panel, the principal source of nutrition information for US consumers. Accordingly, reference daily values for each nutrient, based on a 2000 kcal diet, were obtained from FDA sources. The key beneficial components of the positive NRF subscore are protein (50 g), fiber (25 g), vitamin A (5000 IU), vitamin C (60 mg), vitamin E (30 IU), calcium (1000 mg), iron (18 mg), potassium (3500 mg), and magnesium (400 mg). Unlike reference daily values from the Institute of Medicine (IOM), FDA values are not adjusted by age and sex.

Development of the NRF family of indexes closely tracked US federal regulatory standards. The US FDA allows certain foods to carry nutrition and health claims, based on their content of protein, fiber, calcium, iron, and vitamins A and C. Past dietary guidelines identified potassium, magnesium, and vitamin E as shortfall nutrients in the United States diet. In contrast, foods cannot carry health claims if they contain excessive amounts of disqualifying nutrients, typically saturated fat, added sugar, or sodium. The recent definition of 'free sugars' proposed by the Food and Agriculture Organization of the United Nations includes sugars added to beverages during the manufacturing process as well as sugars naturally present in honey and 100% fruit juice. The negative component of NRF was based on saturated fat, added sugar, and sodium. Maximum

Table 1 Types of beverage listed by 'What We Eat in America' participants

Beverage type	*Three most common varieties reported*
Milk and milk beverages	Whole milk, 2% milk, 1% milk
Citrus juices	Orange juice (canned/bottled), orange juice (w/calcium), orange juice (NFS[a])
Apple juices	Apple juice, fruit juice blend, fruit juice (NFS[a])
Other noncitrus juices	Grape juice, pineapple juice, prune juice
Soda (regular and diet)	Regular cola, regular fruit-flavored soft drink (without caffeine), sugar-free cola
Fruit drinks (regular and diet)	Fruit juice drink, fruit-flavored drink (made from powder), fruit juice drink (w/ vitamin C)
Sports and energy drinks (regular and diet)	Gatorade, Powerade, Red Bull (regular)
Vegetable juices	Tomato and vegetable juice (mostly tomato), tomato juice, carrot juice
Water (bottled and tap)	Tap water, bottled water
Flavored and enhanced water	Carbonated water (unsweetened), vitamin water, sweetened carbonated water (e.g., tonic)
Alcoholic beverages	Beer, light beer, red wine
Coffee	Regular coffee (from ground), regular coffee (from instant), decaffeinated coffee (from ground)
Tea	Unsweetened tea, presweetened tea, tea NFS[a] presweetened with sugar
Meal replacement beverages	High-protein meal replacement, ready-to-drink meal supplement/replacement

[a]NFS, not further specified.

Table 2 Energy and nutrient characteristics of selected beverages

Beverage type	*Energy (kcal per 100 g)*	*Water (g per 100 g)*	*Total sugars (g per 100 g)*	*Added sugar (g per 100 g)*	*Nutrient density (NRF9.3/racc)*
Milk, fluid, whole	60	88.3	5.3		38.2
Milk, fluid, 2% fat	50	89.3	5.1		52.7
Milk, fluid, 1% fat	42	89.9	5.2		60.4
Milk, fluid, skim or nonfat, <0.5%	34	90.8	5.1		69.4
Grapefruit juice, carton, bottled	38	90.1	8.9		125.3
Orange juice, cartoon, bottled	42	89.0	8.4		135.8
Fruit juice blend, 100% juice	53	86.3	12.5		123.1
Apple juice	47	87.9	10.9		21.7
Tomato juice	17	93.9	3.6		92.7
Soft drink, cola-type	42	89.1	10.8	10.8	−51.4
Soft drink, fruit-flavored	40	89.5	10.2	10.2	−49.6
Ginger ale	34	91.2	8.7	8.7	−39.3
Fruit drink	48	88.0	11.3	10.1	−42.4
Lemonade	40	89.4	10.0	9.7	−26.6
Orange drink	46	87.4	12.2	11.4	−38.5
Citrus drink with vitamin C added	51	86.7	13.0	11.1	50.6
Orange breakfast drink	44	88.9	10.7	10.7	2.4
Fruit-flavored drink, from powder	35	90.8	8.8	8.8	7.3
Lemonade-flavored drink, from mix	36	90.4	9.4	9.4	−21.0
Fruit-flavored drink, from mix	37	90.2	9.5	9.5	7.1

Nutrient density based on NRF9.3 score per serving.

recommended values per reference amount are 20 g for saturated fat, 125 g for total sugar, 50 g for added sugar, and 2400 mg for sodium.

To calculate NRF values, nutrient composition data for individual foods and beverages were obtained from the USDA FNDDS (composition), linked to the 'What We Eat in America' surveys (consumption). The FNDDS database was supplemented with data on added sugars from other USDA sources and, at the time, did not include data on vitamin D in milk and dairy foods. For each nutrient, content per 100 g of food was converted to percentage daily values (%DV) per reference amount and capped at 100% DV. The positive and negative subscores are calculated as the sum of %DVs for nine beneficial nutrients and three nutrients, respectively. To arrive at the total NRF score for a given beverage, the negative subscore is subtracted from the positive subscore. Scores shown in Table 2 were calculated per beverage serving (~240 ml).

It can be seen that citrus juices (orange and grapefruit), other 100% juices, and tomato juice have the highest NRF scores, largely due to the absence of added sugars and high vitamin C contents. Scores awarded to milk beverages benefited from the presence of protein and calcium; NRF scores increased progressively as the amount of saturated fat declined going from whole to skimmed milk. Beverages with added sugars scored less well, unless they were fortified with high amounts of vitamin C. The NRF scores for sodas and fruit

drinks were less favorable (negative), due to the presence of added sugars and absence of key nutrients. Water (tap or bottled), diet beverages, and unsweetened coffee and tea contain few calories and are not scored for nutrient content.

Beverage Sources

NHANES provides data on diets and health for a nationally representative sample of children and adults. The present analyses of beverage patterns of consumption used NHANES data from three cycles (2005–10), representing both children and adults who completed a 24 h dietary recall. NHANES 1999–2002 collected data using the USDA Automated Multiple-Pass Method administered by trained interviewers. Respondents reported the types and amounts of foods and beverages consumed in the preceding 24 h, from midnight to midnight. The consumption of drinking water was only assessed from 2005 onwards.

Figure 1 shows the contribution of drinking water, caloric and noncaloric beverages, and moisture from foods in total daily water intake. The data are shown in terms of ml water per day (top panel) and as percentages (bottom panel). It can be seen that water and beverages contribute over 70% of dietary water, depending on age, with the remainder provided by moisture in solid foods. Water, tap and bottled, contributed about one-third of total daily water intake and its consumption increased with age. In contrast, the contribution of milk and milk beverages decreased sharply with age; most children consume milk, while many adults do not. The contribution of

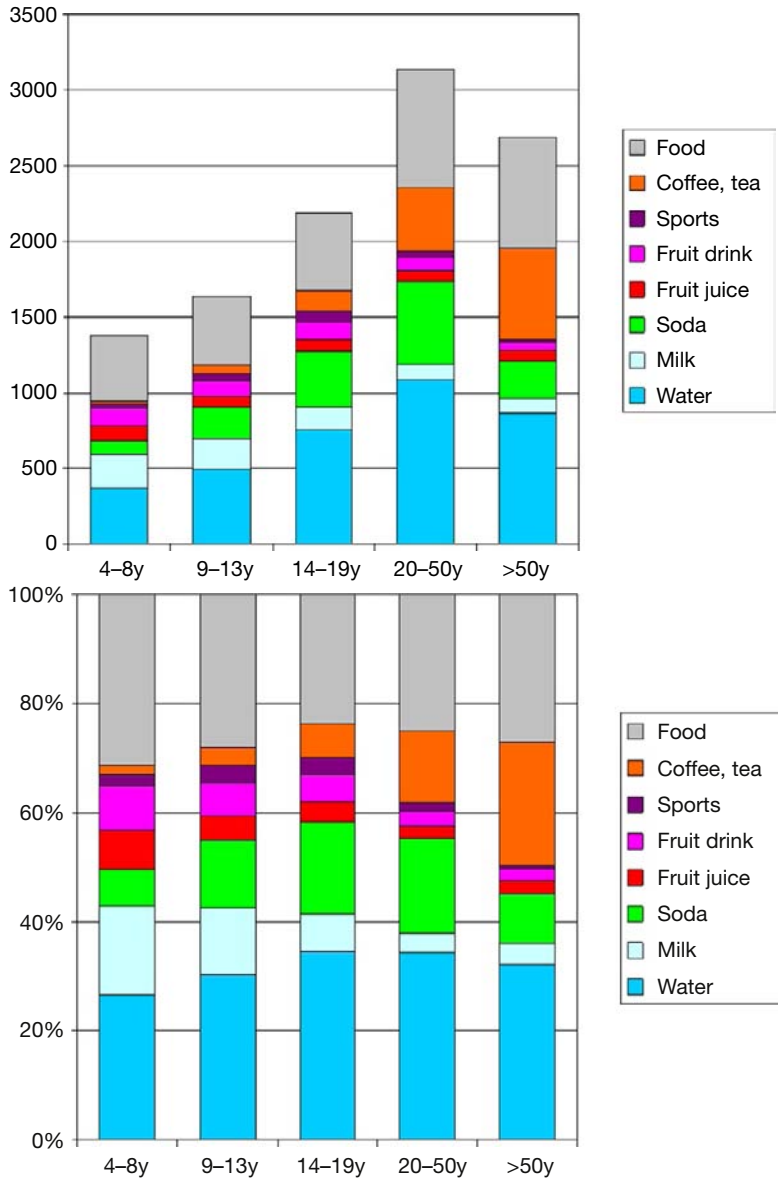

Figure 1 Contribution of water, beverages, and foods to total water intakes by age group. The data are expressed as ml (top panel) and as percentages (bottom panel).

soda to hydration peaked in adolescence and declined in adult life. The amounts of coffee and tea consumed increased with age and were highest among adults aged over 50 years.

Further analyses confirmed that milk was consumed most frequently by younger children (>80%). Soda was consumed by 40–60% of the population, depending on age, with most consumers (60%) in the 20–34-year-old group. The peak consumption of sports and energy drinks was among 14–19-year-olds (11%). Coffee consumption rose dramatically with age: only 1.8% of 4–8-year-olds consumed coffee compared with 68% of adults over 50 years. The age gradient was less dramatic for tea, consumed by 11% of 4–8-year-olds and 33% of over 50s.

Beverages and Hydration

Water requirements to meet hydration needs can be met by plain water, water from caloric and noncaloric beverages, and moisture from foods. As indicated earlier, water and beverages supply much more of the total daily water than food moisture. The contribution of water (tap and bottled) to total water intake has been estimated at 30–37%.

Dietary reference intake (DRI) values for water, established by the IOM in the United States and the European Food Safety Authority in Europe, are based in part on (observed) population intakes of drinking water (tap and bottled), water from other caloric and noncaloric beverages, and moisture from foods. US IOM adequate intakes (AI) for water are shown in Table 3. For children, the recommendations are 1700 ml day^{-1} for boys and girls in the 4–8-year-old group and 2100 ml day^{-1} for girls and 2400 ml day^{-1} for boys in the 9–13-year-old group (IOM 2004).

Table 3 Adequate intake (AI) values from dietary reference values and mean total water intakes (from all sources) by life stage group, NHANES 2005–10

Age	*AI (l day^{-1})*	*Mean (l day^{-1}) (SE)*	*% of sample below AI*
Infants			
0–6 months[a]	0.70	0.91 (0.01)	19.3 (2.7)
7–12 months[a]	0.80	1.16 (0.02)	7.4 (1.9)
Children			
1–3 years[a]	1.30	1.31 (0.01)	55.2 (1.7)
4–8 years	1.70	1.45 (0.02)	74.6 (1.6)
Males			
9–13 years	2.40	1.77 (0.04)	85.2 (1.8)

31–50 years	2.70	2.79 (0.04)	53.1 (1.7)
50–70 years	2.70	2.69 (0.04)	57.5 (1.6)
>70 years	2.70	2.12 (0.03)	80.4 (1.1)

[a]This analysis excludes infants who breast fed. Includes infants consuming infant formula.

Table 3 also shows mean total consumption of water from all sources in relation to IOM guidelines. No group of US children came close to satisfying the DRIs for water. At least 75% of children aged 4–8 years, 87% of girls aged 9–13 years, and 85% of boys aged 9–13 years did not meet DRIs for total water intake. Water volume per 1000 kcal, another criterion of adequate hydration, was 0.85–0.95 l per 1000 kcal, which is again short of desirable levels (1.0–1.5 l per 1000 kcal).

On average, younger adults exceeded or came close to satisfying the DRIs for water. Older men and women failed to meet the IOM AI values, with a daily shortfall of 1218 and 603 ml, respectively. Eighty-three percent of women and 95% of men over 71 years of age failed to meet the IOM AI DRIs for water. However, average water volume per 1000 kcal was 1.2–1.4 l per 1000 kcal for most population subgroups, which is higher than suggested levels of 1.0 l per 1.000 kcal.

Hydration needs are a matter of public health concern. Drinking water is an effective way to assure adequate hydration and may help reduce caloric intake and so improve the dietary nutrient to calorie ratio. However, beverages still contribute fewer calories to the total diet than solid foods.

Beverages and Energy Intakes

Figure 2 shows the contribution of caloric beverages and solid foods, respectively, to total daily energy intakes by age group. These data are from the analyses of the 2005–10 NHANES cycles and are shown as kcal per day (left panel) and as percentages (right panel). It can be seen that total calories, including beverage calories, first increased and then declined with age. Generally, children derive a far greater proportion of their daily calories from liquids than adults.

The principal beverage consumed by young children is milk followed by 100% fruit juice. Soda consumption is low in early childhood, highest in the 14–19-year-old group, and less thereafter. By 50 years of age, only about 10% of total daily energy is provided by beverages.

Added sugars represent a significant proportion of the US diet, supplying 11–17% of total daily energy, depending on age. Soda and sports drinks are the largest food source of added sugars (34.4%) followed by grain desserts (12.7%), fruit drinks (8.0%), candy (6.7%), and dairy desserts (5.6%). Altogether, sweetened beverages contribute about 40% of added sugars to the diet, depending on age.

Sweetened beverages are the largest source of added sugars for every age group. The top sources of added sugars for children 6–11 years are soda and energy and sports drinks (6.6 teaspoons, tsp) (1 tsp ≈ 5 ml) followed by grain desserts (2.5 tsp), fruit drinks (1.5 tsp), candy (1.3 tsp), and dairy desserts (1.1 tsp). Among adolescents, aged 12–19 years, the top sources are soda (10 tsp), fruit drinks (2.5 tsp), grain-based desserts (2.3 tsp), and candy (1.7 tsp). For younger adults, the sources are soda (8.6 tsp), grain-based desserts (2.4 tsp), fruit drinks (1.6 tsp), and candy (1.3 tsp). For older adults, the main sources are soda (3.1 tsp), grain-based desserts (2.5 tsp), dairy desserts (1.2 tsp), and candy (1.0 tsp).

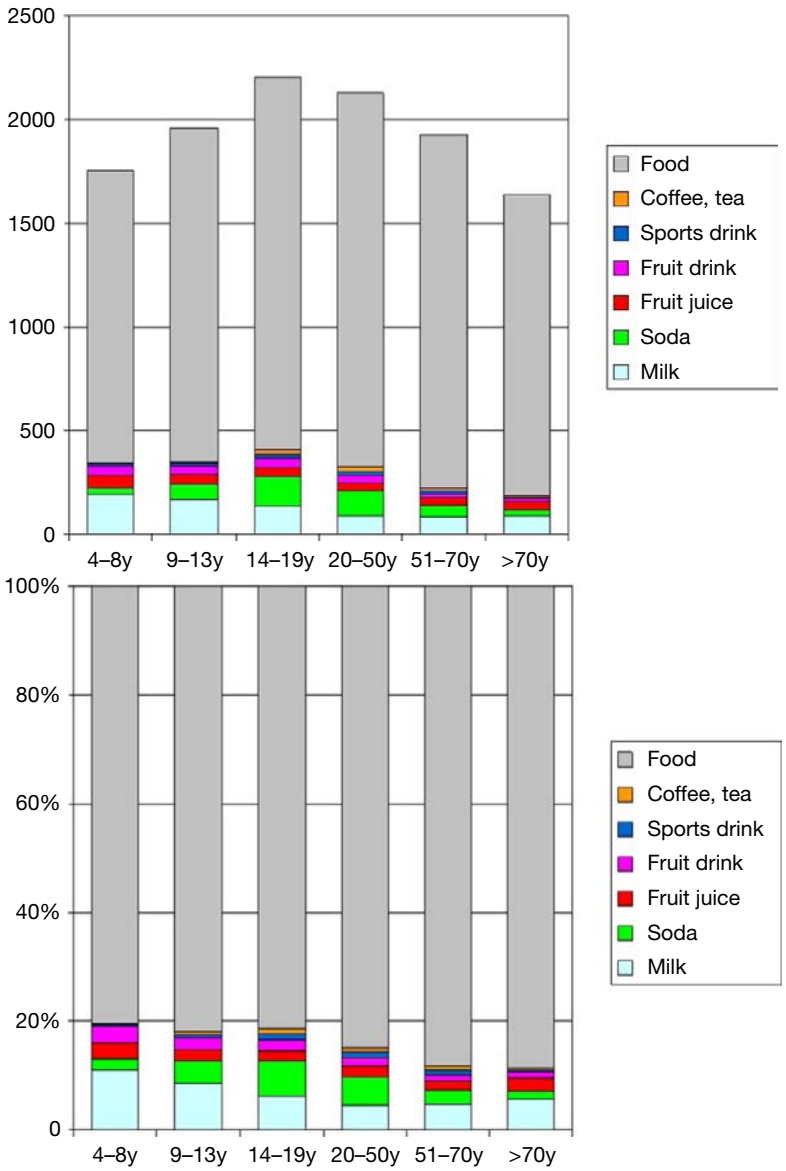

Figure 2 Contribution of water, beverages, and foods to total energy intakes by age group. The data are expressed as kcal per day (top panel) and as percentages (bottom panel).

Whereas soda and energy and sports drinks are clearly the largest single sources of added sugars for every age group, they are not the top sources of calories in the US diet. On average, added sugars from all sources account for ~14% of total dietary energy. Previous estimations by the National Cancer Institute have placed the energy contribution of soda and energy and sports drinks at about 5.5% of daily calories. The present estimate is about 7%, depending on age. As with total calories, most of the added sugars in the US diet are sourced from grocery stores, as opposed to restaurants or schools.

Beverage Consumption Patterns by SES

Few studies have examined beverage consumption patterns by beverage type and SES. In general, lower-calorie beverages are associated with higher incomes. Based on NHANES data, the consumption of diet beverages, sweetened with low-calorie sweeteners, was associated with higher education and higher incomes. Users of diet beverages were also more likely to have better diets, smoke less, and exercise more. Similarly, the consumption of low-calorie skimmed milk was associated with higher SES. Interestingly, the consumption of drinking water (bottled and tap) in the United States was also associated with higher SES. The water effect was significant for adults and marginal for children.

In contrast, the consumption of whole milk and regular SSB has been associated with lower education and lower incomes. The reasons for the observed socioeconomic gradient in beverage consumption are not always clear. Cost provides one explanation. Recent analyses of NHANES data showed a strong SES gradient for the consumption of whole fruit, which was

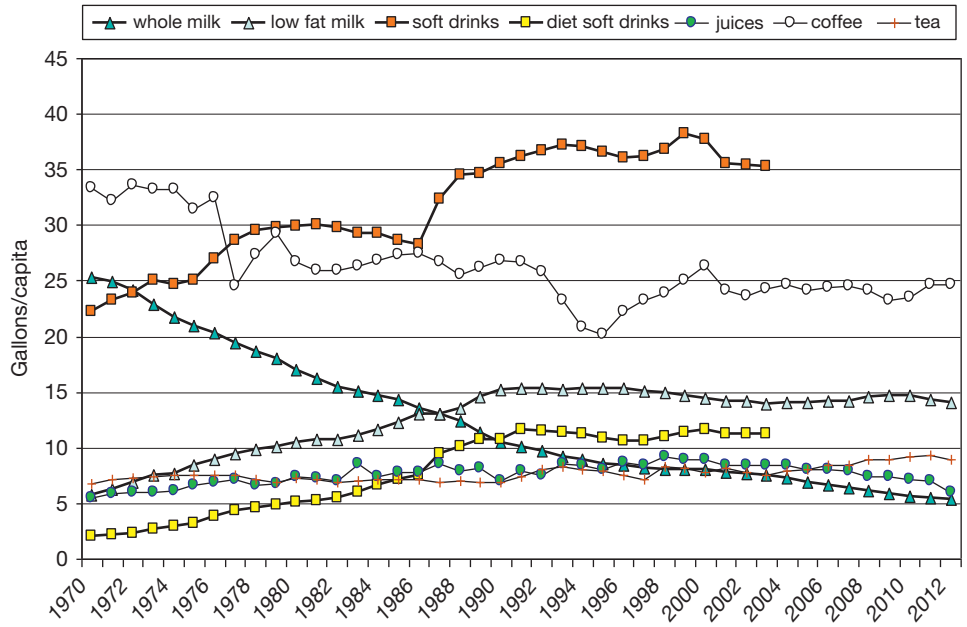

Figure 3 Beverages available for consumption in gallon equivalents per capita per year, USDA trends 1970–2012. Economic Research Service USDA.

attenuated for the lower-cost 100% fruit juice. Whereas whole fruit was more likely to be consumed by higher-income adults with graduate education, 100% fruit juices were more likely to be selected by lower-income teenagers and minority groups. Calls to replace 100% juice with whole fruit in the US diet may result in higher diet costs. On the other hand, there is little cost differential at retail between regular and diet beverages. Why the consumption of tap water should be higher among higher-income group is not entirely clear.

Beverage Consumption Trends

Food balance sheets, prepared by the USDA, represent the annual per capita amounts of food available for human consumption. The figures, expressed in fluid gallon equivalents per capita (for beverages), represent production and imports adjusted for export and stocks.

Figure 3 shows USDA trends data for the period 1970–2012. First, the consumption of whole milk dropped precipitously to be replaced to some extent by low-fat milk. The consumption of soft drinks increased in 1970–2004; subsequent data are not available. The consumption of diet soft drinks has likewise increased in 2004. The consumption of coffee has declined since the 1970s, whereas tea consumption has increase slightly. Bottled waters are missing from the USDA beverage disappearance data. Although no reliable data seem to exist, the consensus is that plain water consumption has increased.

Conclusions
