Drinking water and other beverages, caloric and noncaloric, contribute over 70% of total daily water intakes. Even so, most age and gender groups in the United States are not meeting the hydration guidelines issued by the IOM. Drinking water is one way of meeting hydration needs, reducing calories, and so improving nutrient density of the diet. The contribution of beverages to total daily calories needs to be kept in perspective. Caloric beverages contribute 10–20% of daily energy intakes, on the average, depending on age. The bulk of dietary energy for most people is supplied by solid foods. Beverages contribute more to hydration than they do to energy intakes.

Bifidobacteria in Foods: Health Effects

Y Sanz, Institute of Agrochemistry and Food Technology, National Research Council (IATA-CSIC), Valencia, Spain

Ecology of *Bifidobacterium* spp. in the Human Gut: A First Indicator of Their Biological Functions

Bifidobacteria are indigenous inhabitants of the human intestinal tract, which is one of the most complex microbial ecosystems (microbiota) on the planet, comprising over 100 trillion bacteria in the large intestine. The structure and dynamics of this ecosystem depends on environmental factors as well as on symbiotic interactions with the host that determine their coexistence. After birth, the newborn faces a transition from a sterile-intrauterine life to a foreign environment. The microbial colonization of the newborn's intestine occurs rapidly and constitutes a major exposure to foreign antigens after birth. The newborn's gut is colonized by facultative anaerobes (e.g., *Enterobacteriaceae*, *Enterococcus*, and *Streptococcus*) over the first 24 h and, immediately after, by strict anaerobes (e.g., *Bifidobacterium*, *Bacteroides*, and *Clostridium*), which dominate the ecosystem within a week. The infant gut microbiota shows low diversity and instability within the first 2 years of life and is also highly sensitive to environmental influences, which may partly determine its structure and influence over human health. The ecology of bifidobacteria in the human gut is strongly influenced by the type of milk-feeding at early life stages, when the microbiota constitutes a main factor driving the proper development of the gut anatomy and physiology and the immune system. Epidemiological studies comparing the gut microbiota of breast-fed and formula-fed infants reveal that human milk promotes the dominance of *Bifidobacterium* spp. (representing up to 90% of the total fecal bacteria) in the infant's gut. In contrast, formula-fed infants have a lower abundance of *Bifidobacterium* spp. and an increased abundance of *Clostridium* spp., *Bacteroides* spp., and members of the family *Enterobacteriaceae*. Furthermore, studies show differences in *Bifidobacterium* species composition related to milk-feeding type. Afterward, the progressive introduction of complementary feeding contributes to the establishment of an adultlike microbiota of higher complexity. In adults, *Bifidobacterium* spp. numbers are reduced, representing between 3% and 7% of the microbiota, and tend to decline even more in the elderly.

Bifidobacteria in Human Milk

The effect of breast-feeding on the infant's gut microbiota is mainly attributed to the presence of nondigestible oligosaccharides, which are the third most abundant solid component of human milk, after lactose and lipids, reaching concentrations ranging from 5 to 23 $g\,l^{-1}$ depending on the lactation stage. These are highly diverse glycans that are minimally hydrolyzed by human enzymes and constitute the main energy source for the infant's gut microbiota in the large intestine, exerting a 'bifidogenic' or prebiotic effect. In fact, some species/subspecies of the genus *Bifidobacterium* (*B. longum* subsp. *infantis* and *B. bifidum*) are known to possess genetic and protein machinery (oligosaccharide binding proteins, fucosidases, lacto-N biosidase, etc.) specialized in the utilization of different human milk oligosaccharides. This enables their preferential growth on these substrates and confers a competitive advantage whereby they can outnumber other intestinal bacteria. In addition, other human milk constituents could influence the effect of breast-feeding on bifidobacteria colonization such as relatively lower protein and phosphorus concentrations and lactose content. In recent years, breast milk has also been considered as a potential source of bacteria colonizing the infant's gut. Although the dominant bacterial genera (*Streptococcus* spp. and *Staphylococcus* spp.) in breast milk are not those dominant in the infant's gut, specific strains of *Bifidobacterium* spp. have been identified in the gut microbiota of mother–infant pairs, suggesting their transmission from the mother's breast milk to the infant.

Many epidemiological studies have established associations between breast-feeding and diverse benefits for infant's health, including reduced incidence of infections and to some extent of allergies and obesity, as well as improved bowel function (soften stools and increased stool frequency). This has led to the hypothesis that these beneficial effects may partially result from the role of human milk in promoting the dominance of bifidobacteria. Although direct evidence of the microbiota-mediated effects of breast-feeding is lacking, there are plausible modes of action supporting this hypothesis. The high content of nondigestible oligosaccharides present in human milk promotes colonic fermentation mainly by bifidobacteria, which leads to the generation of organic and short-chain fatty acids and lower stool pH when compared with formula feeding. This presumably contributes to creating a more adverse environment for the growth of pathogenic bacteria, which may also reduce the risk of infections. The reduction in pH and increased short-chain fatty acid concentration might also modulate peristalsis, favoring normal bowel function. Furthermore, increased fermentation is also parallel to increased bacterial mass and osmotic water-binding capacity, contributing to increased stool weight and stool frequency and softer stools in breast-fed babies compared with formula-fed babies. The role of breast milk in immune defenses and allergies could be due to its content in immunologically active compounds (lactoferrin, lysozyme, antimicrobial proteins and peptides, secretory IgA, chemoattractants, cytokines, etc.), which help compensate for the developmental delay of the neonate immune system and gradually stimulate innate immunity and immunologic memory toward of pathogens, while excessive inflammation is avoided, thus preventing immune-mediated disorders. In addition, the primary colonization of the newborn intestine by the microbiota is known to constitute a critical stimulus that accelerates immune system maturation, which could be influenced by the dominance of bifidobacteria

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00065-9

in breast-fed babies. The 'hygiene hypothesis' proposed by Strachan in 1989, and the more recent 'microbiota hypothesis,' suggests that early exposure to pathogens and other microbial antigens helps protect against immune-mediated diseases (Figure 1). This theory is supported by epidemiological studies reporting associations between living in a more 'hygienic' environment and decreased frequency of infections and increased incidence of allergic (e.g., asthma, rhinitis, and atopic dermatitis) and autoimmune disorders. Although this hypothesis does not fully account for the risk of these diseases, it is backed by a plausible mechanistic explanation. In the uterine life, there is a dominance of lymphocyte T-helper 2 (Th2) effector responses to prevent fetal rejection, but persistence of this immune polarization favors the development of a long-lasting atopic phenotype and increases the risk of infections. Nevertheless, appropriate exposure to microbial antigens via infant gut colonization contributes to satisfying the new demands of the neonatal immune system, inducing a change in lymphocyte balance, favoring Th1 and/or Th17 cell responses and T regulatory mechanisms. Accordingly, germ-free mice are deficient in the development of gut-associated lymphoid tissue and antibody production (e.g., IgA) and have fewer and smaller Peyer's patches and mesenteric lymphoid nodes (MLN), isolated lymphoid follicles, CD4+ Th17 cells, and CD4+CCD25+Foxp3+ regulatory cells. Germ-free mice also exhibit epithelial cell immunologic dysfunctions, including reductions in cytokine production, in expression of molecules responsible for interactions with lymphocytes (e.g., MHC) and in antimicrobial peptides (e.g., defensins and REG3γ), in the number of CD8+ T cells with cytotoxic capacity, and in expression (or localization) of innate immune receptors such as Toll-like receptors (TLR). By contrast, these effects can be totally or partially reversed by intentional colonization of the germ-free intestine with commensal microbiota or specific bacteria or bacterial products (e.g., TLR agonists). TLRs are expressed by epithelial cells and antigen-presenting cells (dendritic cells (DCs) and macrophages) and are responsible for the initial recognition of specific microbial components (e.g., RNA, DNA

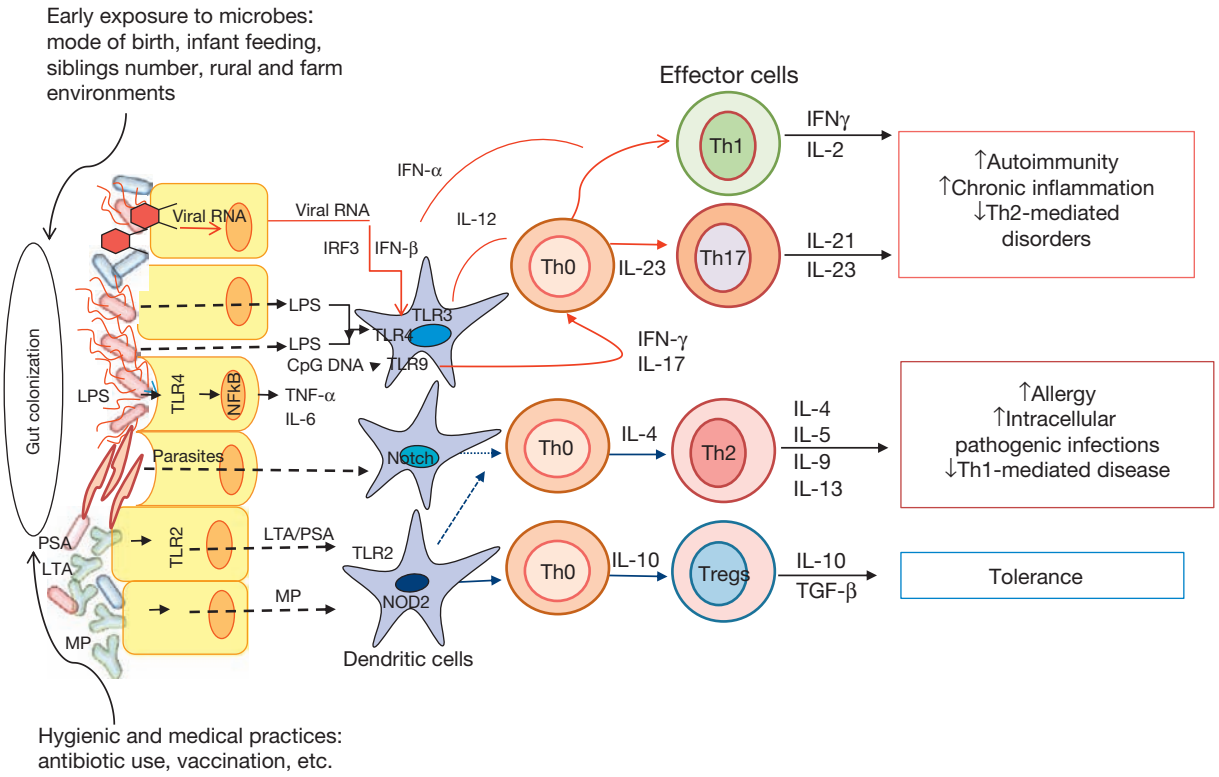

Figure 1 'Hygienic and microbiota hypothesis' according to which early exposure to microbes, partly via gut colonization of the newborn intestine, influences innate immunity and T-cell polarization and determines the risk of developing specific diseases or tolerance. TLR3- and TLR4-activated epithelial and DCs by viral RNA and LPS from Gram-negative bacteria, respectively, may promote the differentiation of T *naive* cells (Th0) into Th1 cells, which increases the risk of chronic inflammatory and autoimmune disorders and reduces the risk of infections by intracellular pathogens and inhibits Th2 responses. TLR9-activated epithelial and DCs by CpG DNA from bacteria enhance Th1- and Th17-type cytokine production (IFN-γ and IL-17, respectively) and increase the risk of autoimmunity and reduce the risk of allergy and infection by intestinal parasites. TLR2-activated DCs by lipoteichoic acids (LTA) from Gram-positive bacteria and some parasites and NOD2-activated DCs by muramyl dipeptide (MP) from Gram-positive bacteria may induce the differentiation of Th0 cells into Th2 cells, which increases the risk of allergy and reduces the risk of chronic inflammatory and autoimmune disorders by inhibiting Th1/Th17 immune responses and contributing to release of anti-inflammatory cytokines (IL-10). TLR-2 activated DCs by cell-wall polysaccharide (PSA) of *Bacteroides fragilis* and Gram-positive bacteria (e.g., bifidobacteria) may be involved in the generation of regulatory T cells (Tregs) by producing high levels of anti-inflammatory cytokine IL-10. Tregs contribute to establishing systemic tolerance by suppressing inflammatory properties of DC and their ability to induce effector Th1, Th2, and Th17 cells; by promoting a tolerogenic DC phenotype; by acting directly on eosinophils, mast cells, basophils, and resident cells and reducing cell migration to tissues; and by acting directly on B cells, reducing allergen-specific IgE.

motifs, LPS, and other cell-wall components), the discrimination between harmful and harmless antigens, and the development of appropriate innate and acquired immune responses. Ligand binding to TLR promotes interactions with different adaptor proteins, thereby activating three major signaling pathways: nuclear factor (NF)-κB, the mitogen-activated protein kinases (MAPKs), and interferon regulatory factors (IRFs). This also leads to the expression of inflammatory genes, encoding cytokines, cytokine receptors, immunoregulatory proteins, adhesion molecules, stress-associated proteins, and other mediators as well as the recruitment of other immune cells (T cells, DCs, etc.) that together activate an inflammatory response leading to pathogen clearance while avoiding excessive inflammation. Signaling through TLRs also stimulates the maturation of DCs, promoting antigen presentation and allowing them to migrate to draining MLN, where they present antigens to *naive* T and B cells. T-cell differentiation into Th1, Th2, Th17, or regulatory T cells depends on the TLRs involved and the cytokine interacting with *naive* T cells, inducing a characteristic array of cytokine production during differentiation. The balance of these T-cell populations and cytokines in early life is thought to influence the risk of developing certain disorders (Figure 1).

A descriptive study of infants has reported correlations between host gene expression and the gut microbiota structure in breast-fed and formula-fed infants, providing the first evidence for microbiota-mediated effects in humans. The study reports significant enrichment of microbiota virulence-related genes linked to enrichment of immunity and defense gene expression in the host transcriptome of breast-fed babies, which could indicate microbiota-mediated stimulation of host-defense mechanisms and explain reduced incidence of infections.

An observational study conducted in infants and young children also reported a reduced ratio of *Bifidobacterium* to *Clostridium* counts associated with the development of atopic dermatitis instead of atopic disease, suggesting that bifidobacteria play a beneficial role in this disorder. Comparisons of intestinal microbiota composition between children with at least two diabetes-associated autoantibodies and child autoantibody-negative also reported that the low abundance of lactate-producing and butyrate-producing species was associated with β-cell autoimmunity. The same association was established for a lack of two dominant *Bifidobacterium* spp. (*B. adolescentis* and *B. pseudocatenulatum*) and an increased abundance of the genus *Bacteroides*. A number of studies in children with celiac disease (untreated and treated with a gluten-free diet) also reported reduced abundance of *Bifidobacterium* spp. and *B. longum* compared with healthy controls. Similarly, healthy infants at high genetic risk of developing celiac disease showed lower numbers of *Bifidobacterium* spp. and *B. longum* compared with low genetic risk infants. In addition, several studies have reported potential associations between the genus *Bifidobacterium* and obesity, although with less conclusive results. In one study, reductions in *Bifidobacterium* numbers have been shown to precede the development of overweight in children. Two other studies showed positive associations of *Bifidobacterium* spp. with normal weight in adults and with normal weight or normal weight gain in pregnant woman compared with subjects with overweight and excessive weight gain during pregnancy, while two other studies indicate the opposite associations.

In the light of all these epidemiological and ecological studies, associations between alterations in the abundance of *Bifidobacterium* spp. and certain human conditions have been drawn, suggesting a role for this bacterial group in reducing the risk or progression of these disorders. This evidence does not necessarily reflect causality of the underlying disease but has constituted the basis for conducting mechanistic studies mainly in animals and intervention trials in humans to provide direct evidence of the health effects of specific species and strains (generally known as 'probiotics'), as described in the following sections.

Modes of Action of *Bifidobacterium* spp. Shown by *In Vitro* and Animal Studies

More than a hundred years ago, Henry Tissier (Pasteur Institute) isolated microbes, including bifidobacteria, from healthy breast-fed infant feces for the first time, but it is in recent decades that the effectiveness and modes of action of specific bifidobacterial strains have been shown by studies *in vitro* and in animal models (Figure 2). Furthermore, whole-genome sequencing data and functional genomics via the use of next-generation sequencing techniques have made it possible to identify the molecular basis of some of the functional traits and health effects attributed to members of this genus, thus helping to provide plausible mechanisms of action.

Bifidobacteria have been acknowledged for their nutritional functions, contributing to the metabolism of nondigestible oligosaccharides, not only from human milk but also from the diet. Over 9% of annotated genes of bifidobacterial genomes encode enzymes involved in carbohydrate metabolism. This feature could partially contribute to energy recovery and to the generation of fermentation products (e.g., acetate) partly by cross-feeding mechanisms with other intestinal bacteria (e.g., butyric acid) with potential health effects. As described previously, colonic fermentation could improve bowel function and create a harsh environment for pathogen survival. Furthermore, butyrate, which can be generated from acetate directly produced by bifidobacteria, is the main energy source for colonocytes and exerts trophic effects stimulating cell growth and differentiation and production of the glucagon-like peptide-2 (GLP-2), which together strengthen the gut barrier function. Butyrate also stimulates GLP-1 production, which induces satiety and improves insulin sensitivity, and exerts an anti-inflammatory role in the gut and peripheral tissues.

Bifidobacteria can also contribute to supplying essential nutrients such as vitamins. Bifidobacteria are known to be involved in folate biosynthesis, although its production depends on the species/subspecies considered. Whereas *B. bifidum* and *B. longum* subsp. *infantis* are considered high producers of folate, *B. breve*, *B. longum* subsp. *longum*, and *B. adolescentis* are considered low producers. The ability of bifidobacteria to produce folate in animals and humans has also been demonstrated by measuring the fecal levels of folate *in vivo*, although the extent to which it is utilized by the host remains unclear. Bifidobacteria could also contribute to

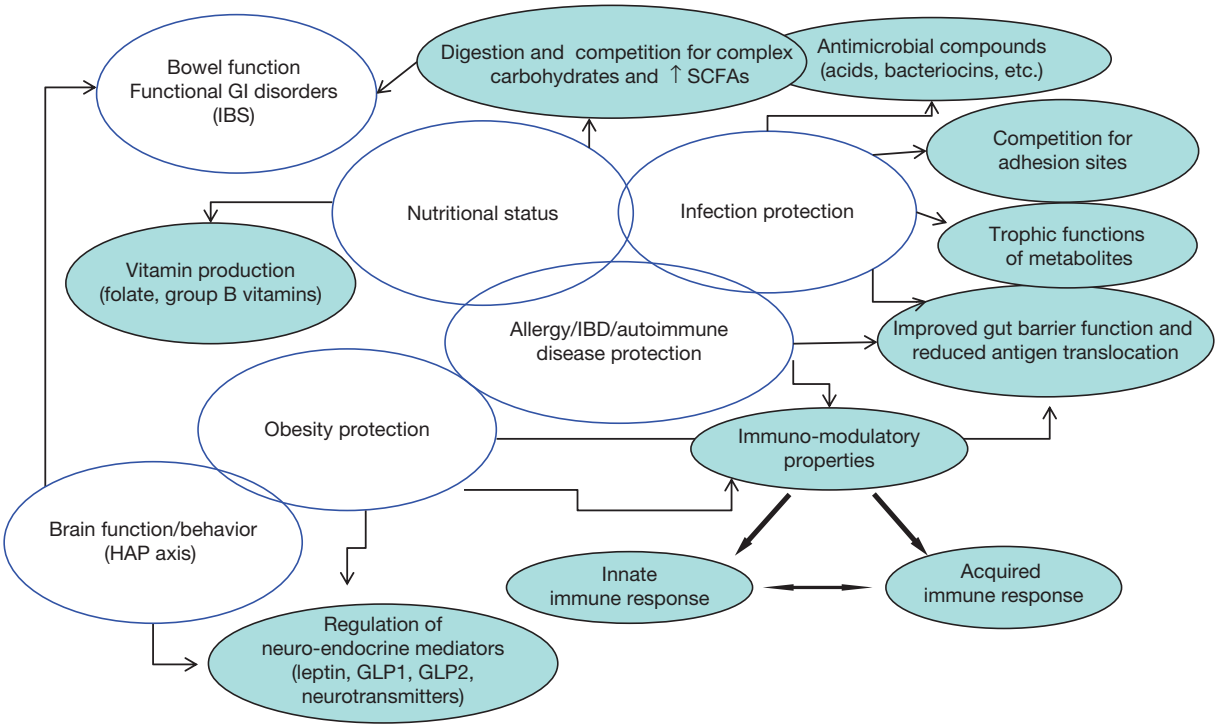

Figure 2 Nutritional and health effects of *Bifidobacterium* strains demonstrated by *in vitro* and animal studies.

synthesizing other B vitamins since transcriptomic analysis revealed that bifidobacterial genes predicted to be involved in biosynthesizing several B vitamins and folate are strongly expressed in fecal samples of adult subjects. Also, the soy fermentation process by *B. longum* R0175 has been reported to lead to thiamine and pyridoxine generation. Although most of the biosynthetic pathways of vitamins are incomplete in the bifidobacteria genomes characterized to date, it is likely that other bacteria complement these pathways since the whole human fecal metagenome is enriched in genes that specify biosynthetic enzymes for biotin, riboflavin, pantothenate, ascorbate, thiamine, and folate production.

Multiple mechanisms have been proposed to play a role in bifidobacterial protection against bacterial pathogens and virus. Such mechanisms include modification of environmental conditions and production of antimicrobial compounds (acids and antimicrobial peptides like bacteriocins), competition for nutrients and adhesion sites, and modulation of the host immune defense mechanisms. Preclinical trials in models of infection have shown that some bifidobacterial strains enhance resistance to microbial pathogens (bacteria and virus) through activating nonspecific cell phagocytosis, increasing cytokine levels, increasing natural killer-cell activity, and/or increasing levels of immunoglobulins. In addition, some bifidobacteria (e.g., *B. infantis* 35624) exert protective effects in models of infection through downregulating the NF-κB pathway, triggered by TLR4 signalling, and inducing T regulatory cells (Tregs) and anti-inflammatory cytokines (IL-10), thereby preventing excessive inflammation.

Bifidobacteria have also been evaluated *in vitro* and in animal models with a view to being used to treat and prevent chronic inflammatory and autoimmune disorders. In animal models, some *Bifidobacterium* strains have been demonstrated to be effective against the deregulated immune response characteristic of allergy, which involves Th2 cell activation with IL-4, IL-5, IL-9, and IL-13 cytokine production; high levels of allergen-specific IgE production and eosinophilia; and recruitment of inflammatory cells to inflamed tissues. Bifidobacteria are thought to help ameliorate or prevent allergy by diminishing Th2 lymphocyte polarization and/or enhancing Th1 lymphocyte polarization and inducing Treg cells and anti-inflammatory cytokines. This has been demonstrated in models of food allergy induced with ovalbumin (e.g., *B. longum* AH1206) and models of atopic dermatitis induced by dermal treatment with house dust mite extract and dinitrochlorobenzene (e.g., IRT5 probiotic product, comprising a combination of bifidobacteria and other lactic acid bacteria).

The role of bifidobacteria in chronic inflammatory bowel disease (IBDs), apparently caused by loss of tolerance to the host's own microbiota, has also been evaluated in animal models of colitis. In this mouse model, the protective action of the product VSL#3, comprising a blend of bifidobacteria and other lactic acid bacterial strains (*Lactobacillus casei*, *L. plantarum*, *L. acidophilus*, *L. delbrueckii* subsp. *bulgaricus*, *B. longum*, *B. breve*, *B. infantis*, and *Streptococcus salivarius* subsp. *thermophilus*), was related to IL-10 induction and TGF-β-expressing T cells.

Animal studies have also evaluated the potential role of bifidobacteria against autoimmune diseases, resulting from the loss of self-tolerance and abnormal reactivity against the host's own antigens. Diabetes type 1 is a T cell-mediated autoimmune disease characterized by a response in which pancreatic insulin-producing B cells are destroyed. Studies using animal models of nonobese diabetic mice have shown that the probiotic mixture VSL#3, containing bifidobacteria and

other lactic acid bacteria, prevented diabetes by diminishing the destruction of insulin-producing beta cells, presumably mediated by increased infiltration of positive IL-10 mononuclear cells in the pancreas and upregulation of IL-10 mRNA expression, as well as mononuclear cells producing IL-10 in Peyer's patches and spleen. Celiac disease, caused by a dysfunctional immune response to cereal gluten proteins of autoimmune nature, has also been considered a target for bifidobacteria. An animal model of gliadin-induced enteropathy has been used to reveal that *B. longum* ES1 administration reduces inflammatory cytokine production (TNF-α) in the small intestine, increases anti-inflammatory cytokine (IL-10) production, and reduces the CD4+ T-cell population in the peripheral blood.

The effects of bifidobacteria and some prebiotics inducing dominance of bifidobacteria in murine models of obesity have also been evaluated in recent years. These studies generally reveal that a prebiotic-induced rise in total bifidobacteria and administration of specific strains (e.g., *B. pseudocatenulatum* CECT 7765) exert beneficial effects by reducing metabolic dysfunction (e.g., increased serum lipids and glucose levels, reduced tolerance to glucose, and reduced hepatic steatosis) and chronic low-grade inflammation associated with obesity. These effects are presumably mediated by the ability of some bifidobacteria to restore alterations in the gut barrier function, reducing the translocation of inflammatory molecules from the gut to the periphery (e.g., LPS from Gram-negative bacteria), modulating the neuroendocrine system function (e.g., stimulating GLP-1 and GLP-2 production and reducing leptin production), and reducing inflammatory cytokine production and the infiltration of macrophages and effector T cells in the gut and peripheral tissues, which leads to metabolic impairment.

Gut microbiota is also thought to influence brain development and function, as well as behavior, according to recent evidence from murine models. In this context, bifidobacteria have been studied for their potential role in regulating the stress response, which involves the hypothalamic–pituitary–adrenal axis (HPA) and is regulated by both psychological and physical stressors (e.g., infections). The exaggerated response of germ-free mice to mild restraint stress, reflected in an increased release of corticosterone and ACTH, has been shown to be reversed by monocolonization with a strain of *B. infantis*. In a maternal separation model of psychological stress, a *B. infantis* strain also reduced corticosterone levels. The modes of action by which bifidobacteria may regulate the HPA axis and stress responsiveness include reduction of proinflammatory cytokine production and/or modulation of neurotransmitters (e.g., serotonin and catecholamines) and neurotrophic factors (e.g., brain-derived neurotrophic factor (BDNF)). In this regard, *B. infantis* 35624 was shown to elevate plasma tryptophan levels, a precursor of serotonin, by modulating the expression of enzymes (e.g., indoleamine-2,3-dioxygenase) involved in the tryptophan degradation pathway in Sprague–Dawley rats. A strain of *B. longum* has also been shown to reverse infection-induced behavioral changes associated with decreased hippocampal BDNF mRNA expression, without affecting cytokine or tryptophan metabolism and independently of vagus nerve activation. Furthermore, administering a blend of *L. helveticus* R0052 and *B. longum* R0175 reduced anxiety in rats. Overall, the ability of bifidobacteria to regulate the stress response demonstrated in animal studies to date may be a mechanism ameliorating stress-related gastrointestinal disorders, such as irritable bowel syndrome (IBS), as well as metabolic disease related to alterations in the HPA axis. However, such possible applications are still speculative.

Health Effects of *Bifidobacterium* spp. Evidenced by Human Intervention Studies

The Probiotic Concept and the Regulation of Health Claims

In 2001, probiotics were defined as "live microorganisms that when administered in adequate amounts confer a health benefit to the host," which implies that microorganisms must be alive and administered in effective doses. Strains of the genus *Bifidobacterium* are one of the main probiotics sold for human consumption because of their safety record in foods and evidence for potential relationships with health from epidemiological, *in vitro*, animal, and some human studies. The probiotic definition supposed an advance in the harmonization of criteria a microorganism must fulfill to be qualified as a probiotic, and this concept has been generally accepted by the scientific community. This term has also been used generically on labels and publicity to communicate a health effect for consumers. However, communicating the health effects of foods and food supplements, such as bifidobacteria, is now regulated in most countries. Regulation stipulates how the benefits of specific bacterial strains should be substantiated and transmitted to consumers. According to the health claim legislation in the European Union (Regulation EC No. 1924/2006), health claims for foods should be substantiated by providing evidence for their efficacy in high-quality human intervention studies and, particularly, in randomized placebo-controlled trials (RCTs) conducted in the target population (healthy general population or subgroups) for which the claim is made. Within this regulatory framework, two types of health claims can be made: (i) claims related the role of a food on maintenance/improvement of normal physiological functions and (ii) claims related to the role of a food in reducing a risk factor for disease. Moreover, the microorganism for which claims are made must be identified at genus, species, and strain levels. In this scenario, provided in the succeeding text is a summary of the existing evidence on beneficial health effects of specific bifidobacterial strains based on RCT in humans.

Evidence of Health Effects of *Bifidobacterium* spp. on Infants and Young Children

Bifidobacterium strains, added to infant or follow-up formulas or as food supplements, have been evaluated in RCT conducted in infants and young children. Such studies have contemplated diverse physiological and health-related effects including reductions in incidence or severity of gastrointestinal infections, antibiotic-associated diarrhea (AAD), respiratory tract infections, colic and irritability, and allergic manifestations (atopic eczema, allergen sensitization, and wheeze/asthma); contribution to normal bowel function (stool

frequency and consistency); and effects on growth related parameters, mainly as part of safety evaluations.

The role of bifidobacteria in reducing the risk of gastrointestinal infections is one of the main outcomes evaluated in infants and children. The results reported in RCTs conducted with *B. lactis* Bb12 alone (also named *B. animalis* subsp. *lactis* CNCMI-3446 and *B. bifidum* in literature) are contradictory. However, several studies evaluating infant formulas supplemented with *B. lactis* Bb12 combined with *S. thermophilus* or with both *S. thermophilus* and *Lactobacillus helveticus* point for a role of the experimental formulas in the reduction of the risk of nonspecific infections compared with control formulas, using diarrhea for diagnosis and as main outcome.

A recent meta-analysis evaluated the efficacy of probiotic in preventing AAD in a pediatric population, showing some probiotics to be effective, particularly at high doses (*L. rhamnosus* LGG or *Saccharomyces boulardii*) but not of the bifidobacteria evaluated (strains of *B. lactis*) to date.

Evidence for the role of bifidobacteria in reducing the risk of respiratory tract infections is much more limited than evidence for gastrointestinal infections. One RCT reported no significant difference in the rate of bronchopneumonia between infants fed with chemically acidified formula with added *B. lactis* Bb12 and infants fed with standard formula. A second RCT also reported no significant difference in the number of days with respiratory illness or in the number of respiratory illness episodes between the *B. lactis* Bb12-supplemented formula group and the control formula group.

The effects of infant formulas supplemented with either *B. lactis* Bb12 or *B. lactis* Bb12 and *S. thermophilus* on colic, crying, and irritability have not been conclusive either, since one study did not report effects on crying, while another reported lower frequency of colic or irritability but failed to define colic and irritability.

Bifidobacterium strains have also been evaluated for their possible role in reducing the risk of atopic disorders (atopic dermatitis, atopic sensitization) and asthma/wheeze in children, based on their immunoregulatory effects evidenced *in vitro* and in animal models. Of the high-quality RCT included in the most recent systematic reviews and meta-analysis reporting these outcomes, only one evaluated a *Bifidobacterium* strain alone, while most of trials evaluated combinations of strains (bifidobacteria plus lactobacilli) or *Lactobacillus* alone. A single study evaluated whether *B. animalis* subsp. *lactis* HN019 administered as a food supplement to mothers and infants prenatally and postnatally could prevent the development of atopic dermatitis (eczema), atopic sensitization (skin prick tests), and parent-reported symptoms of asthma and rhinoconjunctivitis in early life in a high-risk birth cohort of infants. However, infants receiving *B. animalis* subsp. *lactis* did not show reduced prevalence of any of the health disorders after 2 or 4 years of follow-up. Studies using bacterial strains other than bifidobacteria or combined with bifidobacteria (e.g., *B. lactis* B12,*B. lactis* AD011, *B. longum* BL999, *B. bifidum* BGN4, *B. bifidum* W23, *B. lactis* W52, or *B. breve* Bb99) conclude that prenatal probiotic administration to mothers and/or early-life probiotic administration to infants may reduce the risk of atopic sensitization, total IgE levels, incidence of atopic dermatitis, and IgE-associated atopic dermatitis for some probiotic combinations and intervention protocols, but not the risk of asthma/wheeze. The reported effects seemed to be dependent on the duration of the follow-up period, the study population group (general or at risk population), and the probiotic strains evaluated. Results clearly indicated that the effects of pooled data are only indicative and cannot be attributed to specific bifidobacteria but only to the combinations of bacteria tested and to the specific dose and administration pattern applied.

Some studies evaluating the effects of infant formulas supplemented with *B. lactis* Bb12 or *B. longum* BL999 combined with *L. rhamnosus* LPR on bowel function have not reported effects, in either stool frequency or consistency.

Studies evaluating the possible role of *B. lactis* Bb12 alone or combined with other lactic acid bacteria in the growth of healthy infants in early infancy (less than 4–6 months) or beyond have generally reported adequate growth comparable to control groups. Exceptionally, one study showed a significantly greater growth rate toward the end of the intervention period for infants fed probiotics than the control group, but with questionable physiological significance, considering the magnitude of the difference (equal to 0.5 SD). Similar studies on healthy infants of HIV-positive mothers only reported either faster head growth or increased *z*-scores, but parallel differences were not detected in weight for age, length for age, or head circumference between groups, reflecting inconsistency or lack of real significance in the differences detected. One RCT conducted with *B. longum* BL999 alone, as well as combined with *L. rhamnosus* LPR, reported no effects on weight gain compared with the control groups. Studies conducted with other bifidobacterial strains and combinations as food supplements have not reported adverse effects on growth, mainly evaluated as a safety indicator. Although there is very limited scientific evidence on the effects of probiotics on this outcome, it is generally considered that probiotics do not influence growth in healthy infants either positively or adversely. Major flaws in studies conducted to date are the small sample sizes, the short study duration, and the inclusion of wide age ranges with large differences in developmental processes and growth rates.

Therefore, there is modest evidence that a bifidobacterial strain (*B. animalis* Bb12) in formula acidified with lactic acid bacteria could help to reduce the risk of nonspecific acute gastrointestinal infections. Other strain combinations including bifidobacteria together with lactic acid bacteria may also reduce the risk of some atopic disorders. However, studies with strain combinations do not enable us to draw definitive conclusions for a specific role of bifidobacteria.

Evidence for Health Effects of *Bifidobacterium* spp. on Adults

The potential benefits of bifidobacteria on the adult population evaluated to date concern mainly bowel function improvement and reduction in the risk of AAD. The potential therapeutic effects of bifidobacteria on diverse conditions such as IBD, including Crohn's disease and ulcerative colitis, and IBS have also been evaluated in adults but with a view to their use in clinical practice. Despite the relatively large number of RCT conducted with probiotics in adults, most studies evaluating bifidobacteria used combinations with strains belonging to other bacterial genera and, therefore, cannot be used to draw conclusions on the effectiveness of bifidobacteria as such.

A recent systematic review and meta-analysis of RCT related to effects on bowel function of different probiotic strains supplied as foods or food supplements in adults reported that *B. lactis* DN-173 010 and *B. lactis* HN019 reduce intestinal transit in IBS subjects with constipation and in subjects with functional gastrointestinal disorders, respectively. The analysis of pooled data from studies conducted with different strains also suggests that the effect of probiotics on intestinal transit is greater on subjects with constipation compared with controls and in older compared with younger subjects. Nevertheless, these general conclusions are of limited value since effects could be strain-specific and comparisons between different population groups should be performed with the same strain or combination. In addition, the studies pooled had important limitations, including the fact that they were small and of short duration, some populations groups were underrepresented (young middle-aged adults), and some studies administered the probiotics in food matrixes with other ingredients (e.g., prebiotics) influencing intestinal transit.

Although recent meta-analysis combining studies conducted with different strains and strain combinations suggests that probiotics may reduce the risk of AAD in adults, most studies have been conducted with strains belonging to other than the *Bifidobacterium* genus or with bifidobacteria (e.g., *B. lactis* Bb12, *B. breve* Bb99, *B. longum* PL03, and others not well identified) combined with strains belonging to other genera, and therefore, conclusions cannot be drawn on the effectiveness of bifidobacteria alone. A study on the effect of yogurt containing *Bifidobacterium* DN-173-010 in preventing the side effects of *Helicobacter pylori* eradication therapy did not report reduction of diarrhea.

Well-designed RCTs supporting bifidobacteria administration in IBD management are very limited. Two RCTs performed with a bifidobacteria-fermented milk containing *B. breve* strain Yakult, *B. bifidum*, and *L. acidophilus* and pooled data from three RCTs conducted with the product VSL#3 indicated that these bacterial combinations contribute to inducing remission in patients with active UC.

Two studies have demonstrated the efficacy of *B. infantis* 35624 for ameliorating pain and providing global relief, as well as for reducing bloating and flatulence/distension in IBS patients irrespective of bowel habit subtype. In a large-scale study of IBS patients with constipation, *B. animalis* DN-173 010 was reported to improve bloating, particularly when live bacteria were administered. However, this outcome was not beneficially influenced in another trial on women with minor gastrointestinal symptoms but without any specific disorder. A single RCT also reported that a blend of *L. rhamnosus* GG, *L. rhamnosus* LC705, *B. breve* 99, and *Propionibacterium freudenreichii* ssp. *shermanii* JS reduced the total symptom score, which included abdominal pain, distension, flatulence, and borborygmi compared with a placebo, but there was no difference in the individual symptoms except for borborygmi. There are also uncertainties regarding the effects of the probiotic combination VSL#3 on IBS because results are inconsistent across studies.

Therefore, there is evidence that *B. lactis* DN-173-010 and *B. lactis* HN019 may modulate intestinal transit particularly in subjects with functional gastrointestinal disorders and *B. infantis* 35624 may ameliorate IBS symptoms. Strains combinations including bifidobacteria can reduce the risk of AAD and induce remission of UC from a clinical perspective, but the effects of bifidobacteria *per se* cannot be inferred.

In summary, there is a lack of well-designed RCT examining effects of bifidobacteria alone to draw conclusions on their health benefits and to be able to support cause–effect relationships in adults or infants and young children. There is a need to establish effective doses and conditions of use for specific strains or strain combinations and administration patterns. This should make it possible to provide consumers with reliable claims on foods and food supplements that could contribute to healthier lifestyles and reduction of disease risk.

Bioactive Peptides in Foods

L Mora, M-C Aristoy, and F Toldrá, Instituto de Agroquímica y Tecnología de Alimentos (CSIC), Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Bioactive peptides are food-derived peptides that exert a positive effect beyond that of basic nutrition following consumption in humans. Bioactive peptides are small and usually contain between 3 and 20 amino acid residues, and their bioactivities are based on their amino acid composition and location within the sequence of amino acids that make up the peptide. They are inactive in the sequences of their parent proteins but may be released by enzymatic hydrolysis by proteolytic enzymes during gastrointestinal (GI) digestion, during fermentations with generally recognized as safe bacteria such as lactobacilli, or during food processing. In order to exert a positive health effect, bioactive peptides must cross the GI barrier and survive enzyme degradation. Bioactive peptides are often multifunctional and can exert several beneficial physiological effects at different target sites once liberated in the human body. They play different roles in preventing diseases and modulating the physiological systems, being involved in the GI system such as the antiobesity and satiety peptides; the cardiovascular system such as antihypertensive, antithrombotic, antioxidant, and hypocholesterolemic peptides; the immune system such as antimicrobial, cytomodulatory, and immunomodulatory peptides; and the nervous system, such as opioid peptides.

Numerous bioactive peptides have been reported in recent years as naturally present or generated from food proteins of different origins like milk, eggs, soya, fish, and meat. In this sense, the most extensively studied bioactivity during the last decade has been the antihypertensive activity through the measurement of angiotensin I-converting enzyme (ACE) inhibitory activity. The reason for this interest is mainly because high blood pressure is one of the major, independent risk factors for cardiovascular diseases and the main reason of death in developed countries. Peptides with this type of activity are generally termed as bioactive peptides even though other activities such as antioxidant, antimicrobial, opioid, antithrombotic, and antidiabetic also fit into the general bioactive peptide term.

Bioactive Peptides from Food Proteins

Bioactive peptides may already be present in the food as part of its composition like carnosine and anserine, but they can also be generated by spontaneous endogenous hydrolysis of food proteins caused by endogenous enzymes, by controlled hydrolysis with commercial proteolytic enzymes, or by release from parent proteins in foods once ingested and during its GI digestion. All these pathways of generation are briefly summarized.

Bioactive Peptides Naturally Generated from Food Proteins

Proteins in foods contain sequences that can exert a physiological effect when consumed. These sequences are inactive when present in the parent proteins but can exert its bioactive effect if the respective peptide is released. The generation of peptides in food systems can occur:

(i) During aging or storage by the action of endogenous muscle peptidases such as cathepsins, peptidyl peptidases, aminopeptidases, and carboxypeptidases. As an example, meat and fish proteins are frequently hydrolyzed during aging and/or refrigerated storage.

(ii) During food processing such as fermentation or curing processes. In this sense, fermented meat and fish proteins have been described to be hydrolyzed by both endogenous muscle and microbial peptidases, which contribute to the bioactive peptide release during fermentation and ripening processes. A similar situation is reported in dairy products like cheese and yogurt where bioactive peptides are generated by proteolytic activities of starter microorganisms. Some lactic acid bacteria have been reported to be very active from this point of view.

(iii) The generation during long periods of ripening. In this case, endogenous muscle peptidases may act for several months releasing a large number of bioactive peptides in the final product (e.g., dry-cured ham). In ripening processes, the chance to obtain a wide variety of small peptides such as di- and tripeptides is very high due to the prolonged and unspecific action of the muscular enzymes, resulting in a very rich source of bioactive peptides.

Bioactive Peptides Generated Through Hydrolysis of Food Proteins with Commercial Proteolytic Enzymes

The use of commercial proteolytic enzymes for the production of bioactive peptides is another interesting area extensively developed in recent years. Peptidases from animal, plant, and microbial sources, or combinations of these, have been utilized for various processes in the food industry including the digestion of food proteins for the generation of bioactive peptides. Proteolytic enzymes, like papain, thermolysin, Alcalase®, Neutrase®, Flavourzyme®, and Actinase E®, have been used for the production of enzymatic hydrolysates of meat or fish proteins.

The main objective of these studies is focused on getting the maximum use of industry by-products, giving them an added value, and reducing the environmental impact. Thus, in most cases, proteins from food by-products constitute the substrate for obtaining enriched bioactive peptides fractions. Examples of this have been described in studies regarding the use of trimming, bones (or backbones), blood, and skin obtained from meat and fish industries.

A typical industrial production of bioactive peptides from food by-products by using proteolytic enzymes under controlled conditions is described in Figure 1.

Bioactive Peptides Generated Through GI Digestion of Ingested Food Proteins

The ingestion of food proteins can result in the liberation of bioactive peptides that were encrypted in the protein structure.

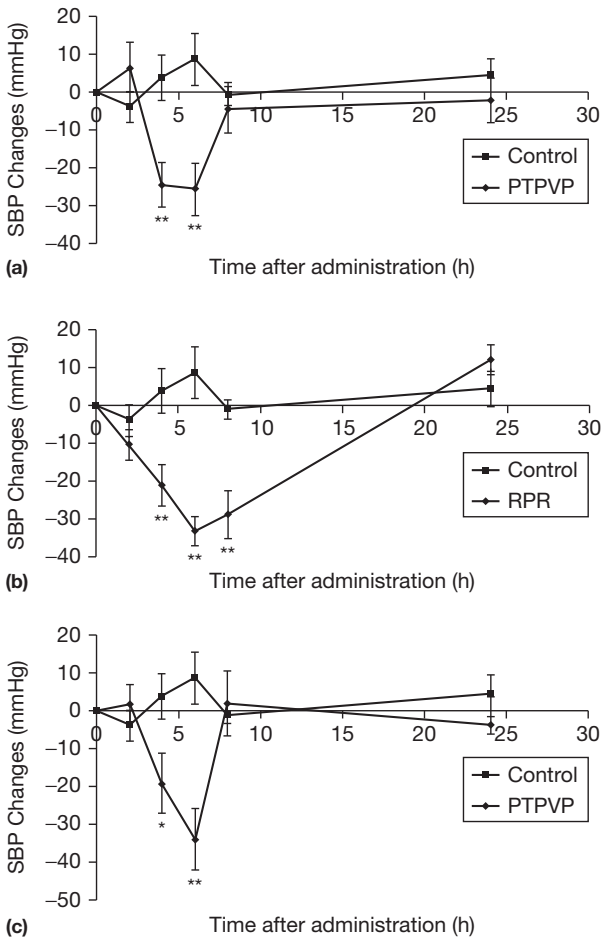

Figure 2 Antihypertensive effect of single oral administration of ACE inhibitory peptides PTPVP, RPR, and KAPVA. Each point indicates the mean of systolic blood pressure of eight SHRs, and the vertical bars represent the standard error. Treatment in each case was control (distilled water) and (a) peptide PTPVP, (b) peptide RPR, and (c) peptide KAPVA, dose 1 mg peptide/kg BW. Significant difference from control at each time: $*P < 0.05$ and $**P < 0.01$. Reproduced with permission from Escudero, E., Toldrá, F., Sentandreu, M. A., Nishimura, H. and Arihara, K. (2012). Antihypertensive activity of peptides identified in the *in vitro* gastrointestinal digest of pork meat. *Meat Science* **91**, 382–384.

Thus, bioactive peptides can be generated when food is consumed during GI digestion by enzymes involved in this digestion such as pepsin, trypsin, and chymotrypsin. The routes of generation have been confirmed by performing *in vitro* studies, using proteins like myosin, actin, tropomyosin, and troponin, as well as by simulated digestion by using trypsin and/or chymotrypsin reproducing the real digestion. These studies are usually followed with *in vivo* studies to verify the bioactivity of the generated peptides. In fact, some of the peptides generated from nebulin (RPR sequence) and titin (PTPVP and KAPVA sequences) proteins after simulated human GI digestion of pork meat were synthesized and tested for their antihypertensive activity in spontaneously hypertensive rats (SHRs) showing an important decrease of the systolic blood pressure in comparison to the control, as shown in Figure 2.

Functional Activity of Bioactive Peptides

As have been previously described, bioactive peptides present in foods can exert a physiological effect when they are consumed. Once peptides have been orally ingested, they are susceptible to be attacked by enzymes involved in the GI digestion. Some small peptides can also be digested by brush border membrane peptidases and intracellular peptidases or even peptidases from the microbial flora present in the intestine. The released peptides must be able to cross the intestinal membrane and be transported intact into the bloodstream where they will reach their target sites and then exert their respective bioactivity. In fact, it is crucial that no degradation of the peptides takes place during their transport in the intestine in order to be allowed to cross the gut barrier with no modifications on their amino acid sequence.

Different types of activity have been reported in the literature, and the most relevant are summarized in the succeeding text.

ACE Inhibitory Activity Peptides

The most extensively studied bioactive peptides generated from food proteins are ACE inhibitory peptides that have the ability

to prevent hypertension and have been used for pharmaceutical and physiological purposes. These peptides reduce blood pressure through inhibition of ACE in the body and usually exert its antihypertensive effects a few hours after oral administration. ACE is the most distributed dipeptidyl carboxypeptidase in mammalian bodies, usually membrane-bound in vascular endothelial cells. ACE plays a critical role in the regulation of blood pressure in the renin–angiotensin system and converts the inactive decapeptide angiotensin I into the potent vasoconstricting octapeptide angiotensin II, resulting in an increase in blood pressure (Figure 3). ACE also inactivates the antihypertensive vasodilator bradykinin. Therefore, by inhibiting the catalytic action of ACE, the elevation of blood pressure can be reduced or even suppressed in the body. Thus, ACE inhibitory peptides interact with noncatalytic binding sites in the ACE enzyme resulting in its inhibition and in lowering the blood pressure. The concentration of an ACE inhibitory peptide needed to inhibit 50% of ACE activity is defined as the IC_{50} value. However, such IC_{50} values do not always correlate with their real antihypertensive physiological effect in the body. In fact, it has been reported in the literature that some peptides with a powerful ACE inhibitory activity *in vitro* are inactive by oral administration. The reason could be that some substrate-type peptides might be hydrolyzed by ACEI enzyme resulting in smaller peptides showing weaker activity.

Originally, ACE inhibitory peptides were obtained from gelatin hydrolysates. Currently, there are hundreds of ACE inhibitory peptides identified in many protein hydrolysates from many types of foods like milk, fish, meat, eggs, soybean, corn, wheat, and seaweed. Recently, ACE inhibitory peptides are also being assayed *in vivo* to test their antihypertensive properties. These studies are developed by using SHRs that receive oral administration of such peptides, and its antihypertensive effects are followed after several hours of ingestion. As an example, peptide AAATP was identified in ACEI inhibitory extract of dry-cured ham, and its activity was tested *in vitro* by using the synthesized peptide obtaining an IC_{50} of 100 μM. The antihypertensive effect of AAATP peptide was clearly established when it was administered to spontaneously hypertensive rats, showing a decrease of systolic blood pressure by 25.6 ± 4.5 mmHg after 8 h of oral administration, as shown in Figure 4.

Opioid Peptides

Endogenous opioid peptides are thought to be involved in the response to stress in animals. Opioid receptors exist in the nervous, endocrine, and immune systems of mammals, and there are three types (μ, κ, and δ). They are known to regulate various endocrine systems, including the hypothalamic–pituitary–adrenocortical axis, and underlie the phenomenon of stress-induced analgesia. Although the first endogenous opioid peptides were identified in the late 1970s, opioid receptor ligands generated from foods not made in mammals were used thousands of years before the detection of endogenous opioids. In this sense, the drug opium was used as analgesic or antidiarrheal agent, whereas the major representative, morphine, was isolated by Serturner around 1800. Opioid peptides derived from foods have some advantages in comparison with endogenous opioid peptides as they are considered more stable and show fewer side effects, with addiction and high dependency caused by synthetic and endogenous opioid peptides being the main concern when they are prescribed.

In foods, opioid peptides are described as peptides that have an affinity for an opioid receptor and are able to exert opiate-like effects by affecting the nerve system and GI functions. Opioid peptides have been reported in hydrolysates from milk casein, wheat gluten, and blood hemoglobin. A tyrosine residue is usually found at the N-terminal end, and an aromatic residue is located in the third or fourth position. The first opioid peptides derived from food proteins were described in milk; β-lactorphin with sequence YGLF showed a decrease in the systolic blood pressure of 23 ± 4 mmHg after oral administration to SHRs. β-Casomorphins are casein-derived peptides very well characterized in literature that are

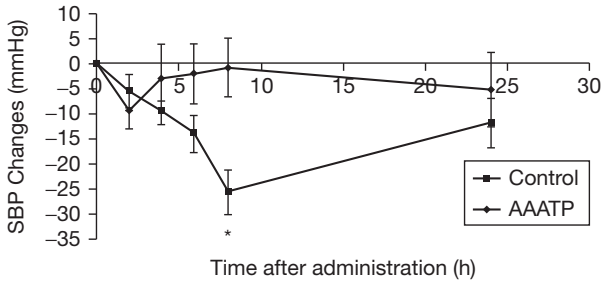

Figure 4 Antihypertensive effect of single oral administration of peptide AAATP. Figure 3 Brief description of the renin–angiotensin system, the main blood pressure, and water balance system in the human body.

involved in the regulation of gut functions, acting as antidiarrheal agents.

Antioxidant Peptides

The intake of antioxidants may decrease the risk of cardiovascular disease and certain types of cancer. Meat and fish contain some endogenous antioxidant peptides in muscle such as glutathione, carnosine, and anserine, which have some relevant physiological roles, especially related to oxidative stress. However, many different commercial enzymes and combinations of enzymes can be used to generate hydrolysates from different meat and fish muscles resulting in the generation of antioxidant peptides. These antioxidant peptides can act by preventing the formation of free radicals or introducing substances that compete for the existing radicals. Its antioxidant properties are highly dependent on the amino acid composition of the sequence of the peptide, so histidine, tyrosine, methionine, lysine, and tryptophan are well-known amino acids present in antioxidant peptides. Several antioxidant peptides have been identified from the hydrolysis of soybean, milk, eggs, fish, and meat proteins.

On the other hand, during the processing of some foods such as dry-cured ham, proteins are hydrolyzed by endogenous enzymes generating a high number of peptides showing bioactive properties. As an example, several peptides identified

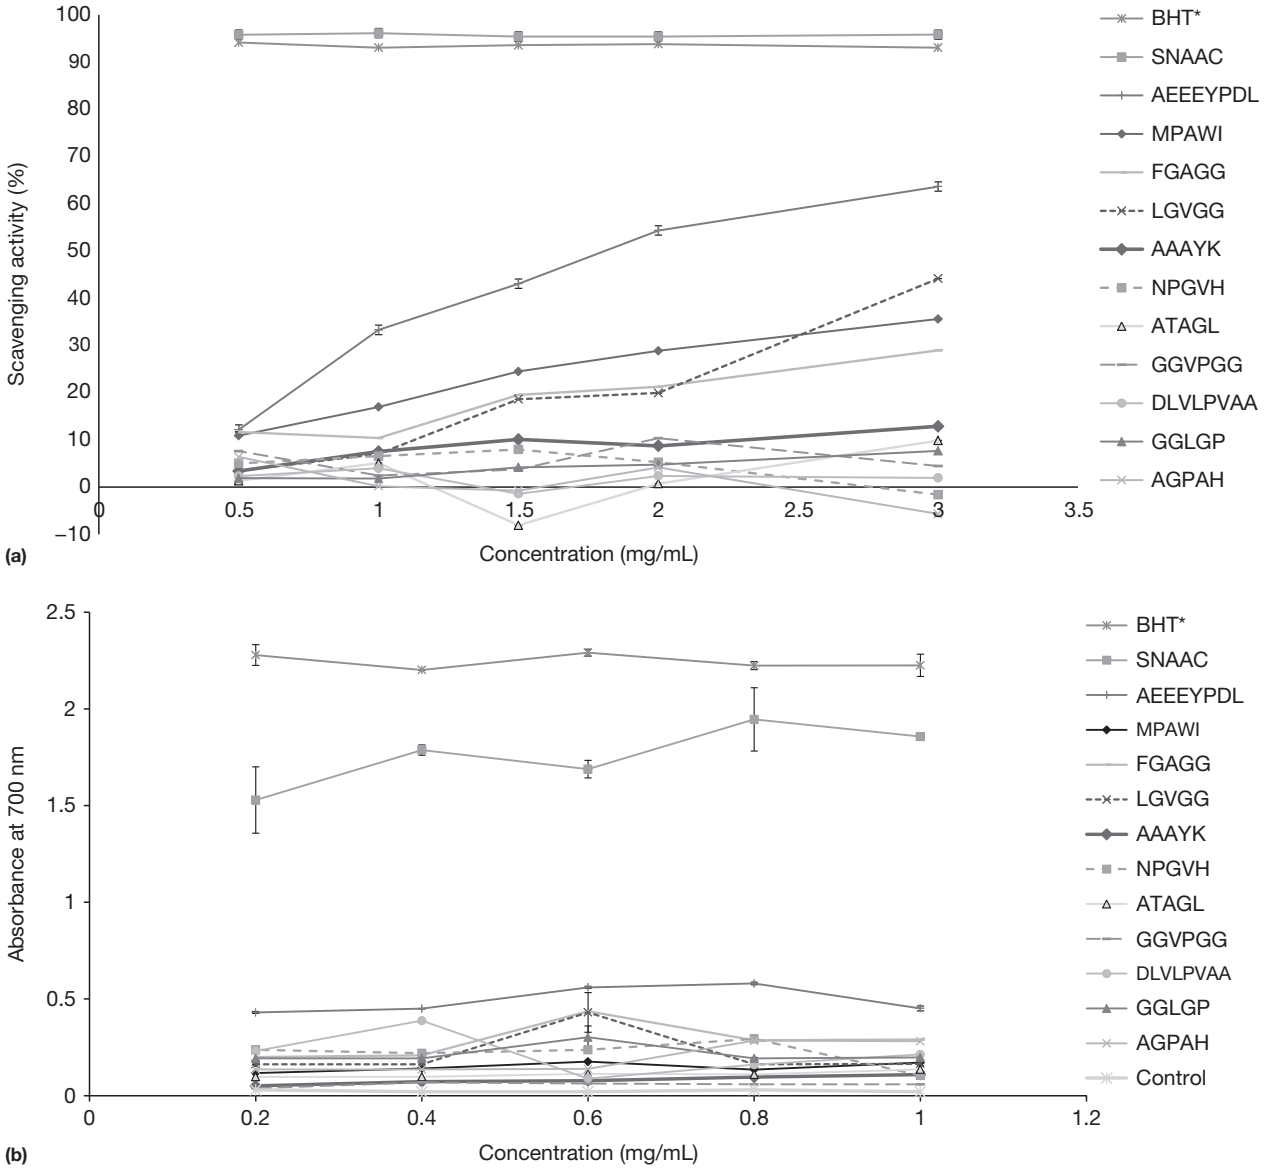

Figure 5 (a) DPPH radical-scavenging activity at different concentrations of the synthesized peptides. (b) Reducing power of different concentrations of synthesized peptides. Values represent means of three independent replicates ($n = 3$). *The synthetic compound 2,6-di-tert-butyl-4-methylphenol (BHT) was used as positive control. Reproduced with permission from Mora, L., Escudero, E., Fraser, P. D., Aristoy, M. C. and Toldrá, F. (2014). from a size-exclusion chromatography fraction in Spanish dry-cured ham that showed antioxidant activity in the analysis of DPPH radical-scavenging and ferric-reducing power have been synthesized and tested *in vitro* at different concentrations as shown in Figure 5.

The most active peptide was SNAAC, showing an IC_{50} of 75.2 μM in DPPH radical-scavenging and 205 μM in ferric-reducing antioxidant power analysis as shown in Figure 6.

Antidiabetic Peptides

Obesity is a major recognized risk factor for type-2 diabetes and constitutes a relevant public health problem. Main strategies that are being recommended to reduce type-2 diabetes incidence are exercise and a healthy diet.

Dipeptidyl peptidase IV is a serine protease able to cleave preferentially X-proline or X-alanine dipeptides from the N-terminus of different substrates. This enzyme is able to act against glucagon-like peptide (GLP-1) and glucose-dependent insulinotropic peptide. A therapeutic strategy against type-2 diabetes could consist of the reduced degradation of GLP-1 by inhibition of dipeptidyl peptidase IV. Thus, some drugs developed for the control of diabetes are based on the inhibition of the enzyme dipeptidyl dipeptidase IV (DPPIV), but they may have secondary effects in human body. This is the reason why natural bioactive peptides with such activity would be very interesting.

In this respect, peptides like KA and AAATP have been reported as strong inhibitors of this enzyme with IC_{50} values of 6.27 and 6.47 mM, respectively. Also, encrypted peptides in canary seed have showed inhibitory activity against DPPIV and ACE, targets for diabetes and hypertension treatments. These seeds are traditionally used in diabetes and hypertension treatment.

Immunomodulating Peptides

Peptides exerting its action on the immune system are very interesting and attractive in clinical medicine, as they affect both the immune system and cell proliferation responses. In fact, immunomodulatory peptides can regulate lymphocyte proliferation in humans, modulate certain cytokines

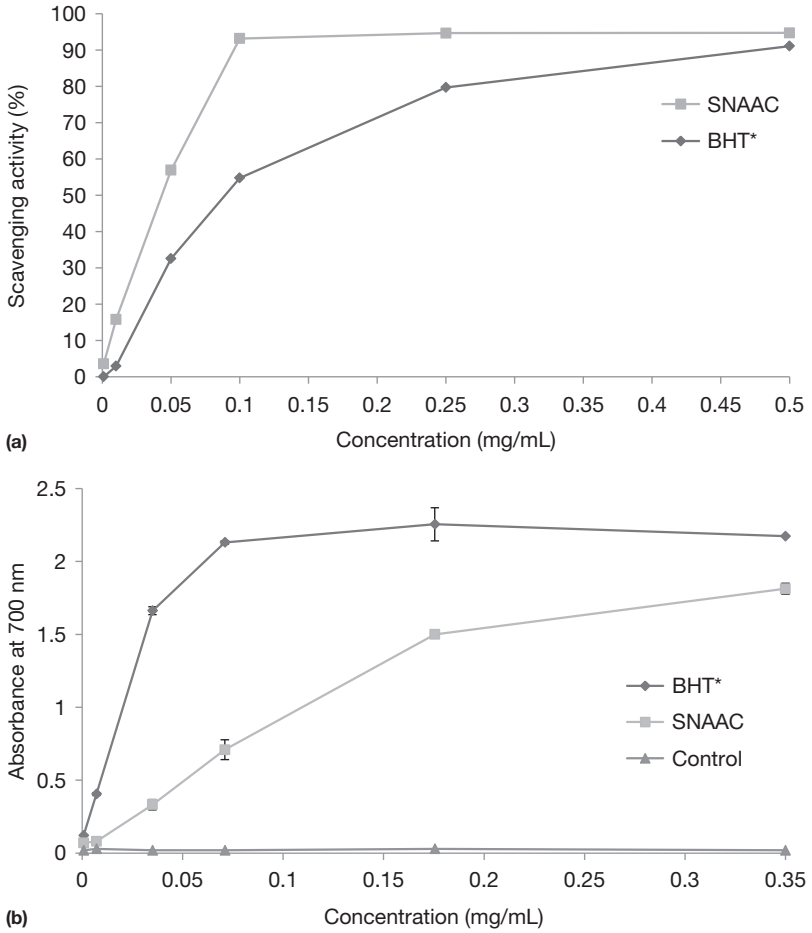

Figure 6 (a) DPPH radical-scavenging activity at different concentrations of the synthesized peptide SNAAC. (b) Reducing power of different concentrations of synthesized peptide SNAAC. Values represent means of three independent replicates ($n = 3$). *The synthetic compound 2,6-di-tert-butyl-4-methylphenol (BHT) was used as positive control. production, and stimulate macrophage activity. Main immunomodulatory peptides described in literature are released from milk proteins, probably due to the high interest in the regulation of the immune system development in newborn infants.

For instance, some milk casein hydrolysates stimulate the immune system, while other peptides generated by pancreatin or trypsin may inhibit the proliferative responses of murine splenic lymphocytes and Peyer's patch cells. Also, whey proteins have been described to contain many immunomodulatory peptides forming part of whey proteins that can be released by GI digestion after consumption or produced *in vitro* after enzymatic hydrolysis. However, in order to get therapeutic amounts of immunomodulatory peptides, it is necessary to obtain them from controlled hydrolysis as bioactive peptides derived from GI digestion are probably scarce for any significant effects on human body due to their low concentration when arriving to the bloodstream. In fact, three immunomodulating peptides were obtained from Alaska pollack through trypsin hydrolysis. The amino acid sequences were Asn-Gly-Met-Thr-Tyr, Asn-Gly-Leu-Ala-Pro, and Trp-Thr, with lymphocyte proliferation rates of 35.9%, 32.9%, and 31.3% in the presence of 20 μg ml^{-1} purified peptides, respectively.

Antimicrobial Peptides

Antimicrobial peptides have been described to be present in humans, plants, and animals, but as most bioactive peptides, they can also be generated through the hydrolysis of food proteins. These peptides constitute a potential source allowing to increase the natural defense of the organism against invading pathogens.

Antimicrobial peptides have been mainly isolated from milk and egg. In fact, lactoferrin and lysozyme bactericidal domains have been widely studied as sources of antimicrobial peptides. The best investigated antimicrobial peptide is the fragment 17–41 of lactoferrin, known as lactoferricin. Ovotransferrin, α-lactalbumin, and β-lactoglobulin are further examples of food proteins that have been described as sources of antimicrobial peptides.

Antimicrobial peptides are effective against different bacteria such as *Staphylococcus aureus* and *Escherichia coli*, among others, and against yeast. The mode of action depends on the type of peptide, but its effects are by forming pores on bacterial membranes, causing thinner membranes interacting with other components in the cell or acting in a detergent-like manner.

Mineral-Binding Peptides

Mineral-binding peptides help solubilizing minerals such as calcium and are considered beneficial in the prevention of dental caries, osteoporosis, hypertension, and anemia. Thus, these peptides are responsible for the remineralization and the increase in absorption of calcium and other minerals in the intestine. Several milk protein-derived peptides generated by enzymatic hydrolysis have shown good ability to trap mineral and trace elements constituting a strategy for the improved absorption of minerals. In this sense, casein-derived phosphopeptides show mineral-binding properties as their phosphorylated serine residues can form salts with some minerals such as calcium. On the other hand, some peptides derived from hoki and Alaska pollack frame proteins have been known due to their calcium-binding properties, showing similar effects to those observed in casein-derived peptides.

Bioavailability of Nutrients

HC Schönfeldt, B Pretorius, and N Hall, University of Pretoria, Pretoria, South Africa

© 2016 Elsevier Ltd. All rights reserved.

Background

Correct assessment of the adequacy of nutrient intakes from the diet requires not only knowledge about nutrient content of ingested foods but also the extent to which the nutrient is available for absorption and utilization in the human body.

Bioavailability is the technical term used to convey the fact that not all of the nutrients ingested will be absorbed, irrespective of whether consumed in the form of food or supplements. Bioavailability aims to describe the effects of a sequence of metabolic events, including digestion, solubilization, absorption, uptake and release, enzymatic transformation, secretion, and excretion, on nutrient utilization. Thus, the supply of nutrients – and increasingly nonnutrient bioactive compounds – to the human body depends not only on the amount in a food but also on its bioavailability. Understanding bioavailability helps to optimize diets and set appropriate recommendations.

The bioavailability of macronutrients, that is, carbohydrates, proteins, and fats, is usually high with more than 90% of the amount ingested being absorbed and utilized in the body. On the other hand, for micronutrients, such as vitamins and minerals, and bioactive phytochemicals such as flavonoids and carotenoids, absorption and utilization can vary widely after ingestion.

Defining Bioavailability

Until a nutrient passes from the digestive system into the bloodstream, it has little or no value. Bioavailability can be explained as the amount of a nutrient absorbed from the gut that becomes available for normal physiological functions or storage.

The Variability of Nutrient Bioavailability

The bioavailability of nutrients is highly variable and can be influenced by numerous factors, including physiochemical properties, such as chemical binding form; the matrix in which the nutrient is incorporated; the presence or absence of other food components that enhance or inhibit absorption; metabolization after absorption; host-related factors (including state of health, genetic factors, age, and lifestyle); and other individual factors.

Enhancers and Inhibitors

Nutrients can interact with one another and with other dietary components at the site of absorption, affecting a change in bioavailability or – if enhancers and inhibitors cancel each other out – a nil effect. Enhancers can act in different ways, such as keeping a nutrient soluble or protecting it from interaction with inhibitors. For example, because carotenoids are fat-soluble, adding small quantities of fat or oil to a meal (3–5 g) improves their bioavailability. Similarly, meat, fish, and poultry, while containing highly bioavailable iron, are also known to enhance the absorption of iron from other foods ingested at the same time. Although this *meat factor* has yet to be identified, it has been suggested that muscle protein may exert an influence.

Inhibitors, on the other hand, may reduce bioavailability by binding the nutrient in a form that is not recognized by uptake systems on the surface of intestinal cells, rendering the nutrient insoluble and, thus, unavailable for absorption, or by competing for the same uptake system. For example, phytic acid is abundant in certain plant foods (e.g., pulses, wholegrain cereals, seeds, and nuts) and strongly binds minerals, such as calcium, iron, and zinc in soluble or insoluble complexes, which are unavailable for absorption. Ways to reduce phytic acid content of foods include fermentation (e.g., extensive leavening of whole-wheat bread dough) or the soaking and germination of pulses.

The inhibitory effect of food constituents can also be used advantageously, as in the case of phytosterols. These compounds can be extracted from certain plant foods and added in higher doses (about 2 g per portion) to a variety of other foods (e.g., spreads and fermented milk drinks) to reduce the absorption of cholesterol, be it from dietary sources or produced in the human body.

Bioavailability of Specific Nutrients

Protein–energy malnutrition, vitamin A, and iron deficiencies are some of the most common forms of malnutrition experienced globally and often coexist. For effective intervention and dietary guidelines, the bioavailability of these nutrients, as supplied from different food sources, is particularly important. The bioavailability of these nutrients is distinct and influenced by different factors, providing good examples of the complexity of nutrient bioavailability.

Protein and Amino Acids

Although protein is a macronutrient that is easily absorbed by the human body, its bioavailability is directly linked to digestibility. To be most bioavailable, a meal needs to supply all the required essential amino acids in the correct proportions.

Amino acids are the central units in protein metabolism. They are incorporated into various proteins and converted to metabolically essential compounds, such as nucleic acids, creatine, and porphyrins. Of the 20 amino acids in human proteins, 12 can be made by the body and are known as nonessential amino acids. The remaining eight (8) (isoleucine,

leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) must be obtained from the diet and, thus, are termed essential or indispensable amino acids. Sufficient intakes of essential amino acids and adequate amounts of nitrogen for the body to produce the nonessential amino acids are important for protein metabolism.

Protein quality

The nutritional quality of food proteins varies, depending on the essential amino acid composition. Foods that contain essential amino acids at levels that facilitate tissue growth and repair are known as complete protein foods, supplying high-quality proteins. Amino acids containing sulfur (including methionine and cysteine) most commonly limit the nutritional value (quality) of proteins in the human diet. Concentrations of these sulfur-containing amino acids are, generally, considered lower in legumes and fruits than in food of animal origin. The roles of these amino acids in the human body are crucial as methionine is the amino acid initiating the synthesis of almost all eukaryotic proteins and cysteine (due to its ability to form sulfur bonds) has an important role in protein structure. Other essential amino acids, lysine and tryptophan, are also consistently found at lower concentrations in plant-based rather than animal-based foods; for example, tryptophan and lysine are limiting in corn; lysine in wheat, sorghum, and other cereals; and methionine in soybeans and other legumes. For further reading on the global protein quality debate, refer to the 2011 report of the FAO Expert Consultation on dietary protein quality evaluation in human nutrition (FAO, 2011).

In addition to protein quality, digestibility (absorption), chemical integrity, and inhibitors are three key properties of foods that can influence the bioavailability of amino acids.

Amino acid digestibility

Amino acid digestibility explains the proportion of amino acids consumed that is absorbed. It is not a fixed value, but reflects the interaction between food and the host and, therefore, may be subject to individual variation. Although the digestibility (absorption) of macronutrients, including protein, is relatively high, protein utilization is influenced by total dietary energy intake and the quality of protein in terms of meeting metabolic demand.

Chemical integrity

Chemical integrity describes the proportion of amino acids absorbed in a form that can be utilized. Some amino acids present in foods may be structurally unavailable (i.e., absorbed in a form that cannot be utilized). This is most likely to be encountered in foods that are heat-treated, oxidized, or subjected to other processes that limit amino acid bioavailability. Heat treatment leads to the formation of Maillard compounds and reduced lysine availability. Oxidization of sulfur-containing amino acids reduced the bioavailability of tryptophan and threonine. High pH induces racemization of L-amino acid residues to D-isomers and formation of cross-linked amino acids, such as lysinoalanine, which also reduces bioavailability.

Inhibitors

Many foods contain bioactive (protein or nonprotein) substances that may inhibit amino acid bioavailability by affecting either digestibility or utilization postabsorption. These inhibitors may be naturally occurring (e.g., tannins, phytates, trypsin inhibitors, glucosinolates, and isothiocyanates), formed during processing (e.g., D-amino acids and lysinoalanine), or formed during genetic modification of crops (e.g., lectins in lentils) (lectins suppress growth at low levels and are toxic at high levels).

Vitamin A

Vitamin A is a generic term used for a group of structurally related chemical compounds known as retinoids, which may be naturally occurring or synthetic compounds with or without vitamin A biological activity. Figure 1 shows the chemical structures of some retinoids.

Vitamin A is often used as a general term for all compounds that exhibit the biological activity of retinol. Vitamin A activity in the diet derives from two sources: preformed vitamin A, such as retinyl esters or retinoids, and provitamin A carotenoids, such as β-carotene, α-carotene, and β-cryptoxanthin. Although an essential nutrient, vitamin A is needed only in small amounts and is necessary for normal functioning of the visual system, growth and development, and maintenance of epithelial cellular integrity, immune function, and reproduction.

Retinol (preformed vitamin A)

Vitamin A *in vivo* is, generally, found in the free alcohol form (retinol) or esterified with a fatty acid (retinyl ester). Available in a pure form by chemical synthesis or as vitamin A palmitate or acetate, it is a pale yellow solid, which dissolves freely in oils and fats, but is insoluble in water. When vitamin A intake is adequate, more than 90% of the total body vitamin A is located in the liver, which releases the nutrient into the circulation as needed. The major dietary forms of vitamin A are long-chain fatty acid esters of retinol, commonly found in foods of animal origin, such as glandular meats, liver and fish liver oils (especially), egg yolk, and whole milk and dairy products.

Preformed vitamin A is absorbed in the small intestine. Generally, the bioavailability of retinol is high, ranging from 70% to 90%. Factors such as dietary fat and intestinal infections can affect the absorption of vitamin A. Products of fat digestion (e.g., fatty acids, monoglycerides, cholesterol, and phospholipids) and secretions in bile (e.g., bile salts and hydrolytic enzymes) are essential for the efficient solubilization of retinol. The absorption of retinol appears to be reduced in individuals with diarrhea and intestinal infections or infestations.

Carotenoids

Carotenoids are lipid-soluble plant pigments found in photosynthetic plants and animal tissues. About 600 carotenoids have been isolated and characterized in nature, and about 10% of these can be metabolized to vitamin A in a variety of animal species, including humans. Both provitamin A carotenoids, such as α- and β-carotenes and cryptoxanthins, and non-provitamin A carotenoids, such as lutein, zeaxanthin, and

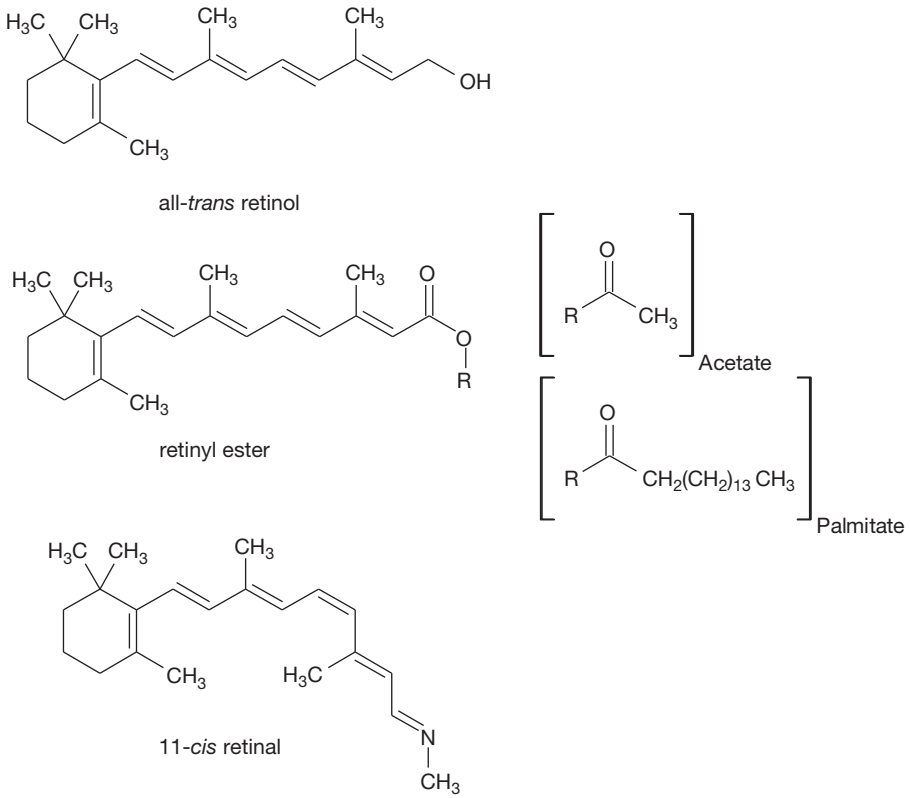

Figure 1 Chemical structures of different retinoids. All-trans retinol is by definition vitamin A, and 1 mg of all-trans retinol is equal to 1 retinol equivalent (RE). When a fatty acyl group is esterified to the hydroxyl terminus of all-trans retinol, retinyl ester is formed for storage. The most abundant retinyl esters are those of palmitic, oleic, stearic, and linoleic acids. Retinyl acetate and palmitate are often used as dietary supplements, but do not occur naturally. Retinol can be reversibly oxidized to retinal, the 11-cis isomer, which is essential for the visual cycle. Reproduced from Packer, L., Kraemer, K., Obermüller-Jevic, U. and Sies, H. (eds.) (2005). Carotenoids and Retinoids: Molecular aspects and health issues, Illinois: AOCS Press.

lycopene, are present in the human blood and tissues and have a variety of functions. The structures of these carotenoids are shown in **Figure 2**. Provitamin A carotenoids are an important source of dietary vitamin A that are found primarily in dark-green leafy vegetables, such as spinach, and in orange and yellow vegetables and fruit, such as carrots, mango, and papaya, although their bioavailability is significantly more variable than that of preformed vitamin A (retinol).

The bioavailability of carotenoids is affected by various factors. Different carotenoids have different levels of vitamin A activity depending upon the *efficiency* of their absorption and the *rate* of their conversion to vitamin A. Recent research has shown that the bioavailability of traditional dietary sources of β-carotene is considerably lower (around half to a quarter) than was previously assumed. Conversion factors for estimating vitamin A obtained from plant foods were revised from 6:1 to 12:1 (μg β-carotene–retinol activity equivalent (RAE)) and 24:1 for other provitamin A carotenoids in a mixed diet. There is also a wide variation in vitamin A equivalency ratios, which can be affected by food- and diet-related factors and health, nutritional, and genetic characteristics among human populations.

Various diet- and host-related factors affect the bioavailability of carotenoids. These factors have been evaluated and extensively reported by Castenmiller and West (1998), De Pee et al. (1998), Van Het Hof et al. (2000), and Yeum and Russell (2002).

Bioavailability of carotenoids

The main diet-related factors influencing carotenoid bioavailability are the food matrix, amounts ingested, and habitual diet type. The nutritional status, health, and genetic characteristics of human populations can also affect the absorption and bioavailability of carotenoids.

Release of the carotenoids from the food matrix is important in the absorption process. The rupture of the plant cell walls by processing (e.g., heating or pureeing) promotes the release of β-carotene from the cells before and during digestion and, therefore, facilitates solubilization and absorption. Generally, the bioavailability of β-carotene from fruits is higher than for vegetables, as the cell wall structure in fruits is usually weaker than in most vegetables and leaves. Furthermore, inhibitors of carotenoid absorption present in fruit are also less than in leafy vegetables.

The composition of the diet (due to nutrient-to-nutrient interactions) affects, to a large extent, the absorption of carotenoids. The second step in absorption, which may affect bioavailability, involves the incorporation of carotenoids into mixed micelles. Among other factors, the formation of these micelles is dependent on the presence of fat in the intestine. Therefore, ingestion of fat, along with carotenoids, is thought to be crucial although only a small amount of fat is necessary to enhance carotenoid absorption. As expected, fat-soluble compounds that cannot be absorbed, such as sucrose polyester (a fat replacer), reduce carotenoid absorption. Also, as dietary

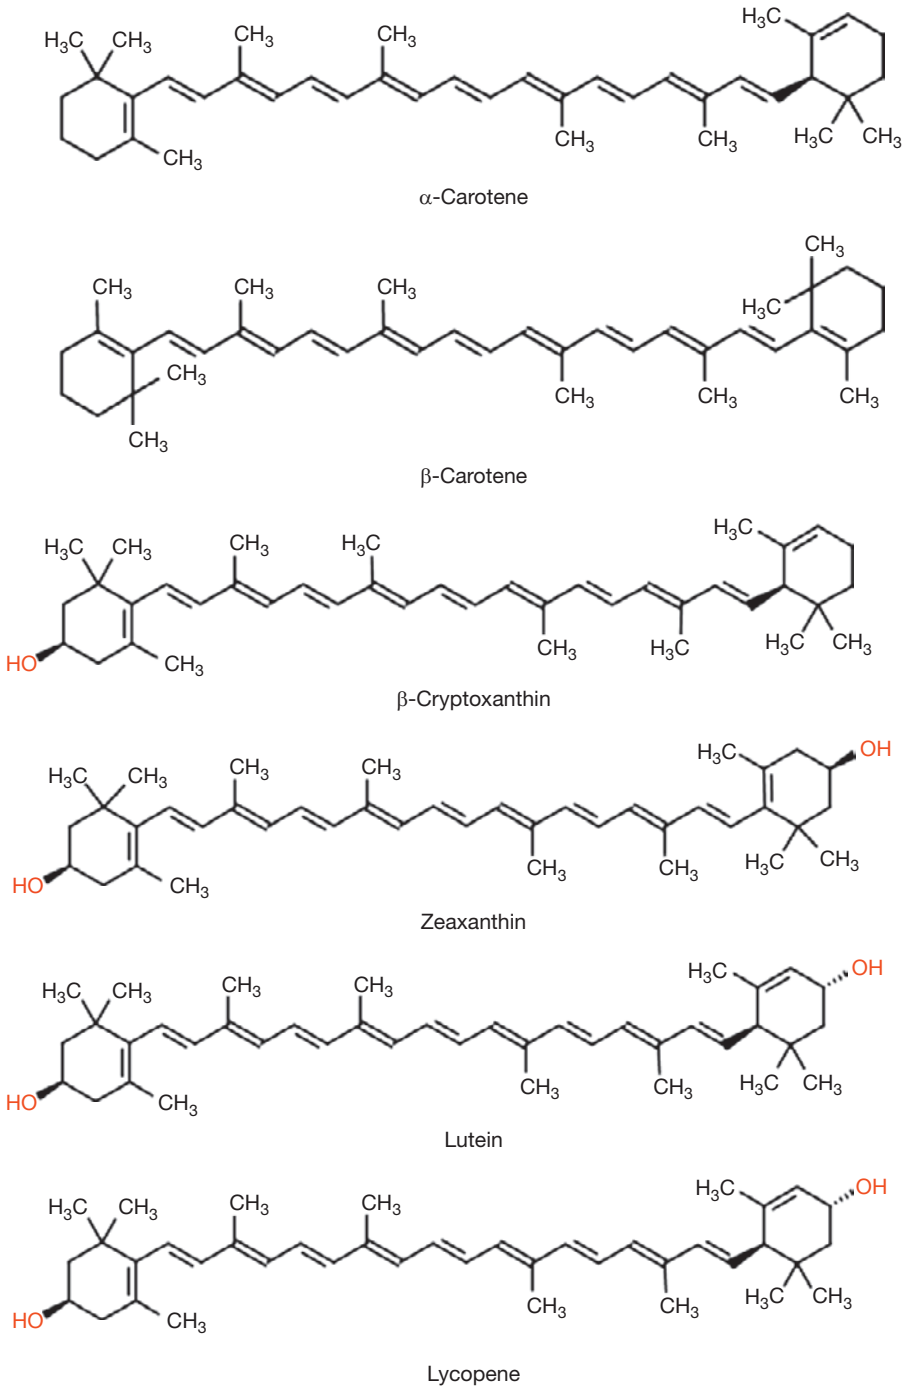

Figure 2 Chemical structures of major provitamin A carotenoids (α-carotene, β-carotene, and β-cryptoxanthin) and non-provitamin carotenoids (lutein, zeaxanthin, and lycopene) found in food.

fiber content increases, the absorption of β-carotene decreases. Dietary fiber reacts with bile acids and, thereby, decreases the absorption of fat and fat-soluble nutrients. The presence of dietary fiber in vegetables and fruits may explain in part the reduced bioavailability of carotenoids from plant foods.

Simultaneous ingestion of carotenoids may also reduce absorption of any of the carotenoids due to interactions at the intestinal level. Studies on simultaneous ingestion of carotenoids indicate that lutein may interfere with the absorption of β-carotene resulting in reduced bioavailability. It has also been found that with pharmaceutical doses of β-carotene, conversion of β-carotene to vitamin A decreases as the oral dose of β-carotene increases. Further research is required to identify the mechanisms behind these interactions.

Furthermore, the absorption of carotenoids is highly likely to be dependent on vitamin A status of the host. Consuming β-carotene-rich foods leads to an increase in serum retinol levels only when these are initially low. The serum response

to β-carotene is higher in women than in men; however, this could in part be attributed to differences in body weight and composition. Intestinal helminthic infections are associated with malnutrition, which may be mediated through impaired fat absorption and reduced vitamin absorption, particularly of vitamin A.

Iron

Minerals (and other nutrients) exist in different chemical forms in food, which can influence bioavailability. Iron is a classic example: there are two primary forms of dietary iron, namely, heme and nonheme. The former is only found in animal products, such as red meat, fish, and poultry. The heme iron content of animal sourced foods is estimated at 40% of the total iron, but data suggest that a portion of red meat provides considerably more heme iron than a portion of white fish, for example. Heme iron is a component from hemoglobin and myoglobin (see Figure 3), which explains why it is only found in animal tissue. Nonheme iron is found mostly in plant-based foods and makes up the remaining estimated 60% of iron found in animal products.

The types of iron (heme or nonheme) notably influence bioavailability. Approximately 90% of dietary iron is consumed in the nonheme form. However, due to low bioavailability, it constitutes only approximately half the iron absorbed by the body. The absorption of nonheme iron is usually much lower than heme iron. In general, the rate of nonheme iron absorption is related to its solubility in the upper part of the small intestine. The presence of soluble enhancers, such as ascorbic acid, and inhibitors, such as phytates, polyphenols, and calcium, consumed in the same meal will have a notable effect on the amount of nonheme iron absorbed. Heme iron is much less affected by other dietary factors and contributes more significantly to absorbable iron.

Inhibitors and enhancers of iron bioavailability

Nonheme iron that enters the common iron pool in the digestive tract is absorbed to the same extent, depending on the balance between inhibitors and enhancers and the iron status of the individuals.

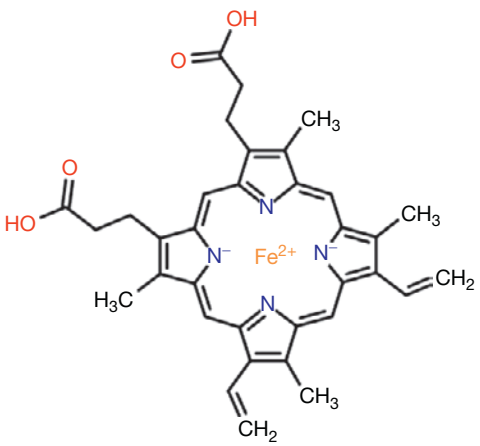

Figure 3 Chemical structure of heme iron as found in food from animal sources.

Phytate and polyphenols in plant-based diets are the main inhibitors of nonheme iron absorption. The negative effect of phytate on iron bioavailability is dose-dependent, and any food processing and preparation methods, such as milling, heating, soaking, germination, and fermentation, which degrade phytate to varying extents, will have a positive effect on iron absorption. Controversies exist on the inhibitory effect of oxalic acid in spinach and cabbage and nondigestible carbohydrates in beans on iron absorption, as these foods are also good sources of ascorbic acid, which enhances iron absorption.

Calcium and dairy products have also been shown to have a negative effect on nonheme iron absorption, but what separates these from other inhibitors is the ability to also inhibit heme iron absorption. Single-meal studies show a negative effect of calcium on iron absorption, but multimeal studies, with a variety of other inhibitors and enhancers, indicate calcium has only limited impact on iron absorption. In a recent study, the two major milk protein fraction (casein and whey) and egg protein (albumin) were reported to have a negative effect on iron absorption in humans. Although phytate has been shown to be the major inhibitor in soy, even after complete phytate digestion in soy protein isolates, significant inhibition of iron absorption can be observed. Thus, in soy, it was concluded that both phytate and a protein fraction inhibit iron absorption.

Ascorbic acid has been shown convincingly to enhance iron bioavailability in a dose-dependent manner. This effect is largely due to its ability to reduce ferric to ferrous iron. Ascorbic acid has also been shown, at least partially, to counteract the inhibitory effects of both phytate and polyphenols on nonheme iron absorption.

Small amounts of meat are recognized to enhance the absorption of nonheme iron from plant foods, although the mechanism(s) is unknown. Studies also support the enhancing effect of cysteine-containing peptides following the proteolysis of meat muscle.

Vitamin A and β-carotene can enhance nonheme iron absorption and increase hemoglobin levels, although several studies suggest this is only observed in iron-deficient individuals. Host-related factors that influence the absorption of heme and nonheme iron include mainly iron status, other nutritional deficiencies, infection, genetic disorders, and physiological state.

As with inhibitors and enhancers, the iron status of an individual mainly influences the absorption of nonheme iron, while heme iron absorption is less affected. There is an inverse relationship between iron status and iron absorption. Protein–energy malnutrition, riboflavin, and vitamin A deficiencies have also been shown to impair iron metabolism and absorption; correction of these nutritional deficiencies will improve iron absorption.

Iron deficiency often coexists in a burden of disease in seemingly well-fed, overweight populations, due in part to iron absorption being reduced by the peptide, hepcidin. Hepcidin is a regulatory hormone secreted by the liver, which inhibits iron absorption. It secretion is increased in chronic inflammation and obesity.

Achlorhydria might also be a substantial cause of iron deficiency, mainly in elderly people, among whom atrophic gastritis is common and gastric acid secretion is low. Gastric acid is needed to maintain ferric iron in solution and make it bioavailable. However, heme iron does not appear to be

affected by the lack of acid and is normally absorbed in individuals with atrophic gastritis.

Other common causes of reduced iron absorption and/or iron deficiency are mucosal atrophy in celiac disease and, possibly, *Helicobacter pylori* infection, although no consensus has been reached. For further reading on iron bioavailability, refer to Heath and Fairweather-Tait (2002), Zimmermann and Hurrell (2007), and Hurrell and Egli (2010).

Conclusions

Nutrients react differently once ingested and absorption can be influenced by a variety of factors, including quality of the food source and the matrix in which it is consumed; the composition of the whole meal, inhibitors, and enhancers; and the status of the host. Although bioavailability is only a partial measure of the benefit from a nutrient, this factor quantifies the amount entering the bloodstream. Once in the bloodstream, the nutrient must cross cell membranes before it can nourish cells. In addition to nutrient content of foods, nutrient bioavailability should also be taken into consideration when nutrition-sensitive policies, nutrition interventions, and dietary guidelines are developed. However, it should be noted that bioavailability is not a constant value and needs to be considered with caution in the context of multiple factors, both intrinsic and extrinsic, which can affect the bioavailability from food- and nonfood sources of nutrients.

Biofilms

SC Chew and L Yang, Nanyang Technological University, Singapore, Singapore

Introduction

Bacteria predominantly exist in nature as complex microbial communities that are attached to surfaces and held together by a matrix of extracellular polymeric substances (EPS). These microbial communities are also known as biofilms, of which the community members are exposed to microbial competition, communication, and collaboration. Bacteria within the biofilm are known to employ physiological cooperation and spatial organization to increase both their metabolic efficiency and their resistance to fluctuations in the local environment. As a consequence, the biofilms have an enhanced metabolic capacity and ability to withstand environmental stresses and host immune responses compared with their planktonic counterparts. The developmental life cycle of the biofilm can be categorized into five stages (Figure 1): (i) initial attachment, where microbial cells adhere to a substratum through weak, reversible van der Waals forces and where the adsorption of inorganic salts and organic compounds to the surface, known as surface conditioning, is important for the initial attachment of microbial cells to abiotic surfaces; (ii) irreversible attachment, where the cells anchor themselves more permanently using EPS components and cell adhesion structures such as surface pili; (iii) maturation I, where a thin biofilm is formed from layered cells and small clusters, during which surface-attached cells can migrate to top of clusters, and increased cell division and aggregation lead to (ii); (iv) maturation II, where clusters develop into large microcolonies and many cells have displaced from the substratum to form channels and voids; and (v) dispersion, where parts of the biofilm undergo cell death and detachment and a subpopulation of cells regain their motility to leave the microcolony to colonize new surfaces. Understanding the biofilm formation mechanisms will greatly facilitate the development of strategies for biofilm control.

Biofilms play an essential role in environmental sustainability and human health. In natural environments, they contribute to bioremediation of toxic compounds released from human activities. In waste treatment, biofilms are used to remove unwanted organic compounds to supply clean water to society. Biofilms formed by commensal bacteria that live on the surface of our skin and intestinal tract behave as a 'virtual organ' and modulate our immune function and facilitate nutrient utilization. However, biofilms formed by bacterial pathogens are also found in the human body and are the root of many persistent and chronic bacterial infections. Examples of biofilm-associated infections include the following: (1) periodontal disease, where dental plaque, a multispecies biofilm, causes dental caries, gingivitis, and periodontitis; (2) cystic fibrosis lung infections, where bacterial biofilms resist antimicrobial treatment and phagocytosis, eventually leading to lung failure; and (3) bacterial infections from medical implants, as many pathogenic bacteria are able to form biofilms on the materials used for catheters, artificial joints, mechanical heart valves, and other devices. Biofilms also cause a significant portion of acute infections, particularly in the food industry. Biofilms formed in food preparation and water distribution systems can result in contamination of food products, causing acute foodborne illnesses. Such biofilms are a burden to public health and industry, in particular when notorious bacterial pathogens form biofilms in the food processing environment. Such pathogens include *Escherichia coli*, *Salmonella* spp., *Shigella* spp., *Staphylococcus aureus*, *Vibrio* spp., *Campylobacter jejuni*, *Clostridium* spp., and *Listeria monocytogenes*.

Methods to Study Biofilms

Microscopy

Microscopy has been one of the major tools to provide information on biofilm morphology, phylogeny, and architecture. Epifluorescence microscopy and confocal laser scanning microscopy (CLSM), which are based on the excitation and detection of fluorescence emission, are the most commonly used microscopy techniques. By using microbial strains that have been tagged with fluorescent proteins, biofilm morphology and structure can be easily observed. Furthermore, the transcriptional fusions of specific gene promoters to the fluorescent proteins can be used to observe the regulation of specific genes within biofilms via fluorescence. Live–dead stains such as SYTO 62 and propidium iodide are useful for cell viability assays. In epifluorescence microscopy, fluorescent objects below and above the focal plane are also excited and emission-detected, resulting in a less sharp image. In contrast, CLSM is able to filter fluorescence emitting from other planes via a pinhole and thus collects fluorescence from the selected focal plane only. Thus, CLSM is preferred for high-quality 3-D micrographs in thick samples (such as biofilms). Figures 2(a) and 3 give a 2-D and 3-D visualization of a mixed-species biofilm by epifluorescence microscopy and CLSM, respectively.

Scanning electron microscopy (SEM) images specimens at subnanometer resolution by scanning it with a focussed beam of electrons. Electrons interact and are scattered by sample atoms to generate signals that contain information about the sample's surface topography and composition. Conventional SEM techniques require that specimens be conductive, and thus, biological samples were usually coated with conductive material such as gold. In addition, specimens were dry as imaging had to be done under high-vacuum conditions. However, samples can be now imaged uncoated in low-vacuum and moist conditions in an alternative low-voltage mode of SEM operation called environmental SEM. Figure 2(b) shows SEM micrographs of biofilms.

Atomic force microscopy (AFM) images specimens at nanometer to subnanometer resolution by scanning the sample surface with a silicon nitride or silicon tip attached to a

I., Falsetta, M. L., et al. (2012). The exopolysaccharide matrix modulates the interaction between 3D architecture and virulence of a mixed-species oral biofilm. *PLoS Pathogens* **8**(4), e1002623. http://dx.doi.org/10.1371/journal.ppat.1002623, with permission.

cantilever. Interactive forces between the tip and specimen surface deflect the cantilever. Tip-sample interaction forces plotted against the tip-sample distance give the AFM force–distance curve. In this manner, AFM is able to quantify aspects of cell adhesion forces and biofilm/substratum interactions. The gradient of the force–distance curve, as the tip is driven into the sample surface, is a measure of sample compliance or stiffness. Figure 2(c) shows AFM micrographs of biofilms.

Fluorescent In Situ Hybridization

A staining technique of particular importance for the study of microbial biofilms is fluorescent in situ hybridization (FISH). FISH is used to assess the phylogenetic identity, morphology, spatial distribution, and quantity of species in polymicrobial communities. In FISH analysis, fluorescently labeled oligonucleotide probes are complementary to and hybridize to target phylogenetic markers at 16S or 23S rRNA in permeabilized microbial cells. Probes can be designed to target narrow or broad phylogenetic groups. After incubation and hybridization with the target, unspecific and unbound probes are washed away. The degree of homology between the probe and target, called the stringency of the hybridization, is adjusted during incubation and washing steps. The biofilm is then observed using fluorescent microscopy such as the CLSM and the images are analyzed by software such as 'daime' (http://www.microbial-ecology.net/daime/). Figure 2(a) shows biofilms analyzed by FISH.

Sequencing Technologies

The rapid progression of the DNA sequencing technology has greatly facilitated the current understanding of the complex biofilm communities. A large percentage of the microbial species from natural biofilm communities is difficult to culture and thus cannot be studied via routine culture-based approaches. Metagenomics and metatranscriptomics are now widely used for characterizing the microbial species composition and their physiology within biofilms. In metagenomic analysis, the entire genetic material is extracted directly from biofilm samples and then subjected to DNA sequencing by either 16S rRNA amplicon pyrosequencing approach or high-throughput short-read sequencing approach. The microbial taxonomy, genome content, and metabolic capacity can be elucidated via metagenomic analysis. To further analyze the activity of different microorganisms within the complex biofilm communities, metatranscriptomic analysis, whereby the total RNA is extracted directly from biofilm samples, converted to cDNA, and then subjected to DNA sequencing by high-throughput short-read sequencing approach, can be employed.

Biofilm Matrix

Up to 50–90% of the total organic matter in the biofilms consists of EPS that are actively secreted by the microbial cells. The EPS mainly consists of exopolysaccharides, proteins, extracellular DNA (eDNA), and humid acids and lipids and creates the heterogeneous biofilm architecture.

Exopolysaccharides

The exopolysaccharides, which often constitute the major portion of the EPS in biofilms, are long-chained in nature and function as a scaffold of biofilms and cross-link the bacterial cells together. A singular bacterial species can synthesize multiple types of exopolysaccharides with distinct roles from each other and in different stages of biofilm formation. Many of the exopolysaccharides are highly charged, which aids in absorption of water and ions, such as calcium and magnesium cations from the environment. This helps protect biofilm cells from desiccation and buffer against pH changes. Exopolysaccharides are also known to protect microbial cells from harmful conditions such as treatment by disinfectants and UV irradiation. Figure 3 shows how exopolysaccharides contribute to these properties in a mixed-species oral biofilm.

Proteins

Secreted proteins are abundant in the EPS and play important roles on structure and physiology. Extracellular carbohydrate-binding proteins such as lectins can link the bacterial cell to the exopolysaccharides and thus stabilize the EPS network. Another group of high-molecular-mass surface-associated proteins belonging to the Bap (biofilm-associated protein) family functions as adhesins for primary attachment of cells to abiotic surfaces and intercellular adhesion. Thus, they are important for biofilm formation and are highly conserved among various bacterial species. The Bap family proteins have also been shown to mediate interactions between bacterial cells and host cells, which facilitate the pathogen colonization and the establishment of persistent infections. In addition to these structural proteins, there are many enzymatic proteins that

are anchored within the EPS that can alter the local microenvironment of biofilms (see section 'Alteration of Microenvironment').

Extracellular DNA

Besides exopolysaccharides and proteins, eDNA is now recognized as a common EPS component, which can constitute a substantial amount of the biofilm EPS. eDNA was initially found to mediate early-stage biofilm formation of *Pseudomonas aeruginosa* and could interact with bacterial cells through surface pilus structures and mediated interspecies interactions. The eDNA is released from bacterial cells by active excretion or cell death. It is able to bind to cationic antimicrobials, such as aminoglycosides and antimicrobial peptides, and stop them from reaching the bacterial cells within the biofilm.

Biofilm Regulation

Cell-to-Cell Communication (Quorum Sensing)

The high cell density and thick EPS in biofilms can retain high concentrations of bacterial secreted signaling molecules and thus enhance the bacterial cell-to-cell communication (quorum sensing). Quorum sensing is an intercellular signaling mechanism widely distributed among different microorganisms that regulate gene expression in response to small diffusible signaling molecules. The three most common signal molecules used by different bacterial groups are the oligopeptides, *N*-acyl homoserine lactones (AHLs), and autoinducer-2 (AI-2) (Figure 4). Quorum sensing regulates the expression of hundreds of genes and many of these genes, which are involved in motility control, biosurfactant synthesis, and EPS synthesis, are required for biofilm formation and effective stress response to harmful environmental conditions. Foodborne pathogens such as *Salmonella*, *Vibrio cholerae*, and *Serratia liquefaciens* all produce quorum sensing molecules to regulate their motility and biofilm development.

The AHL-mediated quorum sensing is well characterized in Gram-negative bacteria. Figure 5 illustrates the LuxI–LuxR quorum sensing system from *V. fischeri*. The *luxI* gene expresses the LuxI protein, which synthesizes the AHL molecule, *N*-(3-oxohexanoyl)-L-homoserine lactone (OHHL), which is also known as autoinducer-1 (AI-1). OHHL is secreted to the external environment. The concentration of OHHL is low in the early phase of growth and increases as the bacterial population increases (especially in biofilms). When the OHHL reaches a critical threshold level, it reenters the bacterial cell to bind to the LuxR protein receptor and activate the LuxR receptor. The LuxR–OHHL complex then recognizes its target genes by a *lux* box (20-base-pair inverted repeat in the promoter region) and activates or represses transcription of these genes. The LuxI–LuxR system is a classic type of quorum sensing system and its homologues are found in many Gram-negative bacteria, including several foodborne pathogens such as *Aeromonas hydrophila* and members of the genus *Vibrio*. The formation of mature biofilms on stainless steel coupons by *A. hydrophila* requires the synthesis of *N*-butyryl-L-homoserine lactone (C4-HSL), and its AHL synthase mutant could not form a mature biofilm. Biofilm formation in *V. cholerae* is controlled by multiple quorum sensing systems that simultaneously regulate the expression of exopolysaccharide biosynthesis genes.

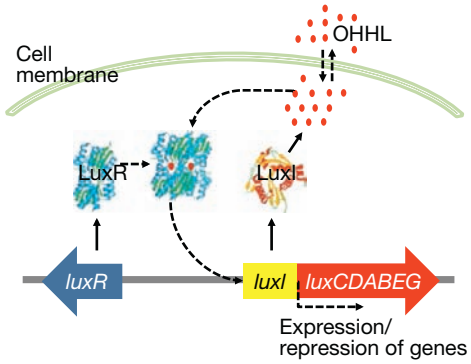

Figure 5 LuxI–LuxR quorum sensing system in *Vibrio fischeri*.

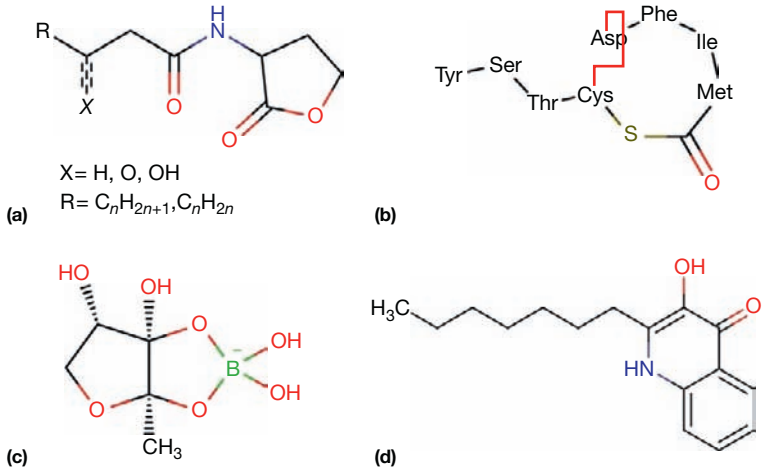

Figure 4 Examples of signaling molecules used in quorum sensing among bacteria. (a) *N*-Acyl homoserine lactones (AHLs), (b) autoinducing peptide-1 (AIP-1) in *Staphylococcus aureus*, (c) autoinducer-2 (AI-2) in *V. harveyi*, and (d) pseudomonas quinolone signal (PQS) in *Pseudomonas aeruginosa*.

Gram-positive bacteria employ oligopeptides as signaling molecules in their quorum-sensing regulation. Unlike the AHL, the oligopeptides bind to their two-component sensor kinase-based receptors on the cell surface, rather than intracellular receptors. The binding of oligopeptides to the receptors can initialize a series of phosphorylation–dephosphorylation reactions and lead to the phosphorylation of the response regulators. The activated response regulators eventually regulate the expression of quorum sensing-controlled genes and biofilm formation. The accessory gene regulator (agr) quorum sensing system was originally identified in *Staphylococcus* spp. and is the best-characterized oligopeptide-based quorum sensing system to date. agr quorum sensing positively controls virulence but negatively regulates the biofilm formation of *Staphylococcus* spp.

The autoinducer-2 (AI-2)-mediated quorum sensing is found in both Gram-negative and Gram-positive bacteria. The LuxS autoinducer synthase produces 4,5-dihydroxy-2,3-pentanedione (DPD), which is the precursor to a set of AI-2s. DPD can be actively transported into cells via the LuxS-regulated (Lsr) transporter. The internalized DPD is then phosphorylated to AI-2 by LsrK family kinase. AI-2 then binds with its specific receptor (LsrR family protein) and subsequently turns on/off the transcription of quorum sensing-regulated genes. The AI-2 quorum sensing is required for biofilm formation on surfaces used in animal production watering systems by the foodborne pathogen *C. jejuni*. Mutants that lack the AI-2 quorum sensing form much less biofilm than wild-type strain. AI-2 quorum sensing positively controls biofilm formation by *E. coli* but negatively controls biofilm formation by *Bacillus cereus* and *Staphylococcus aureus*.

c-di-GMP Signaling

A distinct physiological marker for biofilm cells is the high level of intracellular content of cyclic di-GMP (c-di-GMP). c-di-GMP is a secondary messenger that plays an essential role in determining the lifestyles of a wide range of bacteria. Intracellular c-di-GMP is synthesized by multiple diguanylate cyclases (DGCs) and degraded by phosphodiesterases (PDEs) (Figure 6). The presence of multiple DGCs and PDEs offers bacteria a great degree of flexibility to modulate their intracellular c-di-GMP content under different environmental conditions. c-di-GMP regulates gene expression via c-di-GMP effector proteins (e.g., PilZ domain protein) and c-di-GMP-I riboswitches, which change conformation drastically upon binding to c-di-GMP. High intracellular content of c-di-GMP downregulates bacterial motility and upregulates the synthesis of EPS. In contrast, lowering the intracellular c-di-GMP content facilitates bacterial motility and causes biofilm dispersal. In *Salmonella*, the expression of curli fimbriae and the major exopolysaccharide cellulose is enhanced by high intracellular c-di-GMP. The thin aggregative fimbriae and cellulose were shown to enhance the resistance of *Salmonella* to desiccation and prolong the survival of *Salmonella* colonies on plastic surfaces for several months even without the supply of exogenous nutrients. c-di-GMP positively regulates the production of exopolysaccharide by *V. vulnificus*, which contributes to its biofilm formation.

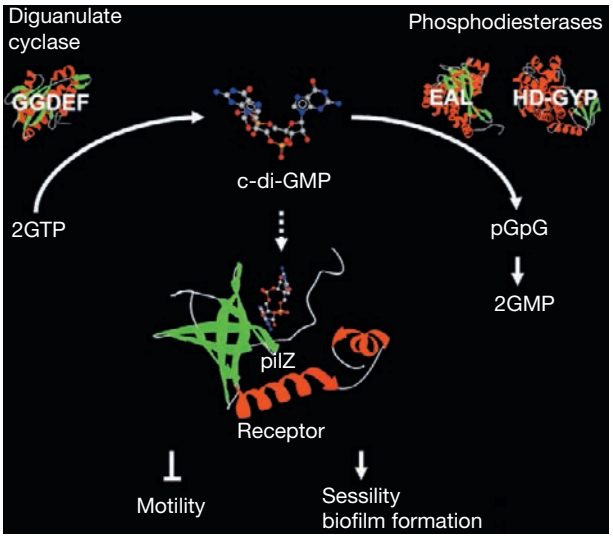

Figure 6 Schematic of c-di-GMP-mediated signaling in bacteria.

Microbial Ecology of Biofilms

Differentiation in Biofilms

Physiological heterogeneity within the biofilm is a main distinguishing factor between the metabolism of biofilm cells and planktonic cells. The EPS fixes bacterial cells in their respective positions, and through their metabolic activities and diffusional processes within the EPS, steep concentration gradients of nutrients, signaling compounds, and bacterial waste are generated within the biofilm. The biofilm cells then differentiate via a spatially patterned gene expression as a response to these gradients, resulting in a wide range of physiological states. For example, cells located at the surface of biofilms are generally fast-growing and behave more closely to planktonic cells, as they have first access to nutrients and oxygen in the medium. In contrast, cells deep within biofilms exhibit slow growth rates and anaerobic respiration due to lack of nutrients. This self-generated diversity acts as a kind of insurance to survival upon attacks that differ mechanistically and increase the overall robustness of the biofilm.

Biofilm growth also drives the production and evolution of genetic variants within bacterial strains. For example, strain variation in colony morphology; swimming and swarming; production of pigments, surfactants, and exopolysaccharides; nutritional requirements; and other phenotypes are commonly found in biofilms but not in planktonic cultures. Endogenous oxidative stress that specifically occurs in biofilms damages cellular DNA and causes double-stranded DNA breaks. These breaks are then repaired by a mutagenic mechanism involving recombinatorial DNA repair genes, including the RecA protein, to generate the genetic variants in biofilms. The emergence of such variants is increasingly being recognized as an important strategy for niche specialization and stress tolerance (see section '**Development of Persister Cells**').

Interspecies Interactions in Biofilms

Biofilms in the natural environment are complex and often consist of multiple microbial species. Microbial cells in the

mixed biofilms interact with each other extensively through metabolite cross-feeding, cross talk of signaling molecules, cross-linking of matrix components, and horizontal gene transfer (Figure 7). These interactions further shape the structures and functions of microbial communities.

Cross-linking of different matrix components is important for coaggregation, a process where different bacterial species attach to one another via specific EPS molecules and receptors. Coaggregation can greatly accelerate the formation of multispecies biofilms and is most well studied in the dental plaque of the human oral cavity using the sequential colonization model. In this model, the primary colonizers, such as *Streptococcus gordonii*, colonize the pellicles on the tooth surface within a short period. The major periodontal pathogen *Porphyromonas gingivalis*, which is a secondary colonizer, can coaggregate with the primary colonizer *Streptococcus gordonii* by binding the streptococcal SspB protein via its fimbrial FimA protein and Mfa1 protein. The secondary colonizer then coaggregates with *Fusobacterium nucleatum*, an essential bridging organism that can coaggregate with many other oral organisms and integrate them into the dental plaque.

It is well known that microorganisms not only communicate with members of the same species but also respond to signal molecules produced by other species to modulate their behavior. The colocalization of different microbial species within multispecies biofilms makes it easy for signaling molecules produced from one bacterial species to diffuse into another bacterial species. Some of these signals are recognized and generate a response, known as cross talk, further shaping the structure and functions of the biofilm community. For example, long-chain AHLs can antagonize the C4-HSL-dependent quorum sensing system in *A. hydrophila*, a Gram-negative, aquatic bacterium that not only mainly affects fish but also can cause gastroenteritis in humans. Interference with quorum-sensing regulation during biofilm formation by foodborne pathogens might open new research avenues toward the current efforts to eliminate these food processing-associated biofilms.

The formation of multispecies biofilms might have important ecological impacts on food safety and human health. For example, the mixed-species biofilms formed by Shiga toxin-producing *E. coli* and *Salmonella enterica* serovar Typhimurium were found to be more resistant to sanitization due to sharing of EPS components. Additionally, environmental bacterial species isolated from fresh produce processing facilities were found to incorporate *E. coli* O157:H7 into their biofilms and increase the survival potential of this bacterium. Mixed-species biofilms of *L. monocytogenes* and *Pseudomonas putida* have greater resistance *to* the disinfectant benzalkonium chloride than *Pseudomonas putida* biofilms alone. Understanding of the interspecies interactions during multispecies biofilm formation and how to prevent them might present a novel antibiofilm strategy for the food industry.

Resistance Mechanisms of Biofilms

Reduction of Penetration by EPS

The protection of microbial cells by EPS is one of the most evident causes of enhanced resistance of biofilms to antimicrobial agents. The high density of the EPS together with its binding properties to toxic compounds results in an effective barrier that is able to dramatically reduce the penetration of antimicrobial agents in deeper parts of the biofilm such as the microcolonies (Figure 8). Thus, the remaining microbial cells can thrive once the antimicrobial treatment is ceased. For example, alginate is able to block the diffusion of gentamicin and tobramycin antibiotics into *Pseudomonas aeruginosa* biofilms, and the diffusion efficiency can be improved after treating the biofilms with alginate lyase. Disruption of eDNA in the matrix, which is able to bind to cationic antimicrobials, was shown via the addition of DNase to the biofilm to enhance the efficiency of antimicrobial treatments.

Alteration of Microenvironment

The thick EPS not only reduces the penetration of antimicrobial agents but also generates antimicrobial-tolerant microenvironment within the biofilms together with microbial cells. Microbial cells are able to secrete enzymes to the surrounding environment under stress conditions, and the EPS can serve as a structure scaffold to hold these enzymes. Typical extracellular enzymes found in the biofilm EPS include catalase, which protect biofilm cells against reactive oxygen species, and β-lactamases, which protect biofilm cells against β-lactam class antibiotics.

Induction of Stress Responses

Biofilm cells have different physiology compared with free-living cells. The slow nutrition penetration and accumulation of waste products within the biofilm matrix can lead to physiological differentiation of biofilm cells and induction of stress response. For example, the sigma factor RpoS, which is normally expressed in stationary-phase cells, was found to be required for biofilm formation by *E. coli*. RpoS was reported to play a role in conferring peroxide resistance in *E. coli* serotype O157:H7 biofilms. Endogenous oxidative stress is able to cause double-stranded DNA breaks for cells in some part of biofilms, and recombinatorial DNA repair can lead to population diversity in biofilms. *L. monocytogenes* biofilms have been shown to accumulate superoxide and hydroxyl radicals, resulting in DNA damage and induction of the DNA repair system and SOS response via the RecA protein for the generation of genetic variants (see section '**Differentiation in Biofilms**').

Development of Persister Cells

Antibiotic stress can lead to the generation of dormant variants that are highly tolerant to antibiotics, known as persisters. Exposure of *E. coli* to DNA-damaging antimicrobial agents can trigger the expression of the *tisB* gene that encodes a small membrane-acting peptide. The synthesis of the TisB peptide can decrease proton-motive force and ATP levels, thus shutting down cell metabolism and inducing the cell to enter a dormant, nondividing state. Antibiotics that are able to kill nongrowing, stationary cells are rare, and none are effective against persisters. After antibiotic stress has been removed, persisters regain their active, dividing state and repopulate the biofilm. It has been estimated that persister cells are present at

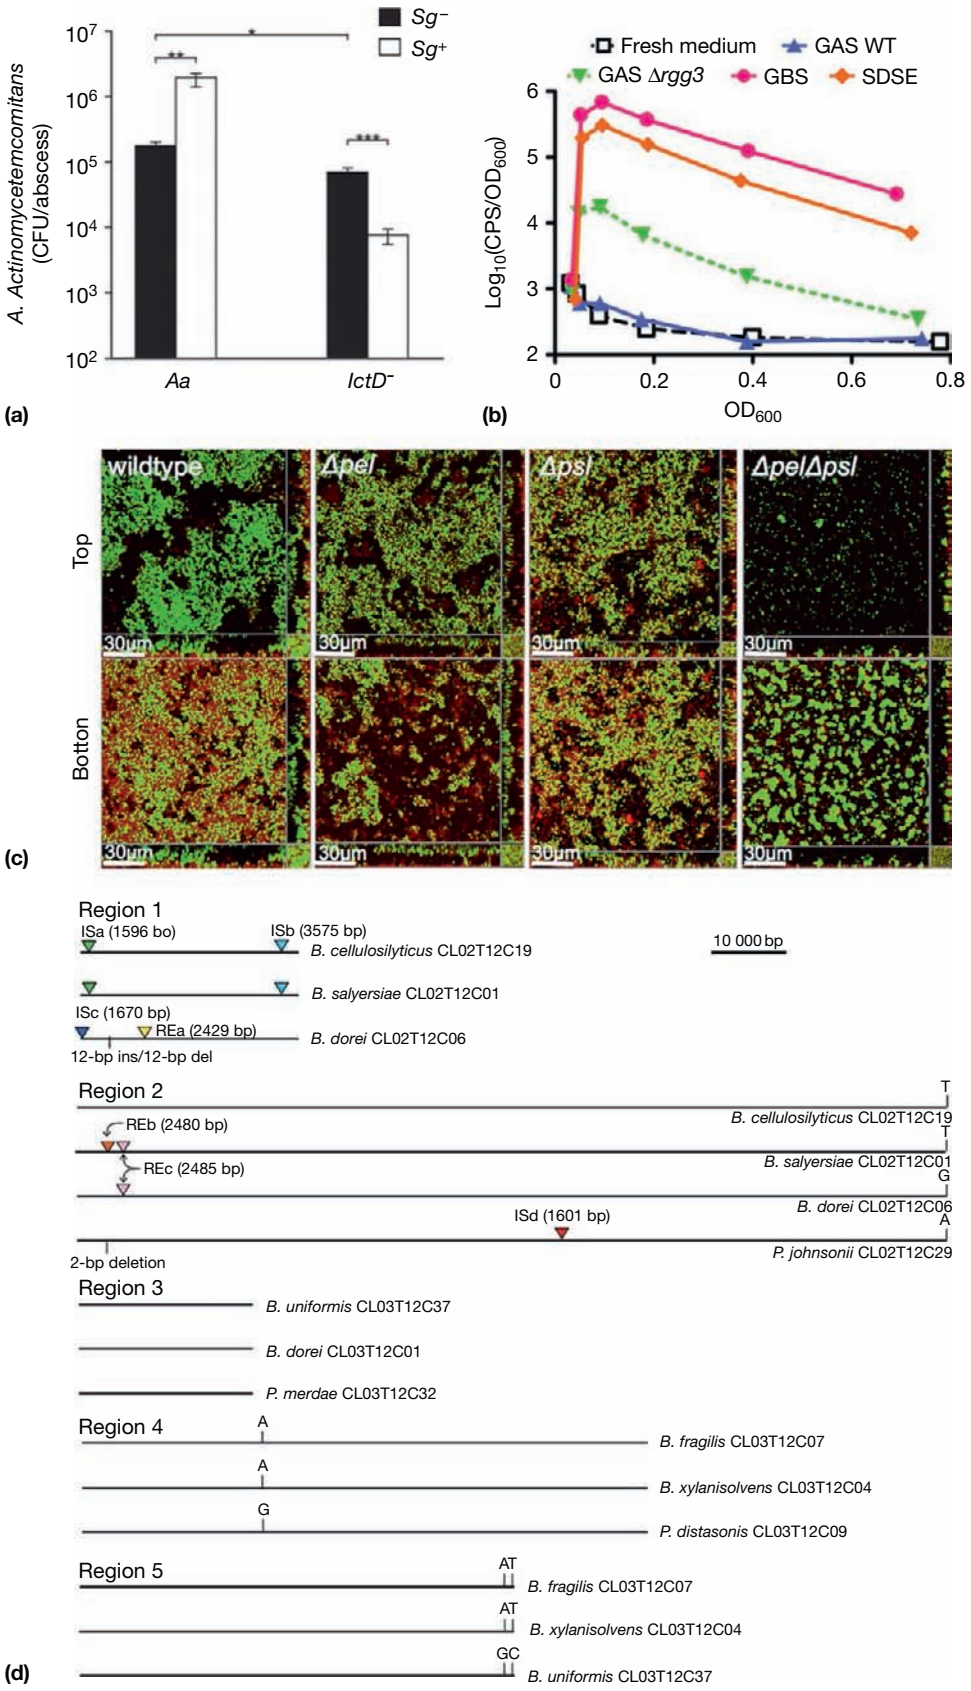

Figure 7 *(Continued)*

0.1–1.0% in the biofilms of *Pseudomonas aeruginosa*, *E. coli*, and *Staphylococcus aureus* (Figure 8).

Biofilm Control Strategies

Conventional Approaches for Biofilm Eradication

A lot of research effort has been focussed on the control and eradication of biofilms that grow in unwanted places and are detrimental to industrial and public health systems. The most efficient approach for biofilm control is to prevent the attachment of bacterial cells to surfaces. Various strategies have been developed for inhibiting microbial attachment. Engineered surfaces with certain physical properties such as special micropatterned topography and surface roughness were shown to reduce microbial attachment. Moreover, chemically modified surfaces with microbicidal capacity and antimicrobial drug-releasing capacity were shown to maintain their antimicrobial attachment properties for long periods of time.

Conventional physical and chemical approaches using cleaning and disinfection procedures have been extensively used over the years to remove biofilm-contaminated surfaces.

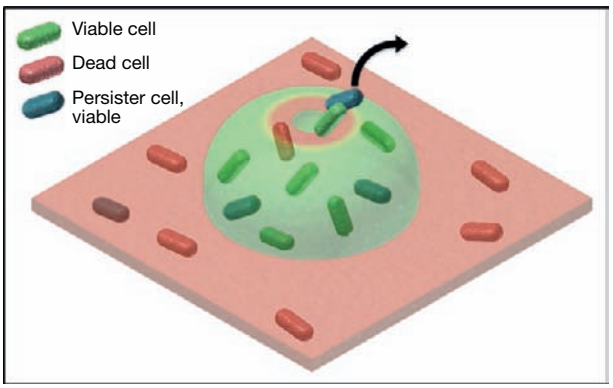

Figure 8 EPS reduce access of antimicrobial compounds and host responses into the biofilm, and cells deep within the microcolonies remain viable. Red shading indicates areas with increased cell death and green shading indicates areas with increased cell viability. Stress from antimicrobials can induce dispersal in biofilms, causing the remaining live and persister cells to leave the microcolony and colonize other surfaces. Persister cells in the thin undifferentiated areas of the biofilm remain viable.

The cleaning procedures are able to remove the thick biofilm EPS via chemical reactions through alkali-based and acid-based agents in combination with mechanical forces (such as flushing and scrubbing). Proper cleaning can significantly disrupt the biofilm EPS and lead to more efficient penetration of disinfectants into the biofilm and increased killing of microbial cells. Conventional disinfectants include ethanol, chlorine dioxide, hydrogen peroxide, and antibiotics. While these chemicals are able to control biofilms to a certain extent, they leave out the possibility of chemical contamination and development of resistant populations. Thus, there is a need for the development of the next generation of biofilm control strategies.

Next-Generation Approaches for Biofilm Eradication

Targeting the microbial quorum sensing and c-di-GMP signaling systems are two promising approaches for biofilm control. These two strategies do not pose a strong selective pressure to raise resistant mutants since they are not based on direct microbial cell killing. Quorum sensing regulates the secretion of antibiotic-inactivating enzymes into the biofilm matrix and cell migration. Small molecules that can interfere quorum sensing have been found from natural and synthetic libraries and were termed as quorum sensing inhibitors. Quorum sensing inhibitors have been shown to be able to greatly impair the biofilm structure stability and resistance. Compounds that activate PDEs and degrade intracellular c-di-GMP have been reported. These compounds are able to cause dispersal of mature biofilms. In addition to quorum sensing inhibitors and c-di-GMP-reducing compounds, phages were also shown to be able to eradicate biofilms due to the fact that they can produce polysaccharide depolymerase enzymes that can specifically degrade the exopolysaccharide of biofilms and cause cell lysis.

Conclusion

Biofilm formation is an important adaptation and survival strategy commonly employed by bacteria. Bacteria in the biofilm are protected from adverse environmental factors and immune response by the EPS. Chemical gradients generated throughout the biofilm enable bacteria to exist in a wide range of physiological states, thereby providing insurance effects in

Figure 7 **(Continued)** (a) Example of metabolite cross-feeding. changing environments. Biofilms can be composed of multiple species that interact with each other.

Microscopic techniques such as CLSM in combination with fluorescent tagging and staining are commonly employed in biofilm research for the visualization and understanding of biofilm physiology. In mixed-species biofilms, FISH and sequencing technologies such as metagenomics and metatranscriptomics are used to study phylogenetic groupings, synergy, and competition among members of the biofilm.

Biofilm formation is regulated by intercellular quorum sensing signaling and intracellular c-di-GMP signaling. New methods for biofilm control are being developed based on interfering these two signaling mechanisms. The employment of novel biofilm control methods is believed to improve the effects of antibiotics and disinfectants, which are often ineffective against biofilm and may also generate drug resistance in bacteria.

Biogenic Amines

M Nuñez, A del Olmo, and J Calzada, Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA), Madrid, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Biogenic amines (BAs) are naturally occurring organic compounds, formed and degraded through the normal or physiological metabolism of microorganisms, plants, and animals, which possess biological activity. Their molecular weight is close to or less than 200 Da. They are basic nitrogenous heat stable compounds, primarily formed by decarboxylation of amino acids or by amination and transamination of aldehydes and ketones. All BAs are invested with some specific physiological roles in live organisms, but their excessive production or intake can induce adverse reactions. The name of most BAs is assigned depending on the name of the precursor amino acid. Based on the number of amine groups, BAs can be classified into monoamines, diamines, and polyamines, and according to the chemical structure into aliphatic, aromatic, and heterocyclic amines (Table 1). Traditionally, the term BAs includes amines that can arise from direct decarboxylation of amino acids such as histamine, tyramine, tryptamine, agmatine, cadaverine, putrescine (which can also derive from agmatine by hydrolase activity), and phenylethylamine. Other BAs such as spermine, spermidine, serotonin, octopamine, dopamine, and norepinephrine require for their generation some condensation and/or hydroxylation reactions, while methylamine and ethylamine can come from direct amino acid decarboxylation but are primarily formed as metabolic and degradative products.

In foods and beverages, BAs can be generated by the enzymatic activity on proteins and amino acids of raw animal or vegetal tissues and by the amination of aldehydes and ketones, but their formation primarily occurs through microbial activity and decarboxylation of free amino acids. BAs most commonly found in foods are histamine, tyramine, tryptamine, cadaverine, putrescine, phenylethylamine, spermine, and spermidine. Other BAs have been reported, such as agmatine in fish, seafood, fermented meats, and fermented drinks; octopamine in meat and fish products; dopamine and serotonin in fish, meat, and fruits; norepinephrine in meat and fruits; and methylamine and ethylamine in wine and fish.

BAs in Organisms

BAs are compounds with biological activity that play specific physiological roles in prokaryotic and eukaryotic organisms, including bacteria, fungi, plants, and animals. They are also nitrogen sources and precursors for the synthesis of proteins, nucleic acids, alkaloids, and hormones.

In microorganisms, BAs are involved in the supply of energy through the generation of proton motive force, protection from acid, osmotic and oxidative stress, and DNA regulation. In some bacteria, the presence of decarboxylases responsible for BA generation has been considered a virulence factor. Bacteria able to produce histamine can cause tissue damage, facilitating the colonization and invasion of the host, while those able to produce tyramine such as *Escherichia coli* O157:H7 can enhance their adhesion to mucosa and colonization. They can act as essential precursors for siderophore biosynthesis in *Bordetella* sp and *Vibrio anguillarum*. In plants, BAs are implicated in physiological processes such as cell division and differentiation, flowering, fruit development, synthesis of nucleic acids and proteins, membrane stability, and response to stress and senescence, and may also play a defense role against insects and herbivores.

Histamine is generated from histidine by the enzyme histidine decarboxylase. In animals, it is produced and stored primarily in mast cells, basophils, eosinophils, enterochromoaffin-like gastric cells, and histaminergic neurons. Histamine is found in the brain, lungs, stomach, intestines, uterus, ureters, and muscles, and exerts its effects by binding to H-receptors (H1–H4). It acts as a neurotransmitter and local hormone, modulating gastric secretion, heart contractibility, cell growth, contraction of smooth muscle, circadian rhythm, body temperature, food intake, memory and cognition, immune response, and allergic and inflammatory reactions.

Tyramine derives from the enzymatic decarboxylation of tyrosine. In humans, it primarily arises from the diet and has been found in the brain, spinal cord, heart, kidney, liver, lungs, and spleen. It acts as a neurotransmitter and as a catecholamine-releasing agent, modulating peripheral vasoconstriction and cardiac output and increasing blood levels of glucose.

Tryptamine comes from enzymatic decarboxylation of tryptophan and has been primarily found in the brain, but also in the lungs, heart, intestines, liver, kidneys, and urine. It acts as a neurotransmitter and as a serotonin-releasing agent, modulating behavior and food intake.

Cadaverine and putrescine derive from the enzymatic decarboxylation of lysine and ornithine, respectively. Putrescine can additionally result from agmatine by ureohydrolase or iminohydrolase activities. They have been found at low levels in all the tissues and organs, including brain and gut and secretions such as urine and sperm, regulating gene expression, membrane stabilization, cell growth and differentiation, gut development, and maturation of newborns, while high levels are usually found in ulcerated, necrotic, and tumoral tissues.

Phenylethylamine comes from enzymatic decarboxylation of L-phenylalanine in nervous tissue and neurons. It has been found in the brain and spinal cord, and acts as a neurotransmitter and stimulant in the central nervous system, inducing the release of norepinephrine, dopamine, and serotonin and modulating cognition, behavior, and perception.

Spermine derives from spermidine, which comes from putrescine, by spermine synthase and spermidine synthase, respectively. They were first described in sperm, but are present in all the tissues of mammals. At low levels, they act as modulators of gene expression, cellular growth and differentiation, embryonic development, and cytokine-mediated inflammatory response. High levels have been found in tumoral tissues.

Table 1 Characteristics of biogenic amines found in foods, animals, plants, and microorganisms

Name (MW g mol^{-1})	*Molecular formula*	*Structural formula*	*Classification*	*Precursor amino acid*
Methylamine (31.06)	CH_5N		Monoamine aliphatic	Glycine
Ethylamine (45.08)	C_2H_7N		Monoamine aliphatic	Alanine
Phenylethylamine (121.18)	$C_8H_{11}N$		Monoamine aromatic	Phenylalanine
Tyramine (137.18)	$C_8H_{11}NO$		Monoamine aromatic	Tyrosine
Octopamine (153.18)	$C_8H_{11}NO_2$		Monoamine aromatic	Tyrosine
Dopamine (153.18)	$C_8H_{11}NO_2$		Monoamine aromatic	Tyrosine
Norepinephrine (169.18)	$C_8H_{11}NO_3$		Monoamine aromatic	Tyrosine
Histamine (111.15)	$C_5H_9N_3$		Monoamine heterocyclic	Histidine
Tryptamine (160.22)	$C_{10}H_{12}N_2O$		Monoamine heterocyclic	Tryptophane
Serotonin (176.22)	$C_{10}H_{12}N_2O$		Monoamine heterocyclic	Hydroxytryptophane
Putrescine (88.15)	$C_4H_{12}N_2$		Diamine aliphatic	Ornithine
Cadaverine (102.18)	$C_5H_{14}N_2$		Diamine aliphatic	Lysine
Agmatine (130.19)	$C_5H_{14}N_4$		Polyamine aliphatic	Arginine
Spermidine (145.25)	$C_7H_{19}N_3$		Polyamine aliphatic	Arginine Ornithine
Spermine (202.34)	$C_{10}H_{26}N_4$		Polyamine aliphatic	Arginine Ornithine

Agmatine comes from enzymatic decarboxylation of arginine. It has been found primarily in the gut but also in the spleen, lungs, and adrenal glands, and at lower levels in plasma, the heart, liver, kidneys, muscles, and the brain. It acts as a neurotransmitter and as a neuromodulator in mental disorders and stress, and exerts hypoglycemic and antinociceptive effects.

Serotonin comes from enzymatic decarboxylation of hydroxytriptophan. It is primarily found in the gut, especially in enterochromaffin cells, but also in the central nervous system and platelets. It acts as a neurotransmitter and modulates circadian rhythm, food intake, cognition, and behavior.

Dopamine derives from decarboxylation of L-DOPA, which comes from tyrosine or phenylalanine by hydroxylase activity in neuron medulla cells and adrenal glands, but it is also found in cardiovascular tissue, the pancreas, and the gut. It acts, by interaction with D-receptors (D1–D5) and other endogenous receptors, as a neurotransmitter and as a hormone, modulating cognitive and motor functions, memory, nausea, and vomiting, inhibiting prolactin secretion, and decreasing food intake. It is the precursor of epinephrine and norepinephrine.

Norepinephrine (or noradrenaline) comes from dopamine by dopamine-β-hydroxylase activity. It is produced and stored in the secretory granules of chromaffin cells of the adrenal medulla and postganglionic neurons, and can be liberated into the blood system and distributed to all tissues in response to alert or stress situations. It acts as a neurotransmitter and as a hormone, and interacts with adrenergic receptors, exerting a sympathomimetic effect inducing vasoconstriction and hyperglycemia and enhancing attention and concentration.

Octopamine comes from degradation and hydroxylation of tyramine. In invertebrates it is equivalent to dopamine, while in vertebrates it is found in nervous tissue and the brain, exerting stimulant effects, mobilizing fat from adipose deposits, and increasing blood pressure.

Methylamine and ethylamine are hydrosoluble volatile BAs, which primarily arise from the metabolism and degradation of products. In animals, they are rapidly eliminated by urine and excretions.

BAs in Foods

As described, BAs are bioactive endogenous compounds naturally present at low levels in raw vegetal or animal tissues. They can be generated by the endogenous enzymatic activity on proteins and amino acids of vegetal and animal tissues, and by chemical amination of aldehydes and ketones in foods, but they are usually associated with microbial decarboxylation of free amino acids. In foods, this process requires the presence of decarboxylase-positive microorganisms, the availability of amino acids, and the existence of conditions (pH, water activity, nutrients, temperature, and redox potential) that allow microbial growth and decarboxylase activity. Practically all foods contain proteins or amino acids and therefore may contain BAs. Their presence has been reported in a wide range of products, including meat, fish, vegetables, fruits, milk and its derivatives, nuts, chocolate, and fermented beverages, some of them at high concentrations (Table 2). The different BA levels greatly depend on the foodstuff, the manufacturing and storage conditions, and even the size and part of the product since BAs are heterogeneously distributed in the food matrix.

In raw-fresh products BAs are usually present at low levels and come from endogenous origin, while in processed and/or stored products they are generated by microbial decarboxylation of amino acids during fermentation and/or spoilage processes. In nonfermented foods BAs are produced during growth of spoilage bacteria, and their presence above certain levels is considered indicative of alteration. However, the concentration of BAs in food does not always necessarily correlate with the counts of spoilage organisms, because they are not all decarboxylase-positive. Moreover, a food product can contain high levels of BAs without showing evident signs of alteration. In fermented foods, the generation of BAs is associated with the growth and metabolism of lactic acid bacteria during the fermentation and/or ripening stages characteristic of these products.

The presence of microbial strains able to decarboxylate free amino acids is essential for the formation of BAs in foods. This capacity has been described in many different genera, species, and strains of Gram-positive and Gram-negative bacteria. Microbial capability of BA production seems to be strain dependent rather than genus- or species-specific. Different genes encoding for decarboxylating enzymes have been identified. These genes may be located on the bacterial chromosome or on plasmids, and can be transferred not only vertically but also horizontally between bacteria.

Foods represent an exogenous source of BAs, which are involved in many physiological functions in animals. But the intake of foods with high levels of BAs can induce toxic or adverse effects such as pseudoallergic reactions and gastrointestinal and vascular or hemodynamic disorders. Even neurological disturbances have been described for tyramine, phenylethylamine, serotonin, dopamine, and norepinephrine, while carcinogenic effects have been associated with cadaverine and putrescine, and cytotoxic effects with spermine and spermidine. Besides this, some BAs such as cadaverine, putrescine, spermine, and spermidine can react with nitrites during processing, storage, and cooking of foods, yielding N-nitrosamines that can act as mutagenic and carcinogenic agents.

Fish and Seafood

Fish and seafood products are among the foods with the highest BA concentrations, usually histamine. Indeed, histamine poisoning or histaminosis associated with fish consumption is also known as scombrotoxicosis. Fish such as tuna, bonito, sardine, anchovies, swordfish, and mackerel, belonging to the *Scombridae*, *Scomberesocidae*, *Clupeidae*, *Engraulidae*, *Coryphaenidae*, and *Pomatomidae* families, are the species most commonly associated with incidents of histamine intoxication. Other nonscombroid species including salmon, amberjack, and cape yellowtail can be also implicated. This is probably due to their high content of endogenous histidine, primarily in dark muscle, and to the capability of marine bacteria, in particular Gram-negative species, of exerting their decarboxylase activity even at low temperatures. The main microorganisms associated with the generation of histamine and other BAs in fish and seafood products are spoilage Gram-negative bacteria belonging to the genera *Citrobacter*, *Klebsiella*, *Escherichia*, *Proteus*, *Salmonella*,

Shigella, *Vibrio*, *Morganella*, *Hafnia*, *Serratia*, *Enterobacter*, *Aeromonas*, *Pseudomonas*, and *Photobacterium*. Storage under inadequate conditions, due to temperature abuse and cold chain break, is considered the major cause of scombroid poisoning.

Besides histamine, other major BAs such as putrescine, cadaverine, tyramine, tryptamine, spermine, spermidine, and agmatine have been detected in fish and seafood products. The amine index $[(\text{putrescine}+\text{cadaverine}+\text{histamine})/(\text{putrescine}+\text{cadaverine}+\text{histamine}+\text{tyramine}+\text{tryptamine}+\text{methylamine}+\text{spermine}+\text{spermidine})]\times 100$ has been proposed as a quality indicator that must be lower than 25. For canned tuna, the chemical index $[(\text{putrescine}+\text{cadaverine}+\text{histamine})/(1+\text{spermidine}+\text{spermine})]$ has been proposed as a quality indicator that must be lower than 1. Minor BAs in fish and fish products include octopamine, dopamine, noradrenalin, serotonin, ethylamine, and methylamine, for which respective levels up to 130, 201, 131, 12, 339, and 195 mg kg^{-1} have been reported. Levels of other amines such as dimethylamine and trimethylamine have been proposed as indicators of frozen storage deterioration and fish freshness, respectively.

In shellfish, cephalopods, crustaceans, and bivalves, BAs different from those described for fish have been found, usually at lower levels due to the fact that these products are more prone to spoilage and evident alterations, which result in rejection by the consumer.

Milk and Dairy Products

In milk, low levels of some BAs such as spermine, spermidine, and putrescine, probably from endogenous origin, are usually found. In cheese and other fermented or ripened dairy products such as kefir or kumis, high levels of BAs can be found, while buttermilk and yogurt do not usually contain significant

levels. The microorganisms associated with the generation of BAs in cheese are Gram-positive bacteria, in particular lactic acid bacteria such as *Lactobacillus*, *Enterococcus*, *Carnobacterium*, *Pediococcus*, *Lactoccus*, *Leuconostoc*, and *Oenococcus*, but also *Clostridium* and *Bacillus*. Yeasts such as *Debaryomyces*, *Candida*, *Yarrowia*, and *Pichia*, and molds such as *Geotrichum* and *Penicillium*, are also able to produce BAs.

After fish, cheese is the product most commonly implicated in outbreaks of histamine poisoning. Cheese represents an ideal matrix for BA generation because of its diverse microbiota and the intense casein degradation that occurs in many varieties. High levels of tyramine, above 1000 mg kg^{-1}, and histamine can be reached, especially in aged cheeses made from raw milk. Tyramine poisoning associated with cheese consumption is known as the 'cheese reaction,' with symptoms such as headache and hypertensive crisis. It was first described in a patient treated with monoamine oxidase (MAO) inhibitors for depression.

Other BAs such as putrescine, cadaverine, phenylethylamine, and tryptamine, and to a lesser extent spermine, spermidine, and agmatine, have also been found in cheese. Their levels greatly differ between cheese varieties, manufacturing processes, and even sections of the cheese. Milk pasteurization and hygiene tend to lower the accumulation of BAs in cheese. On the contrary, the addition of proteolytic enzymes to accelerate cheese ripening may enhance BA formation. The type of starter culture used for cheese manufacture also influences the generation of BAs in cheese.

Meat and Meat Products

Fresh meat usually contains some endogenous levels of spermine, spermidine, putrescine, cadaverine, tyramine, histamine, agmatine, and noradrenaline. During processing and storage, high concentrations of tyramine, cadaverine, putrescine, and histamine can be formed due to fresh meat spoilage bacteria. The sum of cadaverine and putrescine levels has been proposed as an index of freshness or acceptability of the product, which must be under 20 mg kg^{-1}. Microorganisms associated with BA generation in meat and noncured meat products are mostly Gram-positive bacteria of the genera *Lactobacillus*, *Carnobacterium*, *Enterococcus*, and *Brochothrix*, but also Gram-negative bacteria of the genera *Pseudomonas*, *Serratia*, *Enterobacter*, *Citrobacter*, *Hafnia*, *Proteus*, and *Rahnella*.

In fermented or ripened meat products, large amounts of BAs, especially tyramine, cadaverine, and putrescine, can be formed due to microbial activity. The microorganisms associated with BA generation in these products have been reported as lactic acid bacteria including *Lactobacillus*, *Carnobacterium*, *Pediococcus*, *Lactoccus*, *Leuconostoc*, and *Oenococcus*; other Gram-positive bacteria such as *Clostridium and Bacillus;* and Gram-negative bacteria such as *Pseudomonas*, *Citrobacter*, *Enterobacter*, *Serratia*, *Morganella*, *Escherichia*, and *Klebsiella*. Yeasts including *Debaryomyces*, *Candida*, *Yarrowia*, and *Pichia*, and molds such as *Geotrichum* and *Penicillium* are also able to produce BAs. In cured-brined meat products, strains of *Micrococcus* and *Staphylococcus* may also be implicated. The sum of tyramine, histamine, tryptamine, and phenylethylamine has been proposed as an indicator of hygienic conditions and good manufacturing practices in the production of fermented-ripened sausages, in which it should not exceed 200 mg kg^{-1}. In fermented dry-cured products, the sum of putrescine, cadaverine, histamine, and tyramine has been suggested as a quality index that must be lower than 500 mg kg^{-1}.

Other BAs have been described in meat and its derivatives, including agmatine, at levels up to 43 mg kg^{-1}, and octopamine, serotonin, and dopamine, which usually appear at very low concentrations, close to 1 mg kg^{-1}.

Fermented Drinks

Fermented alcoholic beverages, including wine, beer, and cider, can contain significant amounts of BAs, although generally at lower levels than in fish, cheese, and meat products. However, because ethanol is an inhibitor of MAO and interferes with BA detoxification, they may represent a considerable risk for consumer health.

The most abundant BAs in these products are histamine, tyramine, and putrescine, and to a lesser extent phenylethylamine and cadaverine, but also agmatine, methylamine, and ethylamine. These compounds are considered to arise from lactic acid bacteria metabolism, especially during malolactic fermentation, while yeasts (*Debaryomyces*, *Candida*, *Yarrowia*, *Saccharomyces*, *Kloeckera*, *Metschnikowia*, *Brettanomyces*, and *Pichia*) and molds (*Geotrichum* and *Penicillium*) have a lesser influence, although some BAs have been found in grapes and malt.

BA levels can greatly increase during aging and storage of fermented alcoholic beverages. Higher levels have been generally found in red wine, sherry-type wine, and beer than in white wine, rosé wine, cider, or fruit-based wines such as apple, cherry, plum, peach, or pear wines. In aged wines, putrescine levels have been suggested to indicate poor hygiene or inadequate storage conditions. In rice- or cereal-based wines, amounts of BAs higher than 100 mg l^{-1} have been detected, probably due to the intense proteolytic and fermentative steps during their manufacture.

Vinegar is obtained from alcoholic beverages through the conversion of ethanol into acetic acid by bacteria, and therefore it can also contain BAs, although usually at lower levels than in wines. The common BAs in vinegar are histamine and putrescine, and to a lesser extent spermidine, spermine, and agmatine, followed by tyramine. Higher levels of BAs have been reported for balsamic and sherry vinegars than for red wine, white wine, or apple wine vinegars.

Fruits and Vegetables

Low concentrations of different BAs are naturally present in fruits and vegetables as endogenous compounds, metabolites, and intermediates. During processing and storage of fruits and vegetables, BAs can be generated from the enzymatic activity of raw tissues and from microbial activity. The common microorganisms associated with BA generation in fruit and vegetables are Gram-negative spoilage genera such as *Pseudomonas*, *Aeromonas*, *Stenotrophomonas*, *Enterobacter*, *Hafnia*, *Salmonella*, *Escherichia*, *Klebsiella*, *Serratia*, *Morganella*, *Rahnella*, and *Pantoea*. Overall, the main BAs in these products are phenylethylamine, tyramine, tryptamine, putrescine, and cadaverine. Other BAs have been found at high levels, including histamine in tomatoes

and spinach or noradrenaline in plums and orange juice. High amounts of noradrenaline and dopamine have also been reported in bananas. Phenylethylamine may be present at high levels in mushrooms, cocoa, and derivatives such as chocolate. Serotonin concentrations up to 400 mg kg^{-1} have been found in butternuts and up to 36 and 170 mg kg^{-1} in banana pulp and peel, respectively, and high levels have also been reported in roasted coffee grains. Pyrrolidine, a cyclic secondary amine, may accumulate in pepper and soya, while some algae have been found to contain high amounts of histamine, cadaverine, and dopamine.

Fermented vegetable products including sauerkraut, fermented soybean, and kimchee can contain putrescine, histamine, tyramine, and cadaverine at high levels due to the growth and metabolism of their typical microbiota during the fermentation stage of manufacture. Microorganisms associated with the generation of BAs in these products include lactic acid bacteria such as *Lactobacillus*, *Enterococcus*, *Carnobacterium*, *Pediococcus*, *Lactoccus*, *Leuconostoc*, and *Oenococcus*, and some genera of yeasts and molds.

Eggs and Derivatives

Tyramine, cadaverine, and putrescine have been reported in eggs and their derivatives, but generally at low levels. The primary BA formers in eggs are *Enterobacteriaceae* such as *Escherichia*, *Salmonella*, *Shigella*, *Enterobacter*, and *Proteus*, but strains of *Achromobacter*, *Lactobacillus*, *Leuconostoc*, *Pseudomonas*, *Pediococcus*, *Streptococcus*, *Propionibacterium*, and *Clostridium* can also be implicated. Eggs and derivatives are prone to spoilage, which usually results in rejection by the consumer before high amounts of BAs can be formed. These products are more frequently involved in foodborne diseases related to the presence of pathogens such as *Salmonella* than in adverse reactions or intoxications due to BAs.

Legal Limits of BAs in Foods

The incidence of BAs in virtually all foods has been reported worldwide. In spite of these compounds being present at high levels in foodstuffs and beverages (Table 2), specific legislation concerning the maximum allowed concentration of BAs in the different products is still lacking.

According to the European Food Safety Authority (EFSA), by taking into consideration not only the potential BA levels in foods but also the average daily intake of the different products, the highest exposure values for histamine correspond to fish, followed by cheese and fermented sausages; for tyramine to beer and cheese, followed by fermented fish and fermented meat products; for putrescine to fermented vegetable products, fruits, and juices, followed by fermented sausages, meat products, and cheese; and for cadaverine to cheese, followed by fish and fish products. For phenylethylamine the highest exposure values correspond to fermented sausages and cheese; for tryptamine to cheese, fish, and fermented sausages; for agmatine to fermented foods and beverages; and for spermine and spermidine to meat products, followed by fish, cheese, and vegetables.

The most frequent events of BA intoxication have been reported in Japan, the United States, and the United Kingdom, but very likely many cases in other countries have occurred without being detected or officially reported. Foodborne outbreaks associated with BAs are generally underreported because of the usually mild nature of disturbances, confusion with allergic reactions, and misdiagnoses. On this basis, it is very difficult to establish safety levels or legal limits.

The most studied BA in foods and the only one with established legal limits for human consumption is histamine, and to a lesser extent tyramine. Histamine poisoning associated with fish consumption has been frequently reported in the United States, Canada, Japan, the United Kingdom, and other countries, while histamine poisoning associated with cheese consumption has been widely reported in the Netherlands, the United States, France, and Canada. The European Union established legal limits for histamine below 100 mg kg^{-1} for raw fish and below 200 mg kg^{-1} for cured or brined fish belonging to the *Scombridae* and *Clupeidae* families, while a more stringent level of 50 mg kg^{-1} was adopted in the United States. In wine, the European Union established legal limits for histamine, which range from 2 to 10 mg l^{-1} depending on the regulations of the different countries. In meat products, a recommended upper limit of 100–200 mg kg^{-1} for histamine was proposed in the Netherlands and the Czech Republic, and an upper limit of 100 mg kg^{-1} for total BAs in some other countries.

Overall, histamine levels above 500 mg kg^{-1} or tyramine levels above 1000 mg kg^{-1} are considered toxic and dangerous for human health. In susceptible or unhealthy adults and in children, these levels can be considerably lower. Although upper limits of 100–800 mg kg^{-1} for tyramine and 30 mg kg^{-1} for phenylethylamine have been proposed, no legal limits for most foods have been adopted. Information about human toxicity and safety levels for the rest of BAs remain scant.

Analytical Methods for BAs in Foods

In the United States, the official method for analyzing histamine in foods is the Association of Official Agricultural Chemists (AOAC) procedure, which requires homogenization of the food sample in methanol, filtration, separation by anion exchange chromatography, derivatization with *o*-phthalaldehyde, and spectrophotometric determination. In the European Union, the high-performance liquid chromatography (HPLC) technique is the official method for the quantification of BAs.

The main problem for the determination of BAs in foods is the presence of potentially interfering compounds due to the complexity of sample matrices. Samples usually require extraction with solvents or reagents or solid-phase methods, followed by derivatization steps. BAs are of many different chemical structures, and their concentrations in foods greatly vary. Analytical procedures for the separation, identification, and quantification of BAs in foodstuffs include

- HPLC after derivatization of the sample, and determination by fluorescence, ultraviolet (UV), or electrochemical detectors – this analytical technique is the most widely used for BA quantification

- Gas chromatography (GC) coupled to electrical conductivity, flame ionization, or electron capture detectors
- Capillary electrophoresis or capillary isotachophoresis systems, coupled to a UV detector or a mass spectrometry (MS) system
- Thin-layer chromatography (TLC) and visualization under UV light
- Fluorometric methods based on the fluorescence of BAs at certain pH and/or on their interaction with reagents yielding fluorescence derivatives, such as *o*-phthalaldehyde and β-naphthol
- Enzymatic methods including radioimmunoassays, enzyme-linked immunosorbent assay system (ELISA), and biosensors based on enzymatic reactions between enzymes such as MAO and BAs, followed by detection by electrochemical or spectrophotometric devices

Indirect methods, based on the detection of the producer microorganisms instead of the direct determination of BAs themselves, include

- Detection of producer microorganisms, by growth and screening for decarboxylase-positive strains on differential agars
- Detection of microbial genes encoding for decarboxylating enzymes, by conventional PCR (polymerase chain reaction) techniques or real-time quantitative PCR (q-PCR) techniques

Methods for the Control of BAs in Foods

As described, the generation and accumulation of BAs in foods require the presence of decarboxylase-positive microbiota that can exert their activity on free amino acids or protein substrates. In this context, the simplest methods for the control of BA production in foods are based on the reduction or inhibition of microbial growth during processing and storage, which can be achieved by regulating the environmental conditions that affect microbial growth and metabolism such as temperature, pH, and salt concentration, together with the selection of high hygienic quality raw materials and the use of good manufacturing practices. The addition of antimicrobial compounds or preservatives including sulphites, nitrites, sorbates, phosphates, and organic acids such as citric, malic, and succinic acid, can also reduce microbial growth and retard BA accumulation. Some spices and natural substances have been described to inhibit BA formation. Examples are curcumin, capsaicin, piperine, thymol, ginger, garlic, green onion, red pepper, clove, and cinnamon, and some easily fermentable carbohydrates such as glucose and sucrose at concentrations above 3%.

The control of redox potential in foods can be achieved by packaging technologies including vacuum packaging or modified atmosphere packaging (MAP), which inhibit or reduce microbial growth. The use of active packaging, which in addition to providing the food with a protective physical barrier releases substances with antimicrobial properties (chitosan, polypeptides, essential oils, and bacteriocins), is gaining ground for controlling microbial growth and metabolism, and subsequently for preventing the accumulation of BAs. Edible active packaging materials have been designed for specific foodstuffs and purposes. Intelligent packaging systems that provide the user with information on the storage conditions of the food contribute to controlling the risks associated with the accumulation of BAs.

In fermented foods, the typical lactic acid bacteria are primarily responsible for BA generation. Addition of either starter cultures selected on the basis of their decarboxylase-negative traits or strains from which the decarboxylase activity potential has been eliminated constitutes an advantageous straightforward procedure for the manufacture of safe fermented products. Decarboxylase-negative strains of *Lactobacillus sakei*, *Staphylococcus xylosus*, *Staphylococcus carnosus*, and *Pediococcus pentosaceous* allow the fermentation and ripening of meat and vegetable products without generating BAs.

Another interesting approach is the inoculation of foods or beverages with microorganisms able to degrade BAs. Some strains of *Brevibacterium linens*, *Micrococcus varians*, *Virgibacillus* sp, *Lactobacillus curvatus*, *Staphylococcus xylosus*, and *Arthrobacter crystallopoietes* possess enzymes capable of oxidizing and degrading BAs. Further research is still required for their application in foods and beverages with satisfactory results.

Conventional thermal methods such as pasteurization reduce the numbers of pathogenic and spoilage microorganisms, extending the shelf life of the product and retarding the generation of BAs. However, some foods and beverages cannot be submitted to thermal treatments due to the nutritional, sensory, and textural modifications induced by high temperatures. As an alternative, emerging technologies for food preservation are being investigated for the control of BAs in foodstuffs. Ionizing radiation, such as gamma rays, electron beams, and X-rays, achieve microbial inactivation in foods, reduction of BA production, and, potentially, they could also induce the radiolytic degradation of BAs in a dose-dependent manner. Irradiation at 5, 10, and 15 kGy has been shown to breakdown putrescine, spermidine, and histamine, respectively, in distilled water. However, other reports indicate that the irradiation of foods such as pepperoni and ham could increase the formation of BAs such as phenylethylamine, spermidine, cadaverine, and tryptamine, probably due to the generation of free radicals and the alteration of proteins. High pressure processing (HPP) allows the inactivation of microorganisms by alteration of microbial cell morphology, structure, genetic material, and physiological functions, thus extending the shelf life of the product without impairing its quality attributes. Hydrostatic pressures above certain levels also inactivate enzymes, including microbial decarboxylases. The effects of HPP greatly depend on pressure level, time of treatment, moment of application, and type of food. Treatments at 200 MPa for 10 min reduced putrescine and cadaverine levels in meat batter; 350 MPa for 15 min reduced cadaverine, putrescine, and tyramine in fermented sausages; 400 MPa for 10 min reduced tyramine, putrescine, and cadaverine in frankfurters; and 600 MPa for 5 min reduced tyramine, putrescine, tryptamine, histamine, phenylethylamine, and cadaverine in raw ewe milk cheese and tyramine, putrescine, histamine, and cadaverine in raw cow milk cheese. In contrast, treatments at 50 MPa for 72 h greatly increased tyramine levels in goat milk cheese; 300 and 400 MPa for 15 min increased

tyramine levels in squid; and 600 MPa for 5 min increased putrescine, tryptamine, and phenylethylamine in blue-veined cheese, probably by inducing cell lysis and releasing non-inactivated decarboxylases into the medium.

Introduction

Biogenic amines (BAs) (histamine, tyramine, putrescine, cadaverine, agmatine, spermidine, and spermine) are organic, basic, nitrogenous compounds of low molecular weight, present in plant, microbial, and animal cells and can be detected in raw and in fermented foods. On the basis of their chemical structure, they can be divided into three groups: aliphatic (putrescine, cadaverine, spermine, and spermidine), aromatic (tyramine and phenylethylamine), and heterocyclic (histamine and tryptamine). According to the number of amine groups, they can be classified as monoamines (tyramine and phenylethylamine) and diamines (histamine, putrescine, and cadaverine). Generally, exogenous BAs are produced through decarboxylation of amino acids by bacterial activity during food or beverage fermentation or spoilage. However, their production is a strain-specific characteristic, more widely distributed among certain genera or species, suggesting that horizontal gene transfer may account for their dissemination between strains. During food processing, BA formation is possible only under specific conditions: the availability of free amino acids and presence of aminoacid decarboxylating microorganisms and of an environment that is favorable for enzyme activity and bacterial growth. In fact, the amount and type of BAs formed in foods are strongly influenced by both intrinsic food characteristics (pH, water activity, and microbiota) and extrinsic parameters (storage time and temperature). Fish and fishery products, dairy products, meat and meat products, fermented vegetables, soy products, and alcoholic beverages (wine and beer) are rich in BAs with histamine, tyramine, putrescine, and cadaverine being the most common. These compounds show both physiological and toxicological effects for human health (Table 1). They are precursors for the synthesis of hormones, alkaloids, nucleic acids, and proteins and have an important role as neurotransmitters or are needed for critical biological functions. For this reason, in eukaryotic cells, their biosynthesis is essential. They are involved in natural biological processes such as synaptic transmission, blood pressure and body temperature control, gastric acid secretion, allergic response, and cell growth and differentiation. However, if their level reaches a critical threshold, they can be hazardous to human health causing adverse reactions such as nausea, respiratory distress, hot flush, sweating, heart palpitations, headache, bright red rash, burning sensations in the mouth, and alterations in blood pressure.

BAs: Physiological Effects

BAs are involved in the modulation of several pathways related to the physiology and development of eukaryotic cells. For instance, histamine can act as local hormone and neurotransmitter and is present in mast cells, blood cells, and neurons. It shows different effects in different mammalian and invertebrate organisms by binding to its four receptors (H1, H2, H3, and H4) on and/or in the cellular membrane, resulting in multiple biological responses. It causes smooth muscle cell contraction, vasodilatation, increased vascular permeability and mucus secretion, tachycardia, alterations of blood pressure, arrhythmias, gastric acid secretion, and nociception in nerve fibers. These receptors are localized in different sites. H1 receptors are found in the brain and peripheral tissues and are implicated in the circadian rhythm control, attention and cognition, and vascular and bronchial muscle responses to histamine in allergic processes. H2 receptors are widely distributed in body tissues and play a specific role in the regulation of gastric acid secretion and contraction of intestinal smooth muscle. H3 receptors control histamine synthesis and release, allergic hypersensitivity. Its binding to this receptor induces smooth muscle cell contraction, blood vessel dilation, and, therefore, an efflux of blood serum into the surrounding tissues, initiating the inflammatory process. H4 receptors have been found on hematopoietic cells, highlighting their importance in inflammatory conditions.

Serotonin, derived from tryptophan decarboxylation, is a vasoconstrictor and acts on the regulatory system of emotions. Agmatine has an antidepressant action and is involved in pain regulation.

Tyramine and β-phenylethylamine belong to the so-called 'trace amine' family and show strong structural similarities to classical monoamine neurotransmitters and maintain the basal neuronal within defined physiological limits. Trace amines are also involved in amplification/reinforcement mechanisms. Intuitively, such a function could have important implications in higher cognitive functions and memory formation. These compounds also seem to play an important role in Parkinson's disease. This disease is characterized by the loss of dopaminergic neurons. Trace amines potentiate dopaminergic responses; this apparent reciprocal relationship between trace amine levels and dopaminergic tone makes the trace amines a prime candidate for playing a role in the compensation mechanisms against the loss of dopaminergic neurons. Recently, new G protein-coupled receptors activated by trace amines have been discovered. This specificity applies a new nomenclature for these receptors, that of trace amine-associated receptors. They are mainly located in the blood vessels, explaining the effect of tyramine on blood pressure.

Also, dietary polyamines show important physiological roles supporting a normal metabolism and maintaining optimal health and regulating the intracellular polyamine synthesis. They are a group of polycationic amines ubiquitously distributed in microbial, plant, and animal cells. Putrescine (1,4-diaminobutane), spermidine (*N*-(3-aminopropyl)-1,4-diaminobutane), and spermine (*N*,*N*-bis-(3-aminopropyl)-1,4-diaminobutane) are the main polyamines. They originate from decarboxylation of arginine and ornithine by putrefactive bacteria. This explains why polyamines are present in

Table 1 Main biogenic amines present in foods and their toxicological effects

Biogenic amine	*Chemical structure*	*Precursor*	*Food class*	*Physiological effects*	*Toxicological effects*
Histamine		Histidine	Vegetables, fish, fermented drinks and foods, dairy products	Local hormone and neurotransmitter, gastric acid secretion, cell growth and differentiation, circadian rhythm, attention and cognition, onset of allergic reactions	Headache, nasal secretion, bronchospasm, tachycardia, extrasystoles, hypotension, edema (eyelids), urticaria, pruritus, flushing, and asthma
Tyramine		Tyrosine		Peripheral vasoconstriction, increased cardiac output, increased respiration, elevated blood glucose, release of norepinephrine	Headaches, migraine, neurological disorders, nausea, vomiting, respiratory disorders, hypertension
Putrescine		Ornithine		Regulation of gene expression, maturation of intestine, cell growth and differentiation	Increased cardiac output, tachycardia, hypotension, carcinogenic effects
Cadaverine		Lysine		Regulation of gene expression, maturation of intestine, cell growth and differentiation	Hypotension, bradycardia, lockjaw, and paresis of the extremities
β-Phenylethylamine		Phenylalanine	Vegetables, fermented drinks and foods, dairy products	Cognitive functions and memory formation, dopaminergic responses	Increased blood pressure, migraine

high amounts in fermented foods. The estimated values for the daily polyamine intake in different studies vary between 250 and 550 mmol. Mediterranean regions show a higher intake of total polyamines (700 mmol day^{-1}) than the United Kingdom and northern Europe (350–500 mmol day^{-1}). These compounds are absorbed from the intestinal lumen and distributed to all organs and tissues in the body and their levels depend on biosynthetic and catabolic enzymes such as spermidine/spermine acetyltransferase, flavin-containing polyamine oxidase, copper-containing diamine oxidase (DAO), and probably other amino oxidases and on the production by microorganisms residing in the intestinal tract and also contribution from the diet. Polyamines exist in cells in both free and conjugated forms, which regulate the cellular pool of free polyamines. Conjugated forms are bound covalently to a partner molecule and can be released by hydrolysis with a strong acid. On the basis of their chemical structure, under physiological conditions, putrescine, spermine, and spermidine are 2, 3, and 4 positive charges, respectively; therefore, they can interact with negatively charged structures of cells such as cellular membrane constituents and nucleic acids. Generally, polyamine–DNA interactions can modulate DNA–protein interactions: polyamines enhance the binding of gene-regulatory proteins to the respective response elements. For example, spermine facilitated the binding of estrogen receptor to its response element, while Oct-1 binding to DNA was inhibited in the presence of high concentrations of polyamines.

Polyamines are involved in cellular growth, maturation of the intestinal tract, and proliferation. Moreover, they regulate the differentiation of immune cells and the inflammatory reactions, and they inhibit pulmonary immunologic and intestinal immunoallergic responses: in children, high polyamine intake during the first year has been significantly correlated to food allergy prevention, which is important for the maintenance of normal growth and maturation of the intestinal tract. Generally, their concentration decreases with age in the brain, kidney, spleen, and pancreas suggesting that maintenance of polyamine level from the diet is important to keep the functioning of these organs in the elderly. Recently, a possible implication of spermine and spermidine in diabetes has been postulated since they show an antiglycation effect at physiological concentration. Moreover, these two polyamines exert an anti-inflammatory effect through the inhibition of proinflammatory cytokine synthesis and the reduction of leukocyte function-associated antigen-1 expression, which is involved in immune cell activation and inflammation.

BAs: Toxicological Effects

Several studies have demonstrated that BAs have toxicological effects for humans even at low concentrations. Therefore, their occurrence in foods is becoming an economic problem directly linked to the influence of these compounds on health. In healthy persons, dietary BAs can be rapidly detoxified by

amine oxidases, whereas persons with low amine oxidase activity are at risk of their toxicity.

Histamine is physiologically the most important BA. Humans can tolerate up to 180 mg of pure histamine orally without having noticeable effects. Endogenous histamine is generated by the enzyme histidine decarboxylase in mast cells, basophils, enterochromaffin-like cells in the gastric mucosa, histaminergic neurons, and some epidermal cells. It is only synthesized as necessary and is degraded immediately.

Histaminosis symptoms, due to ingestion of histamine-rich food or of alcohol or drugs that release histamine or block DAO that converts histamine into imidazole acetic acid, occur up to few hours after the poisoning and resemble an allergic reaction. The main clinical manifestations are hypotension, flushing, and headache, while the increased capillary permeability causes urticaria, hemoconcentration, and eyelid edema. Histamine also acts on the gastrointestinal system causing the contraction of smooth muscles leading to abdominal cramps, diarrhea, nausea, and vomiting. Moreover, it exerts a stimulatory action on the heart by increasing its contractility and exhibiting palpitations and tachycardia, while it is a potent stimulant of sensory and motor neurons producing pain and itching associated with the rash. Symptoms can be reduced by a histamine-free diet or be eliminated by antihistamines. However, because of the multifaceted nature of the symptoms, the existence of histamine intolerance has been underestimated and $\sim$1% of the population has histamine intolerance.

It is difficult to establish a toxic level of histamine, because this depends on the individual detoxifying activities. In fact, BA catabolic enzymes can be inhibited by different drugs, antidepressant drugs, and alcohol. Intoxication is characterized by an incubation period ranging from a few minutes to hours, with symptoms that are usually noticeable for a few hours only. Results from the limited number of studies suggested a potential no observed adverse effect level of 50 mg histamine for symptoms of headache and flushing, but this was based on a limited number of individuals. The amount ingested leading to acute effects is often unknown and several other factors such as potentiation of acute effects by other BAs, alcohol, or medication could not be excluded. The limited published information available suggested a potential acute reference dose of 50 mg of histamine per healthy person. Fish has been incriminated in the majority of histamine poisoning (scombroid fish poisoning or histamine fish poisoning) with histamine levels >500 mg kg^{-1} or less. Some responses mediated by histamine and its receptors (vasodilatation, smooth muscle cell contraction, alterations of blood pressure, stimulation of nociceptive nerve fibers, tachycardia, and arrhythmias) are related with the main symptoms of scombroid poisoning. Given the role of histamine in this syndrome, alteration in the action of histamine catabolic enzymes can have negative consequences. Four main mechanisms have been described to explain scombroid poisoning, and they are (i) impairment of DAO activity due to either genetic predisposition, gastrointestinal diseases, or medication with DAO inhibitors; (ii) mast-cell degranulation to release endogenous histamine in the human body; (iii) potentiation of histamine toxicity by other compounds present in toxic fish; and (iv) undiscovered histamine receptor agonists. The European Union Commission (EU, 2005) specifies fish species associated with a high amount of histidine and establishes its critical levels: For those matured in brine products, the critical concentration is 200 mg kg^{-1}, while for simple fish products, the concentration is 100 mg kg^{-1}, based on the average of nine samples. Of the nine samples, no two can be higher than 100 mg kg^{-1} (and 200 mg kg^{-1}) levels but none can be higher than 200 mg kg^{-1} (or 400 mg kg^{-1} for enzyme-matured products). In the United States, a level of 50 mg kg^{-1} is used.

After fish, cheese is the next most commonly implicated food item associated with histamine poisoning. The histamine concentrations in cheeses that were implicated in outbreaks ranged between 850 and 1870 mg kg^{-1}. Other foods such as sausages, sauerkraut, wine, or other fermented foods can contain high concentrations of histamine and its potentiators, but these are rarely reported to be implicated in histamine poisoning.

According to Rapid Alert System for Food and Feed (RASFF), about 100 histamine intoxication outbreaks have been registered between 2005 and 2010. The estimation of the dose/exposure level causing histamine intoxication is based on the detection of the BAs in the suspected food or on the patient reports. Moreover, it should be considered that histamine toxic effects are enhanced in the presence of other BAs such as putrescine and cadaverine.

Tyramine, phenylethylamine, and tryptamine are related to neuromodulating functions and could have a role in human disorders such as schizophrenia, depression, attention deficit disorder, and Parkinson's disease. In particular, tyramine promotes the efflux of catecholamines from the sympathetic nervous system and the adrenal medulla increasing arterial blood pressure and heart rate by peripheral vasoconstriction, resulting in hypertensive crisis. Tyramine also dilates the pupils and the palpebral tissues, causes lacrimation and salivation, accelerates respiration, and increases the blood sugar content.

Tyramine is also associated to the 'cheese reaction,' a pathological condition that is commonly associated to adverse interaction between monoamine oxidase inhibitors (MAOIs), a class of antidepressant drugs, and high amounts of dietary tyramine causing hypertensive crisis (Figure 1). Increased amounts of tyramine in the blood can cause the release of excess noradrenaline and blood pressure increase. So clinicians proposed the so-called MAOI diet in which tyramine intake is controlled by the reduction of tyramine-rich foodstuffs in the diet, in particular aged cheese, fermented meat, sauerkraut, soy sauce, etc. In healthy people, from 600 mg to 2000 mg of tyramine administrated in a meal would be needed to cause a minimal systolic blood pressure increase, whereas in individuals medicated with MAOI drugs, much less dietary tyramine is needed to produce negative effects.

Also, polyamines are related to some negative effects on human health. The metabolic requirement for polyamines is particularly high in rapidly growing tissues as it happens in tumors. Polyamines are involved in the proliferation of neoplasms in the gastrointestinal tract, and there is increasing evidence that putrescine and spermidine have a role in promoting the malignant transformation of cells. They are involved in cell growth and proliferation. In particular, putrescine is involved in colorectal cancer development and in gastric carcinomas caused by *Helicobacter pylori*. In fact, putrescine can interact with some pathogenic microorganisms since it is an essential component of their outer structure and has been related to virulence factors in many Gram-positive and Gram-negative pathogens.

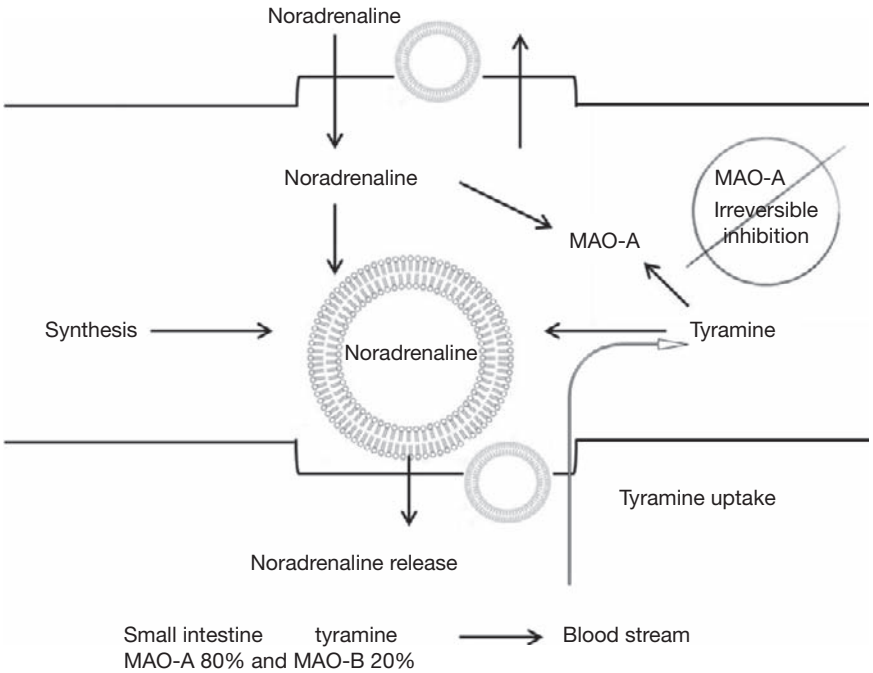

Figure 1 When intestinal MAOs are inhibited, tyramine can induce noradrenaline release from peripheral adrenergic neurons causing hypertensive crisis. Modified from Youdim, M. B. H. and Weinstock, M. (2004). Therapeutic applications of selective and non-selective inhibitors of monoamine oxidase A and B that do not cause significant tyramine potentiation. *Neurotoxicology* **25**, 243–250.

The involvement of polyamines in cancer allowed the development of drugs interfering with polyamine biosynthesis or their biological role. Some examples are ornithine decarboxylase inhibitors and polyamine structural analogs and derivatives. However, tumor cells can uptake extracellular polyamines deriving from the diet or produced by gastrointestinal bacteria, bypassing the effect of these therapeutic agents. Therefore, another approach based on the inhibition of polyamine synthesis in tumor cells and the reduction of the main exogenous sources (e.g., foods rich in polyamines) has been proposed. It gave interesting results also because polyamine deprivation stimulates the antitumoral immune response. However, it has not yet been experimentally proved that altering of the dietary polyamine intake can help cancer patients.

Polyamines are also related to oral acute and subacute toxicity in Wistar rats. The levels for acute toxicity were 2000, 600, and 600 mg kg^{-1} body weight for putrescine, spermidine, and spermine, respectively, while no effects were observed with concentrations of 180, 83, and 19 mg kg^{-1} body weight for putrescine, spermidine, and spermine, respectively.

Apart from a direct effect in promoting the transformation of cells, polyamines subjected to heat can generate secondary amines that can generate nitrosamines with well-known carcinogenic, mutagenic, and teratogenic activities. This is of particular importance in some fermented meat products to which nitrates and nitrites are added as additives.

Detoxification System

The catabolic pathway of BAs is generally regulated by oxidases classified as MAO and DAO that catalyze the deamination of BAs producing hydrogen peroxide and by specific amine methyltransferases (MT) involved in histamine and tryptamine removal. The gastrointestinal tract is the most important source of exogenous BAs. Indeed, the higher activity of BA detoxification system was measured in the gut lumen and liver. In normal physiological conditions, the enzymatic barrier, localized in the intestinal epithelial cells, is considered to play a protective role against the resorption of dietary BAs (Figure 2).

MAO (EC 1.4.3.4) was first discovered as tyramine oxidase by Hare in 1928, since it catalyzed the oxidative deamination of tyramine. Only, in 1968, Johnston discovered that two MAO isozymes existed: MAO-A is primarily present in the stomach, intestine, and placenta with noradrenalin and octopamine as preferred substrates and defects have been linked to depression and abnormally aggressive behavior. MAO-B is predominantly found in the brain and selectively deaminates nonpolar aromatic amines (as phenylethylamine and dopamine). MAO-B expression in the brain increases during aging and may be linked to disorders such as Alzheimer's disease, while a particular allele of the MAO-B gene has been linked to Parkinson's disease. While Parkinson's disease is often treated with L-DOPA, the addition of a MAO-B inhibitor such as deprenyl dramatically increases its neuroprotective effect. They are FAD-dependent enzymes sharing a high sequence identity (~70%) even if they have different substrate specificities, and mammalian MAOs are bound to the outer mitochondrial membrane through a C-terminal transmembrane polypeptide. MAO-A and MAO-B genes probably derive from the duplication of a common ancestral gene as suggested by their identical exon–intron organization. Interestingly, MAO-A and MAO-B amino acid sequences are conserved (>87% and 88.3% identity, respectively) in humans, rats, and bovines underlining the

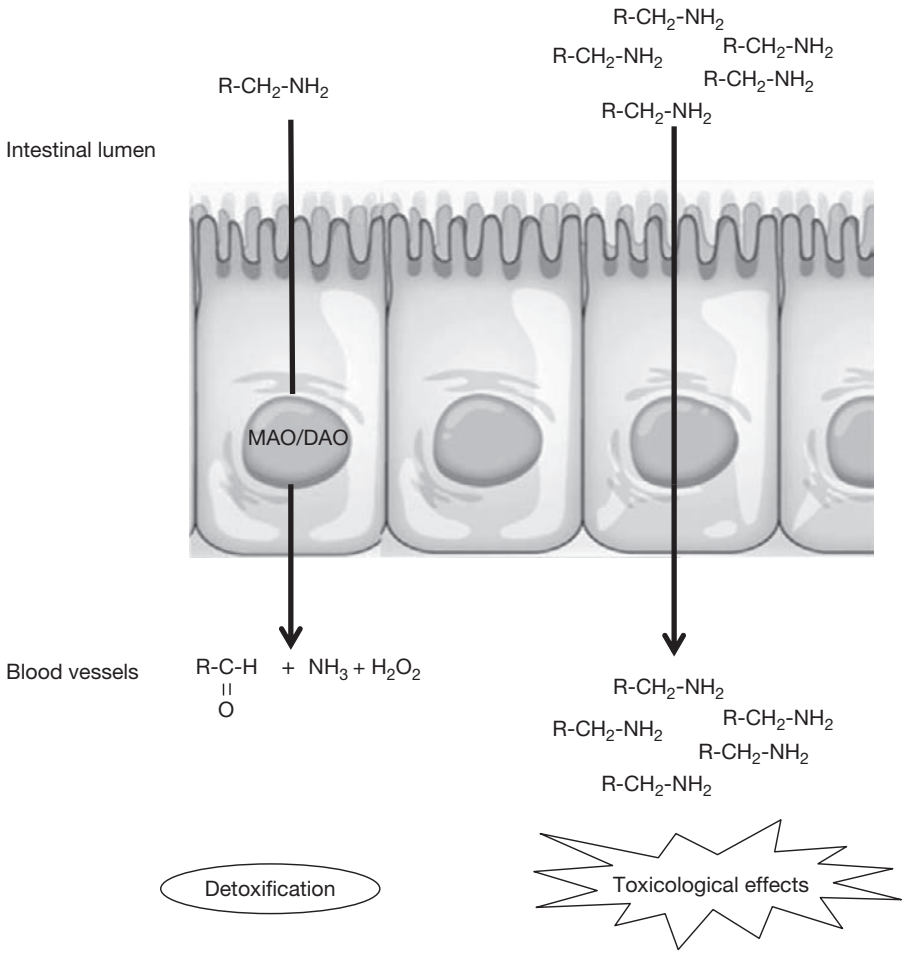

Figure 2 Scheme for the overall oxidative deamination reaction catalyzed by MAOs at the intestinal level. The intake of foods containing high BA amount inhibits detoxification system.

effect of the evolutionary pressure to maintain the physiological function of these enzymes among mammalian species. Tyramine is a substrate for either form of MAO; MAO-A is responsible for tyramine intestinal metabolism preventing its systemic absorption. Tyramine and phenylethylamine are also substrates for *N*-MT; their *N*-methylation generates noradrenaline. Tyramine can be further converted into octopamine.

The main enzyme for the metabolism of ingested histamine is DAO that converts histamine into imidazole acetic acid, which can be conjugated with ribose before excretion. Histamine *N*-methyltransferase (HMT), the other important enzyme inactivating histamine, is a cytosolic protein that can convert histamine only in the intracellular space of the cells. HMT converts histamine into methylhistamine, which is then converted by MAO into *N*-methylimidazoleacetic acid. The ultimate end products of histamine metabolism are excreted in the urine. An impaired histamine degradation based on reduced DAO activity and the resulting histamine excess may cause numerous symptoms mimicking an allergic reaction.

The activity of all of these detoxifying enzymes can be negatively influenced by food components, such as other amines, alcohol and its metabolite acetaldehyde, and phenols, acting as potentiators.

In particular, alcohol and acetaldehyde enhance BA toxicity increasing the permeability of the intestinal wall to these compounds.

Moreover, some drugs can act as inhibitors of MAO and DAO. Some of them are drugs used for the treatment of stress, depression, Alzheimer's disease, and Parkinson's disease and are painkillers, antihypertensive drugs, antibiotics, and agents reducing gut motility. A recent study reported that tobacco smoke reduces MAO levels by up to 40% and several cigarette smoke compounds can also inhibit MAO enzyme activities.

Conclusion

BAs play essential roles in the normal development, metabolism, and physiological functions of humans. However, they are very frequently involved in human pathologies causing neurological disorders, gastrointestinal diseases, abnormal immune responses, cancer, etc. Further studies are needed to evaluate the factors influencing BAs formation to understand how these compounds could affect consumers. In addition, there are large gaps in the establishment of dose–effect relationship. The role of various substances that enhance the

toxicity of BAs and the existence of synergic effects has been demonstrated, and therefore, the determination of the amine concentrations in each case is not enough to assess their toxic potential.

Introduction

Food safety has become an emerging issue since bovine spongiform encephalopathy and dioxins scandals that occurred in the late 1990s. In the European Community, public confidence in healthy food reached the minimum level, and policy makers spent many efforts to improve the healthiness of food products and to enhance the level of consumer's health protection. Different control strategies have been adopted by international, national, and regional authorities in order to reassess consumer confidence and trust in food, food industries, and government. Stringent food safety and quality analysis represent the keystone of the plan of action in order to protect public health. It is a global issue that requires the concerted efforts of all the actors of the entire supply chain, research organism, control authorities, and politicians.

Within the European Community, the hazard analysis of critical control point system has been officially effective since 1995, setting guidelines and musts concerning hygiene in food production and becoming a legal obligation on 1 January 2006. The food sector is imposed to assess and maintain a system for hazard analysis testing to identify critical points relevant to food safety regardless of the process stage, guaranteeing the healthiness of products at each point of the supply chain. The producers have the penal responsibility of food safety. Food plants are heavily constrained to maintain a rigorous monitoring system for food analysis to ensure compliancy with legislation and rules, as laid out by governments and regulatory authorities.

In this context, it is natural to accept the importance of detection systems that are accurate, sensitive, inexpensive, and preferably portable for on-site testing. Biosensors represent rapid screening tools and their use as detection platforms is expected to increase continually, while the conventional methods will be abandoned.

A biosensor is defined by the International Union of Pure and Applied Chemistry (IUPAC) as a "device that uses specific biochemical reactions mediated by isolated enzymes, immunosystems, tissues, organelles or whole cells to detect chemical compounds usually by electrical, thermal or optical signal." It is composed of three main components: the biological recognition element, the transducer, and the signal readout system. Once the analyte interacts with the bioreceptor, the transducer translates the recognition event into a measurable signal that is then converted into an appropriate output.

The first biosensor was realized in 1960 by Dr Leland C Clark. He developed the first prototype glycemia sensor, an 'enzyme electrode' for the measurement of glucose levels in the blood. The device relies on a thin layer of glucose oxidase entrapped onto an electrode via a semipermeable membrane and monitors the oxygen consumed by the enzyme-catalyzed reaction:

$$\text{Glucose} + \text{oxygen} \rightarrow \text{gluconic acid} + \text{hydrogen peroxide}$$

The enzyme is able to convert electroinactive substrates into electroactive products: when monitoring the signal for oxygen, Dr. Leland Clark found that it would decrease in proportion to the concentration of glucose in the solution. Alternatively, H_2O_2 can be monitored as the result of the oxidation of glucose.

Biosensors are considered powerful tools for the analysis of biomolecular interactions in clinical, biochemical, and environmental analyses. Applications of biosensors are developed majorly for environmental and bioprocess monitoring, quality control of food, agriculture, antibioterrorism, and medical systems. Those innovative devices offer advantages over current analytic methods. They are selective, inexpensive, portable, and easy to use. For these reasons, they represent a valid alternative to conventional methods used in the food industry for hazardous food contaminants detection such as mycotoxins, heavy metals, pesticides, antibiotic residues, and pathogenic microorganisms.

Major advantages of biosensors over traditional techniques are reported in Table 1.

Nanotechnology is playing a crucial role in the development of biosensors. The combined use of micro- and nanofabrication techniques leads to the creation of materials and devices typically with dimensions smaller than 100 nm. The advantages of this smaller-scale approach are supported by the possibility to

- reduce unit costs through mass production,
- reduce sample volumes into the range of microliters or less,
- reduce reagent costs,
- reduce analysis time and sample manipulation exploiting microfluidics,
- reduce power consumption,
- realize portable devices,
- increase biosensors sensitivity.

Biorecognition Elements

Biosensors can be classified by their biorecognition elements or their transduction principles.

The bioreceptor is a molecular species that binds the analyte through a biochemical reaction. It is a fundamental part of the device because it influences the overall biosensor performance. It can belong to one of the five major categories: antibodies, enzymes, whole cells, nucleic acids, and phages.

Affinity-based recognition elements specifically bind to the target and are characterized by high sensitivity, selectivity, and versatility because they can be easily generated for a wide range of different targets. Antibodies are the most important affinity-based recognition elements. They are proteins produced by the immune system to bind specific antigens by noncovalent interactions. The antigen binding site has a particular fold that provides a sort of 'lock and key' fit for a specific antigen.

Table 1 Comparison between traditional analytic techniques and biosensors

Traditional analytic techniques	*Biosensors*
Expensive	Cost effective
Time-consuming	Real-time detection
Well-trained personnel	Simple use
Heavy sample manipulation	Limited sample preparation
High-tech equipment	Simple and portable devices

These biological compounds are sensitive and selective but have some limitations in food and environmental analysis. Three types of antibodies are present: polyclonal, monoclonal, and recombinant antibodies. Polyclonal antibodies are produced by immunizing animals and extracting and purifying the sera. They are derived from multiple plasma cells so they can recognize target compounds from different molecular regions. Although polyclonal antibodies can be produced at relatively low cost, they can bind compounds nonspecifically leading to false-positive responses. Moreover, besides the ethical question for the use of animals, toxic molecules or molecules with very low molecular weight are not immunogenic so they cannot elicit immune responses in the host.

Monoclonal antibodies are derived from a single clonal hybridoma, so they have the same structure and recognize only one epitope of the target molecule leading to a higher specificity. However, the production process is very expensive and time-consuming, and like the polyclonal antibodies, they are not highly stable molecules and lose their binding properties under unfavorable environmental conditions. Recombinant antibodies are the product of genetic manipulation of antibody genes for high-affinity antibody production.

Innovative affinity-based recognition elements are represented by phages, nucleic acids, and molecularly imprinted polymers (MIPS). They have different characteristics that will be discussed later, but generally, they show good affinity and specificity and high stability and their production is cheap, fast, and reproducible, avoiding batch-to-batch variations. Since the involvement of animal immunologic systems is not necessary for their creation, it is possible to realize a proper recognition element for the detection of poorly immunogenic or toxic compounds too.

Enzymes are proteins that have an active site for the binding of substrate in their catalytic activity with features similar to the antigen binding sites of antibodies. They are not usually used as biorecognition agent but as a component of a multiple biorecognition system where the enzyme is included for the amplification of the signal. However, biorecognition elements have been reported in literature for the detection of certain organic phosphate pesticides.

Whole bacterial cells can be used in biosensor devices as recognition and processing systems for the analyte as using bacteria induces production of enzymes to detect the desired molecule.

Bacteriophages are viruses that infect bacteria and exploit microbial cell structure to duplicate their DNA and replicate themselves. These viruses display peptides or proteins on their surface that can strongly bind different targets such as proteins, small molecules, and whole cells. Phages can be selected on the basis of target affinity and used as a specific recognition element of a biosensor. In bacteria detection, the phage itself specifically recognizes its particular host strain by specific receptor molecules outside the bacterial cell, and the binding can be so specific that only certain strain could be revealed advantages in using phages are the following: Their production by infecting bacteria is cheap and fast, which takes only a few hours; they are very stable in harsh environmental conditions. For example, they are active in a wide range of pH values (from 3 to 11) and at high temperatures. Moreover, they show high organic solvent resistance, retaining their infectivity of 99% in acetonitrile, 80% in methanol, and 50% in ethanol. Besides phages, the surface peptides or proteins identified as good binders can be chemically synthesized or produced by recombinant expression in bacterial cells and directly used as recognition elements.

Nucleic acids are used to detect specific genes or specific DNA sequences exploiting natural affinity between single-stranded DNA used as the probe and its complementary sequence belonging to the sample. When a specific sequence of DNA is near the probe, the two strands bind and form the classical double-helix DNA structure and the hybridization process is revealed by the transducer. Double-stranded DNA can be used as the probe too, for detection of intercalating agents, which get inserted into the helical conformation of the double-stranded oligonucleotide. Nucleic acids recognition elements are very stable and easily synthesized and stored and can be chemically modified during synthesis, in order to enhance stability, affinity, and specificity and facilitate the functionalization of surfaces. Moreover, they can be easily labeled with fluorophores or enzymes allowing flexibility in assay development.

Aptamers are short strands of nucleic acids properly designed to specifically bind to a target molecule and are considered the next-generation element for molecular recognition. This technology exploits the capability of a single strand of DNA or RNA to fold into three-dimensional structures thanks to self-annealing properties and to recognize the analyte primarily by the shape of the binding site and not by their nucleotide sequences. Aptamers are derived from the Latin word *aptus*, which means to fit. They are isolated from oligonucleotides library using the *in vitro* selection known as SELEX (systematic evolution of ligands by exponential enrichment) technique. A library of oligonucleotides containing a portion of randomized sequence is incubated with the target. Only nucleic acids strongly linked to the target molecule are retained and amplified by polymerase chain reaction, while others are removed by washing steps. Actually, the technology is still in its infancy so various aptamers have been selected for small molecules, supramolecular structures, and whole cells as targets but they have not been tested with biosensing platforms yet. The small size of these nucleic acids ligands allows the formation of a high-density monolayer anchored to the biosensor surface, and thanks to their ability to renature, aptamers can undergo several cycles of denaturation and renaturation. In this way, an aptasensor can be recyclable by adding a chaotroping agent to break the target–aptamer complex, setting the receptor free for next sensing analysis.

The last class of affinity-based recognition elements are MIPs. MIPs are synthetic cross-linked materials with artificially generated recognition sites. Starting from a solution of polymerizable

Table 2 Comparison between different biorecognition elements

Biorecognition element	*Affinity*	*Versatility*	*Specificity*	*Stability*	*Cost*
Polyclonal antibody	+++	++	++	++	++
Monoclonal antibody	+++	++	+++	++	+
Enzymes	++	+	+	++	++
Whole cells	++	+	++	+++	+++
Nucleic acids	+++	++	+++	+++	++
MIPs	++	+++	+	+++	+++

monomers, cross-linkers, and target molecules, the binding sites are formed by polymerizing monomers arranged around the target and removing the template molecule by extensive washing steps. The resulting polymer holds recognition sites complementary to the target in size, shape, and position of the functional groups.

A summary of the characteristics of different recognition elements used in biosensor devices is reported in Table 2.

Immobilization Methods

For better performance of biosensors, biological and physical components must be kept in close proximity to each other. The analyte must have free access to the biocomponent and the integrity of the interaction must be retained. The immobilization step is crucial for biosensing procedure. The functionality of the receptor must be preserved, the recognition sites will be sterically free, and care must be taken to avoid chemical inactivation during the immobilization stages. There is not a universal immobilization method suitable for every application. In order to choose the correct immobilization method, some factors have to be taken into account such as the type of transducing element, the physical properties of the analyte, and the nature of biocomponent to be immobilized.

The biological probe can be anchored on carrier matrices by adsorption, by covalent binding, or by physical retention.

Adsorption of biomolecules on insoluble support relies on nonspecific interaction such as hydrophobic effects: It is a very simple method with wide applicability and it is capable of high biomolecule loading. Physical adsorption mainly relies on van der Waals forces and occasionally on hydrogen bonds so the linkage is weak.

Binding molecules covalently to the support is the most commonly used approach. The covalent binding is very strong, and there is no or very little chance of leaving of biorecognition element from the support.

Biorecognition elements can be bound to the surface through a bifunctional molecule that acts as cross-linker. The most commonly used are glutaraldehyde, cyanogen bromide, and ethyl chloroformate.

Concerning immobilization by physical retention, two different techniques are available: matrix entrapment and membrane enclosure. Entrapping biomolecules in gels or fibers can be useful in analysis involving small substrates and products. Semipermeability of membranes allows both biomolecules confinements and free passage for substrate and reaction products.

Transduction Mechanism

Based upon the transduction method, biosensors are typically classified into optical, mechanical, and electrochemical sensor platforms.

Optical Biosensors

Optical biosensors allow the detection of analytes in complex matrices with minimal sample manipulation; they require a low reagent volume and have a low signal-to-noise ratio. For these reasons, they are particularly appealing in food safety and food quality evaluation. In particular, different optical sensors for rapid detection of pathogenic bacteria, toxins, and contaminants in food have been recently proposed.

Transduction principle is mainly based on changes of surface characteristics of the device when the analyte binds to the sensing layer of the sensors by sorption or complex formation of the affinity binding agent and target molecule.

Target detection and quantification are determined by measuring the refractive index, absorbance, and fluorescence properties of analyte molecules or chemo-optical transducing medium. The working principle of optical biosensors involves measuring changes in the amplitude, phase, frequency, or polarization of light. These devices are composed of a light source, components to generate light with specific characteristics, a modulating agent, a sensing area, and a photodetector. The advantages of optical biosensors are the ease of use, speed of the assay, and the possibility to perform multiplex analysis: samples can be investigated with many wavelengths simultaneously without any interference. Recently, various optical sensors for rapid detection of pathogens, toxins, and contaminants in food have been developed. For example, *Escherichia coli* detection and quantification have been performed in only 15–20 min.

This class of biosensors comprises optical fibers, planar wave guides, resonant mirrors, ellipsometry, total internal reflection fluorescence, surface plasmon resonance (SPR), fluorescence and ultraviolet/visible (UV/vis) spectroscopy, and microarray. Among this group of devices, the most promising are optical fibers and SPR sensors.

Fiber-optic biosensors

The working principle of these devices is quite simple: a light beam goes into the sample through one fiber, interacts with the media, and is reflected and collected from a second fiber to be transferred to a photodetector.

Table 3 Examples of some applications of fiber-optic biosensors

Target analyte	*Matrix*	*LOD*
C. botulinum toxin A	Buffer	5 ng ml^{-1}
Staphylococcal enterotoxin B	Buffer	0.5 ng ml^{-1}
Escherichia coli O157:H7	Ground beef samples	1 CFU ml^{-1}
Listeria monocytogenes	Buffer	10^3 CFU ml^{-1}
Listeria monocytogenes	Hotdog samples	10^7 CFU ml^{-1}
Salmonella	Hotdog samples	10^4 CFU ml^{-1}

The optical fibers can be divided into intrinsic or extrinsic sensors. In the first case, the binding between the probe and analytes occurs within an element of the device, while in the extrinsic sensors type, the optical fiber is exploited in order to couple light to and from the region where the light beam is influenced by the target recognition. Usually, the antibodies are immobilized on the distal end of the fiber, and the incident light introduced at the proximal end travels through the fiber causing excitation of the fluorophores attached to either the antigen or an associated antibody depending on the assay configuration.

There is a rapid development of various fiber-optic biosensors for the detection of botulinum toxin, staphylococcal enterotoxin, *E. coli* O157:H7, *Listeria*, and *Salmonella* spp. Table 3 reports some literature examples of calculated limit of detection (LOD) and tested matrices.

SPR biosensors

SPR is a charge density oscillation that exists at the interface of any two materials with opposite dielectric constants, which can be induced by both electrons and photons.

Plasmons are the collective vibrations of an electron gas or plasma surrounding the atomic lattice sites of a metal. At a specific resonance wavelength of light, the momentums of the photon and the plasmon are matched and the energy of the photons can be transferred to free electrons at the interface. The excited surface plasmons can be considered as an electromagnetic surface wave that propagates along the interface and decays exponentially with distance normal to the interface. SPR determines a dip in reflectance at the specific wavelength, caused by the absorption of optical energy in the metal. This phenomenon facilitates the study of interactions at the metal surface as the evanescent wave propagates to a depth of approximately one wavelength. SPR instruments containing an antibody layer detect minute changes in the local refractive index on binding of the antigen. When target molecules bind to the antibodies immobilized on the metal surface, the resonance shifts to longer wavelengths and amount of shift accordingly reflects the concentration of bound analytes. The most widely used SPR platforms employ the Kretschmann configuration (Figure 1). They are based on prism coupling and angle-dependent detection and show a higher sensitivity and resolution with respect to the devices that operate by diffraction grids. In the case of total internal reflection, the light leaks an evanescent wave field across the interface from the glass to the sample solution characterized by a lower refractive index. In the metal layer, plasmons can be excited by the incident light only at the proper combination of energy (wavelength) and incident angle, and a characteristic absorption of energy via the

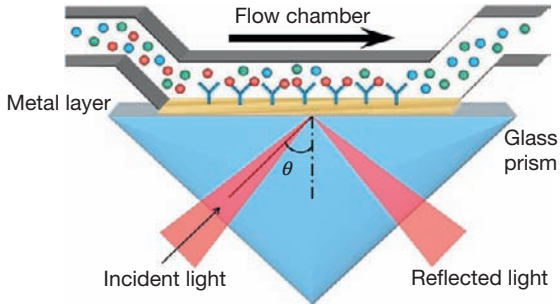

Figure 1 Schematic representation of SPR biosensor in Kretschmann configuration.

evanescent wave field occurs. The SPR is seen as a dip in the intensity of the reflected light at the SPR angle. The refractive index of the medium near the sensor surface affects the SPR angle and changes when biomolecules attach to the surface leading to a shift in the SPR angle.

Considering that antibodies are about 10 nm in diameter, the binding events perturb the evanescent field and hence the SPR, which therefore alters the angle of the light at which the SPR occurs proportionally to the amount of target binding. Since the light does not travel through the sample, it is possible to analyze also nontransparent samples such as serum or food extracts.

SPR biosensors can detect molecules even at femtomolar concentration and were used for detection of whole bacterial cells as *E. coli* O157:H7, *Salmonella*, and *Listeria* at traceable concentrations or *Staphylococcus aureus* enterotoxin B and botulinum toxins.

Quantum dots

Quantum dots are semiconductor nanoparticles that fluoresce when excited by a light source. They are characterized by unique optical properties thanks to their very small sub-wavelength size, which can be exploited for biosensing.

Quantum dots are considered as a promising alternative to traditional fluorescent dyes. Electronic energy levels are governed by the size of the nanoparticles; therefore, emission bands are tunable by changing the size of quantum dots. In contrast to the fluorescent dyes, the emission bands are very narrow due to the quantum electron confinement, so they can be used to detect multiple quantum dots labels without overlap of spectral emission, a feature that has facilitated multiplexed detection.

In contrast to organic dyes, quantum dots are very stable and are not susceptible to photobleaching. Moreover, these nanoparticles are very efficient fluorophores, making them bright labels. A single quantum dot provides signal equivalent to 20 rhodamine molecules, allowing more sensitive assays than those employing organic dyes.

Quantum dots can incorporate a zinc sulfide shell around the core, readily functionalized using amine chemistry methods, which allows water solubility and conjugation to antibodies and oligonucleotide probes. Nonspecific interactions are avoided by a polyethylene glycol modification of the ZnS shell.

Antibody-modified quantum dots have been used for the immunostaining of whole *Listeria monocytogenes* cells, to

visualize *E. coli* and to quantify marine iridoviruses. *E. coli* has been labeled and visualized in samples containing a mixture of bacteria using quantum dots functionalized with specific bacteriophages.

Surface-enhanced Raman spectroscopy

Raman spectroscopy is a vibrational analytic technique able to give detailed structural information on proteins, nucleic acids, and whole pathogens.

Nevertheless, this method shows a low sensitivity, and pathogens can be identified on the basis of their inherent spectra only at very high concentrations. In surface-enhanced Raman spectroscopy (SERS), the signal is enhanced by a factor of 10^4–10^9, simply using receptors to bind or adsorb pathogens to specially designed metallic surface with nanostructured roughness. Two formats are available for SERS-based biosensor devices: intrinsic configuration and extrinsic configuration. In the extrinsic format, a reporter molecule characterized by a simple but strong spectrum is used to generate a signal for detection. The molecule is bound to a metallic nanoparticle functionalized with a specific antibody for the target analyte, and this complex acts as a labeling reagent similar to a fluorophore. The narrow SERS bands are more suitable with respect to broad fluorescent bands and permit multiplexed detection and enhance the sensitivity. Extrinsic SERS detection has been successfully carried out for proteins, viruses, pathogen bacteria, and DNA sequences specific to HIV genes via hybridization assays.

In the intrinsic format, the signal is generated directly by the target molecule. Antibody or oligonucleotide probes on the sensing area anchor target molecule to the nanostructured surface, and the inherent Raman spectrum or molecular fingerprinting is measured. This format is particularly advantageous because it is reagentless and label-free and discriminates specific from nonspecific binding.

Thanks to optimized SERS substrates, it is possible to identify pathogen bacteria. These substrates allow the differentiation of bacterial or viral species, as well as pathogens having minor changes, such as gene deletions, and permit accurate classification of bacteria at the strain level.

Mechanical Biosensors

Generally, mechanical sensors are mass-sensitive sensors and can be considered as balances that react to small mass changes producing a measurable electrical signal. They are based on the piezoelectric effect: Certain solid materials accumulate electric charges in response to mechanical stresses. The phenomenon is reversible so the mechanical distortion can be generated by applying an electrical field to some faces of the crystal.

The main advantage of the piezoelectric transduction approach includes the ability to perform label-free measurements of the binding process, including real-time analysis of binding kinetics.

Quartz crystal microbalance

Quartz crystal microbalance (QCM)-based biosensors are an alternative to conventional analytic methods, due to the sensitive mass detection capabilities and the possibility to monitor binding events in real time. Quartz crystal sensors are coated by a thin layer of a metal serving as an electrode on both sides of the crystal. Applying an alternate current between the two electrodes, an acoustic wave propagates across the devices and the sensor oscillates at a specific base frequency. The resonance frequency depends on the crystal physical properties and those of the medium. The change in the resonance frequency is related to the mass accumulated on the crystal by the Sauerbrey equation:

$$\triangle f = -\frac{2f_0^2}{A\sqrt{\rho_q \mu_q}} \triangle m$$

where $\triangle f$is the change in resonance frequency, f_0 is the resonant frequency of the crystal, A is the active area of the sensors between the electrodes,ρ_q is the density of quartz, and μ_q is the shear modulus of the quartz.

The working principle is the decrease in resonance frequency after the binding of the target organism. The resonance frequency shift is proportional to the mass bound to the vibrating crystal. Bacterial species that have been detected with QCM include *Salmonella*, *Pseudomonas*, and *E. coli*. Concerning the detection of bacterial cells characterized by soft mass, QCM with dissipation monitoring is able to give insight into the viscoelastic properties of the adsorbed mass. The bacterial cells do not fully couple to the crystal oscillations and thus will dampen it and will be underestimated. The main drawback of this type of biosensor is a low sensitivity, because a relatively large mass must be bound to produce a measurable change in signal, so it is not capable of small molecule detection directly, but some sort of signal amplification is required.

An alternative to bulk wave sensing is represented by surface acoustic wave devices. The electrodes are located on the same side of the crystal and the wave transmits along the single side of the crystal, increasing the sensitivity.

Micro and nanomechanical cantilevers

Cantilevers are one-end clamped beams (Figure 2) and represent one of the major promising label-free biosensing platforms.

They can operate in static or dynamic mode. In static mode, the cantilevers are functionalized with a specific receptor only at

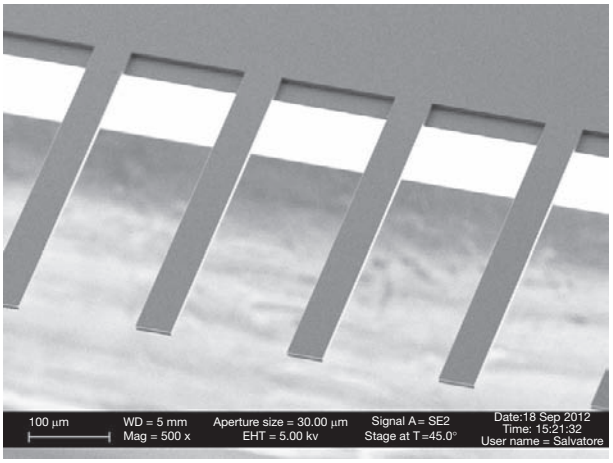

Figure 2 Scanning electron microscopy (SEM) image of a microcantilever array.

the free end of the beam, and when the target binds to the surface, a deflection of the cantilever free end occurs due to the surface stress variation. The static approach is subjected to important restriction as stabilization problems occur due to thermal drift, low sensitivity, and difficulty in comparing deflection with the amount of the added mass. For quantitative analysis, a dynamic approach is recommended. The working principle is rather simple and similar to QCM: cantilever resonates at a specific frequency that can be easily monitored. If target molecules bind to the cantilever-functionalized surface, the mass added to the sensor leads to a shift in the resonance frequency linearly proportional to the total mass bound to the probes. Using the following equation, it is possible to easily link the shift of the resonant frequency $\triangle f$ to the added mass $\triangle m$:

$$\triangle m = -2\frac{\triangle f}{f_0} m$$

where f_0 and m are the resonant frequency and the effective mass before the binding event, respectively. The mass resolution is typically in the nanogram range, if vibrational curves are monitored directly in liquid samples, while in vacuum conditions, the mass sensitivity can be increased, enabling the detection of masses at the zeptogram level. The technique can be successfully integrable as a diagnostic tool on a lab-on-chip platform, reducing assay time and sample manipulation, thus providing portable analytic devices. Simply varying the molecular recognition strategies, these biosensing platforms can be used to detect different targets such as microorganisms, biomolecules, and nucleic acids. In the literature, examples of detection of small immunogenic molecules such as toxins, pesticides, hormones, and antibiotics have been reported.

Electrochemical Biosensors

A chemical sensor is a device that transforms chemical information like concentration of a specific sample component or total composition into an analytic signal, thanks to a chemical reaction. Electrochemical biosensors are a subclass of chemical sensors and specifically react with the target producing electrical signal proportional to the concentration of the analyte. These kinds of molecular sensing devices intimately couple a biological recognition element to a solid electrode surface or electrode arrays, which respond to applied electrical impulses and convert biological recognition process into a useful electrical signal. The major advantage of electrochemical transduction is the possibility to operate in complex and turbid media and to construct inexpensive and miniaturizable devices.

Electrochemical sensors are classified into three groups: amperometric, potentiometric, and conductometric biosensors.

Amperometry is the most common transduction method used in biosensor development thanks to the high sensitivity, wide linear range, and quick response.

In amperometric configuration, a constant potential is applied between the reference and working electrode, measuring continuously the output current associated with the reduction or oxidation of an electroactive species involved in the recognition process: the current generated is linearly related to the target concentration. Amperometry is widely used in enzymatic essays in which hydrogen peroxide is produced in reaction process. Hydrogen peroxide is oxidized at a constant potential to form oxygen molecules, and the electrons result in a measurable current directly proportional to the H_2O_2 concentration. This kind of biosensor is able to detect *E. coli* in 30 min at a concentration of 100 cells ml^{-1}. One of the major drawbacks of these sensors is the interference on the presence of different electroactive compounds within the sample, which can interfere with the signal. In this case, the use of selective membranes can be useful to control the access of compounds to the electrodes.

In potentiometric devices, charge potential accumulation in the working electrode is monitored in comparison with the reference electrode, when no current flows between them; *E. coli* was detected in 1.5 h at 10 cells ml^{-1} concentration, monitoring pH variation caused by NH_3 produced by the bacteria. Potentiometric biosensors can be used in continuous, on-line, and in real-time monitoring, they are portable and cheap devices, but poorly selective.

Conductometric biosensors measure variation in conductance/resistance due to the charges produced during enzymatic conversion; impedimetric-based biosensing platforms detect variations in electrical properties arising from biorecognition events at the surface of modified electrodes. Microbial metabolic activity induces an increase of conductance, while impedance decreases: so these biosensors can be used for pathogen detection. Since 1992, impedance technique is accepted as screening technique for *Salmonella*, *Enterobacteriaceae*, *Listeria* spp., and coliforms that can be successfully detected even if the sensitivity is lower with respect to other sensors. *E. coli* can be quantified in a range of 10^4–10^7 CFU ml^{-1}. *Bacillus cereus* has been detected through antigen–antibody interaction in only 6 min with a sensitivity of 10^1–10^2 CFU ml^{-1}.

The miniaturization of electrodes to micrometric scale allows the packing of numerous transducers elements onto a small biochip device and hence the development of portable high-density arrays, satisfying current requirements for multianalysis. Generally, microelectrodes have great advantages over conventional ones such as low resistance, rapid attainment of the steady state, use of small solution volumes, and high signal-to-noise ratio.

One of the major drawbacks of electrochemical sensors is the inadequate sensitivity. Transport rate on the redox couple to the electrode surface, that is electron transfer kinetics, and diffusivity of electroactive species are very important parameters to consider in order to improve device performances. Moreover, the rate of electron transfer at charged transducer surface is influenced by solvation of redox probes and other ionic species in solution. Other obstacles in adapting electrochemistry to biosensors are the immobilization of the probes, which usually leads to a partial loss of antibody binding capacity, and regeneration, generally incomplete or impossible due to lability of antibodies. However, regeneration is necessary for sensor calibration.

Nanotechnology is a promising way for development of ultrasensitive electrochemical biosensors. Nanomaterials have favorable electronic properties, electrocatalytic activity, high surface area able to enhance the signal, and specific physicochemical bioassays, due to the nanometric size. They have been exploited to promote electrochemical reactions, to achieve direct wiring of enzymes to the electrode surface, and to amplify the signal of biorecognition events.

Impedance biosensors have been investigated for bacteria detection exploiting electrical properties of bacteria cells when they are attached to or associated with electrodes. Magnetic nanoparticles functionalized with antibodies are useful to separate cells from a mixture of bacteria or food matrices, concentrating a target of small volume, applying a magnetic field. In this way, the sensitivity is improved. Recently, the pathogenic bacteria *E. coli* O157:H7 have been successfully detected by impedance biosensors in ground beef samples in 35 min at a concentration of 8.0×10^5 CFU ml^{-1}.

In 2007, Sadik and collaborators described the integration of a fully automated electrochemical sensor with pattern recognition techniques, for the detection and classification of bacteria kingdom at subspecies and strain level. A high-throughput 96-electrode dissolved oxygen sensor measures the difference in the oxygen consumed by different bacteria classes and strains over time, and the oxygen reduction was monitored at a fixed potential.

Biosensors represent a challenging emerging field that has not by any means reached its full potential.

Unfortunately, most biosensors are still prototypes and their introduction in analytic laboratory as routinary commercial devices is not realistic yet. It is not even clear which biorecognition elements or transduction principle will be most productive, so the biosensing research field will continue to evolve in different directions. Generally, robustness of the biorecognition system is the major concern for many applications.

The future of biosensing applications is represented by development of array biosensors, biochips, and lab-on-a-chip for multiplex analysis. They will integrate all processing steps into a microanalytical system, allowing the assay of a large number of samples in few minutes and reducing the use of a high volume of reagents. Actually, microfluidic systems, sample preparation modules, sensitive detection modules, and robust assay methodologies still require further researching efforts prior to develop these kinds of biosensing platforms.

Introduction

Biscuit and biscuit-like products have been prepared and consumed by humans for hundreds of years. The term *biscuit* is derived from the Latin word *biscoctus*, which means twice cooked/baked. Its origins date back to Roman times, when certain foods needed to be completely dried so that they could be stored for long periods of time. The term *biscuit* is widely used for biscuits, cookies, and crackers alike in different parts of the world. In the United States, for instance, it is known as a 'chemically leavened bread type product.' It is also called 'scone' in New Zealand, 'biscuit' in the United Kingdom and 'cookie and cracker' in the United States. Different names are given to different products depending on their textural differences and extent of hardness. Second classification for biscuits, cookies, and crackers is usually done on the forming method used during their manufacturing and are therefore classified as fermented, developed, laminated, cut, molded, extruded, deposited, wire-cut, coextruded, and so on. The biscuits and biscuit-like products can be further classified by type and extent of value addition of products like chocolate chips, dried fruits, cream, jams, jellies, and others and also on the secondary processing applied during their manufacturing, including sandwiching, chocolate enrobing, cream filling, center filling, and others.

Dough Ingredients and Their Role

Wheat flour is the major ingredient used in the manufacture of biscuits. Flour is considered a toughener and provides texture, shape, and hardness to the biscuits and biscuit-like products. Apart from wheat flour, some nongluten flours (rice, maize, barley, millets) are also used to produce gluten-free biscuits (Table 1).

The principle proteins of wheat flour are gliadins and glutenins, which produce gluten on addition of water and in return provide structure to products. Soft wheat flour containing up to 9% protein is preferred for manufacturing most of the biscuits and biscuit-like products, whereas for production of crackers medium-strength flour with a protein content of 10.5% or more is preferred. Sweeteners are the second major ingredient after flour used during biscuit production, and they impart sweetness, texture, and color to the product and also increase shelf life. Usually during the manufacturing of biscuits a combination of sucrose and sugar syrup is used, as the former gives texture by forming amorphous glass during baking, and the latter is responsible for color production of the final baked product by enhancing the browning reactions.

Oils and fats are added during the manufacturing of biscuits, as they lubricate the structure of the product and also contribute to texture. Sources of fat and oil range from animal fat (butter, butter oil) to vegetable oil (palm oil, peanut oil, etc.) and are selected by regional preference. The function of fat during manufacturing of biscuits is to interrupt the formation of the gluten network by surrounding the flour particles and making the product softer or imparting soft and smooth texture. Other than that, fats are also used in secondary processing like preparation of cream for cream fillings, surface spraying, and coatings. Water has various functions to perform in biscuit manufacturing like gluten formation, dissolving minor and major ingredients, and controlling dough temperature.

Surfactants/emulsifiers increase the dispersibility and spread the fat more uniformly over other main ingredients. Mostly lecithin, mono- and diglycerides, diacetyltartaric acid esters of fatty acids, polysorbate 60, and others are used as emulsifiers. Surfactants modify the behaviors of liquids and do form a complex with the protein–starch structure, thereby strengthening the fat film and delaying dough setting during baking. Antioxidants, which retard the oxidative rancidity in fats and increase product shelf life, are also added during biscuit manufacturing, for example, butylated hydroxyanisole, butylated hydroxytoluene and tert-butyl hydroxytoluene. Food additives are added either with the purpose to increase shelf life, ease processing, or enhance sensory properties; different additives, such as leavening agents, colors, acids, flavorings, preservatives, and stabilizers are added. Salt is added as a flavor carrier to make gluten tougher and to slow down the fermentation rate. The common leavening agents utilized during the manufacturing of biscuits are sodium bicarbonate and ammonium bicarbonate, which produce gases/CO_2 and ammonia during dough baking and make them porous and light. Different artificial or natural flavoring compounds are used in biscuits to enhance flavor, taste, and smell. Usually spices, herbs, essential oils, and synthetic flavors are used. Biscuit color is an important indicator of quality, as it makes the product more attractive. Plant pigments, caramel color, or artificial coloring agents are the most commonly used coloring agents. Other minor ingredients like milk and milk products or eggs contribute toward nutrition, color, flavor, and texture of the final product (Table 2).

Manufacturing of Biscuits, Cookies, and Crackers

This section describes the methods, processes, and equipment involved in the manufacturing of biscuits, cookies, and crackers. Differences between these products can be made on formulation, usage level of fat and sugar, method of forming of the dough, and the textural properties of the naked products. The manufacturing process generally involves mixing, shaping, and baking steps, which are common for all the products and are discussed as follows:

Table 1 Functions of ingredients in biscuit, cookie, and cracker manufacturing

Ingredients	*Role*
Flour	Forms a viscoelastic network Holds all the ingredients uniformly in the dough Provides texture, hardness, and shape
Sweeteners	Provide sweetness, color, and flavor Provide texture
Shortenings	Interrupt the gluten network of flour Shorten the dough (reduce hardness) Provide texture and improve the eating quality of biscuit
Water	Form gluten in dough Dissolves ingredients and controls dough temperature
Emulsifiers	Maintain uniform dispersion of immiscible substances Spread the fat more uniformly into dough
Yeast and enzymes	Responsible for fermentation (crackers) Modify the gluten proteins and partially break down pentosans in flour
Antioxidants	Retard the oxidative rancidity in fats Increase storage life of fats and increase biscuit shelf life
Leavening agents	Produce gas Increase volume and improve texture
Salt	Toughens gluten Enhances flavor Slows down the rate of fermentation
Milk products	Add nutrients, flavor, and texture Also responsible for Maillard reaction
Egg	Provides nutritional value, structure, and color
Flavor	Enhances flavor, taste, and smell
Colors	Provide better look Make the product attractive

Premixing

Weighing of ingredients is done according to formulation and considering the batch size before the mixing operation starts. Weighing of ingredients is mostly manually done when the batch size is small, but for continuous operations automatic weighing systems are used. Ingredients like flour and sugar are conveyed pneumatically, while liquid shortening and water can be pumped into the mixer. Minor ingredients are usually mixed with water and then added into the overhead mixer hopper. Ingredients like skim milk powder have a tendency to form lumps, so a proper sequence of adding minor ingredients must be followed.

Mixing

The primary purpose of mixing is to bring about a complete and uniform dispersion of ingredients to form a homogeneous dough within a decided time period. In the case of biscuits, cookies, and crackers, mixing mainly involves blending, dispersing, dissolving a solid ingredient into a liquid medium like shortening or water, kneading, developing of dough, and discharging of dough into trolleys or on conveyor belts for further processing. The mixing time usually ranges from 15 to 25 min and depends on factors like flour characteristics, formulation, and temperature of the dough during mixing. Biscuits and cookies generally differ from other baked products such as bread due to a lower moisture content in the final product, and therefore rheological characteristics of dough are different depending on the formulation. Mixers typically have programmable variable-speed drives, which give bakers the opportunity to gently fold in large inclusions without breaking them apart. The two principal type of mixers used for mixing the dough for biscuits, cookies, and crackers can be categorized into batch and continuous mixers, and the latter ones can be further classified into various types.

Batch mixers

The batch mixers are comprised of high-speed horizontal mixers and vertical mixers with detachable bowl.

High-speed horizontal mixers

High-speed multipurpose batch mixers can handle every type of dough for biscuit, cookie, and cracker manufacturing. They offer high levels of automation, ease of use and cleaning, and outstanding reliability to guarantee low-cost maintenance. Unique blade design ensures good dispersion and rapid dough development. They usually consist of a horizontally mounted bowl that encloses the drive motor and are double jacketed, which helps to control the dough temperature during mixing. Usually cold/hot water is circulated in the jacket as a coolant/heating medium. The bowl of the mixer is fixed and has a door at the bottom, which opens and allows the discharge of the dough. The rate of discharge can be increased by rotating the beaters, which can rotate on a horizontal axis.

The beaters are driven horizontally within the bowl and may be fixed to one or two shafts. The action whereby the dough is cut and sheared depends on the exact shape and speed of the blades, but in many mixers the stator is fixed in the bowl, which provides an additional means for cutting the dough. The production rate of mixers is closely tied to the ingredient feed arrangements, but it can range from 500 to 1200 kg h^{-1} for hard dough and up to 650–1300 kg h^{-1} for short dough. The blades of high-speed horizontal mixers are of several types, including high-speed angled wing, parallel bar, and sprag, depending on shapes, action, and product. The frame is fitted over a base plate to retain the load of the mixing chamber. The Z and sigma type are the most commonly used mixing blades: they are fitted inside the mixing chamber and can rotate at different speeds to facilitate mixing of different dough types. To unload the dough from the mixer, a programmable logic controller (PLC)/electrically operated tilting mechanism is also provided.

The advantages of high-speed horizontal mixers are that they are fitted with a high-speed motor with variable speed options to enhance mixing control. The shaftless blades allow the rapid dispersion of ingredients and efficient blending compared to vertical mixers. The PLC and supervisory control and data acquisition (SCADA) control allow easy operations. It can tilt up to 150°, allowing complete discharge of the dough, which can be transported via conveyor/trolleys into the hopper of depositor/rotary molder or sheeting line. To facilitate easy cleaning, they have a 90° reverse tilt option. For loading the dry ingredients, it has pneumatic slide valves fitted overhead and can be operated at 15–80 rpm. It provides more flexibility to the production line.

Table 2 Formulations of biscuits

	Short dough formulations		*Hard dough formulations*					
			Cream cracker		*Soda cracker*			
Ingredients	*Milk biscuit (%)*	*Butter cookie (%)*	*Sponge (%)*	*Dough (%)*	*Sponge (%)*	*Dough (%)*	*Deposited butter cookie (%)*	*Gluten free cookies (%)*
Flour (soft)	100	100		66.7 + Sponge of cream cracker		36.9 + Sponge of soda cracker	100	
Flour (hard)			33.3		63.1			
Corn flour								97.08
Pregelatinized starch								2.92
Granulated sugar		16.67					35	36.96
Powdered sugar	32.38	15.15						
Cane syrup 80%								1.95
Invert syrup 70%	2.86						4	
Malt extract 80%				1.34		0.95		
Dough fat	17.86			28				11.67
Butter		49.70			12.6		60	11.67
Fresh egg		3.79					3.00	5.84
Lecithin	0.10				0.24			
SMP	0.24						5	9.73
Lactalbumin								1.52
Caseinate								12.65
Fresh yeast			0.5		0.63			
ABC	0.17	0.45						2.04
Soda	0.76	0.17		0.67		0.49	0.2	
ACP	0.10							0.51
Salt	0.29	0.76	0.02	1.68		1.89	1	
Liquid flavor	0.10						0.1	0.1
Protease enzyme						0.005		
Recycle biscuit	7.17						10	
Water	23	0	13	40	23.7	5	7	18

Disadvantages of using a horizontal mixer are that most of the ingredients are fed manually except flour, sugar, and oil through the feeding chute, which is located on top of the mixer, and on several occasions unhygienic conditions can prevail due to spillage of ingredients outside the chute. Due to fully enclosed systems, the mixing process cannot be manually observed. Only a single operation can be performed at an instance like charging, mixing, or discharging. Due to high speed, huge weight vibrations are caused during mixing of dough. The discharge of the dough is not always rapid, and it also prevents free movement of dough, as the blades are centrally located to the shafts.

Vertical mixers

Vertical mixers were used extensively before the introduction of horizontal mixers. These types of mixers are used extensively by small bakeries and also during production of crackers. Vertical mixers are also known as spiral or detachable bowl mixers and usually have a wheeled manger or tub with round ends and flat bottom. Beaters are connected with an overhead frame and mounted vertically with horizontal shafts and arms. It may contain one to three beaters and can operate at fixed positions. Bowl and beater position is adjustable and can move in either planetary or stationary direction, which allows gentle rolling and cutting actions. Capacity of mixers can vary from two to three dough batches per hour, and beaters usually rotate at a speed of 20–25 rpm.

The advantage of vertical mixers is they are suitable for almost all types of dough and are available in different capacities. The ingredients can be loaded manually in the tub from the top of the mixer. The dough requiring fermentation/resting time can be manufactured with this mixer. Different types of dough and batters can be mixed by changing beaters/blades assemblies. The mixing process can be visually monitored, and further mixing of any ingredient can be performed. The sequence of ingredient adding can be controlled, and over- or

undermixing of the dough/batter can be avoided. Cleaning is much easier as compared to horizontal mixers, as the bowl and the blades assembly can be detached from the main frame for cleaning.

Vertical mixers usually operate at a very low speed and therefore require more mixing time as compared to horizontal mixers. In vertical mixers the dough is subjected to different mixing action at the top and bottom of the tub, which results in the formation of an uneven dough. The tub and dough handling equipment are generally very heavy and require special equipment like hydraulic-operated trolleys to move them, which is quite laborious. The jacket and temperature sensors are disconnected and reconnected every time while mixing and moving the bowl of the mixer for loading/discharge of dough (Figure 1).

Continuous mixers

Continuous mixers offer a uniform and consistent dough stream for the production lines, which guarantees a consistent product throughout production. These mixers run on continuous feeding systems and can be operated with a precreaming, dosing section in which ingredients can be fed at start or at successive intervals along the length of the screw/rotor of the mixer. Different arms and stators can be attached in the continuous mixer along the length of the barrel, and the mixing action can be altered depending on the consistency of the dough. The orifice at the end of the rotor/screw provides the desired shape to dough pieces. Dough temperature is controlled by water jackets, and mixing time can be varied by adjusting the barrel length. Continuous mixers can provide complete automation as they have a compact system.

Continuous mixers can operate with minimum manpower, lower supervision, and minimum wastage, and uniformity in dough consistency is required for running the equipment. Continuous mixers are favorable for manufacturing products that require no standing time for the dough. Compared to horizontal/vertical mixers, continuous mixers are only suited for manufacturing a single product, as the changeover is not easy, being difficult to optimize the procedure. The cost and complexity is higher in case of any problem as starting and stopping a continuous mixer is much more difficult.

Figure 1 High-speed horizontal mixer.

The Forming Process

In the manufacture of biscuits, cookies, and crackers, the mixing and baking facilities may be used in common, but the forming process is specific for each type of product. Before starting the forming process the dough may be rested for some time to allow fermentation or gluten development in products like crackers and hard dough biscuits. The standing time and the dough temperature are critical in controlling the final quality of the product. The dough is fed into the hopper usually by a trolley tipping device or manually from the trolley. The forming process is specific for every product and can be generally classified into three types: (1) sheeting, laminating, gauging, and cutting; (2) rotary molding; and (3) extrusion of dough through dies. Dough with a fully developed gluten network is generally sheeted and strong, inextensible dough is laminated. Rotary molding is applicable to dough with less-developed gluten, and the soft dough is generally extruded.

Sheeting, Gauging, and Cutting

Sheeting and cutting is the most preferred method for the manufacturing of products like cracker and cookie dough pieces. In this method the fully developed dough is fed by an automatic dough feeder in different configurations onto the hopper of a three- or four-roll sheeter. The rolls are configured to create a compression chamber, which makes a homogeneous dough. This unit allows constant dough feeding and scrap integration to form a consolidated dough sheet of even volume prior to the first gauge roll section of the downstream forming equipment. These sheets are then converted into a uniform sheet of desired thickness (4–5 mm). Three-roll arrangements are generally used for the sheeting process, but on many occasions two-/four-roll arrangements are also deployed. The three rolls are arranged in the form of an inverted triangle below the hopper. In the three-roll arrangement, the two top rollers are known as forcing rolls, and one of the top rollers along with the third roll forms a gauge and hence is called gauge roll. One of the forcing rolls has a rough/grooved surface so that it can facilitate the drawing of the dough from the hopper into the sheeter, and the rest of the two rolls are smoothed. The thickness of the outcoming dough sheet is adjusted by varying the gap between the forcing and the gauging rolls. After the sheet is prepared, it is discharged onto the conveyor belt, and it can be either a front or a back discharge (Figures 2 and 3).

The series of heavy steel rolls called rollers is used to reduce the thickness of the dough sheet to a desired thickness and smoothness. The diameter of the gauge rolls varies from 150 to 400 mm; they have a smooth surface and are mounted vertically one above the other. The last gauge roll acts as a calibration unit, and it has larger diameter rolls. They can be completed by a height scan unit and skinning air ventilators, whereas all conveyors are provided with automated belt tensioning and tracking systems. For most of the products, two to

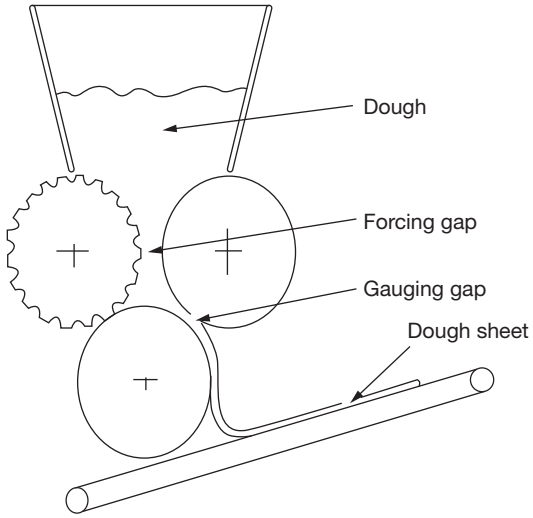

Figure 2 Front discharge sheeter. Sheeting process. See text for explanation. Reproduced from Duncan, M. (eds.) (2011). *Sheeting, gauging and cutting in biscuit manufacture*, *Manley's Technology of Biscuits, Crackers and cookies* (4th ed.). Cambridge: Woodhead Publishing Limited.

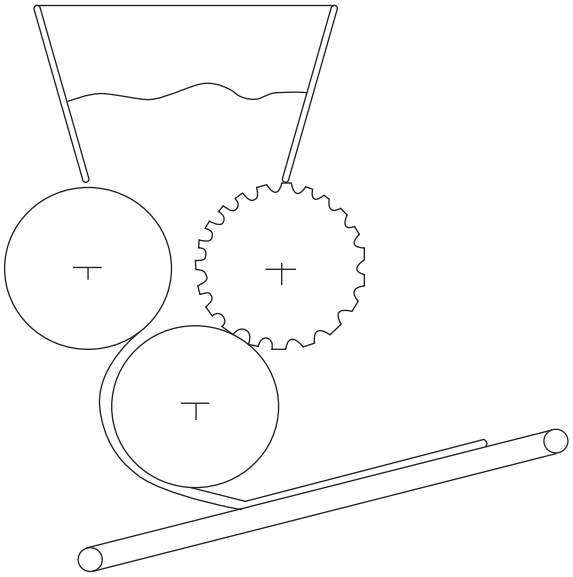

Figure 3 Back discharge sheeter. Sheeting process. See text for explanation. Reproduced from Duncan, M. (eds.) (2011). *Sheeting, gauging and cutting in biscuit manufacture*, *Manley's Technology of Biscuits, Crackers and cookies* (4th ed.). Cambridge: Woodhead Publishing Limited.

three pairs of rollers are used, and the gap between the two rollers can be adjusted up to a clearance of 0.1 mm by moving the rollers in an upward or downward direction. Care has to be taken while adjusting the gap between the consecutive pair of rollers, and the thickness of the sheet must not be reduced more than 50% at any rolling operation. As the rollers are smooth, the chances of dough sticking to the roller are increased, so to avoid this, a scraper is fitted that helps to scrap the sheet and transfer the same onto the conveyors.

The laminator is used in the production of laminated products such as crackers, hard-sweet biscuits, and baked snacks that have a unique property of a light and crisp texture. Laminators are available in two forms, that is, vertical and horizontal, the former of which is often used by cracker manufacturers. Laminating is done for several reasons: (1) it helps to repair the sheet that was formed using a simple pair of rolls; (2) uniform stress distribution can be achieved by turning the folded dough through 90°; (3) consecutive and repetitive cycles of rolling and folding cause more working of dough and develop a delicate structure in baked products; and (4) flaky structure can be obtained in products by spreading fat between two layers. Before the use of automatic laminators the process was performed by hand. Cut-sheet laminators are also used, which are servo motor driven and can operate at high production rates, where the dough sheets are precisely cut into sheets and layered before passing on to the forming and cutting equipment. The number of layers formed during the laminating process affects the final quality of the product, and therefore the takeaway conveyor and the relative rate of the laminator must be controlled for obtaining an equal number of layers.

After the dough sheet is sheeted out from the final gauge roller, a relaxing web is placed between the final gauge roll and the cutting assembly. It is desirable to relax the dough more often in puff or other laminated types to facilitate shrinkage. Flutes are formed on the relaxing web as the speed of the relaxing web is less as compared to the conveyor after the final gauge roll. After the relaxing web, the sheet is again straightened by increasing the speed of the conveyor carrying the sheet to the cutter. The cutting operation can be carried out either to only cut the sheet with a die or to create different designs on the dough piece. Reciprocating and rotary cutters are the two types of cutting processes used by the biscuit and cracker manufacturers. Reciprocating cutters consist of heavy block cutters that stamp out one or more pieces at a time. For maintaining a perfect size and shape, it is necessary that the dough sheet travels at constant speed under the cutter, which drops over the dough sheet, moves along with the dough, and comes to the original position before dropping again. The speed of reciprocating cutters usually ranges from 100 to 200 cuts per minute. Rotary cutters consist of a rotary metal cylinder and may be available either as single or double rotary cutters. A pair of engraved rolls embosses and then cut the dough pieces from a continuous sheet. The rotary cutting rolls are generally made up of bronze or gunmetal and are fitted with molded plastic cups that are engraved. The number of cups on each roll depends on the diameter and length of the roll. After the cutting, the remaining dough, called scrap, can be reused either by mixing it with a fresh batch of dough in the sheeter with the help of the 'scrap return,' or it is added in the horizontal mixer while kneading a new batch.

Rotary Molding

Rotary molding is of great use for handling short dough type biscuits: a single machine produces dough pieces, whereas a huge line is involved in sheeting and cutting. Rotary molding is used to manufacture short dough products like biscuits and sandwich cookies because it is possible to control biscuit

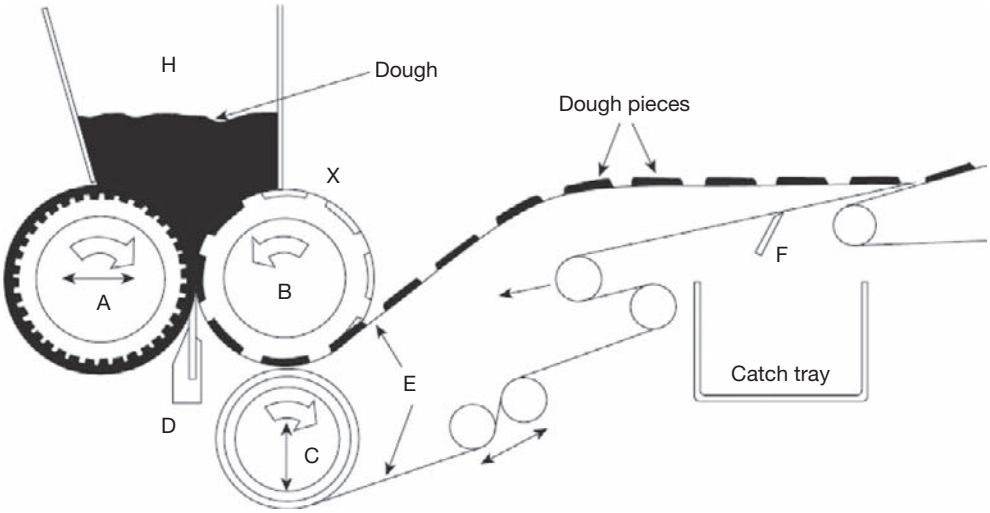

Figure 4 Rotary molding process. See text for explanation. Reproduced from Duncan, M. (eds.) (2011) *Laminating in biscuit manufacture*, *Manley's Technology of Biscuits*, *Crackers and Cookies* (4th ed.). Cambridge: Woodhead Publishing Limited.

weight and texture. The process involved in rotary molding is illustrated in Figure 4.

The general arrangement of a rotary molder consists of a set of three rolls arranged in triangular fashion and placed below the dough hopper. The forcing roller (a) made of steel, holds onto a blanket of dough as it has grooves of various patterns and then forces the dough into the engraved roller. The mounting roller (b) is engraved over a smooth surface, which forms the dough pieces, and the molds are made of plastic or bronze. The molds are engraved with the name and the design pattern, which creates impressions on the dough piece when it is extracted with the help of the extraction web and the extraction roll (c). Excess dough from the forcing roller is scrapped away by a scrapper (d), which is made of steel, and the tip is located below the center of the forcing and the mounting rollers. The extraction roller is made up of steel with rubber coating, and an extraction web (e) passes around it, which is pressed against the forcing roller to extract the dough pieces. The extraction web is usually made from mainly polyurethane or cotton and is cleaned for excess dough/broken dough pieces by a scraper knife (f), and the scrap is collected in the catchment tray. The dough pieces are than passed on to a web, which then transfers the dough pieces onto the baking belt.

Extrusion

Extrusion is one of the simplest ways of making dough pieces and is done by forcing soft short dough through orifices by means of a pump or rollers. Batter like dough is easy to extrude rather than mold or sheet. Extrusion is of great advantage while handling sticky dough and dough containing coarse particles such as nuts, flakes, or chocolate chips. The extrusion process involves wirecut machines and rout presses, which may be further subdivided into angled overhead wirecut and dualtex rout press. Operating speed of wirecut can be as high as 300 rows per minute with a minimum wastage of dough (1–2%) and up to 3800 kg for dualtex root presses.

Dough extrusion machines consist of a hopper placed above a set of two rolls, which force the dough into a balancing/pressure chamber underneath. The rolls can run continuously or intermittently, with a reverse motion for a short period, which causes a suck back action at the nozzle or dies located at the base of the pressure chamber. The extruder is generally positioned directly over the oven band or on a moving conveyor with continuous feeding of trays. Rout types and wirecut extruder are positioned over a normal canvas conveyor. The dies of the extruding machine are placed approximately 70 mm above the takeaway conveyor, or oven band, and its positioning can be adjusted to meet specific product requirements. The orifice size of the dies determines the size of the dough piece, whereas the extrusion rate can be adjusted by the speed of the forcing rolls. The extrusion rate is affected by dough consistency, head of the dough inside the hopper (it is advocated to maintain the dough within a fairly close limits and it is usually found that low levels of dough tend to give less weight variation than high), and pressure in the chamber.

Baking

Baking is the most important manufacturing process, and the final product quality and shelf life rely on the effectiveness of the oven to bake the product. During baking, dough pieces experience changes in density, the structure becomes porous, moisture is reduced, and the surface becomes colored. A traveling or band oven is extensively used for industrial baking processes, whereas small bakeries rely on simple ovens or static ovens, which usually have a heated box with a door and different trays and can be heated by means of electricity, gas, or wood.

The traveling or band oven is a tunnel that is enclosed, is insulated, and bears different sections/zones. Oven length ranges from 30 to 150 m, with an average length of about 60 m and a band width of 1–2 m. The oven consists usually of 3–7 zones with different temperature and air profiles, which

are controlled separately as for the baking profile of the product. In a continuous oven, temperature and heat transfer conditions can be controlled throughout the oven during the baking process. Industrial ovens usually run on fuels such as petroleum gas, oil, or electricity, which heat the atmosphere around the product either directly or indirectly via heat exchangers. The band or trays serve as the baking surface inside the oven. The selection of the oven band is product specific as it affects the quality of the finished product by altering the heat transfer at the bottom of the product itself. The band can be a continuous sheet of steel, which may or may not be perforated and is also available in the form of a wired mesh type. A terminal drum is provided at each end of the oven, and the drive drum, which drives the continuous band and also returns it to the panning end, is located at the oven exit. The feed end is equipped to adjust the tension of the band to hold it tight and prevent any damage. The oven band is supported by metal or graphite skids to prevent sagging. The speed of the band usually decides the baking time of the product, for example, short dough biscuits as compared to hard dough biscuits require a shorter baking period.

Ovens for industrial baking purpose are classified into direct fired, indirect fired, and hybrids. The fuel combustion provides heat to the oven, and usually oil and gas-fired ovens are used. The most common type of oven is the direct gas-fired (DGF) oven, as it offers great flexibility for baking products with different characteristics. In DGF ovens process conditions can be varied for different products including temperature profile, turbulence, and humidity conditions. Ribbon burners burn the fuel and transfer the heat on the band from above and below by an air circulation (turbulence) system. DGF ovens can handle a wide range of products such as hard crackers to very soft cookies. Other direct-fired ovens include the forced convection direct fired and the convector-radiant type. The indirect-fired oven is also known as the convective oven in which hot gases are passed evenly above and below the band and across the full width of the oven. Indirect-fired ovens are provided with separate burners for each zone and usually the fuel is burned outside the baking chamber. Indirect-fired ovens are further classified into indirect-fired forced convection and indirectly fired cyclotherm. In the latter type, parallel tubes run above and below the oven throughout the length of oven in which hot air is supplied through fans to heat the product and circulates back the outgoing cold air to burners. The indirect-fired forced convection oven is similar to the forced convection direct-fired oven, but the difference is that zone burners heats the air through heat exchangers that pass through the plenum chamber. Hybrid ovens are a combination of DGF, direct, and indirect ovens and have varying heating, thermal efficiency, heat transfer, and airflow characteristics that affect product quality. Hybrid ovens respond to specific needs for any kind of biscuit, cookie, and cracker. Most hybrid ovens feature a DGF section for the first part of the baking when the air movement is often undesirable as it dries the outer layers and prevents proper flow and lift. During the drying and coloring processes in the later stages of baking, the air movement is beneficial so a convection section is used.

The baking profile is different for almost all types of biscuits, cookies, and crackers and depends on the formulation and the desired textural product characteristics. Baking time varies from 3 to 12 min and depends on the product. The shortest baking time is usually for crackers and the highest one for cookies. Temperature also varies from 140 to 240 °C, varies from zone to zone, and is product specific.

Cooling

Freshly baked products leaving the oven must be cooled before packaging or secondary processing. The product leaving the oven has a temperature of about 100 °C. Cooling is important because warm biscuits or cookies might not able to withstand the packaging process if too soft, and also the packaging material may shrink and the product quality may deteriorate due to condensation of water vapor inside the packed product. In the industrial production, the cooling process starts at the oven exit: the biscuits are transferred from the oven band to an open conveyor using a doctor's knife and then transferred on the cooling web, which is made of cotton canvas, and carried through the cooling conveyor to cool naturally in the ambient air. The cooling conveyor is either a single- or a two-tier arrangement, depending on the factory layout. A two-tier system is often used when it is desirable or necessary to turn biscuits over during cooling. This avoids uneven moisture distribution, which leads to biscuit cracking. The turning of biscuits also helps in quality control by identifying the faults on the bottom of the biscuits/cookies like burned particles. The length of the cooling conveyor varies from 1.5 to 2 times the length of the oven. Usually the product is cooled up to 40–45 °C, and those who require secondary processing like cream filling are cooled to 18–26 °C. To achieve greater control over the biscuit temperature, forced air cooling is also employed at the end of the cooling process.

Secondary Processing

Typical secondary processing involves the deposition of cream, jam, or marshmallow on the biscuit or the enrobing with chocolate or coating with icing, which gives the product a different appearance, texture, and taste. Cream sandwiching is a process in which two or three biscuits are sandwiched with cream filling between them. The filling generally contains sweet cream with 30–40% fat and 60–70% sugar with added color and flavor. Sandwich machines usually contain 2–6 lanes and can produce 400–800 sandwich biscuits/lane/minute. Apart from sandwiching, icing, jellying, marshmallowing and chocolate coating can also be done.

Packaging

Biscuits require immediate protection as they are highly hygroscopic in nature and tend to gain moisture from the atmosphere, which leads to spoilage. The overall biscuit packaging involves primary, secondary, and tertiary packaging that have different functions and requirements. The primary package is generally in the form of flow wraps, slugs, sachets, displays, tubes, and shrink wrappings, which are usually laminates made up of polypropylene, plastic-coated papers, and

metal boxes. The secondary packaging is usually carried out for packing of wholesale/bulk packets. The tertiary packaging generally utilizes corrugated boxes.

Introduction

There are hundreds of varieties of biscuits, cookies, and crackers found across the globe. Diverse terminology in different parts of the world causes some confusion regarding the distinction between biscuits and cookies. In North America, the term biscuit refers to baking powder biscuits or buttermilk biscuits, which are savory quick breads made with flour, shortening, milk, salt, baking powder, and occasionally baking soda. High levels of shortening in the formula produce a tender and flaky texture. They are similar to British scones but are prepared with a leaner formula, which does not contain egg and sugar. In the United Kingdom and most English-speaking countries outside of North America, the term biscuit refers to small, chemically leavened, cake-like products, which have high sugar, high shortening, and low moisture contents. These products are called cookies in the United States and Canada. In this text, biscuits are the type found in the United Kingdom that is synonymous with cookies.

Biscuits and Cookies

In general, biscuits and cookies are small, flat, cereal-based, baked products containing shortening, sugar, and chemical leavening. While soft wheat is the most common, other cereal grains such as oats, rye, corn, and barley are sometimes utilized. Most biscuits and cookies have a low moisture content of less than 5%. They vary widely in size, shape, formulation, preparation method, and flavor. The texture varies from crisp and hard to soft and chewy. Some undergo secondary processing to create sandwiched, iced, coated, filled, and multiple other types of final products. Biscuits and cookies have a relatively low risk of microbial spoilage due to the high shortening, high sugar, and low water contents. They also do not stale like bread and other higher-moisture baked products. The most common cause of loss of eating quality is due to moisture migration. Moisture uptake by crisp, hard products causes them to become undesirably soft and soggy, while moisture loss from soft, chewy products renders them dry and hard.

Biscuits and cookies are often broadly characterized based on their dough properties and then further distinguished by the technique used to shape and place the dough onto the oven band for baking (Figure 1). The two broad categories of biscuit and cookie doughs are hard doughs or short doughs. Wafers are a third category. Although wafers are not technically biscuits or cookies, they are often included in the category because they are manufactured by biscuit and cookie manufacturers.

Hard Dough

Hard doughs contain higher water, lower shortening, and lower sugar than short doughs. The most common mixing method is a single-stage mix in which all of the ingredients are mixed together in one step. The gluten is developed during mixing in hard doughs. The formulation and developed gluten network result in a tight, stiff dough that can be sheeted and then cut or stamped into shapes.

One problem with hard doughs is that if the gluten is too strong and elastic, the dough has a tendency to tear during sheeting and the cut pieces shrink back and distort prior to entering the oven. In order to manufacture hard dough biscuits and cookies on a continuous production line, some formulas contain sodium metabisulfite or sodium sulfite. These are reducing agents that break some of the disulfide bonds in the gluten. As a result, mixing time is shortened, resting time between mixing and sheeting is eliminated, and the dough becomes less extensible so it does not tear or shrink back after cutting. Hard dough biscuits and cookies do not spread (become larger in diameter) during baking. However, they do rise in the oven then shrink or collapse during cooling to produce a thicker final product.

Short Dough

The most common type of biscuits and cookies found around the world is made from short doughs. Short dough biscuits and cookies are also the most diverse, varying greatly in ingredients, size, shape, and flavor. Short doughs are typically made using weak soft wheat flours that contain 9% or lower protein content, and the formulas contain low levels of water and high levels of sugar and shortening. Most short doughs are prepared using a multistage mixing process that starts with creaming the sugar, shortening, and liquid. The liquid may be added as water, or it may be a component of wet ingredients such as fresh eggs, milk or other milk products, and liquid flavorings. The flour and dry ingredients are added to the creamed mixture in a separate mixing step. Short doughs can also be made using a single-stage mix procedure in which all of the ingredients are mixed into a dough in one mixing step. Biscuits and cookies made using a single-step method are inferior to those made with the multistage process. The structure of the cream plays an important role in the properties of the dough and of the final products. The gluten in short doughs is not developed during mixing for several reasons: the high levels of sugar and shortening delay gluten development; the water level is not high enough to completely hydrate the gluten, which prevents it from developing; and the water is encapsulated in the shortening cream where it is not available to hydrate the gluten. In contrast to hard doughs, which are extensible and elastic, short doughs are cohesive and plastic. Short dough consistency is thick enough to almost be pourable but not as thick as bread dough. Some short doughs can be sheeted and then cut or stamped into the desired shapes, while other short doughs are extruded through nozzles or dies. Most

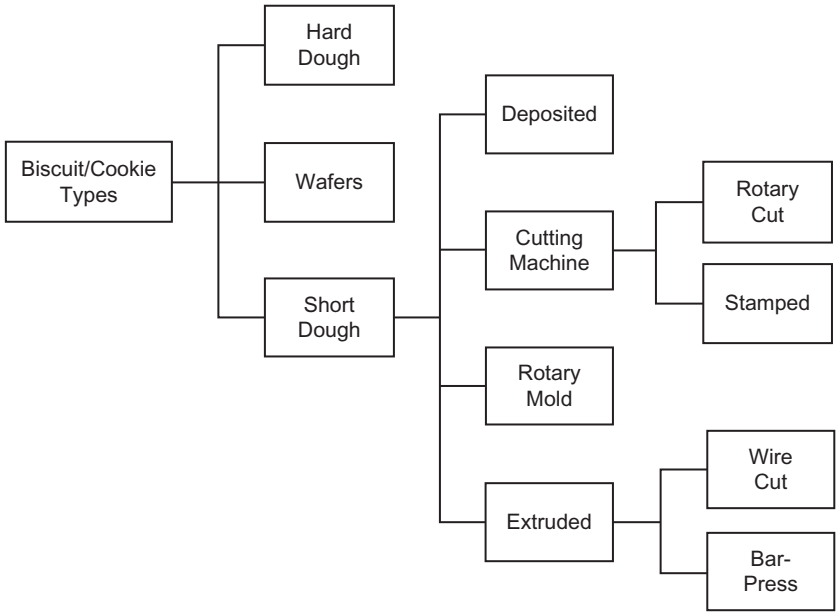

Figure 1 Types of biscuits and cookies.

short dough products retain their shape until they go into the oven and then spread or flow during baking, becoming thinner and larger in diameter. Some types of short doughs, however, do not spread at all and maintain their shape and any designs that are embossed on them.

There are several processes for shaping short doughs, which are classified by how the biscuits and cookies are placed on the baking band (Figure 1). They include deposit, rotary molding, cutting machine, and extruded processes. The cutting machine process includes both rotary cut and stamped products, while extruded products are subdivided into wire cut and bar-press (also known as rout-press) processes.

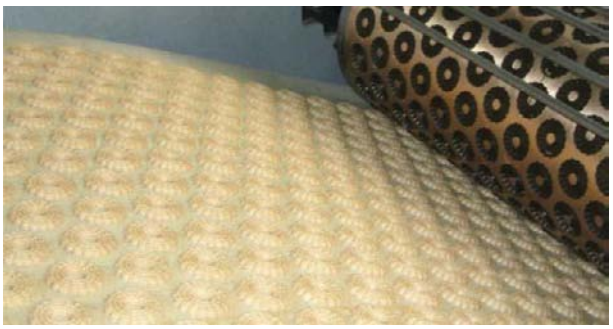

Figure 2 Rotary mold process. Photo courtesy of Reading Bakery Systems (Robesonia, PA).

Rotary Mold Process

Rotary mold is one of the most common production processes for short doughs. The formula is high in sugar, high in shortening, and low in water (less than 20% including the moisture in the flour). The resulting dough not only is crumbly, lumpy, and stiff but also is cohesive and pliable due to the high level of shortening. The dough is forced into engraved molds on a rotating roll for shaping and embossing the top surface. As the roll turns, the shaped dough pieces are extracted and fall onto a canvas belt where they travel into the oven and are baked (Figure 2). Rotary mold biscuits and cookies do not rise or spread in the oven and retain the designs that were embossed on the surface. This process only works with dry, crumbly doughs. Rotary mold biscuits and cookies are economical to produce because there is no scrap dough to recycle, the labor requirement is low, and there is little water to drive off in baking, which keeps energy costs low. The most famous example of a rotary mold cookie is the Oreo®.

Extruded Process

A wide variety of biscuits and cookies are produced using the extrusion process. These are made from soft doughs that rise and spread during baking. Extruded short dough products fall into two categories: wire cut and bar-press (also known as rout-press).

Wire cut process

Wire cut is another widely used production process for short dough products. In the wire cut process, soft, short dough is extruded through an orifice or die and cut with a reciprocating wire (Figure 3). The size of the orifice and speed of the wire control the size of the dough pieces. The dough hopper is positioned directly above the oven band so the cut biscuits or cookies fall directly onto the band. The dough must be cohesive enough to hold together but short enough to be cut cleanly by the wire. If dough consistency is not correct, the pieces are distorted during cutting and are not consistently or correctly positioned on the baking band. The wire cut process works

Figure 3 Wire cut process. Photo courtesy of Reading Bakery Systems (Robesonia, PA).

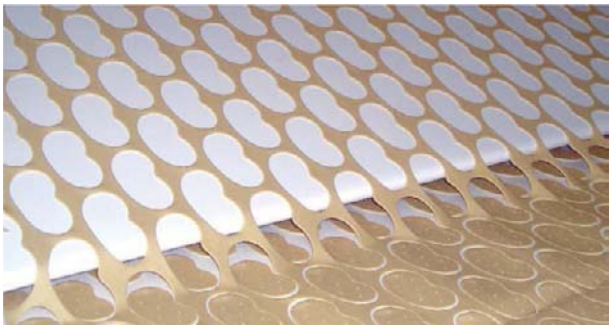

Figure 4 Rotary cut process. Photo courtesy of Reading Bakery Systems (Robesonia, PA).

well for biscuits and cookies with inclusions such as flavored baking chips, dried fruit pieces, and nuts. Chocolate chip and oatmeal raisin are examples of wire cut biscuits or cookies. The wire cut process can also be used to make coextruded products. This is done by extruding two different doughs or a dough and a filling from separate hoppers through a single orifice to combine them into a single product.

Bar-press process

The bar-press or rout-press production process is similar to the wire cut procedure except that the base of the dough chamber contains a die plate with nozzles. The nozzles are shaped to form a design. Some nozzles can rotate while the dough is extruding to produce twists, swirls, or other fancy designs. Inclusions are not added to the formula to prevent clogging of the nozzle. The dough is continuously extruded in short strips, which are then cut into individual pieces and baked. The formula contains high levels of shortening and sugar. Proper dough consistency is critical to ensure the dough is short enough to cut cleanly yet cohesive enough to hold the shape and design. The resulting biscuits and cookies have a soft, delicate texture and are quite fragile. They are difficult to package due to their fragility and irregular shapes. Biscuits or cookies made by this process include Danish butter cookies, Viennese whirls, and spritz. Multiple depositors can be used to combine doughs of different flavors or colors (coextrude) into a single product or to make filled products such as fig bars.

Deposit Process

Biscuit and cookie doughs that are deposited contain the highest level of shortening and sugar in the short dough category. They are also called soft doughs because their soft, semifluid consistency is more similar to batter than dough. The dough is extruded through a nozzle and deposited directly onto the oven band. The pieces are formed by cutting off the flow of the dough at the appropriate interval to get the desired size. Biscuits and cookies made with this method exhibit high spread during baking. Some products increase in diameter as much as 80%. Nilla Wafers® are produced using the deposit process.

Cutting Machine Process (Rotary Cut or Stamped)

In the production of biscuits and cookies by the cutting machine process, shapes are cut from a sheet of dough. The cutting is done by a rotary cutter or a stamper. Historically, the shapes were cut using a stamper that is a heavy block with the desired shapes cut into it that stamps down into the dough. This technique has been widely replaced with the rotary cutter (Figure 4), which is a rotating metal cylinder with the desired shapes cut into it that rolls continuously over the dough sheet.

In the process, the thickness of the dough sheet is gradually reduced by passing it through a series of rollers. The sheeting line typically contains two or three pairs of rolls. The thickness of the dough is reduced less than 50% in each subsequent pass through the rolls. This method produces a fair (20%) to large (60%) amount of scrap (pieces of dough between the cut shapes) depending on the shape being cut. The scrap is collected and either returned to the mixer or, more commonly, reincorporated into the dough during the sheeting stage.

Cutting machine short dough formulas contain more water than rotary mold formulas but are lower in sugar compared with many other types of biscuits and cookies. The high water, low sugar, and sheeting process develop the gluten in the flour. This keeps the shapes from spreading and distorting during baking. Animal cookies and gingerbread people are produced using the cutting machine process.

Wafers

Wafers do not fit the definition of biscuits and cookies but are categorized with them because consumers view them in the category, and they are manufactured and sold by biscuit and cookie manufacturers. Wafers are thin and extremely crisp. They are available in many diverse shapes including flat sheets, hollow sheets, cups, cones, and fancy shapes. They are typically not consumed as is but are components of biscuits, cookies, and candy bars and serve as edible containers for ice cream and other desserts.

The wafer formula contains no or low sugar, no shortening, and high water. The flour used is typically soft white wheat flour of short extraction, so it is very low in protein with high purity (low ash). The resulting batter is very thin and smooth. The gluten is not developed in the batter. Gluten formation in the batter is detrimental and leads to processing issues. For this

reason, batters are mixed in small batches to avoid overmixing and to minimize holding time between mixing and baking. The batter is deposited into heated molds that close and lock, which sets the thickness. Baking temperature is high and baking time is short, between 1.5 and 2.5 min. Although the formula contains sodium bicarbonate, it is added to adjust the pH rather than as a leavening agent. The leavening action comes from steam produced during baking. After baking, the wafer sheet is flexible enough to form into desired shapes before it cools. Some products are formed from the baked sheets, and others are produced by baking the batter in shaped molds. After baking and forming, the wafers are extremely dry, which gives them an undesirably soft texture. For this reason, wafer products go through a conditioning process in which the moisture content is increased to 5–6%. This increases the hardness and crispness of the wafers and makes the final products more stable. Wafer products, especially cones and bowls, are extremely fragile; thus, there is a high level of product loss due to breakage during processing.

Crackers

Crackers are regarded by some as being savory cookies, while others consider them to be unsweetened, salty, crisp biscuits. Crackers are typically consumed as a snack or as a bread substitute. The wheat flours used for cracker production typically contain higher protein content and are stronger than flours used for biscuits and cookies. Saltine crackers and cream cracker formulas contain both hard and soft wheat flours. In general, crackers contain low shortening, low sugar, and low moisture. Their low moisture content makes them resistant to microbial spoilage and gives them a long shelf life. Depending on the type, the leavening is by yeast or chemical leavening. Some types are also leavened by steam during baking.

Crackers are made from hard doughs that are laminated. Laminated doughs are thin sheets of dough, which are alternately layered with shortening. Puffing occurs between the layers, producing a light, crisp product. The stronger flour allows the dough to retain the layers formed during laminating.

The three types of crackers are saltine crackers (soda crackers), cream crackers, and snack crackers (Figure 5). The formulation and production processes vary widely for the three types.

Saltine Crackers

Saltine crackers (also known as soda crackers) are the best known fermented crackers consumed in the United States. They are made using a sponge and dough process. First, a sponge containing strong hard wheat flour, yeast, water, and an inoculum (also called a buffer or old sponge) is prepared and given a long fermentation time of 16–24 h. This long fermentation is critical to develop the proper flavor and texture in the final crackers. During fermentation, flavor compounds are produced by the action of the baker's yeast (*Saccharomyces cerevisiae*) and the *Lactobacillus* bacteria, which were introduced into the sponge in the inoculum. The quality of the saltine

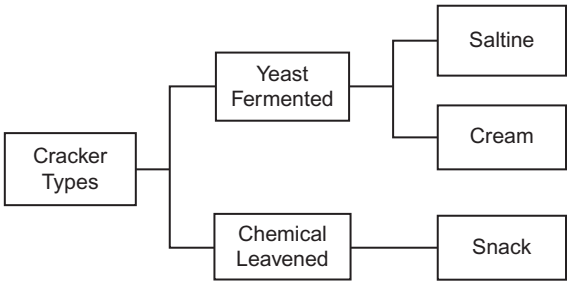

Figure 5 Types of crackers.

crackers is greatly impacted by the activity and addition level of the inoculum. The yeast and bacteria compete for the fermentable carbohydrates in the sponge. When the activity and level of the yeast is lower than that of the *Lactobacillus*, the bacteria dominates and produces enough acid to lower the pH from 6 to 4. This is the desired situation. The drop in dough pH is the most important reason for the lengthy fermentation. Wheat flour contains a native protease enzyme that becomes active at pH 4.1. This protease is thought to be important in creating the correct texture of the saltine crackers. On the other hand, if the yeast level is too high or the activity of the *Lactobacillus* is too low, the yeast dominates and saltine crackers have a completely different flavor and texture profile. The action of the native protease enzyme is also the reason why saltine crackers produced with short fermentation are of poor quality with a bland flavor and hard texture.

After the sponge fermentation is complete, weak soft wheat flour, shortening, salt, and sodium bicarbonate (baking soda) are added and mixed into a fully developed dough. The dough is then allowed to ferment for an additional 4–6 h after which additional sodium bicarbonate is added to raise the dough pH into the 7–8 range. This step is important for several reasons. The raise in pH stops the action of the native protease, so the gluten is not too degraded, which would result in a dough that is too weak to be sheeted and to maintain the distinctive layers. The yeast also becomes active again and dominates fermentation at the higher pH to produce more flavor compounds and strengthen the dough to help produce the correct texture. Additionally, the sodium bicarbonate gives the crackers their characteristic taste and is the reason they are also known as soda crackers.

When the dough has been properly fermented, it is sheeted to about 0.3 mm thick and laminated into six or eight layers. Laminating is folding (lapping) the dough back upon itself in the same direction to create layers. During the process, the dough is also turned 90° so that it is sheeted in both directions (cross sheeted). Cross sheeting aligns the gluten in both directions so that it will expand properly during baking to prevent misshapen crackers. The laminated dough is then passed through several sets of sheeting rollers, which gradually reduce the dough thickness from 2.5 cm to 0.3 mm. A rotary cutter perforates the dough into 50 mm squares. The dough is then docked using a nine-pin pattern consisting of three rows of three docking holes. The docking pins pass through the entire sheet and seal the top and bottom layers together. Salt is sprinkled on top of the dough if desired and the crackers are

baked. The dough sheet is baked intact and then mechanically broken into individual crackers after cooling.

Saltine crackers are baked on mesh bands in tunnel ovens that are 100 m long at very high temperatures of 250–300 °C in a very short time of 2.5–3 min. At these high temperatures, the water in the dough flashes off as steam and causes the layers to puff. The docking holes seal together the layers of dough, so the puffing is controlled and occurs only between the holes. The mesh band allows the moisture to be removed from under the crackers so they do not curl. The thickness of the cracker increases from 0.3 to 4 mm during baking.

The crackers have a low moisture content of 2–2.5% when they exit the oven. They must be cooled slowly to prevent checking or cracking. The puffing between the layers and the low final moisture content give saltine crackers a light, flaky, layered texture. Proper storage is critical to maintain the crisp texture. If the crackers take up even a small amount of moisture, the texture will become undesirably soft and soggy.

Cream Crackers

Cream crackers are popular fermented crackers consumed in the United Kingdom. Cream crackers differ significantly in size, appearance, flavor, and texture compared with saltine crackers. Cream crackers can be made by a sponge and dough process or using a single-stage procedure. The sponge and dough process used to make cream crackers is similar to that used for saltine crackers, but the formula is quite different as shown in Table 1. Compared with saltine crackers, the cream cracker sponge contains much less flour and half the level of yeast. An inoculum is not added into the cream cracker sponge, so the pH of the sponge does not drop appreciably from its original value of around 6. After the sponge fermentation is complete, weak soft wheat flour, shortening, salt, and sodium bicarbonate are added. The majority of the flour is added in the dough stage rather than into the sponge. Additionally, the level of shortening is significantly higher, and the level of sodium bicarbonate is significantly lower than the levels used in saltine cracker production. In cream cracker production, the sponge is fermented for 12–16 h, and the dough is fermented for an additional 1–3 h.

Cream crackers can also successfully be made using a single-stage process in which all of the ingredients are mixed into a dough in a single mixing step. The formula typically contains a blend of 50% strong flour and 50% weak flour, shortening, yeast, salt, sugar, sodium bicarbonate, and water. The yeast level is higher than that used in the sponge and dough system and is set at a level such that the dough will double in size between completion of mixing and end of fermentation. The dough is fermented for 4–16 h.

Table 1 Basic formulas for saltine and cream crackers

	Flour weight basis (%)	
Ingredient	*Saltine crackers*	*Cream crackers*
Sponge		
Flour (strong)	70.0	30.0
Compressed yeast	0.4	0.2
Water	33.0	30.0
Dough		
Flour (weak)	30.0	70.0
Shortening	11.0	20.0
Salt	1.5	1.0
Sodium bicarbonate	1.0	0.2

The makeup procedure is the same for doughs made by both the sponge and dough and the single-stage methods. After fermentation is complete, the dough is sheeted and laminated. Laminating is folding (lapping) the dough back upon itself in the same direction to create layers. Cracker dust (a mixture of 100 parts flour, 33 parts shortening, and 1 part salt) is sprinkled onto the dough between the layers during the lamination procedure. The application rate is 9–18% based on the dough weight. The cracker dust keeps the dough layers separated and provides some lift (rise) during baking to produce a cracker with a flaky structure. During the lamination process, the dough is also turned 90° so that it is sheeted in both directions (cross sheeted). Cross sheeting aligns the gluten in both directions so that it will expand properly during baking and prevent misshapen crackers. The laminated dough is then passed through several sets of sheeting rollers, which gradually reduce the dough thickness to the desired level. Individual crackers measuring 65×74 mm are cut from the dough and docked to seal the layers. The scrap (dough between the cut pieces) is recycled back into the dough at the dough mixing step. The crackers are baked on a mesh band in a very hot oven (210–250 °C) in a short time (4.5–5 min). During baking, the layers expand between the docking holes. The final thickness of a typical cream cracker is 6.5 mm. Cream crackers have a higher moisture content and higher shortening content than saltine crackers, which gives them a softer texture and a richer flavor. The high shortening level makes oxidative rancidity a problem during storage. As with all dry products, moisture uptake during storage can degrade product quality by making the crackers soft and soggy.

Snack Crackers

Snack crackers are also known as savory crackers, cocktail crackers, or cheese crackers. They come in many different flavors, shapes, and sizes. Some are topped with items such as seeds, herbs, cheese, and salt. The most common shape is round. Round and unusually shaped products yield a large quantity of scrap after cutting that is reincorporated back into the mixer or into the dough during sheeting. Compared with saltine crackers and cream crackers, snack crackers contain sugar and more shortening. A few types are yeast-leavened and fermented, but most are chemically leavened. Some contain flavoring compounds. In addition to imparting flavor, many flavoring compounds have a weakening effect on the dough, which may help with sheeting and laminating by making the dough more extensible. If the dough is too strong, proteolytic enzymes or sulfite (sodium metabisulfite or sodium sulfite) is often added to break down some of the gluten to make the dough more extensible during sheeting and lamination, so the cracker pieces do not shrink or distort after cutting.

Snack crackers are prepared using a single-stage mixing process in which all of the ingredients are mixed together at once to make dough, which then may or may not be rested. The dough is then sheeted, laminated, cut, docked, and baked.

Most snack crackers are sprayed with oil as they leave the oven. The oil gives the cracker a shiny appearance, imparts flavor, and helps any applied toppings adhere to the surface.

Sources and Patterns of Consumption

Boron is a ubiquitous mineral element that is present naturally combined with oxygen in seawater, freshwater, rocks, and soil. Boron concentrations in surface water range widely from 0.001 to 150 mg l^{-1}. Most freshwater concentrations of boron, usually in the form of boric acid, are below 0.4 mg l^{-1} and are not lowered by the treatment for drinking water. Boron is recognized as an essential nutrient for plants; thus, all plant material contains boron. The amount of boron in plant tissues and species varies greatly. Monocotyledons are lower in boron content (usually in the range of 2–6 mg kg^{-1} dry weight) than dicotyledons (usually in the range of 20–60 mg kg^{-1} dry weight). The amount of bioavailable boron in soil can affect the boron content of plants. Foods from plants grown on soil low in boron will have lower boron content than from the same plants grown on soil high in boron because boron accumulates in terrestrial plants. However, boron does not magnify through the food chain. Boron is distributed throughout animal soft tissues and fluids in concentrations mostly between 0.015 and 2.0 μg g^{-1} fresh weight. Bone, fingernails, and teeth can contain several times these concentrations. For the general population, diet and occasionally drinking water are the major sources of boron. As shown in Table 1, the richest sources of boron are fruits, vegetables, pulses, and nuts. Wine, cider, and beer are also high in boron. Dairy products, fish, meats, and most grains are poor sources of boron. A typical daily intake of boron through the diet ranges from 0.75 to 1.35 mg. However, the consumption of specific foods with high boron content will increase its intake significantly. For example, one serving of wine or avocado provides 0.42 and 1.11 mg of boron, respectively. Diets high in meat and processed grains often will provide less than 0.75 mg day^{-1}.

Availability, Absorption, and Metabolism

Boron biochemistry is essentially that of boric acid, which is readily soluble in water. Borates are converted into boric acid when dissolved in water. Dilute aqueous boric acid solutions are composed of $B(OH)_3$ and $B(OH)_4^-$ at the pH of blood (7.4). Because the pK_a of boric acid is 9.15, the abundance of these two species at pH7.4 is 98.4% and 1.6%, respectively. Boric acid forms ester complexes with hydroxyl groups of organic compounds when they are adjacent and *cis*. The importance of the *cis* arrangement of the hydroxyl groups is shown by the lack of reaction of boric acid with polysaccharides such as glucose, glucuronic acid, and xylose because of the lack of appropriately paired hydroxyl groups. Among the many substances of biological interest with which boron forms complexes are pyridoxine, riboflavin, dehydroascorbic acid, and ribose. Through its formation of a diester with the ribose moiety in adenosine, boron also forms complexes with biomolecules such as diadenosine polyphosphates, cyclic ADP ribose, *S*-adenosylmethionine, and oxidized nicotinamide adenine dinucleotide (NAD). The formation of boroesters most likely is a determinant of the response to nutritional and toxic intakes of boron. Several naturally occurring organoboron compounds have been identified. These compounds include antibiotics produced by microorganisms, the plant cell component rhamnogalacturonan-II, and the bacterial extracellular signaling molecule autoinducer-2. All these compounds are boroesters.

About 85–90% of ingested boron is rapidly absorbed; it is excreted mostly in the urine shortly after ingestion. Because there is no usable radioisotope of boron, the study of its metabolism has been difficult. It is believed that most ingested boron is converted into boric acid, the dominant species of boron compounds hydrolyzed at the pH of the gastrointestinal tract, and then absorbed and excreted in that form. During transport in the body, boric acid most likely is weakly attached to organic molecules containing *cis*-hydroxyl groups.

Health Effects

Early Benefits Discoveries and Their Fate

Recognition that there are benefits and detriments to boron in defined quantities in food apparently began in the 1870s. At that time, it was determined that borax and boric acid could be used to preserve foods. For the next 50 years, borates were considered one of the best methods for preserving or extending the palatability of foods such as fish, shellfish, meat, sausages, bacon, ham, cream, butter, and margarine. Boron probably was more beneficial to humankind at this time than most people realize; it had a vital role as a preservative in preventing food crises during World War I. However, as early as 1902, German and American scientists began to question whether large amounts of borates in foods were innocuous. In 1904, a report summarized a study performed for the US Department of Agriculture (USDA) in which human volunteers were fed borax or boric acid in small doses for extended periods or large doses for short periods of time. Boric acid in doses greater than 500 mg (77 mg boron) per day for 50 days resulted in disturbances in appetite, digestion, and health. It was concluded that boric acid at 4000 mg (699 mg boron) per day was a limit beyond which harm to humans would occur. Subsequent to this report, the opinion that boron posed a risk to health grew. By the mid-1920s, many countries of the world began legislating against the addition of borates to food. The study performed for the USDA apparently is the only one in which humans were exposed to regular controlled, relatively high dosages of boron. However, that study combined with a few cases of misuse of boric acid in hospitals, such as using boric acid as a bactericide on massive burns and open wounds, which do not have skin to prevent entry into the body, and mistakenly feeding babies a boric acid solution instead of a

Table 1 Examples of boron content in foods in various food groups

sugar solution, created the general belief that boron was nothing more than a poison for humans. Only during World War II were the restrictions against boron eased; food shortages were making food preservation a major concern in many countries. After the war, restrictions were gradually reimposed, and by the middle 1950s, boron as a food preservative was essentially forbidden throughout the world. Joint Food and Agricultural Organization/World Health Organization Expert Committee on Food Additives stated in 1962 and 1967 that boric acid and borates should not be used as a food preservative. The restrictions and statements occurred in spite of the fact that no case of boron intoxication was ever reported when boron was properly used as a preservative in food.

In 1910, findings were reported indicating that boron is essential for plants. However, conclusive evidence and acceptance of the essentiality of boron for plants are usually considered as coming from reports in the 1920s. Boron deficiency in plants has multiple and diverse physiological consequences including abnormalities in sugar transport, respiration, free radical generation and detoxification, and in carbohydrate, indole acetic acid, RNA, ascorbate, and phenol metabolism. Interestingly, although over 50 years have elapsed since boron was discovered essential, the biochemical reason for many of these deficiency signs has not been definitively identified. Finding boron essential for plants apparently was a stimulus for the efforts to show boron as an essential element for animals in the 1930s and 1940s. These attempts were unsuccessful, most likely because of the use of unsuitable diets and the determination of variables, such as growth, that were not sensitive to boron deprivation. As a result, students were taught that boron was a unique element because it was essential for plants, but not for animals.

The dogma about boron being a poison and being only essential for plants apparently inhibited the examination of whether nutritional intakes of boron were beneficial for higher animals and humans until 1981 when seminal reports about boron being beneficial for bone health appeared. Since then, similar to plants, boron has been found to have diverse beneficial effects in animals and humans including in bone growth and maintenance, brain function, and perhaps cancer, cardiovascular disease, and diabetes risk reduction. In addition, boron was found essential for frogs and zebra fish to complete their life cycle. Boron deprivation in male frogs resulted in atrophied testes, decreased sperm counts, and sperm dysmorphology, and, in female frogs, atrophied ovaries and impaired oocyte maturation. Boron deprivation also resulted in necrotic eggs and high mortality in embryos. Boron deficiency also resulted in high mortality in zebra fish embryos. Although there are some suggestive findings indicating that boron might impair embryonic development in mice, the critical experiment demonstrating boron is essential for mammals is lacking.

Bone Health

Early findings indicating that boron was beneficial for bone health included boron deprivation decreasing the maturation of the bone growth plate in chicks and inducing limb teratogenesis in frogs. Since then, much evidence from animal and cell culture experiments supports the limited human findings suggesting that nutritional amounts of boron are beneficial for bone growth and maintenance.

Animal experiments indicate that the beneficial effect of boron on bone is especially noticeable in trabecular and alveolar bone growth and maintenance. Boron deprivation of rats from conception to age 21 weeks was found to detrimentally affect trabecular bone characteristics. In lumbar vertebra, bone volume fraction and trabecular thickness were decreased, and trabecular separation and structural model index were increased. An increase in the structural model

index indicates less of a more desirable platelike structure. Boron deprivation in rats also has been shown to decrease alveolar bone (primary support structure for teeth) repair that is initiated immediately after tooth extraction. Boron deprivation decreased osteoblast surface and increased quiescent bone-forming surface in the alveolus such that bone volume fraction was depressed 14 days after tooth extraction. Boron deprivation for 9 weeks also impaired alveolar bone formation without tooth extraction in mice. The deprivation decreased osteoblast surface and increased quiescent bone-forming surface in both the lingual side and the buccal side of periodontal alveolar bone.

The changes in trabecular bone induced by boron deprivation may affect bone strength and thus might increase the risk for osteoporosis. Boron deprivation has been found to decrease bone strength variables in femurs of pigs and rats. Boron supplementation also was found to increase mean trabecular density and thickness, trabecular bone volume, and cortical bone volume of femurs from rats with retinoic-induced osteoporosis. One human study examining the possibility that boron may reduce the risk for osteoporosis found that 6 months of a daily supplement of 226 mg (6 mg boron) of a sugar–borate ester commonly found in fruits and vegetables (calcium fructoborate) incorporated into margarine improved bone density in 66 of 100 patients with osteoporosis. This finding resulted in the suggestion boron in the form fructoborate may be a good adjuvant in the treatment of osteoporosis.

Other human studies involving boron also support the suggestion that boron is beneficial for bone maintenance and thus reduces the risk for osteoporosis. Proinflammatory cytokines stimulate osteoclastic bone resorption, which apparently is the basis for inflammatory stress being associated with osteoporosis. Such inflammatory stress also is associated with arthritis, which has been found to be affected by nutritional intakes of boron. A 6 mg day^{-1} boron supplement in the form of calcium fructoborate alleviated subjective measures of mild, moderate, or severe osteoarthritis in 20 subjects. After 8 weeks of supplementation, 80% of patients with mild or moderate osteoarthritis reported reduced or eliminated use of painkillers. In addition, joint rigidity essentially disappeared, and mobility was markedly increased. Patients with severe osteoarthritis, who were supplemented with 12 mg day^{-1} of boron as calcium fructoborate, had a more subdued improvement in mobility and rigidity but did report a significant reduction in painkiller use. The findings in this study, however, are weakened by the nonblinding to treatment and the lack of placebo controls. Subsequently, a double-blind, placebo-controlled pilot study with middle-aged subjects with primary knee osteoarthritis found that, when compared to a placebo, boron supplemented at 3, 6, or 12 mg day^{-1} as calcium fructoborate for 15 days significantly improved inflammatory markers serum C-reactive protein, plasma fibrinogen, and erythrocyte sedimentation rate. In another short-term double-blind, placebo-controlled study of subjects with knee osteoarthritis, ingestion of 108 mg (2.9 mg boron) calcium fructoborate twice daily resulted in decreased C-reactive protein at days 7 and 14 compared to day 1 baseline. In addition to these osteoarthritis studies, a cross-sectional study that enrolled 106 subjects with rheumatoid arthritis and 214 controls found significantly lower serum boron concentrations in rheumatoid arthritis subjects, and rheumatoid factor titer was a significant predictor of low serum boron concentrations.

In addition through modulating inflammatory stress, boron may be beneficial through enhancing the utilization of hormones involved in bone health. In postmenopausal women, the increases in serum 17β-estradiol and plasma copper induced by estrogen therapy were significantly higher when boron at 3.25 mg day^{-1} instead of about 0.25 mg day^{-1} was consumed. The higher boron intake also enhanced the effect of estrogen therapy on serum triglyceride and immunoreactive ceruloplasmin concentrations. The combination of estrogen therapy with the higher boron intake was most effective in increasing serum 25-hydroxy vitamin D concentration. The human findings are consistent with a report that boron increases the efficacy of estrogen supplementation in rats. In ovariectomized rats fed with an AIN-76 diet containing 0.4 mg kg^{-1} boron, a 5 mg kg^{-1} boron supplement significantly increased the beneficial effect of 17β-estradiol supplementation on trabecular bone volume fraction, bone growth plate density, and trabecular separation. The combination of boron and 17β-estradiol, versus either of these alone, also markedly improved the apparent absorption of calcium, phosphorus, and magnesium and the retention of calcium and phosphorus.

Other findings supporting the suggestion that nutritional amounts of boron have beneficial effects on bone health include cell culture studies showing that boron supplementation at 1 or 10 ng ml^{-1} compared to supplementation at 0 and 0.1 ng ml^{-1} increased mineralized nodule formation and mineralized tissue-associated mRNA expressions of type 1 collagen, osteopontin, bone sialoprotein, osteocalcin, and RunX by cultured osteoblasts (MC3T3-E1). In addition, the boron supplementation increased bone morphogenetic protein 4, 6, and 7 levels.

High circulating homocysteine and depleted *S*-adenosylmethionine also have been associated with the incidence of osteoporosis and arthritis. It has been reported that plasma homocysteine increased and liver *S*-adenosylmethionine decreased in rats fed diets containing 0.05–0.15 mg kg^{-1} boron compared to rats fed diets supplemented with 3 mg kg^{-1} boron.

Recent studies involving bioactive glasses, which are used for bone tissue engineering and in situ bone tissue regeneration, provide supporting evidence that boron is beneficial for bone formation. Animal and cell culture studies indicate that bone formation is enhanced when bioactive glasses are modified to contain boron. Some of this enhancement might be the result of inducing angiogenesis, which is critical for wound repair and tissue engineering. Borosilicate bioactive glass ionic dissolution products were found to increase angiogenesis in quail embryos.

To summarize, animal studies have shown that boron deprivation detrimentally affects the structure and makeup of bone. Human, animal, and cell culture studies have shown that nutritional amounts of boron are positively associated with factors involved in bone formation and maintenance and have identified several potential mechanisms through which boron might affect bone health. The findings described strongly support the contention that nutritional intakes of boron are beneficial for bone formation and maintenance.

Central Nervous System Function

Findings showing that nutritional intakes of boron have beneficial effects on central nervous system function are more limited than those with bone. However, they are among the most supportive in demonstrating that boron is a beneficial bioactive food component for humans. Under well-controlled dietary conditions, boron supplementation (3 mg day^{-1}) to older men and women consuming diets providing boron at about 0.25 mg day^{-1} for 63 days altered electroencephalograms (EEGs) such that there was a shift toward more activity in the low frequencies and less activity in the high dominant frequencies of the EEG spectrum. Increased low-frequency activity is typical of states of reduced behavioral activation and has been associated with impaired memory performance. Subjects supplemented with boron after deprivation exhibited improved psychomotor skills of motor speed and dexterity and cognitive processes of attention and short-term memory. Studies with rats gave findings consistent with those from the human studies. Boron deprivation in rats affected brain electrical activity in a manner similar to nonspecific malnutrition and heavy-metal toxicity. Since the 1990s when the human findings were obtained, further studies involving the effect of boron intake on central nervous system function in humans apparently have not been reported. Recently, however, it was found that boron-deprived rats were less active than rats fed diets supplemented with 3 mg kg^{-1} boron. Boron deprivation reduced the number, distance, and time of horizontal movements, front entries, margin distance, and vertical breaks and jumps in a spontaneous activity evaluation. Feeding fish oil (has anti-inflammatory effects) instead of safflower oil in the diet attenuated the response to boron deprivation.

Additional human studies are needed to confirm that boron deprivation has a negative effect on central nervous system function. However, based on findings indicating that boron has positive effects on vitamin D metabolism or utilization, circulating homocysteine levels, and *S*-adenosylmethionine, which affect brain function, it seems reasonable to suggest that nutritional intakes of boron have a positive effect on the central nervous system.

Cancer Risk Reduction

One of the most recently suggested beneficial effects of boron is a reduced risk for some types of cancer. This suggested benefit was initiated by an epidemiological study that found an inverse association between dietary boron and prostate cancer. Since then, several studies have shown that boron inhibits the growth of some types of cultured prostate and breast cancer cells and human prostate adenocarcinoma tumors in nude mice. Boron also has been inversely associated with cervical and lung cancers. A study of cervical smears from 472 women with a mean boron intake of 8.41 mg day^{-1} and 587 with a mean intake of 1.26 mg day^{-1} found 15 cases of cytopathological indications of cervical cancer in the low-boron-intake women and none in the high-boron-intake women. In a study of 763 women with lung cancer and 838 matched healthy controls, boron intake was inversely associated with the incidence of lung cancer. The odds increased substantially if the women were not on hormone replacement therapy. This finding is consistent with that of nutritional intakes of boron enhancing estrogen therapy in human and animals described earlier.

The beneficial effect of boron in cancer risk might be through affecting the immune response. Pigs fed with a low-boron-diet (1–2 mg kg^{-1}) for 95 days exhibited a significantly higher skinfold thickness response to an intradermal injection of phytohemagglutinin than pigs supplemented with boron (5 mg kg^{-1} diet). A nutritional amount (3 mg kg^{-1}) supplemented to a low-boron diet (0.2 mg kg^{-1}) more than doubled the serum antibody concentrations to injected antigen (human typhoid vaccine) in rats. Boron status also was found to affect populations of blood cells involved in the immune or inflammatory response in humans. Perimenopausal women with average boron excretions of 1.1 and 3.0 mg day^{-1} during placebo and boron supplementation periods, respectively, had an increased white blood cell numbers, an increased percentage of polymorphonuclear neutrophils, and a decreased percentage of lymphocytes during the boron supplementation period.

Other Possible Health Effects

In addition to animal and human studies showing that nutritional intakes of boron affect circulating homocysteine and C-reactive protein, boron in concentrations similar to those in blood was found to decrease Ca^{2+} release from ryanodine receptor-sensitive stores. Thus, it has been hypothesized that boron is bioactive through binding NAD^{+} and cyclic ADP ribose, which induce the release of Ca^{2+} from the endoplasmic reticulum. This binding might result in the inhibition of the release of Ca^{2+}, which is a signal ion for many processes including insulin release and the inflammatory response.

Biochemical findings suggest that boron might be beneficial through reducing the risk for the metabolic syndrome and diabetes. Chronic inflammatory stress is a risk factor for these pathological conditions. Some limited evidence has been reported supporting the suggestion that boron facilitates the action or release of insulin. In rats fed a diet containing 0.2 mg kg^{-1} boron, a boron supplement of 2 mg kg^{-1} diet reduced plasma insulin but did not change plasma glucose concentrations. Another finding was that peak insulin release from the isolated perfused pancreas of boron-deprived chicks was almost 75% higher than from the pancreas of boron-supplemented chicks. The difference was especially noticeable when the perfusate was supplemented with glucose. Boron deprivation also has been reported to induce a modest but significant increase in fasting serum glucose concentrations in older men and women fed with a low-magnesium, marginal copper diet.

Both high circulating homocysteine and chronic inflammatory stress indicated by high serum C-reactive protein are considered risk factors for cardiovascular disease. Because both animal and human findings indicate that nutritional intakes of boron may alleviate these risk factors, boron might have a positive effect on heart health. However, these biochemical changes are the only findings that indicate such an effect. Perhaps, an effect on cardiovascular health had an influence on the finding in northern France that the mortality rate was significantly lower when drinking water contained greater than 0.3 mg l^{-1} than when it contained less than 0.3 mg l^{-1}. The

biochemical and drinking water findings suggest that further studies should be considered for the determination of whether there is an association between boron intake and cardiovascular health.

Intakes Affecting Health

Nutritional

Both animals and humans deprived of boron exhibit positive health effects when provided with intakes of boron that may be achieved through consuming foods of plant origin. In human depletion–repletion experiments, participants responded to a 3 mg day^{-1} boron supplement after consuming a diet supplying boron at only 0.2–0.4 mg day^{-1} for 63 days. Extrapolations from animal experiments indicate that to achieve optimal health effects of boron, intakes greater than 0.5 mg day^{-1} are needed and that boron supplementation is unlikely to elicit a response in individuals consuming at least 1 mg day^{-1}. These data were used by the World Health Organization to suggest that an acceptable safe range of population mean intakes of boron for adults could be 1–13 mg day^{-1}. This indicates that usual intakes of boron above 1 mg day^{-1} promote human health.

In the United States, a survey conducted between 1994 and 1996 indicated that boron intakes ranged from a low of 0.35 mg to a high of 3.25 mg day^{-1} for adults. The median intakes for various age groups of adults ranged from 0.87 to 1.13 mg day^{-1}. Findings from a study involving 43 postmenopausal women in eastern North Dakota found that average urinary excretion of boron, which is a good indicator of dietary intake, was less than 0.5 mg day^{-1} for two women and between 0.5 and 1.0 mg day^{-1} for 14 women. These findings suggest that a significant number of people could benefit through an increased intake of boron through diets high in fruits, vegetables, nuts, and pulses.

Safe intakes

The US Institute of Medicine Food and Nutrition Board has not set an adequate intake level for boron. However, they set a tolerable upper intake level of 20 mg day^{-1}. As indicated earlier, the World Health Organization first suggested that 13 mg day^{-1} would be a safe upper intake level, but this was later increased to 0.4 mg kg^{-1} body weight or about 28 mg day^{-1} for a 70 kg person. The European Union established an upper intake level for total boron intake based on body weight that results in about 10 mg day^{-1} for adults. These safe upper intake levels indicate that people living in areas where boron is high in food and water are unlikely to be adversely affected. Support for this statement is the finding that no adverse effects on health were found in 66 men (mean age, 39 years) residing in a high-boron area for 36 years who had a calculated daily boron excretion of 6.77 mg l^{-1}. The drinking water in the area where they resided had boron concentrations that ranged from 2.05 to 29.00 mg l^{-1}, with a mean of 10.2 mg l^{-1}.

Conclusion

Substantial evidence exists indicating that boron in nutritional amounts and by plausible mechanism of actions has health effects that may impact the risks for or severity of arthritis, osteoporosis, cancer, and impaired central nervous system function. Limited evidence suggests that boron intake also might affect the risk for diabetes and cardiovascular disease. Consideration should be given for providing dietary guidance for boron. Such guidance could be to consume foods resulting in a diet that provides about 1 mg of boron per day.

Brandy in a Global Spirit Context

Market Trends

According to Euromonitor, the global spirit market in 2014 was estimated to be around 21 billion liters. Brandy and Cognac sales contributed to 8% of the global spirit sales at approximately 1.6 billion liters, making it the third largest category, after vodka and whisky that sold around 4 billion and 3 billion liters, respectively. The IWSR reported that the retail value of brandy and Cognac sales in 2013 amounted to 31.4 billion USD. The top markets for brandy are Brazil, Germany, Russia, India, and the Philippines, while substantial volumes are also sold in the United States, South Africa, China, and the Ukraine. In comparison, the main markets for Cognac, according to the Bureau National Interprofessionel du Cognac (BNIC), are the United States, Singapore, China, the United Kingdom, Germany, Hong Kong, France, the Netherlands, Norway, and Finland. Interestingly, sales in the Western markets are driven by the more affordable VS category while the Eastern market sales are driven by superior quality Cognacs. Over recent months, numerous Cognac producers have announced a decline in their profits, largely attributed to the Chinese government's crackdown on luxury spending and gifting, which has resulted in a slowdown in the country's Cognac and high-end Scotch market. Nevertheless, the region remains a priority export market.

Consumer Trends

Volume and sales trends indicate that there is a growing consumer penchant for expensive luxury spirits. Yet, according to Euromonitor's trend forecast for 2014 and beyond, Cognac will be seen less as a traditional drink that can be given as a gift and will feature more prominently in the mixology arena. Younger Cognac and Armagnac products in the VS category are increasingly being consumed in tall drinks and cocktails. Brandies that contain larger portions of more neutral column distilled spirits, such as South African blended brandies, can be also served very successfully in long mixed drinks and is often consumed mixed with cola soft drinks. Modern mixology trends move toward using ingredients that complement the fruity, sweet, and spicy attributes of brandy. The wide variety of combinations, featuring botanicals, fruit juices, confectionary ingredients, and spices being used in brandy cocktails, demonstrates the versatility of the product category.

In contrast, premium pot distilled brandies and older Cognac and Armagnac products are generally consumed neat or diluted with water or on ice to preserve the flavor complexity. Brandy, Cognac, and Armagnac have also become part of the fine dining experience as food pairing partners due to its smoothness and rich flavors.

Production of Brandy

Grape Varieties Used for Brandy Production

A wide variety of grape cultivars are used to produce Cognac, Armagnac, and brandy. Cognac is made mainly from the cultivars 'Ugni Blanc' and 'Folle Blanche' and Armagnac with 'Folle Blanche', 'Ugni Blanc', 'Baco', and 'Colombard'. Brandy produced in other countries is made not only from the previously mentioned cultivars but also from 'Chenin Blanc', 'Arien', 'Flame Tokay', and many other cultivars. The unique character of the individual cultivars contributes to the distinctive taste profiles of the eventual brandies.

Base Wine Production

Base wine, or the wine made specifically for the production of brandy, Cognac, and Armagnac, differs significantly from table wine. First, the grapes are picked early to ensure high acid concentrations and lower sugar levels (18–20° Balling). The addition of sulfur dioxide is common practice with the production of table wine. However, the addition of sulfur during the production of base wine for brandy is uncommon. For example, the level of total sulfur in the base wine must be lower than 20 mg l^{-1}. Otherwise, a reaction between sulfur and copper of the pot stills results in the undesirable formation of copper sulfate. In other countries, such as Spain, the base wine is transported over long distances from the point of winemaking to the point of distillation. Consequently, sulfur is used to protect the base wine from oxidation. The levels of volatile acidity and total phenolic content must be below 0.7 g l^{-1} and 250 mg l^{-1}, respectively, depending on the regulations per country. The yeast sediment that forms during the fermentation of the base wine is either included or not in the distillation process, depending on the style of brandy produced.

Distillation Process

The base wine is now distilled, and during this process, the alcohol concentration is increased from 9–11% to 72% alcohol by volume (abv) for Cognac and brandies from South Africa and other countries or 53–60% abv for Armagnac. In this process, depending on the method used or style that is needed, the wine is heated in a still until it separates into its components, which evaporate at various points on the temperature scale. The more volatile the component, the lower the temperature at which it evaporates, leaving behind the impurities and heavier compounds.

For Cognac and some brandies, distillation is performed in copper pot stills in a two-phase process that creates a complex spirit. In the first phase, the base wine is distilled into low wine. The alcohol concentration of the low wine is between 28% and 30% abv. This is essentially a concentration process resulting in

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00082-9

the removal of a large proportion of water and soluble solids from the wine. The second stage of distillation involves distilling the low wine into brandy. Three fractions of the liquid are drawn in sequence. These fractions are known as the heads, hearts, and tails, respectively. The heart fraction is the most important, as it is rich in desirable aromas and flavor compounds and it is this fraction that is retained for maturation.

Although the main apparatus used for the production of brandy is the pot still, distillation can also be carried out using a column still (continuous distillation). Armagnac from France, Spanish brandy, and several brandies from the United States are produced with column stills. This apparatus is composed mainly of stainless steel and not copper, although some stills are modified to consist both materials. Distillation takes place continuously and not in batches as with the case of pot still distillation, and the distillate obtained has an alcohol concentration ranging from 50% to 90% abv. Distillates having a high (80–90%) alcohol concentration is less aromatic than that obtained from pot still distillation. The decision made as to what apparatus should be used for the production of brandy is dependent on the style of brandy desired.

Maturation and Blending

After the distillation process, the distillate is placed in oak barrels to mature. These barrels vary with regard to their size, type of wood, and the length of the maturation period that is determined by the laws and regulations that govern each country. After maturation, the brandy is blended with distilled water to decrease the alcohol concentration, and additives such as caramel, sugar, and oak infusion may in certain instances be added. Again, these additions are dependent on the legal classifications of each country.

Sensory Perception and Flavor Chemistry

The sensory perceptions that form part of the brandy, Cognac, and Armagnac consumers' product experience include appearance, aroma, and mouthfeel. These perceptions are the response to a complex chemical structure that is influenced throughout the entire brandy production process as described earlier in the text.

Color and Appearance

Brandy color hues range from greenish tints to straw yellow, golden, and topaz. Brandy can also differ in terms of color intensity, from lightly colored to dark, but never hazy or opaque. Brandy color is influenced by barrel maturation and color rectification with flavorless caramel. The color of brandy has a significant impact on how the aromas and mouthfeel of the product are perceived. Both Cognac and Armagnac color hues tend to darken with aging; young products are typically described as golden or honey in color, while older products are described as amber or mahogany.

Brandy Aroma: Origin and Perception

The compounds responsible for brandy aroma can be traced back to those originating from the grapes and formed during alcoholic fermentation, which are subsequently concentrated into the heart fraction during distillation. Cognac literature also describes the formation of notes such as cocoa and grilled nuts, derived from the cooking process that occurs as the base wine is heated for distillation. Compounds that are extracted, formed, or modified during wood maturation also have a significant contribution to the flavor profile of brandy, Cognac, and Armagnac.

Aroma compounds that originate from grapes include six-carbon alcohols, terpenes, aldehydes, and products of carotenoid degradation such as α-ionone. These compounds typically impart fruity, floral, and green aromas. The presence of grape-derived compounds is influenced by the grape cultivar, terroir, climate, and viticulture and harvesting practices.

Esters are one of the major fermentation-derived flavor compounds contributing to brandy aroma and are known to impart fruity aromas. The final ester content of brandy is influenced by several factors: the ester composition of the base wine, the occurrence of malolactic fermentation during base wine production, the presence of yeast lees during distillation, and the point at which the heart fraction is cut during distillation. Other by-products of alcoholic fermentation that contribute to brandy aroma, through synergistic and masking effects, are higher alcohols, volatile medium- and long-chain fatty acids, and aldehydes.

During Cognac distillation, the heating process can result in ester and terpene hydrolysis. Maillard reactions and Strecker degradation processes can also take place as a result of the heating process, leading to the formation of furans, pyridines, pyrazines, aldehydes, and acetals, all of which can contribute to Cognac aroma.

The most important aromatic compounds that can affect brandy aroma, as a result of wood maturation, are oak lactones, phenolic aldehydes, and furanic aldehydes. The quantities at which these compounds can be found in brandy depend not only on the wood species used but also on the seasoning and toasting practices during barrel manufacturing. Wood maturation affects brandy aroma through flavor compounds present in the wood that are directly extracted from wood lignins into the spirit, where they can undergo further conversions. Alcohol in the spirit can also react with wood lignins to form new flavor compounds, as well as modifications of spirit congeners carried over from distillation.

The wood species used during barrel maturation have been found to impact significantly vanilla, woody, caramel, burned/toasted, green, tails, and rubbery aromas. Oak wood tends to have more intense woody notes due to the presence of *cis*- and *trans*-β-methyl-γ-octalactones, which do not occur in other wood species. Wood toasting has been associated with an increase in vanilla, woody, spicy, caramel, burned, toasted, dried fruits, and smoke notes. However, this is not a linear effect, as degradation of oak lactones and furanic aldehydes at very high toasting temperatures can result in a decrease in woody and vanilla characters. Wood toasting has also been found to have a decreasing effect on fruity, green, tails, and glue-like aromas in brandy. These characters are further decreased during the maturation process. As the maturation period lengthens, the vanilla, woody, rancid and spicy, toasted, smoke, and caramel notes become more intense. Reports have indicated that most of the flavor evolution that takes place during brandy maturation occurs within the first 3 years of maturation.

In Cognac production, the presence of 'rancio' notes is an indication of the age and refinement of the product. This term refers to a complex set of aroma notes that develop during the

maturation process and is the result of a mixture of aromatic methyl ketones and compounds resulting from the oxidative degradation of oak components after at least 10 years of maturation.

Evaluation of Brandy Aroma

Due to the volatility of the flavor compounds at the alcohol level of brandy, it is recommended not to swirl the product prior to nosing as is commonly done during wine evaluation. Instead, brandy aroma can be best appreciated by starting to hold the glass a few centimeters away from the nose. Here, the delicate fruity and floral notes can be observed without being overpowered by ethanol. Gradually, the product can be brought closer to the nose to introduce first the sweet and nutty flavors and finally the heavier woody flavors. Aroma wheels have been developed for South African brandies and Cognac and Armagnac as aroma recognition aids during product evaluation.

Brandy aroma wheel

The South African brandy aroma wheel categorizes the types of aromas perceivable in brandy into a two-tiered system shown in Figure 1. Although the aroma wheel was developed for South African brandies, the wheel is representative of the characteristics that can be perceived in brandies from other countries. The fruity, muscat, floral, woody, toasted, nutty, sweet, and spicy characters indicated on the aroma wheel are considered as positive and, therefore, adding to quality. In contrast, characters such as tails, green, rubbery, and solvent-like detract from quality.

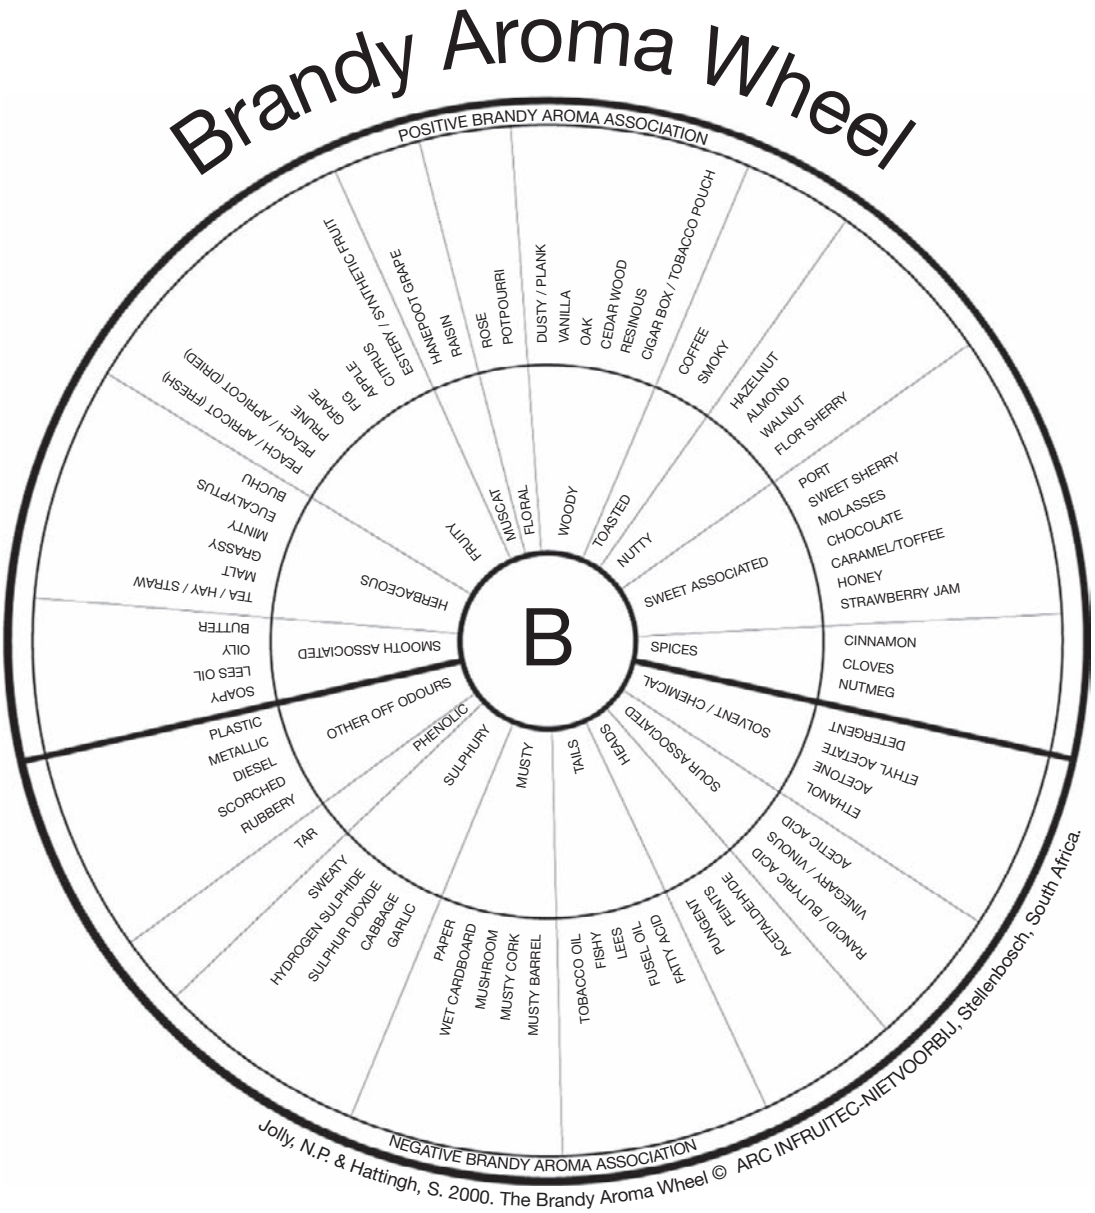

Figure 1 Aroma wheel developed for South African brandies. Reproduced from Jolly, N. P. and Hattingh, S. (2001). A brandy aroma wheel or South African brandy. *South African Journal of Enology and Viticulture* **22**, 16–21.

Cognac aroma wheel

The Cognac aroma wheel was developed by the BNIC and includes over 60 aromatic notes. Unlike the brandy aroma wheel, where the tiers are organized into aromatic families that contribute positively and negatively to brandy quality, the Cognac notes were categorized into four families corresponding to the four seasons: spring, summer, autumn, and winter (Figure 2). The reasoning behind this unique format was to encourage consumer engagement in Cognac appreciation. Prior to the development of the seasonal aroma wheel, the flavor developments that occur during Cognac maturation have been modeled for each of the four main aroma families: fruity, floral, woody, and spicy.

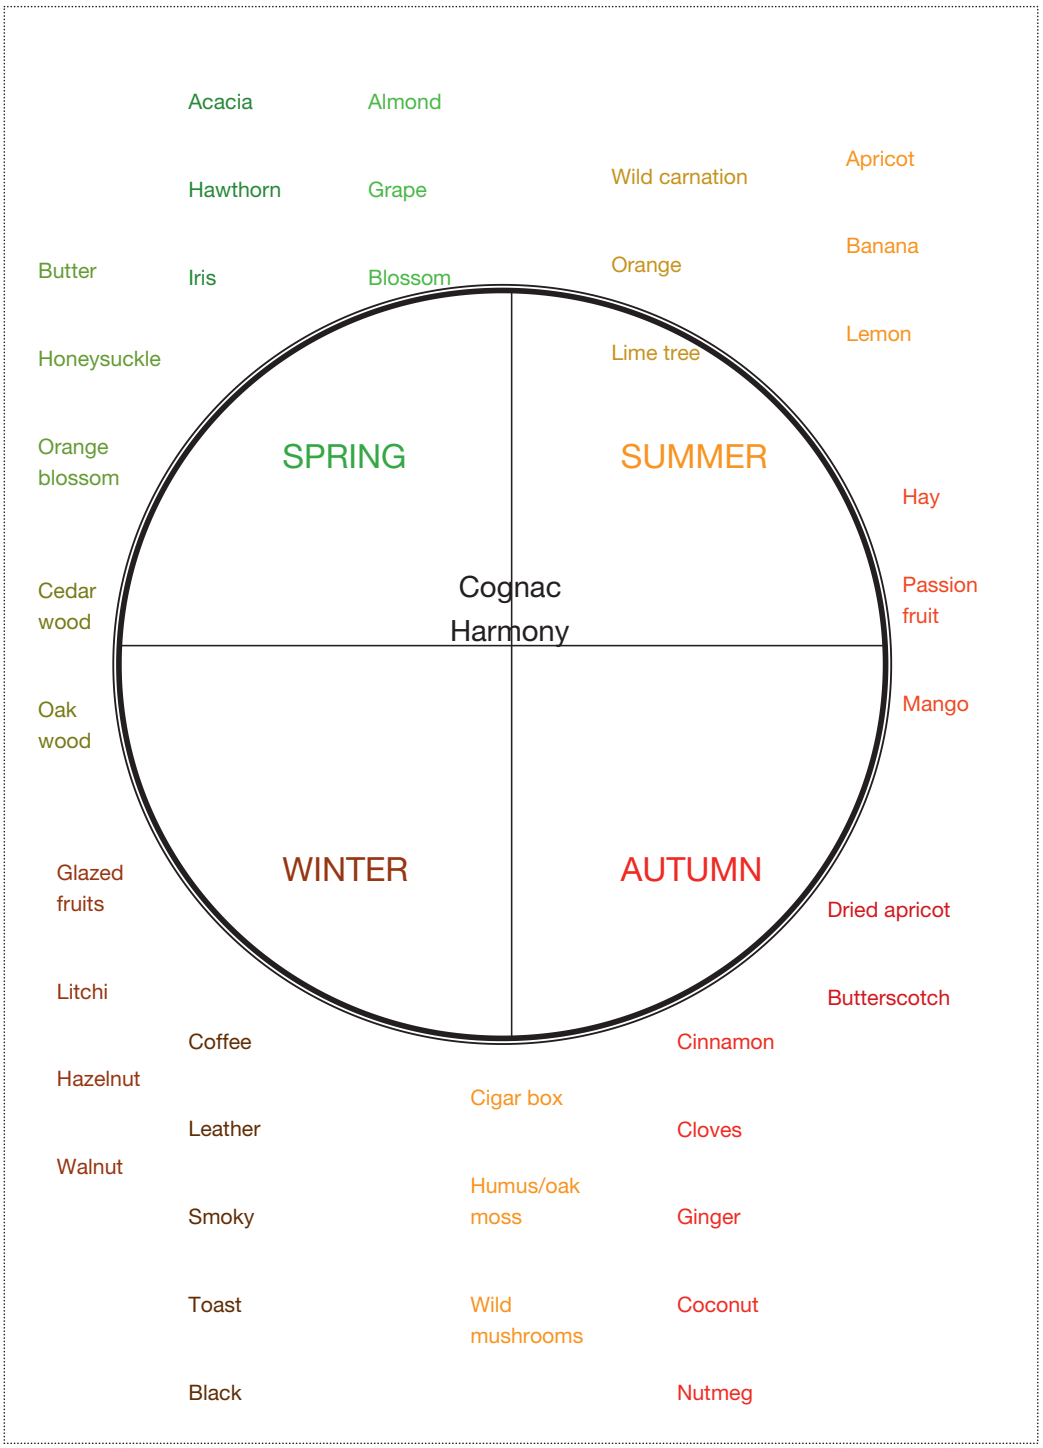

Figure 2 The cognac aroma wheel (Lenoir J (2009) *Cognac Aroma Wheel*. Second International Cognac Summit. Bureau Interprofesionel du Cognac).

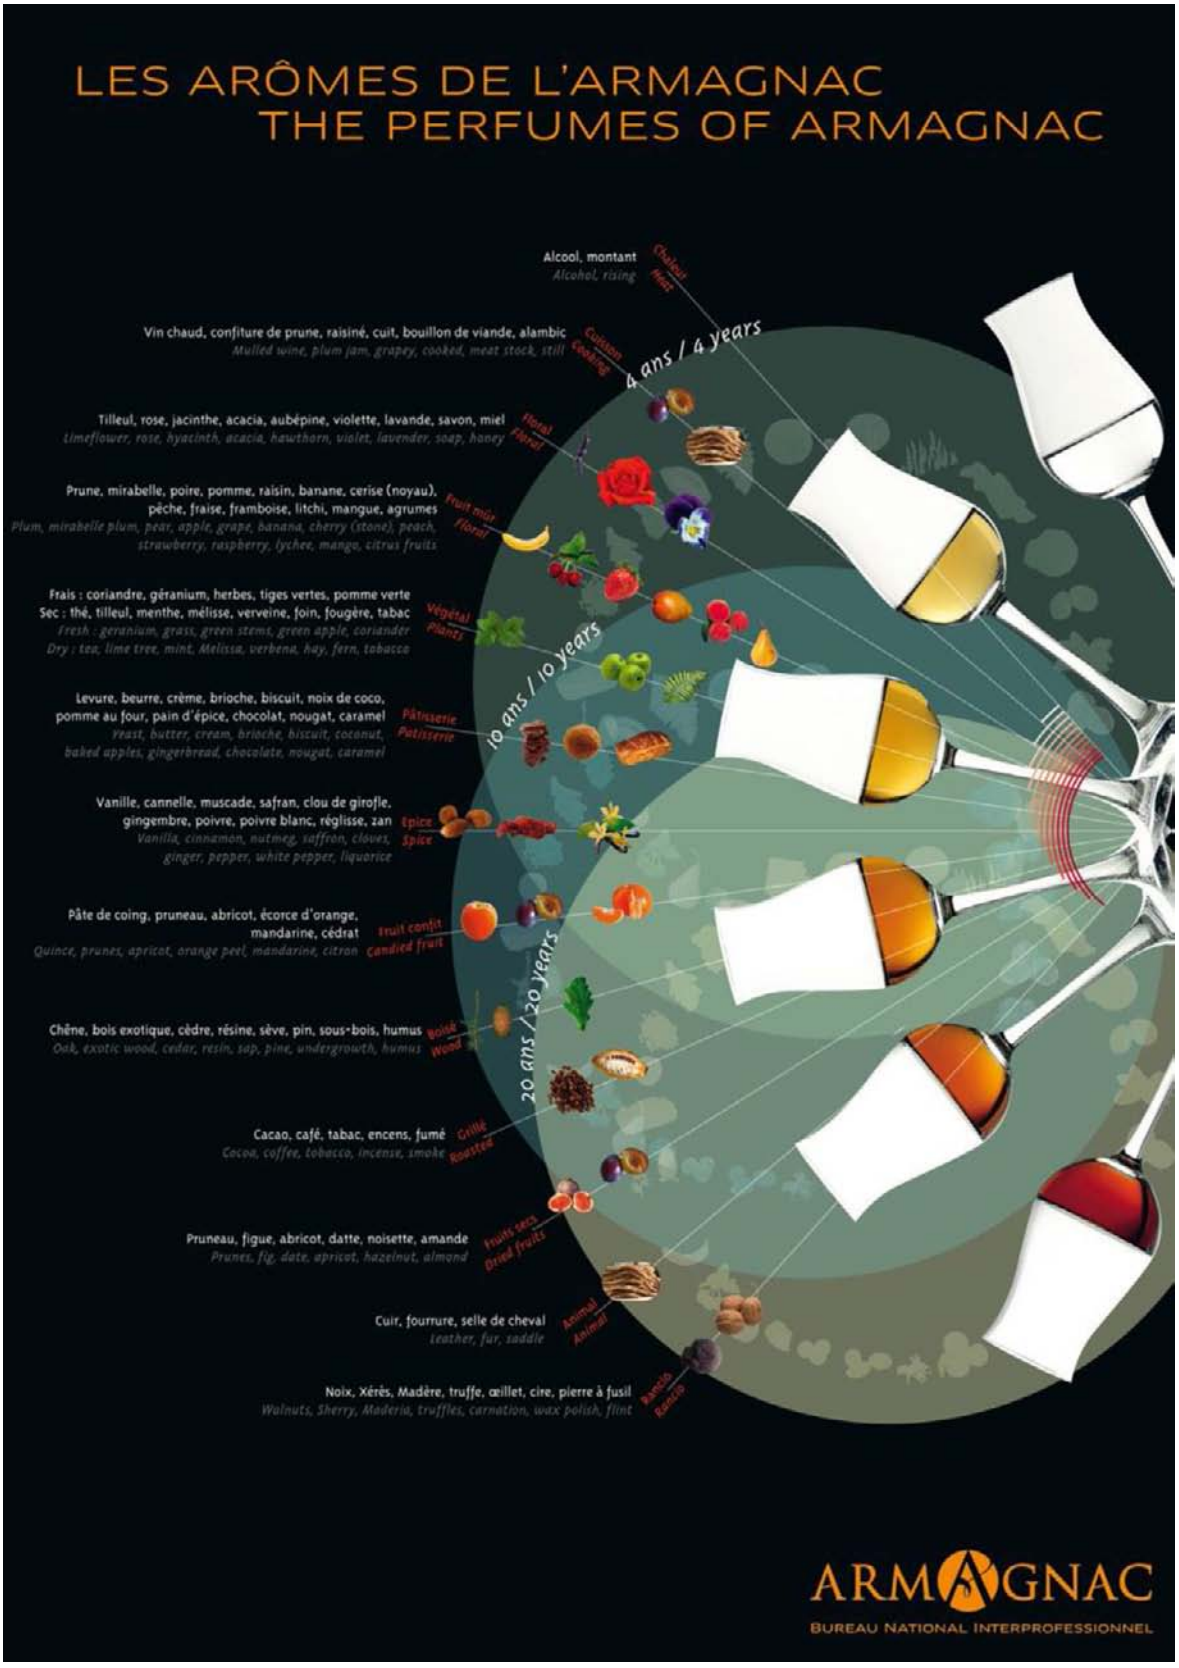

Figure 3 Aroma wheel developed for Armagnac (Bureau National Interprofessionel de l'Armagnac).

Armagnac aroma wheel

Similarly, the Bureau National Interprofessionel de l'Armagnac (BNIA) developed an aroma wheel for Armagnac evaluation. The Armagnac wheel is organized into three overlapping circles that illustrate the flavor evolution that takes place during Armagnac aging (Figure 3). The first circle shows the notes associated with Armagnac products aged for up to 4 years, followed by those associated with 10-year-old products, and finally 20-year-old products. The wheel also includes a color chart showing the variety of color hues associated with Armagnac, ranging from pale to amber.

Brandy Mouthfeel Perception

Brandy mouthfeel develops during wood maturation as low-molecular-weight and hydrolyzable tannins are extracted from oak. These compounds impact the perception of smoothness, burning, astringency, bitterness, and body. As brandy matures, its body and flavor complexity increases, whereas astringency and alcohol burn decrease.

A Comparison of the Cardioprotective Effects of Brandy and Wine

It is well-known that moderate alcohol consumption has a beneficial influence in decreasing the incidence of coronary heart disease. In fact, several epidemiological, case–control, and cohort studies suggest that there might be a causal relationship. Recent reports also indicate an association between light to moderate consumption of red wine and a decreased incidence of diabetes and reduced risk of cardiovascular disease and consequential mortality.

The health benefits of wine are thought to be linked to interactions between the antioxidant, polyphenol, and ethyl alcohol contents that are especially prevalent in red wine. These compounds are known to have anti-inflammatory, anti-atherogenic, and vasorelaxant properties and can also contribute to preventing lipid toxicity, decreasing aggregation of platelets, which leads to blood clotting, and improved blood viscosity.

A South African study recently compared the health effects of the moderate consumption of brandy, which contains more ethyl alcohol and less health-promoting polyphenols than wine, to those of moderate consumption of red wine in healthy adults. The consumption of both wine and brandy resulted in a significant increase in high-density lipoprotein (HDL) cholesterol, which favors heart health.

However, evidence suggests that not everyone may benefit from the health benefits of moderate alcohol consumption; gene–environment interactions may play a role in whether consuming moderate amounts of alcohol has a positive or negative effect on an individual's cardiovascular health. For instance, it has been found that moderate consumption of both red wine and brandy resulted in a significant increase in triglyceride levels in individuals carrying risk-associated, low-penetrance mutations of the HFE gene, previously shown to underlie hereditary hemochromatosis.

Genotyping performed as part of personalized risk assessment may identify a high-risk genetic subgroup of individuals likely to derive less benefit from alcohol consumption. Nutrition intervention may be more effective to lower cardiovascular risk when the genetic background is taken into consideration to identify of gene–environment interactions. This type of assessment may be particularly relevant to patients expressing the metabolic syndrome: a constellation of cardiometabolic risk factors including central obesity, hypertension, impaired glucose tolerance, and dyslipidemia (high triglyceride levels and/or low HDL levels). Further investigations into the role of genes and environment, in assessing mechanisms underlying the benefits of alcohol use and cardiovascular disease risk, may lead to the development of standardized limits for safe alcohol consumption, guided partly by individual genotype.

Introduction

Various spirit drinks (alcoholic beverages) are produced globally today under the name brandy. This term includes alcoholic beverages obtained exclusively from wine spirits or from a mixture of wine spirits and wine distillate. Wine spirit is produced by batch distillation, in small pot stills (alembic), or by continuous distillation, in small column-still distillation. On the other hand, wine distillate is produced by continuous distillation in tower column stills. For the production of most brandies, a maturation period in wooden barrels is required. Expanding the definition even more, in some countries, brandy includes spirits from other fruits like plum and apricot, molasses, or even pure alcohol. In this article, we will consider only the grape brandy.

The term cognac, according to European legislation, falls within the category of 'wine spirits,' and not in that of brandies. It is produced solely in the homonymous Cognac region of France. But while the word brandy is considered a generic term, cognac is referred to as a variety. Juxtaposition of the words brandy and cognac, even in the title of this article, can create various kinds of misunderstandings. Confusion also results from the fact that 'wine spirits' in official European Union documents is used as for broad category of alcoholic beverages, to which cognac belongs to, and simultaneously serves as raw material for the production of both cognac and brandy. Brandy, according to European Union legislation, can only be produced from wine spirit (distillate at $<86\%$ (v/v)) or by mixing wine distillate (distillate at $<94.8\%$ (v/v)) provided that wine distillate does not exceed a maximum of 50% of the alcoholic strength of the final product. Besides the difference in the alcoholic strength, there is no other legal distinction between wine spirits and wine distillates. In practice, wine spirits contains a higher amount of volatile aromatic compounds (congeners) than wine distillate. Wine distillate may be similar in composition to wine spirits, or more often, it is almost identical to pure ethyl alcohol. Pure ethyl alcohol 96.1% (v/v) is used for the production of other alcoholic beverages and is almost completely free of volatile aromatic compounds. Some brandies are made using similar processes as cognac, that is, without the addition of wine distillate, but for the production of 'wine spirits,' redistilled wine distillate can also be used as starting material. Moreover, always in accordance with EU legislation, 'wine spirits' may be released without employing a maturation step, while for brandy, this step is obligatory. US legislation considers cognac as a geographically designated type of brandy. It is thus obvious that the definition of brandy is quite complex since it reflects not only actual differences in the production process but also economic interests. Even more complicated is the case of labeling. There is a gap of legal EU definitions regarding sweetening and maturation indications on the label. On the contrary, cognac maturation period and the corresponding indications are strictly defined by French legislation. It should also to be noted that spirit drinks originated from grape fermentation fall in the category of fruit spirits. Grape marc is another category of spirit drink.

Regarding chemical composition, wine spirits (such as cognac) are characterized by a higher content of aromatic components compared to brandies made by wine distillates. Sensory characteristics of both categories are very closely related to the region of origin. Cognac is considered a superior-quality product and as such it enjoys higher prices. Sensory evaluation of wine spirits is similar to that of wine tasting since it includes assessment of color, odor, mouth feel, flavor, and aftertaste. The primary concern of a producer is the lack of features that render a product defective. Such defects are the perceptions of sulfur; oxidation odors; unripe, rotten, sour taste; and burning sensation. Nose examination involves typicality and elegance, a complex of aromatic richness, and complexity. Mouth evaluation focuses on intensity, harmony, and persistence. It is difficult to define precisely the sensory characteristics and correlate them with the corresponding chemical composition. The simultaneous existence of more than one attributes along with their interactions defines elegance and hence quality. Several olfactory attributes are characteristic. The most significant are the aromas of grape and fermentation origin, such as the flower and fruity odors and the maturation aromas of wood origin, like smoke, vanilla, wood, and spice. The characteristic mouth feel sensation is the low content of acids and a burning sensation due to the high ethanol content. The world production of spirit drinks is about 20 billion liters, 1.2 of this is brandy, while only 0.1 is cognac.

Grape Production

Viticulture and Grape Varieties

The soil in which the vines are grown is an important factor that determines wine quality. The composition and structure of the soil affect the productivity of the vineyard and consequently the quality of the distillates. High production yields are undesirable, since they result in excessive dilution of the aromatic ingredients. Grapes should undergo a progressive maturation, in order to reach the best possible aromatic quality. Plantation and cultivation of a vineyard should follow the best viticultural practices to produce high-quality grapes, wines, and distillates. Abundant rainfall during maturation period may lead to the development of diseases and to the presence of putrid odors in the distillates. Low temperatures could lead to insufficient ripening and immature flavors, while high temperatures can accelerate the oxidation of many

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00081-7

odorant compounds. The condensation that takes place during the distillation process results in a significant increase in the concentration of the compounds responsible for the brandy's intense and strong flavor. For this reason, the selection of white wines with relatively neutral flavor is preferred for brandy and wine spirit production. Aromatic grape varieties with strong and persistent flavor may be appropriate for the production of high-quality wines. However, they are unsuitable for brandy production since they result to distillates with too intense an aromatic character.

An acre, depending the region and year, can produce 5000–50 000 kg of grapes and potential strength in ethanol (after fermentation) 7–14% (v/v). For example, one acre producing 15 000 kg of grapes can produce 10 000 l of wine for distillation at 12% (v/v) ethanol at 20 °C, corresponding to 1200 l of pure ethanol. From this wine is produced approximately 2500 l of spirit drink of 40% (v/v). A small part of ethanol is lost during distillation and maturation.

Grape Berries

Grapes constitute the raw material for winemaking. Sometimes, in order to enhance vine protection, pesticide application is required. Wine spirits, wine distillates, and consequently the grapes should be as free as possible from pesticides used against insect, fungal, or viral pests. Although pesticides may have an influence on the fermentation process, they do not affect the sensory quality of the wine and distillate. In contrast, the addition of sulfur during vine spraying or dusting can produce undesirable reduction odors, often attributed to H_2S. Carbohydrates (mainly glucose and fructose) are the most abundant constituents of must after water. Sugar concentration in normally ripened grapes varies from 130 to 260 g l^{-1}, resulting, after fermentation, in wines with alcohol strengths ranging from 8% to 14% (v/v), respectively. Regulation of must acidity (mainly due to tartaric, malic, and citric acids) is not essential for distillate quality, since these acids are not volatile. Moreover, wine phenolic compounds, like tannins and anthocyanins, are not volatile and thus do not affect distillate quality. This is the reason why fresh distillates are always colorless.

Vinification

Must Extraction from Grape Berries

The harvest should not necessarily coincide with maximal sugar concentration, but with aromatic ripening. Grapes must be transported as quickly as possible to the winery for must extraction. Putrid grapes should be removed with careful screening. Must extraction and vilification is similar to white wine making. The stalks are removed from the grapes, which are then crushed and pressed. Continuous presses have the disadvantage of increasing the presence of solid particulates from the grapes and releasing undesirable compounds with herbaceous aromatic character. Only the must that is produced by the application of low pressure (extraction of about 80% of the total must) is used. Must that is extracted using high pressure is usually fermented separately and it is distilled in continuous tower column stills to produce pure alcohol.

In general, sulfur dioxide is not added to musts and wines, since it could be transferred into the distillate and consequently decrease its quality by neutralizing the aromatic perception. In certain cases, however, where the hygienic condition of the grapes is not adequate, 0.01 g $l^{-1}$of sulfur dioxide may be added to the must. The time that elapses between pressing and the start of fermentation should be the minimum possible, due to the absence of sulfur dioxide that protects must and wine from oxidation and microbial spoilage.

Methanol (methyl alcohol) is not produced by alcoholic fermentation. It is formed exclusively from the enzymatic hydrolysis of the methoxyl groups of pectins during fermentation. It is always present in very small quantities in wine. However, in wine spirits, it is found in higher concentrations ranging 0.30–0.70 g l^{-1} of pure alcohol (ethanol). Its smell and taste are similar to ethanol, and since it is present in low concentrations, it does not affect the sensory quality of the spirit. It affects, however, spirit safety since its toxicity is well known. EU legislation requires a limit lower than 2.0 g l^{-1} of pure alcohol. Unripe grapes and continuous presses may induce herbaceous character by liberating compounds, such as hexanols (1-hexanol and 2-hexanol) and hexenols (*cis*-3-hexene-1-ol, *trans*-2-hexen-1-ol, *cis*-2-hexen-1-ol). 1-Octen-3-ol is characterized by a mushroom odor and it is found in grapes infected by *Botrytis cinerea*. β-Damascenone is an isoprenoid ketone that is naturally present in grapes, and it is a highly odoriferous compound with a powerful and pleasant fragrance providing a fruity-flowery and honey-like character.

Fermentation, from Must to Wine

Wine designed for wine spirits and brandy production is produced from must by yeast fermentation. Alcoholic fermentation of must occurs spontaneously or by addition of dry industrial yeasts. During the period between fermentation and distillation, several chemical reactions take place and the wine composition alters. Care should be taken to keep this period as short as possible. Distillation can immediately take place after the end of fermentation.

Volatile Substances, from Wine to Distillate

Ethanol (ethyl alcohol) is the most abundant compound in wine after water. It is produced by the alcoholic fermentation of glucose and fructose and ranges at levels 8–14% (v/v). During alcoholic fermentation, various aromatic compounds (congeners) are produced besides ethyl alcohol. It is obvious that the aromatic content of the distillate is much higher than that of the corresponding wine. The content of congeners in distillate is expressed in grams per liter of pure alcohol (g l^{-1} of pure alcohol), in order to be independent of distillation and dilution with water. The ethyl alcohol content of both wine and spirit drinks is expressed as volume per 100 cubic centimeters of finished product at 20 °C and is denoted by % (v/v).

Alcohols possessing more than two carbon atoms are known as higher alcohols or fusel oils. They are synthesized by yeasts during fermentation. Wine higher alcohol content remains

almost unaffected before distillation. Quantitatively, the most important higher alcohols are the straight-chain alcohols 1-propanol, isobutyl (methyl-2-propanol-1), and amyl (a mixture of 2-methyl-1-butanol and 3-methyl-1-butanol) alcohols. Most straight-chain alcohols and their esters have a strong pungent smell. At low concentrations, they contribute to the aromatic complexity but, at higher levels, are characterized by penetrating odors, which mask the aromatic finesse. They reach concentrations in the order of 2.5–5.0 g l^{-1} of pure alcohol in distillates.

Acetic acid is the main volatile acid that has a significant contribution to volatile acidity. It has a vinegar-like intense odor. Although it commonly occurs in wine, it typically occurs at detectable levels only in wines spoiled by acetic acid bacteria. In distillates, its concentration ranges from 0.20 to 1.0 g l^{-1} of pure alcohol. Other carboxylic acids, such as propionic acid and butyric acids, may also be present and they are also associated with bacterial activity before distillation. Butyric acid is characterized by unpleasant buttery and cheesy aromas. Hexanoic, octanoic, decanoic, dodecanoic, myristic (14 carbon atoms), palmitic (16 carbon atoms), and stearic (18 carbon atoms) acids are mainly formed by yeasts.

Ethyl esters are produced by yeasts. They can also be present in grapes, but their amount and sensory importance are often negligible. Esters are present in fresh brandies, and since they have fruity aspects, they have an important contribution to the development of their aroma. Over 160 esters have been identified in wines and most of them are also present in brandies.

Of the monocarboxylic acid esters, the most important are those based on ethanol and saturated carboxylic acids, such as hexanoic (caproic), octanoic (caprylic), and decanoic (capric) acids. Preserving wines before distillation in the presence of lees has been connected with increased content of ethyl esters.

Distillates of wines that have remained in contact with lees contain greater amounts of ethyl decanoate and ethyl dodecanoate. Wine and distillates also contain ethyl esters of long-chain fatty acids (14–18 carbon atoms). The presence of the fatty acid ethyl esters in quantities higher than 5 mg l^{-1} may deteriorate the quality of the bottled spirit, depending on the alcohol content of the product and the storage temperature.

The most prevalent ester in wine is ethyl acetate. A small quantity is produced by yeasts during fermentation, but it is mainly formed by the activity of the aerobic acetic acid bacteria. Wine distillates and brandies contain about 0.4–0.8 g l^{-1} of pure alcohol.

Esters of acetic acid and higher alcohols are also significant since they may provide a fruity character. For example, isoamyl acetate, which has a characteristic banana odor, influences positively wine distillate and brandy aroma. Low fermentation temperatures favor synthesis of fruity esters, such as isoamyl, isobutyl, and hexyl acetates, while higher temperatures favor the production of higher-molecular-weight esters. Juice clarification favors ester synthesis and retention.

Acetaldehyde (ethanal) is the major aldehyde found in wine. It is one of the early metabolic by-products of yeast fermentation. More acetaldehyde is produced through autoxidation of ethanol. An important quantity is bound to sulfur dioxide in cases where it is has been added to the base wine. In distillates and brandies, it is found in concentrations ranging from 0.20 to 0.25 g l^{-1} of pure alcohol.

Other aldehydes that may be found in brandies are formaldehyde, 5-hydroxymethylfurfural, acrolein, propionaldehyde, butyraldehyde, benzaldehyde, isovaleraldehyde, and *n*-valeraldehyde.

Isobutanal at concentrations higher than 25 mg l^{-1} may provide a herbaceous character to the wine distillate and brandy. *trans*-Nonenal is characterized by a paperlike sense, while octanal contributes to the aroma complexity by adding an orange flavor.

Diacetyl (2,3-dioxobutane) is a ketone produced during wine fermentation through oxidation of acetoin, a degradation product of citric acid. It has an important influence on sensory evaluation since its odor is characterized as sweet, buttery, or butterscotch-like.

Distillates may contain extremely low concentrations of different unpleasant (rotten eggs and garlic) volatile sulfur compounds, like hydrogen sulfide, carbonyl sulfide, sulfur dioxide, thiols, sulfides, polysulfides, and thiosterols.

Most aldehydes and acetals are more volatile compared to other aroma-related compounds, and hence, they are distilled early giving a pungent odor in the heads. The volatile acids are distilled throughout the distillation process. Higher alcohols and ethyl acetate are found in higher proportions in the first distillate fractions, and gradually, their presence decreases, while the opposite is a trend observed for ethyl lactate.

Finally, distillates derived from alembic batch distillation contain 99% of initial content of ethanol, 50–60% of methanol, 90–95% of higher alcohols, 3–5% of the 2-phenyl ethanol, 70–75% of esters, and in particular 40–60% of ethyl acetate.

Wine with higher alcohol and polyol content is not influenced by the time that elapses after the end of fermentation in contrast with its ester content, which can decrease significantly. The most affected esters are those that possess the aromatic properties of interest (such as isoamyl, hexyl and phenylethyl acetate, ethyl caproate, ethyl caprylate, ethyl caprate, and ethyl laurate). An undesirable increase in ethyl acetate, ethyl lactate, diethyl succinate, acetaldehyde (ethanal), and acetic acid of the base wine content is usually observed simultaneously.

Distillation

During the distillation process, volatile components are extracted from wine and are partially concentrated into the distillate. The aim of the distillation is to remove the largest amount of water and recover the maximum amount of ethanol and the positive characteristic aromas while minimizing the off-flavors.

A peculiarity of the production of spirits is that the base wine is distilled while it is in contact with the lees. The lees contain dead yeast cells, whose autolysis enriches wine with aromatic components present in the cell walls. It should be noted, however, that the lees must be as free as possible from grape material, since they may provide herbaceous odors that will be transferred into the distillate. In continuous distillation, wine lees are removed just before distillation since their presence could block the distillation equipment and delay the whole process. Thus, in order to modify the spirit

composition, the distillers should control two crucial parameters: wine flow rate and the temperature of distillation and distillate.

Small Pot-Still Batch Distillation

Apparatus

Small pot stills (Figure 1) for batch distillations are usually made of copper. Copper is an excellent conductor of heat and is the most common material used for distillation apparatus. Moreover, it is considered advantageous as it is easily manipulated and reacts with undesirable components of the distillate, such as fatty acids and sulfur compounds, creating insoluble sediments. In this way, components with unpleasant odors are partially removed during distillation.

The pot still can be heated indirectly by steam circulating through copper heating exchangers located a few centimeters above the bottom of the apparatus. The heating may also be achieved by passing steam through a jacket located at the bottom. Habitually, wine is heated directly by flame. For this purpose, a stove fed by wood or gas is required. The type of heating system should be carefully designed to perfectly adjust the shape and the distance of the flame from the boiler, in order to avoid local overheating, which may result in burned odors.

The pot still consists of four consecutive sections. Above the boiler, a cover (hat) is mounted that ends in a pipe, which leads vapors to the fourth part, the cooling coil. The cover prevents overflow during boiling and acts as a reflux condenser. A further part that the pot still may have is the preheater. It can save energy (fuel), time, and cooling water by increasing the temperature of the wine just before distillation. The disadvantage of using an alcohol preheater, however, is the loss of ethyl alcohol.

The condenser comprises a serpentine or many flutes. The temperature of the cooling water must not be too low or exceed 20 °C, since aromatic substances might prematurely condense or ethyl alcohol may evaporate, respectively. The distillate must be collected in stainless steel containers. The sampler is an essential component of the machinery that provides sample shots when needed. An alcoholmeter permits the simultaneous measurement of the alcoholic strength of the distillate during the distillation process.

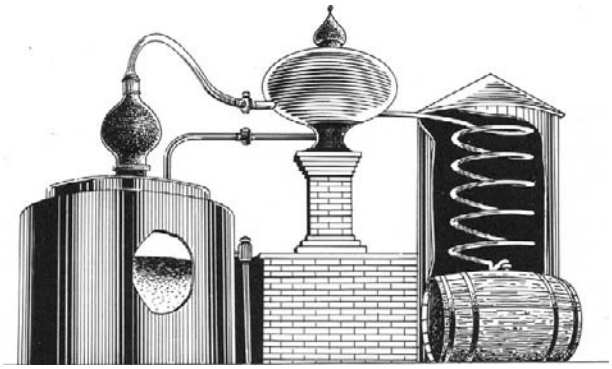

Figure 1 Small pot still (alembic), for batch distillation.

First Distillation

Distillation is accomplished at two successive times (steps). The first step is to produce a distillate called 'low wine' and the second one gives the 'heart,' the wine spirit. Both steps are necessary since after the first, a distillate of approximately 30% (v/v) is obtained, while the second step raises the alcohol content up to 70% (v/v).

When the temperature reaches the boiling point, vapors pass through the preheater, the cover, and the pipe and enter the condenser where condensation takes place. And the distillate is collected in an appropriate container. Since ethyl alcohol is more volatile than water, vapors are initially very rich in ethyl alcohol, while a gradual reduction takes place with time, increasing the boiling point. Thus, during the distillation process, the composition of the distillate changes continuously and the liquid becomes gradually poorer in ethyl alcohol. Finally, the residual consisting mainly of water and nonvolatile wine components remains in the boiler. Such ingredients are organic acids, salts, tannins, and minerals. The average alcoholic strength of 'low wine' is between 24% and 32% (v/v), depending on the alcohol content of the wine distilled and the distillation rate.

In some cases, separate heads and tails are isolated, even after the first distillation step, in order to result in a distillate with less congeners.

Second Distillation

After the first distillation, the boiler is emptied of the distillation residue. The second distillation is called the final distillation. Usually, the whole quantity of wine is distilled before proceeding to the second distillation, in order to avoid possible spoilage.

The second distillation requires special attention and expertise, since the distillate must be separated into three fractions, the 'heads,' 'heart,' and 'tails.' The 'heart' is the wine distillate, the part of the distillate that contains the desirable volatile components necessary for maturation. The distillation rate is adjusted taking into account that after the end of the process, the alcohol content of this fraction should be higher than 70% (v/v). The separation is achieved through monitoring of the temperature and volume of the distillate, the indication of the alcoholmeter, and the results of the sensory evaluation. The separation between the heart and tails is performed at 54% (v/v). The distillation technique employed depends on the wine and the desired final product.

Examples of Distillation

For example, 2500 l of wine, at 12% (v/v), can produce about 1000 l of 'low wine' (28% (v/v)) after 12 h of distillation. Distillation is ended when the indication of the alcoholmeter, placed at the exit of the distillate, is about 2% (v/v). A small portion of the ethanol content is lost during distillation. 2500 l of 'low wine' 28% (v/v) will yield about 40 l of 'heads,' 900 l of 'heart' (70% (v/v)), and 500 l of 'tails' after 14 h of distillation.

According to another technique, three fractions are obtained in the first distillation and four fractions are obtained after the second distillation. This greater fractionation allows

better separation. For example, the first distillation results in 1% heads, 28% heart, and 5% tails. The second distillation results in 1% heads, 28% heart, 28% second, and 5% tails. Heads and tails of the first and second distillations are mixed with the wine or the first distillate and redistilled or are distilled separately to produce a distillate of inferior quality.

Volatile Compounds Formed During Distillation

During the distillation process, a number of chemical reactions take place together with the evaporation of the volatile compounds. These reactions, which involve esterifications, acetalizations, Maillard reactions, and Strecker degradations, can greatly affect spirit quality.

An aldehyde having a sensory impact of 'baked' in distillates is furfural (ranging 0.5–82.5 mg l^{-1} of pure alcohol). Its synthesis involves sugar oxidation and is activated by heat. It is mainly produced during distillation from the remaining pentose content of the lees, and consequently, it is highly influenced by the distillation system employed. For this reason, the concentration of wine distillate and brandy in furfural varies largely. Furfural and its derivatives may also derive from both the wooden cask and the possible addition of caramel. Double distillation enhances the amount of all furanic species.

Ethyl carbamate is a potential carcinogenic compound and its presence is strictly monitored in wines and spirits. Yeasts may be involved in its synthesis through the production of carbamyl phosphate and by the synthesis and degradation of urea.

Minerals Found in the Distillate

Although wine contains different metals, these metals are not volatile and, therefore, are not found in the distillates. Distillates acquire their metallic content by contact with different metals, like aluminum and cadmium. Copper is a very important trace element, due to its heat-conducting and chemical properties. Distillates always contain a small amount of copper. This is not due to the copper content of the base wine, but rather to the copper parts of the distillation apparatus. During distillation, copper combines with other compounds such as butyric, caproic, caprylic, capric, and lauric acids resulting in precipitates, improving the quality of the distillates. Most of the copper found in wines originates from sprays based on the disinfectant properties of copper sulfate, used to treat vines for mildew. Copper could combine with caprylic, caproic, and lauric fatty acids, whose odor resembles that of cheese, as well as with long-chain fatty acids, which could produce insoluble soaps. As far as distillation is concerned, its presence is connected with higher-quality distillates. Distillation in stainless steel distillers results in poorer-quality brandies. The process can be improved by the addition of exogenous copper or copper sulfate.

Small Column-Still Continuous Distillation

Small column-still continuous distillation apparatuses (Figure 2) comprise a boiler with 5–15 plates (disks), a limited number of perforated trays, and a cooler with two chambers. In the upper chamber, wine for distillation is preheated by vapors of distilled wine, and in the lower chamber, the vapors are condensed by cool water. The wine to be distilled initially enters in the cooling chamber, and then, it enters into the second plate. The liquid passes progressively though the plates until it reaches the lower part of the boiler where it is simultaneously heated and evaporated. The vapors of ethanol, being more volatile, reach the upper part of the apparatus, passing progressively through the plates. Condensation occurs when vapors come in contact with the liquid, which is simultaneously heated. Parts of the vapors reach the upper part of the boiler, where they are cooled in the preheater chamber. Such distillation equipments operate continuously, with a constant supply of wine to be distilled. The distillate produced, depending on the number of disks used, has an alcohol content of approximately 70% (v/v). This process is used for the production of Armagnac, a wine distillate produced in the homonymous region of France.

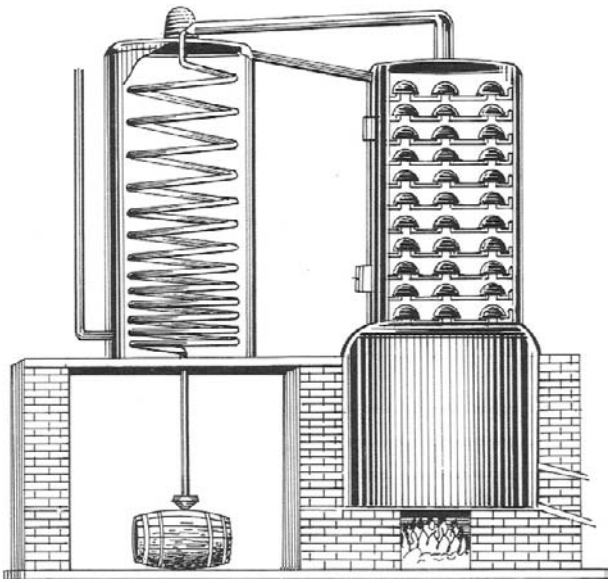

Figure 2 Small pot still, for continuous distillation.

Continuous Tower Distillation

In order to produce pure ethanol, continuous tower distillation columns (Figure 3) are employed. The liquid to be distilled is constantly supplied into the apparatus, which may consist of 2–6 towers. In this way, water is removed together with part or whole of the volatile compounds (flavor components and congeners). A very common continuous distillation apparatus used for the production of pure alcohol or wine distillates consists of three columns. The wine to be distilled enters the first column, where steam sequentially passes through the disks flowing from the lower to the upper part of the column. The column material is bronze or stainless steel and the disks contain 'bells' (Figure 4). In each bell, the steam comes into contact with the descending liquid, resulting in the gradual depletion of ethanol. The liquid reaching the lower part of the tower is thus free of ethanol, while the vapors rich in

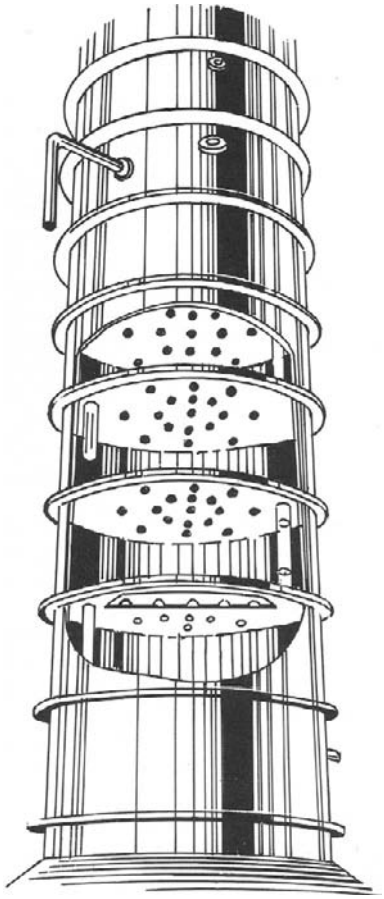

Figure 3 Tower columns still for continuous distillation. Every tower column still contains the appropriate number of discs.

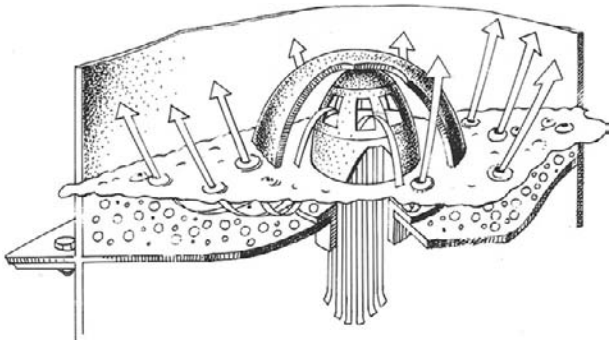

Figure 4 Every disc contains a number of 'bells.' In each 'bell' steam comes into contact with the descending liquid causing the gradual depletion of ethanol.

ethanol (50–96% (v/v)) enter the converter. Part of the steam is condensed and refluxes in the column. The nonvolatile components and most of the water are removed from the lower part of the first column as 'washy' (vinasses). The undesired components are further removed from the second and third columns. Ethyl alcohol is isolated from the third or fourth disk of the third column. Fusel oils (mainly higher alcohols) are also collected from the lower part of this column from different disks. Depending on their volatility, they are grouped in low and high fusel oils. The term 'oil' is due to their insolubility in water. Part of the water is deposited on the bottom of the column as 'washy phlegm.' The wine distillate is collected from the first, second, or third column depending on the desired amount of congeners.

Maturation in Wooden Casks

Maturation may be defined as a period of oxidative and/or nonoxidative aging. Maturation of the distillates ('wine distillate' or 'wine spirit') takes place in wooden, mostly oak, casks. This process may last from several months to several years. Relatively young distillates are placed in casks with a maximum capacity of 225–1000 l, while distillates aged for longer time periods can be stored in 5000 l casks. During this period, there is a loss of 2–3.5% of the distillate volume per year due to evaporation.

During the aging process, the distillate acquires a very characteristic flavor, distinctly different from that of the fresh distillate. The sensory attributes of the distillates such as color, flavor, and mouth feel are greatly influenced by the botanic species of the wood, the different heat treatments applied to barrels, the time that the wooden barrel has been used, and the aging time. The aroma complexity is enhanced due to the extraction of certain wood compounds (volatile and nonvolatile) into the distillate. For instance, tannins, which are polymeric phenolic substances, are extracted from the wood and have a significant contribution to brandy and cognac flavor. Furthermore, during barrel aging, chemical reactions may also occur between the components of wood and distillates, which can also add complexity to the sensory character of the final product.

Oak wood consists of 40–45% cellulose, 20–25% hemicellulose, 25–30% lignin, and 8–15% tannins. The natural color of brandy and cognac is due to the presence of tannins. During its first use, the wood contributes mainly to the toasty aroma of spirits and, while during the second and third uses, donates more vanilla flavor.

The first year of aging usually takes place in new oak casks, whereas subsequently, they may be placed in used casks. Sherry brandies (Brandy de Jerez) are aged in casks of American oak (*Quercus alba*) that previously contained sherry wine. Brandy de Jerez ages according to the traditional dynamic system known as *Soleras y Criaderas*. The phenolic and furanic content of Brandy de Jerez increases considerably during aging.

In spite of their wide acceptance, the use of wooden barrels is both time-consuming and expensive. Therefore, recently, the use of wood fragments (staves and tablets) in order to promote accelerated aging process has become an interesting economic alternative.

Volatile Compounds from Casks

The different volatile compounds extracted from wood, mainly furanic and phenolic compounds, are positively correlated with overall brandy and cognac quality. Concentration of furanic compounds, such as furfuryl ethyl ether, furfural,

2-acetylfuran, and 5-methylfurfural, varies according to the type of cask and aging time. Furanic aldehydes derive from the thermal degradation of polysaccharides derived from wooden casks.

Eugenol, cis-β-methyl-*c*-octalactone, furfural, 4-hydroxy-2-butenoic acid lactone, hexanoic acid, and guaiacol are considered important compounds and are derived from wood. Toasting, a typical process in barrel construction, can strongly modify the volatile composition of the wood, particularly the levels of furanic aldehydes (furfural, 5-methylfurfural, with toasted almond aromas, and 5-HMF), volatile phenols (syringol and 4-allyl-syringol), propanoic acid, 4-hydroxy-2-butenoic acid lactone, and vanillin. When the wood is not toasted, extraction during aging is limited.

Nonvolatile Compounds from Casks

The aging of spirits in oak barrels is a complex process. Direct extraction of wood components, degradation products of wood macromolecules, and reactions between the components of the distillate itself and those originating from the wood (polymerizations, esterifications, acetylizations, and hydrolysis) may occur, in addition to major oxidation processes. Apart from ellagitannins, oak releases a certain number of other compounds into brandies, mainly lignins. Depending on conditions, oak may also release polysaccharides, mainly consisting of hemicelluloses that contribute to spirit flavor.

Total acidity in brandies is initially due to the presence of volatile acids, such as acetic acid. Acetic acid content increases during aging by oxidation of ethyl alcohol. In addition, total acidity progressively increases due to the extraction of phenols from oak casks. Phenols are weak acids that gradually contribute to fixed acidity. New brandies have pH values between 4 and 5, while during maturation, pH falls to 3.5.

Change of Volatiles during Maturation

The ethyl ester content increases during aging, as a consequence of the slow esterification of different organic acids with ethanol. As the distillate matures, ethyl esters become less flavor-active, due to an increase in their solubility in aqueous ethanol by the wood-extracted materials.

Methanol is reduced during aging in casks. Ester synthesis and hydrolytic breakdown continue nonenzymatically during aging, based on the distillate chemical composition and storage conditions.

Isobutanal provides a herbaceous character to the brandy. During maturation, its content declines due to acetylization and selective evaporation.

Blending and Bottling

In order to obtain the final product, various wine distillates of different ages, from different casks, are blended. Pure water is added to reduce the alcoholic strength to 40% (v/v). In most cases, caramel is also added, since it contributes to the development of color. Caramel addition is quite common in the production of aged spirit beverages because it provides an amber coloration attractive to consumers. The chemical composition of caramel is complex, owing to the large number of substances produced, as a result of the pyrolysis of carbohydrates, such as sucrose, glucose, and starch.

Cold stabilization usually follows to ensure the removal of the excess quantity of ingredients, such as tannins, which could develop turbidity and thus affect the quality of the final product. Brandy and cognac are stabilized after two days at −4 °C. Finally, filtration and bottling follow.

After the Sale

Spirits are microbiologically more stable than wines and beer, due to the high alcohol content. In addition, brandy and cognac are not suitable for bottle aging. After opening, spirit drinks gradually become oxidized and their quality deteriorates.

Brassica: Characteristics and Properties

JW Fahey, Johns Hopkins University, Baltimore, MD, USA; Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD, USA

© 2016 Elsevier Ltd. All rights reserved.

Background

The brassicas comprise a large and diverse group of widely consumed vegetables. *Brassica* is the Latin name of a genus that is taxonomically placed within the Brassicaceae (Cruciferae), which is one of the ten most economically important plant families in the world. The genus *Brassica* includes, but is not limited to, the following vegetables: bok choy, broccoli (calabrese and sprouting broccoli), Brussels sprouts, cabbage, cauliflower, Chinese cabbage, kale, kohlrabi, mizuna, swede (rutabaga), and turnips. Rapeseed or canola, one of the world's most widely grown oilseed crops, is also a nonvegetable *Brassica* species and is discussed elsewhere. Other closely related vegetables within the Brassicaceae family (also known as brassica or cruciferous vegetables, crucifers, cole crops, or mustards) include radish (*Raphanus sativus*), watercress (*Nasturtium officinale*), arugula (*Eruca sativa*), horseradish (*Armoracia rusticana*), maca (*Lepidium meyenii*), mashua (*Tropaeolum tuberosum*), wasabi (*Wasabia japonica*), and cress (*Lepidium sativum*). One of the common characteristics of brassica vegetables is that they all contain glucosinolates, sulfur-containing compounds that are hydrolyzed to produce the so-called mustard oils, which impart characteristic tastes and odors to these vegetables.

Vegetables are considered to be an essential part of a balanced diet. The brassica vegetables in particular add considerable visual or aesthetic appeal to a meal, since many of them are leafy and green. They are rich sources of dietary fiber, and many are good sources of calcium, carotenoids (provitamin A), vitamin C, and certain beneficial phytochemicals. They also have distinctive flavors and textures, which enhance palatability in the eyes of many consumers, though they evoke quite violent negative emotions in others.

Historical Origins of Modern Brassica Vegetables

Most scholars place the wild cabbage at the head of the family tree that has led to the development of the 400 or so varieties of *Brassica oleracea*. Although there is still considerable disagreement among scientists as to precisely how all of the modern brassica vegetables arose, there are widespread references to these vegetables in writings dating back many centuries. Their taxonomy, too, is a subject of considerable debate and should be regarded as being in a state of flux. Genus, species, variety, subvariety, subspecies, botanical group, and cultivar designations are frequently interchanged in the descriptive literature. Commonly recognized taxonomic designations are used herein, wherever possible.

It is widely agreed that there are six major vegetable *Brassica* species. Three are monogenomic, and three are amphidiploid (being diploid for two genomes, each originally contributed by a different species). These major categories are thus commonly designated as having A, B, or C genomic compositions, and their relationships are shown in **Table 1**.

The ancestral wild cabbage was almost certainly a seaside plant of northern European or Mediterranean origin. All of the wild brassicas today occur in cliffs and rocky islets in fairly isolated places. Wild *B. oleracea* varieties still grow as perennials along the coasts of northern Spain, western France, and southern and southwestern Britain. Over time, some 400 varieties have been created, which include cabbages, kohlrabi, oilseed rape, Brussels sprouts, cauliflower, and broccoli. Cabbages were not eaten by the Hebrews or the Egyptians. None of the crucifers are mentioned in the Old Testament, and the only crucifer mentioned in the New Testament (Mark 4:30–32) is mustard seed. The ancient Romans and Greeks, however, were quite familiar with cabbages and cauliflower and believed that eating cabbage during a banquet would prevent one from becoming drunk. Dietary cabbage intake was discussed in the writings of Pythagoras, Diogenes, and Cato, to name a few. Cato, for example, recommended cabbage in the diet to prevent disease and prolong life and claimed to owe his procreative prolificacy (he had 28 sons) to cabbage. In the Middle Ages, cabbage plasters were used for medicinal purposes, and cabbage was used for cough syrup and wound dressings. In the 1700s, they were used aboard ships for their vitamin C content and were used as dressings to combat gangrene.

Broccoli (from the Italian 'brocco,' arm or branch) is widely presumed to have developed from the wild cabbage that was native to coastal Europe and spread through the Near East to the Orient between 2000 and 2500 years ago. Some authorities consider that sprouting broccoli (something resembling modern-day broccoli) was first domesticated and cultivated in Italy during ancient Roman times. A vegetable that was probably broccoli was described by the Roman botanist Pliny (first century CE). There is no consensus, however, on the translation of the early name 'cyma,' and there is concern that the writings of early botanists may have confused 'broccoli' and 'cauliflower' as we know them today. Others maintain that early selection and domestication of broccoli may have been made in Asia Minor, with a cultivated form being brought to Italy by early traders in the 1500s. What is certain, however, is that broccoli (also known at that time as Italian asparagus or sprouting broccoli) was introduced to England around the 1720s. The following passage from Stephen Switzer's *The Practical Kitchen Gardiner* (1727) illustrates the point:

> As for the broccoli, there are three kinds of it, one of which yields sprouts button'd at their points, or headed like small collyflowers; another sort with curl'd leaves, which produce sprouts button'd on the points like asparagus; and a third with curl'd leaves of a pale green colour, which yield sprouts like the red kind; the two are to be had at several places about London; but the first is very rare to be had, but from some few gentlemen that have them yearly from Italy. . .

Table 1 Haploid chromosome number and genomic compositions of the six major *Brassica* species

Species	*Haploid chromosome number*	*Genome*
B. rapa	10	A
B. nigra	8	B
B. oleracea	9	C
B. juncea	18	AB
B. napus	19	AC
B. carinata	17	BC

By the late 1700s, broccoli was introduced to the American colonies, where it was grown by Italian immigrants on the East Coast of the United States but was otherwise little known until the 1920s. In 1912, the Stokes Seeds company brought broccoli seed into the United States and started selling to growers in 1918. In 1923, the D'Arrigo Brothers Company initiated field trials in California and, by 1925, was shipping ice-pack freight car loads of broccoli back to the east coast.

Commonly Cultivated Brassica Vegetables

Broccoli, Including Broccoli Sprouts (*B. oleracea* var. *italica*)

This is also known as calabrese or sprouting broccoli. The most valued portions of broccoli plants are the heads, which are inflorescences consisting of immature fully differentiated flower buds and tender upper stems. Both primary and secondary inflorescences are eaten, and lower stems are eaten too, but are not as prized due to their tough outer 'rind.' Broccoli is available commercially as fresh or frozen florets and is used raw in salads or as vegetable crudités. It is also frequently cooked and served by itself as well as being a component of many cooked and stir-fried dishes. There are over 100 commercial hybrid cultivars of broccoli, derived from a limited number of landraces or open pollinated cultivars that include purple sprouting, purple cape, purple Sicilian, white sprouting, and calabrese or green sprouting broccoli. Cut broccoli shoots or florets are very perishable and must thus be cooled (e.g., vacuum cooling) very soon after picking. Crushed ice or an ice slurry is typically blown into cartons of broccoli within a few hours of their being picked. California and Mexico in North America and Italy, France, and Spain in Europe are the major production areas. Consumption of broccoli in the United States has been steadily climbing since about 1970. In 1970, the total per-capita consumption was about 0.7 kg and is presently (2012 figures) about 3.6 kg. The development of hybrids in the late 1970s and their subsequent marketing by the vegetable seed companies were responsible for much of the increased consumption in the 1970s and 1980s. Impetus for the dramatic increase in consumption over the past 20 or so years has come from the health aura, which broccoli has recently enjoyed. Broccoli and kale are regularly identified as the vegetables eaten most often for health reasons, including cancer prevention and high-fiber, vitamin C, folate, and calcium content. Broccoli sprouts (seeds germinated in water, without soil, and grown as green sprouts for a few days) have added further evidence to the literature on broccoli's health benefits and are currently being evaluated in clinical trials for their ability to mitigate or prevent a wide spectrum of chronic diseases.

Broccoli Raab (*B. rapa* var. *rapa*)

Broccoli raab is also known as broccoli rabe, broccoli babe, rapini, broccoletti di rape, broccoletto, turnip broccoli, cima di rapa, Italian turnip, sparachetti, or taitcat. Broccoli raab has also been classified botanically as *B. campestris* or *B. ruvo*. It is a bitter-tasting vegetable similar in appearance to Chinese kale but non-heading and with thinner stems and smaller flowers than broccoli. It is long been considered a delicacy in Italy, typically lightly sautéed with garlic. It has recently gained interest in the United States and is considered a 'new' vegetable by some.

Brussels Sprouts (*B. oleracea* var. *gemmifera*)

Brussels sprouts are a relatively young member of the brassica family. They originated in Belgium in the 1500s and by the 1700s were appearing on tables around the world. Brussels sprouts grow as a tall ($\sim$1 m) single-stem biennial from which the axillary buds, resembling miniature cabbage heads, are harvested. They are generally eaten after cooking (steaming or boiling) and are available commercially either fresh or frozen. Brussels sprouts require a long growing season, and vegetable quality is adversely affected by warm weather.

Cabbage (*B. oleracea* var. *capitata*)

Cabbage has been cultivated, and even revered, as a vegetable by the ancient Greeks as far back as 2600 years ago, and it has also had a long history of medicinal use. There are scores of references to its use for such diverse purposes as the prevention of drunkenness, headache, stomach ailments, and even cancer. Cabbage leaves have long been used as poultices for application to tumors, and even in modern times, they have been under investigation as a means for preventing or treating breast engorgement in nursing mothers.

All cabbages have heads formed from tightly packed leaves. There are many distinct head types, the most common being Wakefield (with small, early, white, pointed heads; for fresh market), red (leaf surfaces are pigmented and they have medium very firm, round heads; for fresh market and storage), Danish Ballhead (round, very firm heads and light green leaves; for fresh market and storage), and Savoy (some authorities designate this *B. oleracea* var. *sabauda*) (round, loose heads with crinkled or blistered leaves; for fresh market and storage). Cabbage is typically eaten fresh, processed into a salad-like dish called coleslaw, and boiled or eaten as a fermented and pickled product called sauerkraut. Cabbages are important as a fresh market crop as well as a processing crop in most parts of the world and rank in the top ten vegetables in both sales and volume in North America and much of Europe.

Cauliflower (*B. oleracea* var. *botrytis*)

The edible portion or head of cauliflower is composed of tightly clumped, undifferentiated shoot apices on top of

hypertrophied, highly branched fleshy stem tissue commonly referred to as curds. Referred to by Mark Twain as "nothing but a cabbage with a college education," cauliflower curds, unlike broccoli, are actually degenerate shoot tips that are most frequently white in color (lacking chlorophyll), although purple, green, and orange cultivars now exist. Cauliflower is not as cold-tolerant as many other brassica vegetables. It is grown commercially in France, Italy, the United Kingdom, and North America, and it is eaten in the same manner as broccoli as well as being pickled. It is available commercially as fresh or frozen curds.

Charlock (*B. kaber*, also *B. arvensis*, or *Sinapis arvensis*)

Charlock is also known as kaber. The seeds of this plant, likely of Mediterranean origin, are used as a condiment, and the leaves are eaten as a potherb. The seeds are not as pungent as those of other mustards.

Chinese Cabbage (*B. rapa* var. *pekinensis*)

Chinese cabbage is also known as napa, napa cabbage, pe-tsai, wongbok, or chihli. This is a vegetable of major importance in China (over 300 000 ha grown), Korea, Taiwan, and Japan. Grown as an annual crop, most cultivars are biennial and produce tight, compact, cylindrical heads. This vegetable has been cultivated in China for over 1600 years and accounts for a major fraction of the total vegetable consumption in certain (northern) areas of the country. In Korea, it is fermented to produce (preserved) kimchi, which is thus a yearlong, ubiquitous commodity in that country.

Chinese Kale (*B. oleracea* var. *alboglabra*)

This is also known as gai lan, Chinese broccoli, gai lon, gai larn, kai laan, white-flowered broccoli, or fat-shan. Compared to broccoli, Chinese kale has more, slender, dark green leaves, longer stems, and very few florets, which are similar to those of broccoli. Flower buds, flower stalks, and young leaves are consumed, primarily in salads and stir fries. Chinese kale is relatively new to Japan, western Europe, and US cuisines but extensively grown in Taiwan, Southeast Asia, and China. It is relatively fast growing and heat-tolerant.

Chinese Mustards (*B. rapa* ssp. *chinensis*)

These include bok choy, pak choi, choy sum, and Shantung cabbage and are also known as Chinese white cabbage and celery mustard. Pak choi and bok choy are sometimes errantly referred to as Chinese cabbages. *B. rapa* ssp. *parachinensis*, also known as mock pak choi, choy sum, cai tai, or saishin, has been cultivated since the fifth century CE in Asia and continues to be very important vegetables, especially in China. Pak choi is the more leafy cultivar, and bok choy is notable for its massive leaf midribs, which are white and fleshy. This subspecies is a biennial, which is grown as an annual for its edible leaves. Plants can reach 0.6 m tall and can weigh over 2 kg. Leaves are usually consumed fresh but are also dried after blanching, for use through periods when fresh vegetables are not plentiful.

Collards (*B. oleracea* var. *sabellica*)

Available commercially as fresh, canned, or frozen leaves, collard greens are popular in the southern United States, where they are grown along the eastern portion of the country. As such, it is a much more heat-tolerant crop than its close relative, kale. The plants are nonheading and up to 1.25 m tall, and the broad, flat, or slightly furrowed leaves form as a rosette on a minimal stem.

Colza (*B. napus* var. *napus*)

Colza is also known as vegetable rape, xi yang you cal, and chou navet. Colza oil (expressed from seeds) is commonly consumed in India and China. Foliage and sprouted seeds are eaten in salads or as a potherb; inflorescences are prepared like broccoli.

Kale (*B. oleracea* var. *acephala*)

There are many 'kales,' some of which are classified taxonomically into other *Brassica* species or varieties. Kale includes kitchen kale, green kale, dwarf Siberian kale, marrow stem kale, tronchuda kale, curly leaf kale, Scotch kale, tree kale, and borecole. Although highly variable, kale is characterized by a nonheading rosette-like whorl of foliage; a short, erect stem; and large, upright, curly leaves. They are used mainly for their edible foliage and are generally eaten cooked, but are sold fresh, canned, and frozen, or used as garnish. Among the commonly grown kales are the following:

- Branching bush kales (sometimes classified as *B. oleracea* var. *fruticosa*): also known as cow kale or borecole (sometimes classified as *B. oleracea* var. *selenesia*), these were often cultivated in the past for their edible foliage and have been used extensively for animal fodder.
- Thousand-headed kale (*B. oleracea* var. *ramosa* or *B. oleracea* var. *millecapitata*).
- Inflorescence kales (a term used by some to describe cauliflower, broccoli, and related brassica vegetables).
- Galega kale (also known as couve galega): a traditional and widely grown Portuguese nonheading kale with long petioles, large midribbed leaves, and an elongated stem that can reach 3 m; leaves are picked one by one and used for traditional soups or for animal feed.
- Marrow stem kale (*B. oleracea* var. *medullosa*): a particularly prolific type of kale used exclusively for animal feed.
- Siberian kale (also classified as *B. napus* var. *pabularia*): also known as Hanover salad, a leafy vegetable, similar to collards, which is used fresh in salads and cooked as a potherb.

Kohlrabi (*B. oleracea* var. *gongylodes*)

This is also known as knol khol or turnip cabbage. The edible portion of kohlrabi is the fleshy, swollen, tuber-like enlargement of the short, unbranched stem, which may be white, green, or purple and develops just above the surface of the soil. This vegetable developed in northern Europe about five centuries ago. It resembles turnip and rutabaga in flavor and texture but becomes highly fibrous if not harvested at peak maturity.

Mizuna (*B. rapa* ssp. *japonica*)

Also known as mibuna, curled mustard, or Japanese greens, mizuna is a cool-tolerant relative of the leafy turnips that has recently been introduced to the West.

Mustard (Various Latin Binomials)

Plants from this diverse group have been used worldwide for centuries as a condiment (mustard seed; also known as black mustard, brown mustard, and *B. nigra*) and as a vegetable (mustard greens; *B. juncea*). Most well known among the mustards are

- white or yellow mustard (*B. hirta*, *B. alba*, or *Sinapis alba*),
- Chinese mustard (*B. japonica*),
- black mustard (*B. nigra* or *Sinapis nigra*) and field mustard (*B. campestris*),
- Ethiopian mustard and Abyssinian mustard (*B. carinata*).

Many of the so-called brown mustards (*B. juncea*) have been assigned unique variety names. Common English and Chinese names are as follows:

- *B. juncea* var. *capitata* (capitata mustard, jie qiu jie)
- *B. juncea* var. *crassicaulis* (bamboo shoot mustard, sun zi jie)
- *B. juncea* var. *crispifolia* (cut-leaf mustard and curled mustard, mi tuo jie)
- *B. juncea* var. *foliosa* (small-leaf mustard, xiao ye jie)
- *B. juncea* var. *gemmifera* (gemmiferous mustard, bao zi jie)
- *B. juncea* var. *involuta* (involute mustard, juan xin jie)
- *B. juncea* var. *latipa* (wide petiole mustard, kuan bing jie)
- *B. juncea* var. *leucanthus* (white-flowered mustard, bao hua jie)
- *B. juncea* var. *linearifolia* (line mustard, feng wei jie)
- *B. juncea* var. *longepetiolata* (long petiole mustard, chang bing jie)
- *B. juncea* var. *megarrhiza* (tuberous-rooted mustard, dal tou jie)
- *B. juncea* var. *multiceps* (tillered mustard, fen nie jie)
- *B. juncea* var. *multisecta* (flowerlike leaf mustard, hua ye jie)
- *B. juncea* var. *rugosa* (large-leaf mustard, brown mustard, Indian mustard, and mustard greens; rai and dai ye jie)
- *B. juncea* var. *strumata* (strumous mustard, tsatsai and zha cai)
- *B. juncea* var. *tumida* (swollen stem mustard, jing liu jie)
- *B. juncea* var. *utilis* (peduncled mustard, tai jie)
- *B. rapa* var. *narinosa* (broad-beaked mustard, wu ta cai and taasai)

Swede (*B. napus* var. *napobrassica*)

Also known as rutabaga in the United States, swede is considered a 'root crop,' though, technically, this is not accurate. It is an annual crop grown as animal fodder and consumed by human beings after cooking or pickling. It has been grown for about three centuries, originating in Sweden and spreading throughout Europe. The flesh is white or orange and similar in flavor and texture to turnips with equivalent, excellent storage characteristics but low commercial value. Swede not only is much more hardy than the turnip but also takes much longer to mature. The leaves are used as a potherb.

Tendergreen (*B. rapa* ssp. *perviridis*)

Also known as spinach mustard, mustard spinach, or komatsuna, this leafy relative of the turnip is reasonably cold-tolerant, surviving temperatures as low as $-15\,^{\circ}C$. It has large, dark green, mildflavored foliage, which is eaten fresh and pickled, primarily in Korea, Taiwan, and Japan.

Texsel Greens (*B. carinata*)

Of Ethiopian origin, the early growth of this plant is valued for its high protein and vitamin C content and is eaten raw in salads or lightly boiled as a spinach substitute. It has a milder flavor than collards or mustard greens.

Tronchuda Cabbage (*B. oleracea* var. *costata*)

Also known as Portuguese cabbage, couve tronchuda, Galician cabbage, braganza, or sea-kale cabbage, these are loose-headed cabbages that have large leaves with succulent midribs. It is believed that the many landraces of this vegetable arose from an initial hybridization of cabbage and kale.

Turnip (*B. rapa* var. *rapifera*)

Turnip is very similar to rutabaga in that it is a 'root crop' (technically incorrect) that produces high amounts of biomass per hectare, is high in starch content, and has very favorable storage characteristics. It appears to have been around for about 4000 years, originating in eastern Europe and Siberia and gradually spreading across Europe. As with swedes, turnips are generally eaten after cooking and can also be processed for use in pickled or mixed vegetables. Turnip greens are eaten in season as a fresh leafy green vegetable.

Turnip Rape (*B. campestris* var. *oleifera*)

The seeds of this plant produce an oil that is sometimes used in cooking, and it has relatively high levels of unsaturated lipids. It is becoming more popular as an oilseed but is distinct from the very widely grown oilseed rape (*B. napus* var. *oleifera*). The foliage of the plant is used as a potherb and garnish.

'New' Brassica Vegetables

A number of 'new' brassica vegetables have been produced under trade names, primarily by cross hybridization between existing taxa. These include the following:

- Broccolini: a cross between Chinese kale and broccoli trademarked by Mann Packing Co. (California, the United States)
- Asparation: a cross between Chinese kale and broccoli trademarked by Sakata Seed Inc. (California, the United States)
- Broccoflower (*B. oleracea* var. *botrytis*): a bright green cauliflower originating in Holland and trademarked by T & A (Tanimura & Antle, California, the United States) about two decades ago

Regional Preferences

Brassica vegetables are a large group of primarily herbaceous plants that includes a number of the world's most commonly cultivated vegetables. Though the progenitor species likely originated in the Mediterranean region, the cultivated brassica vegetables are of cosmopolitan distribution. Cultivars have been adapted for worldwide production, from the tropics to the Arctic Circle. The largest cabbages in the world have, in fact, been grown near Fairbanks, Alaska, the United States.

Brassica vegetables include a large number of taxonomically closely related, but morphologically and organoleptically diverse, plants. These species have been cultivated for many centuries and have been extensively crossed and hybridized. Many cultivars have been developed in microenvironments or very small geographic regions where they have remained essentially isolated for decades, or even centuries. For example, certain small villages or regions in Italy have their own very distinctive broccoli cultivars. Since these vegetable gene pools have remained isolated for hundreds of generations of selection, there has been considerable development of phenotypes that diverge from a common ancestor. The relationships of some of the more common brassicas are detailed in Figure 1.

Dietary and Commercial Importance

From a nutritional standpoint, these vegetables are perhaps best recognized as excellent sources of vitamin C, fiber, calcium, and certain phytochemicals such as carotenoids (provitamin A) and glucosinolates (which have been the source of considerable recent scientific research as cancer protective agents). The contents of vitamins, minerals, and phytochemicals are, however, highly dependent on both genetic and environmental variables. Plant cultivar or variety; the environment in which the plant is grown (e.g., amount of sunlight, drought stress, and temperature); the conditions under which it is harvested, stored, and transported to market; and the way in which it is prepared for the table and consumed all play key

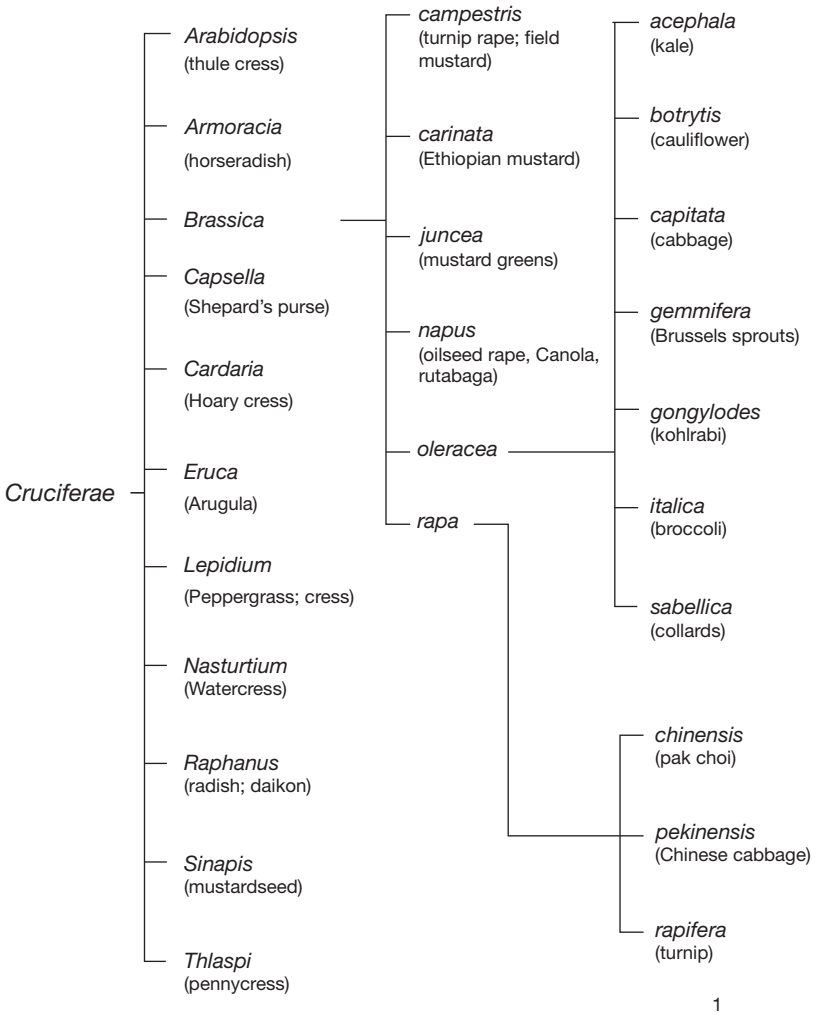

Figure 1 The world's most commonly known brassicas. Note that there are many hundreds of edible brassica species. Three of the well-known species are not commonly eaten, *Arabidopsis* (a genetic 'model organism'), *Capsella*, and *Cardaria*, which actually contains a pervasive and invasive weed in western US rangeland in which the phytochemical sulforaphane was first identified.

roles in the ultimate nutritional value of that vegetable. Water-soluble components such as vitamin C and glucosinolates (see succeeding text) are easily leached out in the pot liquor during cooking. These and other beneficial chemicals can exhibit a tremendous gradient from one portion of the plant to another, and it is often quite difficult to assess these differences without performing sophisticated chemical analyses. Nonetheless, the brassica vegetables remain among the best sources of the dietary components mentioned earlier and should be consumed regularly as part of a diet rich in fruits and vegetables.

In the West, broccoli, Brussels sprouts, cauliflower, cabbage, and kale are the most significant brassica components of the diet. In the East, the so-called oriental brassicas (Chinese cabbage, tendergreen (spinach mustard), bok choy, pak choi, mizuna, celery mustard, and Chinese mustard) as well as spinach mustard and mizuna greens, Chinese kale (Chinese broccoli), and daikon (Japanese radish – a cruciferous root crop) are the main brassica vegetables of commercial and dietary importance.

Cultivation and Postharvest

The brassica vegetables are hardy, cool-season vegetables that grow best in temperatures in the range of 15–20 °C and have similar cultural requirements. Cabbage plants that have been hardened off can tolerate temperatures as low as −4 °C for short bursts, and broccoli and cauliflower plants thrive in light frosts. Almost all cole crops decline in quality when temperatures are in excess of 26–27 °C. Under irrigation (guaranteed water supply), broccoli crops can be harvested in 10–15 weeks from direct seeding, cabbage crops in 13–17 weeks, and cauliflower crops in about 13–16 weeks, depending on the temperature and climate. Brassica vegetables can be grown on a wide range of soil types, and in addition to direct seeding, many crops are now grown from glasshouse transplants. All brassica vegetables are more or less susceptible to the same diseases and insect pests. More specific agronomic advice is beyond the scope of this article.

Although some brassica crops do not need cooling after harvest, broccoli and cauliflower require immediate prechilling to 4 °C. These crops are typically hydrocooled or immersed in an ice slurry. They must be refrigerated for transport and storage and have a storage life of about 2 weeks (broccoli), to 4 weeks (cauliflower), to as much as 6 months for some cabbage varieties grown in cooler climates.

Nutritional Value and Chemical Composition

Table 2 summarizes the nutritional value and chemical composition of broccoli, Brussels sprouts, cabbage, red cabbage, Savoy cabbage, Chinese cabbage, cauliflower, collards, cress, kale, kohlrabi, mustard greens, tendergreen, and swede.

Vitamin A, Vitamin C, Selenium, Calcium, and Fiber

The brassica vegetables are excellent sources of calcium, fiber, vitamin A (in the form of β-carotene) or provitamin A, and vitamin C (especially broccoli, kale, and tendergreen). The element selenium can be incorporated into the tissues of brassica vegetables (in particular broccoli), where it can reach rather high levels, and the vegetable may be of therapeutic value as a source of this antioxidant element due to its special availability from such tissues.

Phytochemical Attributes (e.g., Glucosinolates/Isothiocyanates, Carotenoids, and Flavonoids)

All of the brassica vegetables contain glucosinolates, at concentrations of up to 3% by weight in the seeds of some plants. These sulfur-containing compounds and their breakdown products have long been known for their fungicidal, bactericidal, nematicidal, and allelopathic properties, as well as for the goitrogenic or antinutritional glucosinolates in the protein-rich, defatted meal from widely grown oilseed crops (e.g., rapeseed) and in some domesticated brassica vegetables (e.g., Brussels sprouts). When used as animal feed, rapeseed meal can have pronounced deleterious health consequences on livestock due to ingestion of excessive quantities of 'progoitrin' (e.g., when livestock are fed a meal produced from defatted rapeseed containing the progoitrin), which may interfere with thyroxine production, drastically reducing iodine supply to the thyroid gland and resulting in the development of goiter and other associated problems. Recently, however, other members of this large group of compounds (e.g., glucoraphanin, sulforaphane, phenethyl isothiocyanate, benzyl isothiocyanate, crambene, and indole-3-carbinol) have attracted intense research interest because of their cancer chemoprotective and antioxidant attributes. Certain compounds (e.g., sulforaphane) have been shown to be potent inducers of mammalian detoxication enzymes, which facilitate the deactivation and excretion of many carcinogens from the body. The use of a number of these compounds in a dietary strategy for cancer prevention is now being investigated in clinical trials worldwide, particularly as very young plants (e.g., broccoli sprouts).

The brassica vegetables are generally very rich sources of the antioxidant and provitamin A carotenoids (e.g., lutein, zeaxanthin, and β-carotene). These compounds are long-chain, fat-soluble substituted hydrocarbons, which are the light-gathering accessory pigments typically found in the leaves, stems, and inflorescences of most plants. Since these are typically the plant organs that are eaten, they can be regarded as typical 'dark green leafy vegetables' and good sources of such compounds (Table 2). Certain *Brassica* vegetables, such as kale and broccoli, are particularly rich in these compounds, and the edible head of cauliflower is devoid of them. A mutant, orange cauliflower plant was found growing in a Canadian field about 40 years ago, however, which is currently being investigated as a very potent source of β-carotene and a very useful system for scientists to unravel some of the biochemical and molecular mysteries still surrounding carotenoid production in plants. Though an orange cauliflower is now being marketed, the application of this research may result ultimately in the introduction of higher-carotenoid varieties of some of the world's staple crops and a reduced incidence of vitamin A deficiency (which can be reduced by the ingestion of β-carotene-rich foods).

The brassica vegetables, though not unique in this respect, are also good sources of various flavonoids and their

Bread: Breadmaking Processes

Breadmaking Processes

Different methods that allow the conversion of flour and other ingredients into bread have evolved with time. In practice, many of the variations in the common breadmaking processes are small and usually consist of variations about a central 'standard' process, so that we are able to group them into a small number of generic processes in order to consider the changes that occur within them and their contribution to final product quality.

The different processes have a single, common aim, namely, to convert wheat flour into an aerated and palatable food. In achieving this conversion, there are a number of largely common steps that are used; they may be described as follows:

- The blending of wheat flour and water, together with yeast and salt and other specified ingredients in appropriate ratios
- The hydration of the gluten-forming proteins and development of the gluten structure through the application of energy during mixing (sometimes referred to as 'kneading')
- The incorporation of air bubbles within the dough during mixing
- The continued 'development' of the gluten structure and modification of the rheological properties of the dough so as to improve its ability to expand when gas pressures increase with the generation of carbon dioxide gas during fermentation (often referred to as 'ripening' or 'maturing')
- The creation or modification of flavor compounds in the dough
- The subdivision of the dough mass into unit pieces
- A preliminary modification of the shape of the pieces
- A short delay in processing to modify further the rheological properties of the dough pieces
- The final shaping of the dough pieces
- The fermentation (proof) and expansion of the pieces
- Final expansion of dough pieces and fixation of the final bread structure during baking

The differences between breadmaking processes are mainly associated with mixing and kneading, air incorporation, and the creation and development of the gluten structure, in summary all of those operations that in practice deal with the formation of a large dough bulk. The dividing and shaping processes make small contributions to product quality, and the processes of proving and baking are common to all breadmaking processes. Since it is mixing stages, which determine most of the bread quality, this section will concentrate on the main features of the different types of breadmaking process.

The Nature of Dough Development and Its Contribution to Bread Quality

Dough development is a poorly defined term covering complex changes in bread ingredients, which are set in motion when the ingredients first become mixed. The changes are associated with first the formation of gluten, which requires both the hydration of the proteins in the flour and the application of energy through the process of kneading. In the process of developing bread, dough changes are brought about to the physical properties of the dough and in particular its ability to retain the carbon dioxide gas, which will later be generated by yeast fermentation. This improvement in gas retention ability is particularly important when the dough pieces reach the oven. The modification of gluten structure can be achieved by a number of different physical and chemical processes, and various combinations of these form the basis of the different groups of breadmaking processes, which are in common use.

It is important to distinguish between gas production and gas retention in fermented doughs. Gas production refers to the generation of carbon dioxide gas as a consequence of yeast fermentation. Not all of the gas generated during processing, proof, and baking will be retained within the dough before it finally sets in the oven. The proportion that will be retained depends on the development of a suitable gluten matrix within which the expanding gas can be held. Gas retention in dough is therefore closely linked with the degree of dough development that occurs and as such will be affected by a large number of ingredients and processing parameters, which are not necessarily independent of one another.

The production of a defined cellular structure in the baked bread depends entirely on the creation and retention of gas bubbles in the dough during mixing. During mixing, these are a mixture of air (oxygen and nitrogen) and later the carbon dioxide gas coming from fermentation. The numbers and size of gas bubbles, which are created in the dough during mixing, have the greatest impact on bread quality. There is some modification of the gas bubble size populations in the dough during processing, but by the time that the dough leaves the mixer, the final cell structure has largely been decided.

The Major Breadmaking Process Groups

The methods by which dough development is achieved in the bakery may be fitted into five described as follows:

- *Straight dough bulk fermentation*, where resting periods (floor time) for the dough in bulk after mixing and before dividing are used
- *Sponge and dough*, where a part of the dough formulation receives a prolonged fermentation period before being mixed with the remainder of the ingredients to form the final dough, which is then processed without further delay
- *Rapid processing*, where the dough is fermented in bulk for a limited period or not at all before dividing
- *Mechanical dough development*, where significant and measured quantities of energy facilitate dough development and the dough moves without delay from mixer to divider for further processing

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00087-8

- *Sourdough methods* based on the spontaneous fermentation from naturally occurring wild yeast and other microorganisms

Straight Dough Bulk Fermentation

Variations in this group are based on different periods of bulk fermentation time and fermentation control by temperature, yeast level, or both. The essential features can be summarized as follows:

- Mixing of the ingredients to form a homogeneous dough usually at low speeds and for extended time periods (20–30 min) with a temperature at the end of mixing in the region of 21–27 °C.
- Resting of the mixed dough in bulk for a prescribed time (sometimes called floor time), commonly based on flour quality, yeast level, dough temperature, and the bread variety being manufactured.
- Partway through the bulk fermentation period, there may be a remixing of the dough, commonly referred to as 'knock-back' or 'punching down.'

Typical straight dough formulations only contain a few ingredients as shown in Table 1. Usually, recipe yeast levels are higher with shorter bulk fermentation times. Since the mechanism for dough development in bulk fermentation depends to a significant degree on yeast activity, dough temperature plays a major role in determining the time at which full development is achieved for a recipe with a given yeast level. For a given flour, bread volume improves with increasing bulk dough standing time (Figure 1). However, the protein content and qualities of flours used in bulk-fermented doughs are closely linked with the length of the bulk fermentation period, and in general, the stronger the flour, the longer the fermentation period. Typical white flour protein contents would be 12–13% (14% moisture basis) or greater.

While the only essential ingredients required are those given in Table 1, other ingredients are sometimes added for making bread by bulk fermentation. The typical rates of addition for these optional ingredients and the properties they confer to the dough and the bread are given in Table 2. 'Improvers' consisting of a low level of oxidizing agent or enzyme-active material may be added to bulk-fermented

Table 1 Recipes for bulk-fermented doughs

	3 h (%)	*1 h (%)*

Skimmed milk powders	Up to 2.0	Crust color Flavor

Figure 1 Effect of bulk fermentation time on bread quality.

doughs. 'Knocking back,' 'punching down,' or remixing of the bulk dough may occur partway through the fermentation time. Advantages that are claimed for these operations include equilibration of dough temperatures throughout its bulk and the incorporation of more air into the dough to improve yeast activity.

Sponge and Dough

The elements of sponge and dough processes are similar to those for bulk fermentation in that a prolonged period of fermentation is required to effect physical and chemical changes in the dough. In sponge and dough, this is achieved by the thorough fermentation of part of the ingredients rather than all of them. The key features of sponge and dough processes are the following:

- A first stage in which parts of the total quantity of flour, water, and other ingredients from the formulation are mixed to form a homogeneous soft dough with a final temperature around 20 °C.
- A bulk resting period for the sponge so formed under controlled conditions.
- Mixing the sponge with the remainder of the ingredients to form the dough with a final temperature of 20–27 °C.
- Immediate dividing and processing of the final dough.
- The sponge may be replaced with a flour brew based on a higher proportion of liquid.

The preparation of the sponge may be carried out with low- or high-speed mixers. Key roles for the sponge are to modify bread flavor and contribute to the development of the final dough through the modification of its rheological properties. To maintain the right flavor profile in the finished product, the sponge fermentation conditions should be closely controlled. During sponge fermentation, there is a decrease in sponge pH. This low pH makes a unique contribution to the rheological character in the final dough and has the effect of producing a softer and more extensible gluten network after the second mixing.

Table 3 Examples of sponge and dough formulations (ingredient proportions expressed as percentage of total flour weight)

	Sponge	*Dough*
UK 16 h sponge		
Flour	25.0	75.0
Yeast	0.18	1.75
Salt	0.25	1.75
Water	14.0	43.0
Fat	0.0	1.0
North American 4 h sponge		
Flour	65.0	35.0
Yeast	2.4	0.0
Salt	0.0	2.3
Water	40.0	25.0
Improver	0.1	0.0
Milk solids	0.0	3.0
Sugar	0.0	6.0
Fat	0.0	3.0

Examples of sponge and dough formulations are given in Table 3, one of which is for a typical 16 h (overnight) sponge in the United Kingdom and the other a 4 h example from North America. Additions of improvers are not essential to the production of bread by sponge and dough methods since a contribution towards dough development is made directly by the sponge. However, as shown by the example of a North American recipe in Table 3, improver additions are common. There will be different potential effects from the different oxidizing agents present if the improver is added to the sponge side of the process. Late-acting oxidizing agents have little or no effect until the dough reaches the prover (proofer) while faster-acting oxidizers, such as ascorbic acid and azodicarbonamide, will act in the sponge-mixing stage. In the case of ascorbic acid, oxygen is required for oxidation of the dough proteins to occur. Flour protein contents are usually not $<12\%$ (14% moisture), and Hagberg falling numbers are high.

Rapid Processing

Some short-time dough processes based on no bulk fermentation time are included under this heading. They have the common element that they include improvers to assist in dough development and the reduction of any bulk fermentation period.

Activated Dough Development

This process was developed during the early 1960s and became popular in smaller bakeries. Its essential features are

- the addition of a reducing agent, usually L-cysteine hydrochloride,
- the addition of oxidizing agents,
- the addition of a fat or an emulsifier,
- extra water in the dough to compensate for the lack of natural softening,
- extra yeast to maintain normal proving times.

When first introduced, potassium bromate, ascorbic acid, and L-cysteine hydrochloride were common components in the improver, but in many parts of the world, potassium bromate is no longer used. Since the dough development process in activated dough development was mostly chemically induced, low- or medium-speed (spiral) mixers can be used. A short period of bulk fermentation (typically <30 min) before dividing may follow mixing, and final dough temperatures are in the region of 25–27 °C.

The Dutch Green Dough Process

This process was developed in the Netherlands, and while the mixed dough passes without delay to dividing, significant periods of resting are involved in the total process. The name 'green' refers to the fact that after the mixing, the dough is considered to be underdeveloped or 'green' in classic bakery parlance. Dough development continues not in bulk but by resting the divided dough pieces between successive (two or three) processes. The essential features are as follows:

- Mixing in a spiral-type mixer or extra mixing in a speeded-up conventional low-speed mixer to a final dough temperature of 25–27 °C.
- The dough is divided immediately after mixing.
- The divided dough pieces are rounded and rested for 35–40 min.
- The pieces are rerounded and again rested before final molding.

Improvers are often added to assist with dough development in the absence of bulk fermentation time. The most common ingredients of the improvers are ascorbic acid, enzyme-active materials, and emulsifiers. Flour protein contents are around 12% (14% moisture basis). There is no appreciable softening of the dough from fermentation before dividing, and so water additions will be higher than in bulk fermentation.

Mechanical Dough Development

With mechanical dough development, there is no bulk fermentation period, and dough development is achieved in a short space of time in the mixer with the addition of improvers and extra yeast. The most common process considered under this heading is the Chorleywood bread process (CBP), which was developed by the British Baking Industries Research Association based at Chorleywood, the United Kingdom, and launched in 1961. The essential features of the CBP are

- mixing and dough development in a single operation lasting between 2 and 5 min at a fixed energy input carried out with a high-speed mixer;
- the addition of low levels of an improver (0.3–1.0% flour weight), commonly containing ascorbic acid, a high melting point fat, emulsifier or fat, and emulsifier combination and process enzymes;
- the addition of extra water to adjust dough consistency to be comparable with that from bulk fermentation;
- the addition of extra yeast to maintain final proof times comparable with those obtained with bulk fermentation;
- the control of mixer headspace atmosphere to achieve given bread cell structures.

The aim of the CBP is the same as all other breadmaking processes, which is to modify the protein structure in the dough to improve its ability to stretch and retain gas from yeast fermentation in the prover; in the case of the CBP, this is achieved within 5 min of starting the mixing process. Compared to bulk fermentation, the CBP offers a number of advantages including

- a reduction in processing time,
- space savings from the elimination of the bowl of dough at different stages of bulk fermentation,
- improved process control and reduced wastage in the event of plant breakdowns,
- more consistent product quality,
- financial savings from higher dough yield through the addition of extra water and retention of flour solids, which are normally fermented away.

The role that the delivery of energy to the dough mixing plays in optimizing bread quality with the CBP can be seen in Figure 2. As the level of energy per kilogram of dough in the mixer increases, so bread volume increases, and with this comes a reduction in cell size and increased cell uniformity. Typical work inputs lie in the range of 11–13 Wh kg^{-1}, though some strong flours may require higher work input so as to fully develop their breadmaking potential. Consequently, flours used in the CBP are commonly based on wheat blends, which deliver flours requiring close to 11 Wh kg^{-1} dough. The CBP makes more effective use of flour protein than some other breadmaking processes, and so in some circumstances, it is possible to reduce the overall level of flour protein with compromising bread quality. The role of that energy input during mixing has yet to be fully explained, and while it is

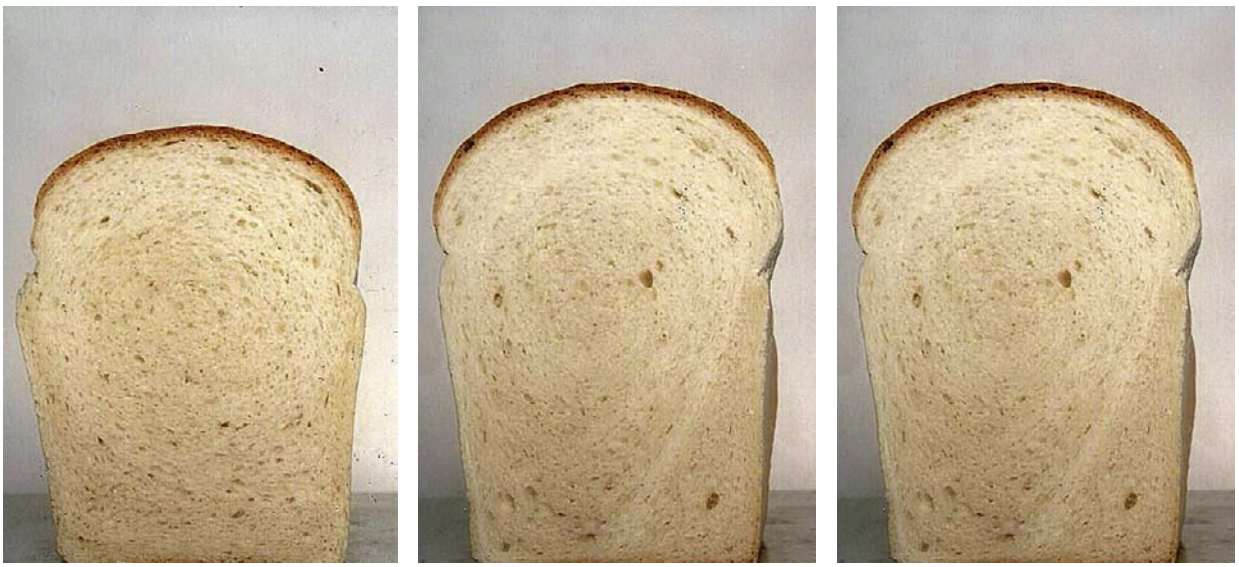

Figure 2 Effect of energy input during CBP dough mixing; left to right, 5, 8, 11 Wh kg^{-1} dough in the mixer.

very likely that the high energy inputs are capable of mechanically breaking the disulfide bonds holding the original protein configurations together, this is not the only reactions that are involved. No doubt, the breaking of weaker hydrogen bonds is also involved.

The input of energy during mixing with all breadmaking processes causes the final dough temperature to rise above that that can be calculated from the weighted average of the dough ingredients. Temperature rises in the CBP are higher than many other mixing actions, and some bakers may see this as a disadvantage in trying to control yeast activity. Control of final dough temperature is delivered using chilled water, the addition of flaked ice, or from the use of chilling jackets around the mixing bowl itself. Commonly with the very short processing times, which are used after mixing, it is possible to run final dough temperatures up to 30 °C that offers the advantage that chemical reactions are enhanced, which can lead to reductions in the level of additives needed in the improver.

In contrast to the situation in other breadmaking systems, many CBP-compatible mixers offer the advantage that the cell structure of the final product can be manipulated by changing the atmospheric conditions in the mixer. When first launched, the main control in the CBP was achieved by the application of a partial vacuum during mixing. Changes in permitted ingredients and the greater reliance on ascorbic acid as the oxidizing agent led to the development of the so-called 'pressure–vacuum' mixer, which could be used with above and below atmospheric pressures sequentially to deliver a wide range of product cell structures. The requirement to add extra water in the CBP arises because dough mixed under partial vacuum has a drier, firmer feel, and the requirement is for soft easily machined dough in most plant bakeries.

Sourdough Processes

The manufacture of sourdough bread has a long history and is based on the spontaneous fermentation of flour through the symbiotic relationship between bacteria and wild yeasts. Variations in the microflora, fermentation conditions, types, and ratios of raw materials are responsible for differences in the functionality of the sour and subsequent flavor in the bread. Sourdough technology is commonly based on wheat or rye flours or a mixture of both. Such breads have distinctive acid flavors largely arising from the ratio of acetic to lactic acid flavor notes, and the manufactured breads are denser with a less aerated structure than many other wheat breads. The preparation of a mother dough cannot proceed without a continuing food source for the microbial activity, and so its reproduction requires a 'top-up' with more flour (source of starch) on a regular basis. The symbiotic relationship between bacteria and yeast is important in sustaining fermentation with bacteria fermenting the more complex (larger molecular weight) sugars and yeasts metabolizing the by-products of the bacterial fermentation. For bakers who do not wish to manufacture and maintain their own starter, pre-prepared, dried sours are commercially available.

Some of the common sours may be described as follows:

- *Levain* based on 'wild yeasts' including *Saccharomyces* (S.) and *Candida* (*C.*) families and the presence of *Lactobacilli* (*L.*)
- The San Francisco sourdough associated with *L. sanfranciscensis* because it was in San Francisco, the United States, that the microorganism concerned was first isolated and identified from dough
- The *Poolish* (Polish-style sponge) that is a relatively liquid system comprising equal parts of flour and water
- The *Biga* commonly used in Italy with the addition of baker's yeast and fermented overnight (12–16 h)
- Rye flour sours

Processing the Dough to Bread

Each of the breadmaking processes has particular advantages and disadvantages, but most types of bread and fermented goods can be made with each of them. Much of the difference between the different processes revolves around the mixing and processing equipment; there may be some variations, but essentially, the processes of proving, baking, and cooling are common to all of the earlier processes.

After the bulk dough has been mixed, it will be cut into smaller unit pieces for processing to the required product. The weights of the individual pieces vary according to local custom and practices, but commonly, there will be some legislative control on the final bread weight that impacts the size of the dough piece, which will be used for processing.

Commonly, the dough pieces are subjected to two shaping processes separated by a short resting period. For many processes, the common first shaping is to a round or ball shape. The resting periods will vary from a few to 20 min or so with the longer periods encouraging gas production by the yeast and the creation of more open cell structures in the final product. The second molding stage fixes the final shape of the product whether it is destined to be baked in a pan or the oven hearth. Care is usually taken not to damage the gas bubble structure in this stage. Many final shaping operations are based on elongating the ball shape, rolling it up like a Swiss roll and then adjusting the shape of the cylinder that has been formed.

Once the final shape has been achieved, the individual pieces in pans or on trays are transferred to the prover for the last of the fermentation stages. In the prover, controlled conditions of temperature encourage gas production by the yeast, and the dough expands in volume. Humidity is also controlled to avoid drying out of the dough piece surface, which would otherwise restrict dough expansion.

The final stage of the breadmaking process is the conversion of the foam in the dough (the closed bubble structure) into an open spongelike structure in the bread. This foam-to-sponge conversion is achieved by heating the dough at temperatures above 200 °C and is accompanied by further expansion (oven spring) and the loss of water, especially from the crust. The complex changes require control of many different molecular, chemical, and physical changes to the dough components and are further complicated by the fact that the poor thermal conductivity of dough means that the changes occur at different parts of the product at different times. In essence, the foam-to-sponge conversion happens on a thermal front moving from the crust to the center of the product, and it is progressive change that is responsible for much of the character that we see in the final product.

However, the key to achieving a particular product character lies with choices made at the mixing stage; in essence, the nature of the baked products is set up by creating a stable foam in the mixer (the dough), expanding the foam in the prover, and converting the foam to a sponge (bread) in the oven.

Introduction

The breadmaking process is a dynamic process in which flour constituents are subjected to numerous physicochemical changes. Physical changes have been considered in a previous article; thus, only chemical variations in flour until bread will be considered in this article. Breadmaking is a dynamic process with continuous physicochemical, microbiological, and biochemical changes induced by the mechanical–thermal action and the activity of the yeast and lactic acid bacteria (LAB) together with the activity of the endogenous enzymes. Mixing involves mechanically and hydration-induced alterations, whereas during proofing, enzymes are mainly implicated and changes related to temperature increase occur during baking. The two main flour biopolymers, starch and proteins, undergo the most dramatic changes during the breadmaking process. The gluten proteins are largely responsible for the rheology of wheat flour dough, structural formation during mixing, and gas holding, whereas the role of starch is mainly implicated in final textural properties and product stability after baking.

Nevertheless, it must be also taken into account that breadmaking has experienced numerous changes in the way of processing and raw materials used. Commercial bakeries have understood very soon the changes in consumer lifestyles and shift their production processes, products, and even distribution channels to meet the new society requirements. Different alternatives have been developed for adapting breadmaking to the consumer demands and for facilitating the baker's work. Breadmaking stages have been extended including mixing the ingredients, dough resting, dividing and shaping, proofing, and baking, with great variation in the intermediate stages depending on the type of product. Low-temperature technology has been initially applied to bakery products to solve the economic losses associated with the bread staling problem that produces a decrease of consumer acceptance. Nowadays, the technology of frozen dough, par-baked bread, and frozen bread is being incorporated as routine processes. The partial baking consists in baking the bread dough until the structure is fixed, giving a product with structured crumb and without a crunchy crust that only requires a very short baking time in the retail bakery. Therefore, these alternative breadmaking processes promote additional chemical changes that were not considered in conventional breadmaking.

Additionally, the nature and extent of the chemical alterations produced during breadmaking are greatly dependent on the specific characteristics of each cereal flour. Since wheat flour is the most common flour used in making bread specialties, this article will be focussed on changes occurring in wheat flour during breadmaking.

Chemical Changes During Mixing

In breadmaking, mixing is one of the key steps that determine the mechanical properties of the dough, which have a direct consequence on the quality of the end product. Mixing allows hydration of flour constituents and it supplies the necessary mechanical energy for developing the protein network. Protein particles are disrupted during mixing and aligned yielding a three-dimensional viscoelastic structure with gas-retaining properties. Part of the protein phase (gliadin and glutenin) of flour has the ability to form gluten, a continuous macromolecular viscoelastic network, when sufficient water is available for the hydration of constituents and mechanical energy input is supplied for distributing flour components. Gluten consists of two main subfractions: glutenins that confer strength and elasticity and gliadins that impart viscosity to dough. In particular, proteins mainly involved in the viscoelastic properties of the dough are the high-molecular-weight glutenin subunits (HMWGS), which affect dough viscoelasticity in a similar and remarkable way than the water content. Gluten proteins contain a predominance of hydrophobic amino acids, particularly glutamine that has a strong tendency to form hydrogen bonds between protein strands. Moreover, the glutenin protein chains of the subunits contain amino acid cysteine with thiol groups, which form disulfide bridges that embrace the glutenin macropolymer and the gluten complex together. The more complex glutenins comprise high- and low-molecular-weight glutenin subunits that are linked together by disulfide bonds. Nevertheless, noncovalent interactions of mesoscopic glutenin aggregates are also involved in the development of the viscoelastic network. The proportion and size distribution of those proteins are critical for breadmaking and influence the mixing, kneading, and baking properties of dough. The properties of this network are governed by the quaternary structures resulting from disulfide-linked polymer proteins and hydrogen bonding aggregates. In this structure, also, tyrosine cross-links contribute to dough elasticity, suggesting that a radical mechanism involving endogenous peroxidases might catalyze the dityrosine formation during breadmaking.

During mixing, dough is exposed to large uni- and biaxial deformations, and a continuous protein network is formed, which is stabilized by disulfide bonds and modified thiol/disulfide interchange reactions. Depolymerization and repolymerization or cleaving and reforming of the sodium dodecyl sulfate (SDS)-unextractable polymers occur by the repeated breaking and reforming of disulfide bonds within and between gluten proteins, where glutenin subunits are released in nonrandom order, indicating a hierarchical structure. These exchange reactions require the participation of oxidizing–reducing systems, whose components occur naturally in flour. Mixing studies confirmed glutenin aggregation changes at constant temperature during dough processing and handling. Mixing induces an increase in the amount of total unextractable polymeric protein and large unextractable monomeric proteins; particularly, the amount of HMWGS increases with a parallel decrease in the amount of polymeric proteins from SDS-extractable proteins. Monomeric proteins and medium-molecular-weight proteins

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00088-X

do not change in quantity during breadmaking. It seems that some type of rearrangement takes place during the breadmaking process to release proteins of smaller molecular weight. A direct relationship between polymeric glutenin in flours and loaf volume has been found with different wheat genotypes.

Gluten is a nonpure protein system with a main contribution to the unique properties of wheat dough properties, but nonprotein components also have significant effects on dough rheological properties. Mixing also promotes the solubilization of arabinoxylans due to mechanical forces, and this solubilization continues during resting due to the endoxylanase, xylosidase, and arabinofuranosidase activities.

The other large biopolymer that plays an important role in the breadmaking process is starch. Amylose and amylopectin are the constituents of the starch granule. This biopolymer provides fermentable sugars to yeast and has a significant contribution to dough rheology, especially during the baking process.

Protein–lipid interactions are also crucial in the breadmaking process. Polar lipids or the free fatty acid component of the nonstarch lipids has a positive effect on dough formation and bread volume. Conversely, nonpolar lipids have a detrimental effect on the bread volume. During mixing, free lipids in flour are majorly associated with gluten proteins, and nonpolar lipids are retained within the gluten network through hydrophobic forces, leading to the physical entrapment of lipids within the proteins. In addition, glycolipids are associated with glutenins through hydrophobic interactions and hydrogen bonds, and phospholipids interact with either the gliadins or lipid-binding proteins.

Fermentation of Bread Dough

Bacteria, yeasts, and fungi are naturally present in cereal flours at levels around 10^4–10^6 CFU g^{-1}. Flour endogenous microflora together with baker's yeast and sourdough is responsible of the main biochemical changes during fermentation. *S. cerevisiae* is present in bakery's dough due to its intentional addition to speed up proofing. Sourdough comprises yeast and LAB, generally at a ratio of 1:100. The main genera of yeast include *Saccharomyces* and *Candida*, whereas most common LAB are *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Weissella*. Nevertheless, the dominant LAB in sourdoughs depend on flour type (refined or whole wheat), environmental and processing conditions, and recipe. In this scenario, it can also be taken into account the role of endogenous and added enzymes that are commonly used as processing aids in bakeries.

Flour, yeasts, and LAB contain different enzymes that modify dough characteristics and fresh bread quality. Proteolytic enzymes from both flour and microorganisms also act on proteins releasing short-chain peptides and amino acids that will contribute to the organoleptic and nutritional quality of bread. The specific metabolic activities of microorganisms are responsible for the dynamics in nitrogen compounds, showing different metabolic rates for acidic, basic, aliphatic, and aromatic amino acids.

Yeast Action During Fermentation

During proofing or fermentation, the yeast metabolism results in carbon dioxide release and growth of air bubbles previously incorporated during mixing, leading to the expansion of the dough, which inflates to larger volumes and thinner cell walls before collapsing.

The yeast breaks down carbohydrates (starch and sugars) into carbon dioxide and alcohol during the alcoholic fermentation. A significant reduction in the level of reducing sugars occurs along fermentation. The carbon dioxide causes the dough to rise (ferment or proof), and the alcohol produced mostly evaporates from the dough during the baking process. Amino acids are absorbed by yeast and LAB and metabolized as a nitrogen source for growth producing an increase in the amount of gas released.

During fermentation, thousands of tiny bubbles surrounded by a thin film of gluten grow as fermentation proceeds. The endoenzyme α-amylase facilitates the breakdown of hydrated starch granules to shorter chained, unbranched molecules known as dextrins. Subsequently, the enzyme β-amylase, an exoenzyme abundant in flour, hydrolyzes available glucose chains (oligosaccharides) or damaged starch to maltose.

Yeast metabolism during fermentation is responsible for bread aroma. Aroma development in bread crumb has been found to be dependent not only on yeast concentration and fermentation time but also on the mixing stage. Major aroma compounds are alcohols, aldehydes, 2,3-butanedione (diacetyl), 3-hydroxy-2-butanone (acetoin), and esters. Aldehydes and their respective alcohols are produced inside the yeast cell from the degradation of flour amino acids via the Ehrlich pathway. The esters are produced in the yeast cell by an enzymatic reaction between acetyltransferases, acetyl coenzyme A, and various alcohols, whereas the ketones are formed from acetohydroxy acids leaked from the yeast cell. In addition, oxidation compounds from flour lipids greatly contribute to the aroma profile of bread crumb. The formation of the aroma compounds increases with yeast concentration, but the formation of volatile compounds derived from the lipid oxidation compounds is independent of yeast concentration. Fermentation temperature affects the concentration of products of lipid oxidation. Specifically, increasing fermentation temperature favors the formation of 1-heptanol, hexanal, heptanal, octanal, decanal, and 2-pentylfuran, whereas low fermentation temperature favors the formation of ethyl acetate, ethyl hexanoate, and ethyl octanoate in bread.

The type of baker' yeast used during fermentation affects the bread aroma profiles because they lead to different volatile compounds. The fermentation compounds 2,3-butanedione and 1-propanol are the predominant aroma compounds followed by 3-methylbutanal, 2-methyl-1-propanol, and ethyl acetate.

Long yeast fermentation could result in excessive degradation of the protein network leading to the flattening of bread rolls and/or the production of monochloropropanediol isomers, which are considered potential genotoxic carcinogens. Changes in the total or individual content of amino acids and peptides along the different steps of breadmaking modify the organoleptic characteristics of bread. The contribution of low-molecular-weight proteins to the taste and flavor of bread depends on the content of peptides rich in basic and hydrophobic amino acids released during fermentation and baking, the proportion of hydrophilic peptides in unfermented bread, and the balance of endo- and exoproteases activities. The

amino acid profile during breadmaking reveals that the total amino acid content (particularly for ornithine and threonine) increases by 64% during mixing and undergoes a decrease of 55% during baking, being the most reactive amino acids glutamine leucine, ornithine, arginine, lysine, and histidine.

Since initial studies with *S. cerevisiae*, great advances have been reached using specific strains to improve nutritional quality of breads. γ-Aminobutyric acid (GABA) is consumed by yeast during fermentation. To prevent the loss of GABA, mutants defective in the assimilation of GABA have been isolated from a baker's yeast strain. These mutants could be applied to breadmaking fermentation in order to maintain GABA at a high level in dough.

When bread is enriched in inulin-type fructans, the added fructans can be degraded up to 75% by yeast during dough fermentation. The extent of this hydrolysis strongly depends upon the average degree of polymerization of the fructan.

Biochemical Changes Promoted by Sourdough

Sourdough greatly contributes to the flavor and functional properties of the final product. LAB play a major role in sourdough fermentations. Sourdoughs are usually grouped into three types. Type I includes the sourdough that uses part of the previous fermentation. Type II is a semifluid preparation that contains dough-souring supplements and type III refers to dried preparations: both these two require the addition of baker's yeast as leavening agent.

Facultative heterofermentative LAB are important for the production of sourdough bread with porous crumb and contribute to the sensory quality, while obligately heterofermentative LAB, with their metabolic products, influence the flavor and promote the leavening. LAB action results in the production of short-chain fatty acids that decrease the dough pH (Figure 1), which in turn induces the activation of cereal proteases involved in the proteolysis of gluten. The released peptides are then hydrolyzed to amino acids by intracellular LAB peptidases, which release into the media peptides and amino acids, and the former might be flavor precursor compounds. Therefore, the sourdough fermentation leads to an increase in the amount of amino acids, in opposition to yeasted dough where only a decrease in the amino acid content is observed due to the microorganism metabolism. In general, wheat doughs started with LAB show a gradual increase of valine, leucine, lysine, and also proline. Additionally, the action of LAB proteases and peptidases on soluble polypeptides and proteins leads to an increase of short-chain peptides that contribute to dough plasticity and gluten elasticity. Nevertheless, the amino acid dynamics during breadmaking are greatly dependent on the breadmaking process; for instance, in the production of steamed bread, alanine undergoes the highest loss (17.1%), followed by tyrosine (12.5%), whereas leucine was the least affected amino acid.

Lately, a careful sourdough selection has been presented as an alternative for reducing the allergenicity of gluten containing baked goods, thanks to its action on the proline-rich

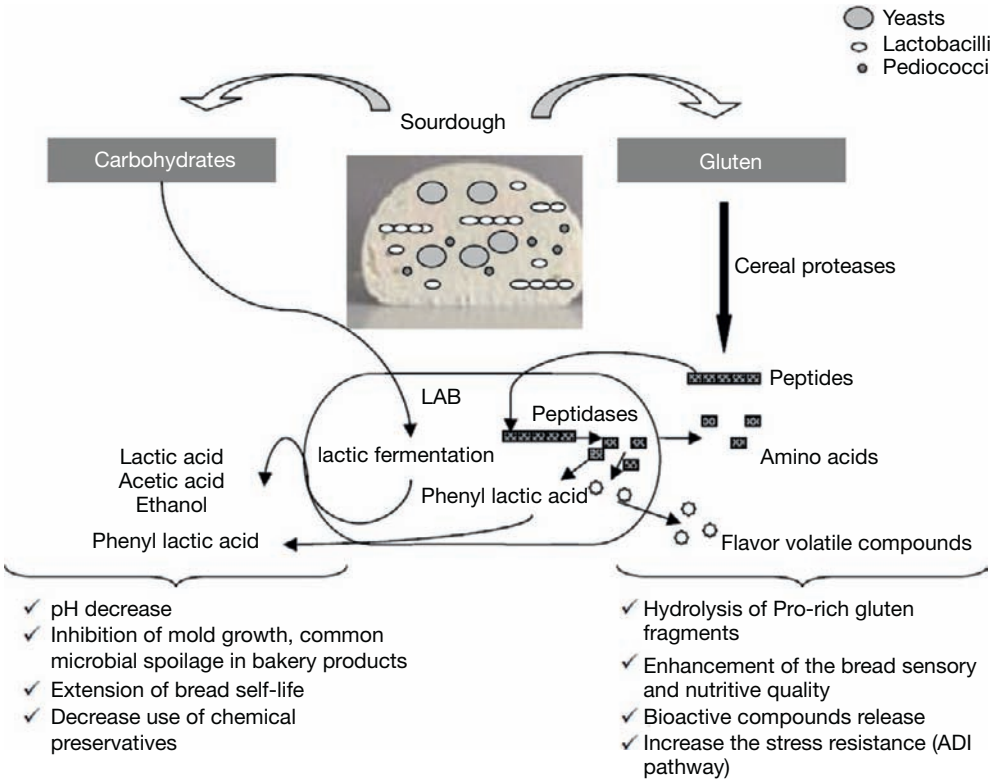

Figure 1 Action of lactic acid bacteria in sourdough fermentation. Reproduced from Rollán, G., Gerez, C. L., Dallagnol, A. M., Torino, M. I. and Font, G. (2010). Update in bread fermentation by lactic acid bacteria. In: Mendez-Vilas, A. (ed.) *Current research, technology and education topics in applied microbiology and microbial biotechnology*. Badajoz, Spain: Formatex, with permission.

peptide fragments. Sourdough LAB, after a careful selection, have been used as sources of proteolytic enzymes to decrease the concentration of gluten during breadmaking with the objective to reach complete degradation of gluten to get gluten-free breads (with less than 10 ppm gluten content).

LAB action increases the shelf life of bakery products due to the production of antifungal compounds. Lactic and acetic acids, together with other bioactive compounds like phenyllactic acid from phenylalanine metabolism and cyclic dipeptides (L-Leu-L-Pro and L-Phe-*trans*-4-OH-L-Pro), are very effective antifungal compounds against *Aspergillus*, *Fusarium*, and *Penicillium*, the main contaminants in bread. Selected LAB like *Lactobacillus plantarum* VTT E-78076 and *Pediococcus pentosaceus* VTT E-90390 or *Lactobacillus brevis* are able to inhibit the growth of rope-forming *Bacillus* strains (*Bacillus subtilis* and *Bacillus licheniformis*). Moreover, the acidification induced by LAB effectively delays the starch retrogradation associated with bread staling. In fact, the current trend for green label products drives to look for propionate-producing strains that could replace preservatives.

Different sourdoughs have been used as a source of microbial phytases resulting in a more efficient reduction of the phytate content in wheat sourdough breads than in yeast-fermented breads. Most LAB produce phosphatase activity with low levels of activity against phytate. The use of selected LAB with specific activities like phytate-degrading enzymes as starters for breadmaking could be a good alternative for obtaining whole wheat bread with low phytate content and in consequence with increased nutritional value regarding mineral bioavailability. Two lactobacilli L-M15 and L-ID15 have shown high phytate-degrading activity hydrolyzing phytates and leading different low-phosphate complex compounds.

Enzymes Contribution During Fermentation

Different processing aids, namely, enzymes, are also used in breadmaking to improve the quality of the baked products by reinforcing the role of gluten, providing fermentable sugars, and/or contributing to stabilize the hydrophobic–hydrophilic interactions. Enzymes have been extensively used in the production of cereal-based products with different purposes. In addition to the traditional starch-hydrolyzing enzymes – amylolytic/dextrinizing, saccharifying, and debranching enzymes – incorporation of nonstarch polysaccharide-degrading enzymes and lipid- and gluten-modifying enzymes has proved to be effective as dough conditioners and strengtheners, initial crumb softeners, enhancers of the activities of yeast and endogenous flour enzymes, bread flavor enhancers, and antistaling principles. α-Amylases are the enzymes most frequently used in baking. The polysaccharides obtained from the hydrolytic activity also participate in the Maillard reactions that take place during baking. Enzyme effects are already apparent immediately after mixing and continue during resting, significantly changing the viscoelasticity of doughs and the biochemical protein pattern.

Three different enzymes activities (transglutaminase, glucose oxidase, and laccase) have been used with the aim to increase gluten strength and consequently to improve dough functionality for breadmaking. Commercial lipases developed for breadmaking are able to reach and act on the low amount of triglycerides of the dough, even though in a limited free water environment. Lipases show a synergistic effect with pentosanases and/or amylases, reducing or avoiding their softening effect on doughs.

Whole wheat flour is rich in fiber, minerals, vitamins, and many phytochemicals (phenolic compounds, sterols, tocopherols, tochotrienols, phytic acid, etc.), which may partly account for its beneficial effect on human health. However, phytic acid (myo-inositol hexakisphosphate) or phytate is considered an antinutrient due to its complexing action on minerals decreasing their bioavailability. A reduction of the phytate content can be achieved by adding exogenous phytic acid-degrading enzymes that release lower myo-inositol phosphates decreasing or eliminating their antinutritional effect.

Chemical Changes During Baking

When dough gets into the oven, a progressive increase in the temperature is produced along baking. Dough constituents and microorganisms are affected by thermal constraints, although the extent of the effect is dependent on their thermal stability. As the temperature raises, the rate of fermentation and production of gas cells increases and this process continues until the temperature of yeast inactivation is reached (around 45 °C). In the case of yeast and LAB, they are acting and generating carbon dioxide and alcohol until their thermal death. The yeast metabolism is even sped up as a consequence of the increased amylolytic activity due to the starch gelatinization. The action of amylase on starch is approximately two-fold every 10 °C rise. Endogenous enzymes present in the dough are inactivated at different temperatures during baking. β-Amylase denatures at lower temperature (57–71 °C) as compared to alpha-amylase, which denatures at temperatures ranging from 65 to 95 °C.

A decrease in extractable protein is produced with time of baking. That insolubility is due to the protein cross-linking derived from the formation of disulfide bonds during baking. As temperature increases, a progressive reaggregation of disulfide-linked SDS-insoluble proteins is produced. Heat-induced reaggregation of glutenin macropolymer starts at around 36 °C. Glutenin apparently starts aggregating into SDS-insoluble structures between 35 and 45 °C. It is rather difficult to detect a variation in the amount of free thiol groups between 30 and 50 °C, but a significant decrease occurs at temperatures higher than 50 °C. Those thermally induced aggregations result in a decrease of the storage modulus (G') of the gluten proteins that has been associated with protein unfolding. In general, gluten proteins show a minimum value of G' at 57 °C, reflecting the thermal transition derived from the protein cross-linking involving SH/SS interchange, oxidation, and hydrophobic interactions. When proteins are denatured, the gluten strands surrounding the individual gas cells release water molecules with a simultaneous transformation into the semirigid structure that will yield the bread crumb.

In parallel, starch granules absorb the water available in the medium and swell, although the degree of swelling is restricted by limiting availability of water. Starch gelatinization begins at around 55 °C (depending on the type of starch), and it is associated with absorption of water, while gluten denaturation

is associated with its removal. Therefore, a major change during baking is the redistribution of water from the gluten phase to the starch phase. After starch swelling, the amylose chains leach out into the aqueous intergranular phase promoting the increase in the viscosity that continues until the temperature constraint leads to the physical breakdown of the granules, which is associated with a reduction in viscosity. Pasting performance of wheat flours during cooking and cooling involves many processes such as swelling, deformation, fragmentation, disintegration, solubilization, and reaggregation that take place in very complex media primarily governed by starch granule behavior. During cooling of the loaf, the gelation process of the starch takes place, in which the amylose chains leached outside the starch granules during heating are prompted to recrystalize. The reassociation between the starch molecules, especially amylose, results in the reordering of the starch molecules leading to a gel structure.

The sugars and breakdown products of proteins released from the enzyme activity are then available to sweeten the breadcrumb and to participate in the Maillard or nonenzymatic browning reactions, responsible for the attractive brown color of the crust. When sugar is heated to around 170 °C, which only occurs on the bread surface, the caramelization reaction where the molecules polymerize to form colored substances proceeds. The browning reaction occurs at high temperatures and low water activity, consisting of the reaction between reducing sugars and either protein- or other nitrogen-containing substances, and it produces colored compounds, named melanoidins. These reactions impart color and flavor to bread. Free amino acids play an important role in the generation of bread flavor precursors, through the formation of the Maillard compounds during baking. In fact, leucine, proline, isoleucine, and serine reacting with sugars form typical flavors and aromas described as toasty and bread-like, while excessive amounts of leucine in fermenting doughs lead to bread with an unappetizing flavor.

However, besides the beneficial chemical reactions, during baking, some other undesirable chemical interactions also occur. Alarm bells sounded some years ago due to the levels of acrylamide present in bakery products. The asparagine is the precursor of acrylamide formation in cereal baked products, especially bread. Other precursors of acrylamide include gluten, but their role is only important when low levels of asparagine are found in dough. In this context, glycine acts hindering the formation of acrylamide from asparagine, and the more asparagine is in the dough, the stronger is the inhibitory effect of glycine. The content of reducing sugars also affects the formation of acrylamide. Because of that, the selection of LAB excreting lower amylolytic activity in the medium and with higher proteolytic activity is recommended to reduce the formation of acrylamide. The addition of glycine but not asparagine caused an increased browning reaction during baking. The addition of glycine also increases the intensity of the browning reaction during baking. Different ways for controlling the production of acrylamide have been proposed, like monitoring the content of asparagine in the raw materials, selecting ingredients, adding the enzyme asparaginase for reducing the content of asparagine during breadmaking, and even applying glycine on the surface of the fermented dough.

Vitamin content is also affected during the breadmaking process. The yeasted breadmaking process leads to a 48% loss of thiamine and 47% of pyridoxine in white bread. Native or endogenous folates show good stability to the baking process and in some breadmaking processes even an increase in endogenous folate content in dough and bread has been observed.

Alternatives to the Common Breadmaking Process: Low-Temperature Technologies

In the last decades, breadmaking processes have been adapted to the new consumer demands, and subzero and low temperatures have been included in the flow diagrams for interrupting the processes before or after fermentation, or when partial baking was completed, for obtaining partially baked breads. These new technologies have facilitated the launching of a great number of fresh baked goods available at any time of the day.

Freezing affects the baking performance of frozen bread dough due to its effect on yeast and gluten network. The freezing rate and the frozen storage conditions have strong influence on yeast activity. A slow freezing rate is usually recommended to preserve its activity; for instance, low-freezing-rate conditions (air velocity of 1 m s^{-1}, −20 °C) result in the highest yeast activity, and in opposition, high-freezing-rate conditions (air velocity of 4 m s^{-1}, −40 °C) result in the lowest gassing power. During freezing and frozen storage, the number of viable yeast cells decreases and, as a consequence, a reducing compound (glutathione) is released, which can break down the disulfide bonds among proteins leading to a weakening effect on the gluten. Besides, hydrophobic interactions become weak when temperature decreases, which can partially explain the steady deterioration of the gluten network during frozen storage. Therefore, the reduction in the dough resistance induced by freezing and thawing operations has been partially related to certain compounds released from dead yeast cells after freezing and thawing.

The gluten network can also be disrupted due to the presence of ice crystals formed during freezing; as a consequence, the gluten network weakens and decreases its water retention ability, affecting its ability to retain CO_2. Frozen hydrated gluten forms a continuous, homogeneous, and not fibrous network that can be deteriorated due to the growth of ice crystals confined into dough matrix capillaries and the growth of bulk ice. Water transport from the gluten to the starch occurs during frozen storage, although the extent depends on the storage temperature. At −15 °C, the water content in the gluten phase decreases by approximately 1% over the first period of storage, and then, it reaches an apparent steady state. In opposition, at −25 °C, the amount of ice does not change. In general, the amount of freezable water in frozen doughs increases with frozen storage, confirming the water migration and ice crystallization.

The lipid fraction is removed from the gluten protein due to the decrease in water in the continuous protein phase promoting the fusion of lipid droplets and an increase in their size. Final effect will be baked breads with a flat surface, harder and coarser crumbs, and uneven distribution of big air cells. After prolonged frozen storage, the proportion of alcohol-soluble

protein increases with a simultaneous decrease in the HMWGS, which suggests depolymerization of the protein matrix during frozen storage, and some starch granules exhibit internal damage and become separated from the gluten matrix.

The technology of bake-off or partially baked bread is another type of breadmaking where low temperatures are applied. The market of partially baked bread has rapidly grown owing to the product being already sized, shaped, and partially baked: thus, no skilled personnel are needed at the retails for finishing the product. Nevertheless, a careful control of proofing, partial baking, chilling, and freezing conditions is necessary because of their great impact on the fresh bread quality. The critical time and temperature control required for the two-step baking is a major problem. Full baking has a superior quality in comparison with its frozen and thawed full-baked counterpart. Optimal time for the initial partial baking lies within the range from 74% to 86% of the time needed for the full baking in conventional breadmaking. Par-baked bread can be stored under frozen or low-temperature conditions. Par-baked loaves stored at low temperatures show progressive crumb hardening and rapid crystallization of the amylopectin chains, but the heat applied during the full-baking process can reverse those processes and the extent of that improvement is directly related to the duration of par-baked bread storage. When par-baked loaves are stored under subzero temperatures, no retrogradation of amylopectin is detected during storage, but some structural changes are produced on the starch as indicated by the increase in amylopectin enthalpy observed during aging of the full-baked breads. Nevertheless, the Milton-Keynes process has been designed to stabilize the par-baked breads by using a vacuum cooler to stabilize the crusty par-baked structure without producing wrinkling or shriveling of the loaf during the storage at ambient temperature.

Breadmaking is a very complex process, in which diverse sources of alterations are compiled in a food system. Mechanical stress besides the biochemical action of microbial and flour endogenous enzymes and finally thermal constraints are responsible for unaccountable changes in all the flour constituents. The understanding of the ingredients (flours, yeast, sourdough, and enzymes) and the process conditions allows the modulation of the biochemical changes associated with breadmaking.

Introduction

The fundamental basis of utilizing wheat flour as one of the most important food source around the world is its unique property of forming dough and developing gluten when it is mixed with water. Wheat gluten is a protein–lipid–carbohydrate complex formed as a result of specific covalent and noncovalent interactions from flour components during dough making as the components are hydrated and energy from mechanical input from the mixing process is provided.

Wheat varieties at the same protein level were found to differ in their bread-making quality, giving the first indication of protein quality. Protein content and its composition are important determinants of good bread-baking quality. Gluten-forming proteins contribute 80–85% of the total wheat protein and are the major storage proteins of wheat. They belong to the prolamin class of seed storage proteins. Gluten proteins are largely insoluble in water or dilute salt solutions. Two functionally distinct groups of gluten proteins can be distinguished: monomeric gliadins and polymeric (extractable and unextractable) glutenins. Gliadins and glutenins are usually found in more or less equal amounts in wheat. Large level of polymorphism of wheat prolamins results in a special effect in relation to the overall functional properties of wheat dough. During dough formation when prolamin proteins are hydrated and form the gluten network, the numerous structurally similar but slightly different proteins produce a mass in which several characteristics (such as size, polarity, charge distribution, solubility, and viscosity) show a continuous distribution in a relatively large interval. This structural feature provides a unique characteristic of gluten proteins among any other protein systems.

Phases of Bread-Making Process

The bread-making process has several functions, accomplished at different stages in the preparation and baking of dough: (a) mixing of flour and water, together with yeast, salt, and other ingredients in specified ratios to form the dough; (b) developing the gluten structure of hydrated proteins through application of energy during mixing (a stage often termed 'kneading'); (c) incorporating air bubbles within the dough during mixing; (d) continuing the development of the gluten structure after kneading to improve its ability to expand when gas pressures increase (a stage termed 'ripening' or 'maturing'); (e) creating or modifying flavor compounds in the dough; (f) subdividing the dough mass into unit pieces; (g) modifying the shape of the divided dough pieces; (h) resting to allow further modification of the dough pieces' physical and rheological properties; (i) shaping to achieve required configuration; (j) proofing (fermenting and expanding) the dough; and (k) expanding and fixing the dough into its final shape by baking.

Mixing and Dough Making

Dough mixing is a very important stage in the bread-making process. The extent of mixing has a critical impact on final bread quality. The mixing process promotes different physical, chemical, and physicochemical modifications that contribute to the dough development.

Chemical, Physical, and Physicochemical Alterations during Dough Mixing Stages

Dough chemistry involves a series of interactions between carbohydrates, lipids, and proteins. The principal physical science involved with dough making is rheology (see in the succeeding text). Good baking quality depends on several rheological properties such as extensibility exceeding a minimum level, viscosity, strain hardening, and optimal resistance to deformation. Dough is viscoelastic, combining properties of a Hookean solid with those of a non-Newtonian viscous fluid. Dough is essentially foam, which becomes sponge after baking. The transformation from the closed cell structure of a foam to the open cells of a sponge is one of the many changes that occur during dough processing.

Individual dough-property parameters describe only certain essential elements of dough properties. Depending on the final product, different levels of these attributes are required to get superior processing quality. For example, the balance of dough strength and extensibility is believed to be the most important factor governing the suitability of a flour to make good bread. However, for different types of breads and even for different types of processing technologies, a diversity of dough strength and extensibility values may provide the optimum balances needed in each case.

The complexity of relating protein composition to quality derives from the fact that the question can (and has to) be investigated on different levels of protein composition, namely, protein content, the ratio of polymeric proteins to monomeric proteins, the ratio of high-molecular-weight (HMW) glutenin subunits to low-molecular-weight glutenin subunits, and the proportions of x-type and y-type HMW glutenin subunits. These various parameters can be determined for a specific flour sample to see if there is a 'good balance' between the various components in the sample, thereby to satisfy quality-related criteria. The polymeric glutenin is mostly responsible for the elasticity of the dough, whereas the monomeric gliadins are the extensibility-related characters in the system. Thus, the ratio of polymeric proteins to monomeric proteins (the glutenin-to-gliadin ratio) can be directly related to the balance of dough strength and extensibility of the sample.

Two preconditions must be met for the production of dough with the right properties: (a) appropriate proportioning

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00086-6

of the individual ingredients as established in a well-balanced dough formulation and (b) homogenous distribution of these ingredients throughout the dough mass. In its essentials, dough mixing involves the combining and blending of the formula ingredients and then applying sufficient physical work to the mixture to transform it into a cohesive mass with the requisite viscoelastic properties. In large-scale commercial bakery production, the major ingredients (flour and dry sweeteners) are normally weighed by automatic scales that feed directly into the mixers, while water, liquid shortener, and liquid sweeteners are piped into the mixer through meters that can be preset to deliver specified volumes.

In addition to achieving a thorough dispersion of the ingredients into a homogeneous mixture, the dough mixing process in bread making has the further important objective of physically developing the gluten proteins into a coherent three-dimensional structure that will impart to the dough the desired degree of plasticity, elasticity, and viscosity. The initial mixing phase must physically hydrate the flour particles and incorporate air to nucleate gas cells responsible for leavening. In other words, mixing has three functions: (a) creating a homogenous mass from ingredients of differing characteristics, (b) developing (kneading) the dough sufficiently to ready for subsequent processing, and (c) occluding air into the mass to form the cell structure necessary for finished crumb quality.

At the beginning of the mixing, blending action leads to an even distribution of the dough ingredients and ensures hydration and swelling of flour particles. Wheat flour dough or batter may appear to be uniform and well mixed, but actually, it is multiphasic: starch, gluten proteins, lipids, and water representing the principal phases. Furthermore, the form of these phases changes during periods of mixing that prepare them for separation or food uses. Microscopic changes begin with the instant formation of protein fibrils at first contact of water and flour particles. Slow mechanical development induces these fibrils to coalesce into fibrous bands or tendons and segregates the starch into clusters. When flooded with a displacing fluid, this open, spongelike structure readily releases the entrained starch. Additional development disbands the protein into relatively fine, uniformly distributed, and networked or webbed filaments that entrap the starch and gas bubbles formed when the dough is fermented and baked. The physical properties of hydrated wheat proteins are the result of covalent and noncovalent interactions of wheat gluten proteins. These interactions are altered by the repeated extension, tearing, and compression during mixing or development. Specific chemical effects include (1) disulfide bond disruption, (2) chain disentanglement and rupture, (3) disulfide–sulfhydryl interchange, (4) formation of dityrosine cross-links, (5) formation of new disulfide cross-links, (6) free radical interactions, and especially (6) reorientation leading to enhanced hydrogen bonding.

Mixing produces a homogeneous gluten film regularly distributed around the starch granules. The dough must be mixed for a specific time (referred to as optimum dough development) to ensure optimal loaf volume and bread texture. Stopping mixing before the optimal point results in undermixed dough that gives bread of inferior volume and crumb quality. The optimal mixing requirement is a specific characteristic of each wheat flour. Beyond optimum dough development time, overmixing induces dough stickiness, decreases dough consistency (due to degradation by shearing effects), and negatively affects bread quality.

Stability of the gluten–starch matrix – the primary stabilizing factor for expanding gas cells against disproportionateness and coalescence – depends on its tendency to strain harden. The phenomenon of strain hardening appears to depend on the balance between strength and extensibility of the entangled network of polymeric proteins of wheat flour. Extensibility ensures slippage of the maximum number of statistical segments between entanglements, whereas strength prevents disruption of the entangled network of polymeric proteins. Thus, to ensure stability of gas cells, the dough needs to be not only sufficiently extensible to respond to gas pressure but also strong enough to resist collapse.

A good gas-holding capacity of dough is necessary for producing a loaf of bread with light and even crumb. The strain hardening properties of gluten are vital to avoid early rupture of gas 'cell wall' during proofing. The gas phase of bread, which makes up more than 70% of the final volume of a loaf, has a major influence on its textural and sensory attributes. Controlling the gas phase volume is a major challenge as during proving and early stages of baking gas must be captured within bread dough, only being released at the end of baking. The main factors, important in determining the gas cell structure, include (1) the formation of the initial foam structure during mixing and (2) stabilization of the foam structure, including those factors governing bubble disproportionateness and coalescence. There is particular focus on the role that the thin film lining the bubbles may play in stabilizing the foam structure of a risen dough. The surface properties of components have been suggested to be the important factor to the stability of gas cells. Recently, proteomic methods have been used to identify foam-forming soluble proteins from dough that may play an important role in stabilizing gas bubbles in dough and hence influence the crumb structure of bread. Proteins from a soluble fraction of dough (dough liquor) or dough liquor foam have been separated and identified. Major polypeptide components included β-amylase, tricitin, and serpins, with members of the α-amylase/trypsin inhibitor family being particularly abundant. Neither prolamin seed storage proteins nor the surface-active protein puroindoline was found.

Differences in gluten quality can significantly affect the bread-making potential. Strength is conferred by the fraction of polymeric proteins having molecular weight greater or equivalent to a critical size, MT, (250 000 kDa), and the fraction of gluten protein smaller than MT may counter the strength by acting as diluents. The optimum balance seems to exist when the relative proportions of polymeric proteins greater and smaller than MT are roughly 60:40. Shift in the balance to either side will decrease loaf volume. Increase in smaller proteins (less than MT) may decrease stability of the gluten–starch matrix due to a lesser number of entanglements per chain. On the other hand, increase in strength conferring proteins may prevent sufficient expansion of the gluten–starch matrix required to increase loaf volume due to reduced slippage of gluten polymers through entanglement nodes as a result of increase in number of entanglements per chain. The secondary stabilizing mechanism involves thin liquid lamellae stabilized by adsorbed surface-active compounds (lipids and

proteins) at the gas–liquid interface. Liquid lamellae prevent coalescence and disproportionateness of gas cells when they come in close contact with each other during the late proving and early baking stages of bread making, that is, when discontinuities begin to appear in the gluten–starch matrix. Flour lipids at their natural levels do not influence rheological properties of the gluten–starch matrix surrounding the gas cells, as measured by the dough inflation system. Nevertheless, the small amounts in which these lipids are naturally present are sufficient to influence surface properties.

This short and simplified description of well-accepted observation-based hypothesis of dough behavior underlines the essential importance of size distribution of gluten proteins in relation to their role in determining dough properties. As a consequence of this, a combination of reducing agents, oxidizers, and proteolytic enzymes is frequently used in the baking process to alter dough properties through their effects on the disulfide bonds in the gluten structure. Functional additives play a big role in modern bread making. Among the improvers, ascorbic acid is the most important in modern bread formulation to oxidize flour proteins to improve gluten strength. Other such ingredients (and their functions) include azodicarbonamide (oxidizing agent), cysteine (reducing agent), mono- and diglycerides (emulsifiers and antistaling agents), calcium propionate (mold inhibitor), stearoyl lactylate (dough strengthener), soy flour (crumb whitener), dextrose (fermentable sugar source for the yeast), ammonium chloride (nitrogen source for yeast), enzymes (starch and protein adjustment), and, occasionally, gluten (strengthener).

Dough Preparation Systems

No single standard method for mixing ingredients to create dough is followed by all bakers; instead, more than a half-dozen different procedures can be used. The detailed characterization of these methods is shown in Table 1. Baker preference, product type, and plant practice determine the choice of method. Preparation of the dough can be done in batches or continuously, and fermentation times vary from none to several hours.

Today, most commercial bakers prepare dough as separate batches, sized sufficiently to permit an uninterrupted production schedule but not too large to risk overaging the dough as it waits in the divider hopper. The continuous mix method was developed during the 1950s to automate dough preparation. At one time, it was used by the majority of bakeries producing white pan bread, but this method fell out of favor when consumer demand for variety bread increased starting in the late 1970s. Technologies that grew up around continuous mix such as water brews and liquid sponge, however, remain in wide use for lines dedicated to baking long runs of fast-food buns and similar products.

Table 1 Overview of the most generally used dough preparation systems

Dough system	*Bread and related product produces*	*Advantages*	*Disadvantages*
Straight dough	Lean formula hearth bread, pita bread, 100% whole wheat	Good flavor Medium process time Good mixing tolerance	Difficult dough handling Long mixing time Poor fermentation tolerance
Sponge and dough	Sponge and dough bread and rolls	Good fermentation tolerance Superior product score Good dough handling Longer product shelf life	Poor mixing tolerance Long process time High-cost equipment Larger space equipment
Liquid sponge	Sponge and dough bread and rolls	Uniformity of product Medium process time Good flavor with high amount of flour in the sponge	High-cost equipment Limited to 50–60% of flour in sponge Lack of flavor and shelf life with low flour in sponge
Continuous mix	White pan bread, hamburger/hotdog buns	Same advantages as liquid sponge if fermented Less equipment, labor, and space used	Limited to 50–60% of flour in sponge Lack of crumb strength Lack of flavor and shelf life with less fermentation
No-time dough	Frozen dough, bagels, hard rolls, pizza crusts, dinner rolls, variety pan bread, English muffins	Short production time Greater flexibility Less equipment and space Superior yeast survival in freezing	Lack of flavor Lack of shelf life Higher ingredient costs Problem with floor time
Chorleywood process	Hamburger/hotdog buns, variety pan bread, rye bread	Tolerant to low-protein flours Short production time Greater flexibility No floor time problems	High equipment cost High energy cost Lack of flavor Lack of product shelf life
Authentic sourdough process	Authentic sourdough breads and buns	Sourdough flavor Increased shelf life 'Blistered' appearance Chewy, resilient texture	Very long process times Nurturing of sponge Less consistency Increased space requirement

Source: O'Donell (1996).

Among mixing methods being practiced commercially, the most prevalent is the sponge-and-dough process that involves two mixing stages, namely, one of the sponge and the other of the dough. The sponge mixing stage aims at homogeneous ingredient dispersion and flour hydration and is normally of relatively brief duration, whereas the more critical phase of dough development is reserved for the more extensive mixing of the final dough. In the straight-dough method, as well as in those systems that employ various forms of liquid preferment, there is but one mixing stage in which complete dough development must be achieved.

White pan bread is highly standardized, has well-recognized quality characteristics, and represents the main product style in many parts of the world. Some countries, notably France, take the baguette as the standard product. Table 1 shows the advantages and limitations of the most important methodologies based on the excellent review of Mihalos.

Testing Operations

Introduction

Dough testing methodologies are essential tools through the whole wheat chain from basic research, prebreeding, selection for quality attributes during breeding, characterizing source material, quality control, process, and product development in the wheat-based food industry.

Testing operations can be classified as direct dough testing methods and indirect methods where dough properties are estimated from chemical, physicochemical (spectral), or physical (sedimentation) characteristics. Dough properties, directly related to the bread-making quality of the sample, describe certain viscosimetric or rheological properties of the dough, so the dough testing investigations apply viscosimetric and rheological principles. In general, viscosimetric methods show strong relationships to the starch composition of the samples, while the rheological properties are directly related to both qualitative and quantitative aspects of gluten protein composition.

Some basic information on the direct dough testing methods is given here, with special emphases on the small-scale and microscale testing methods, which revolutionized our understanding about structure–function relationships in wheat dough in the last 30 years. Only some key references are given about the principles, solutions, and achievements of indirect methods in the paragraphs summarizing future trends in the area.

Basic and Empirical Rheology

Rheology is the science of the deformation and flow of materials as a response to physical stresses. The deformation can be classified as elastic or inelastic, while the flow properties of a material can be described as plastic or viscous behavior. Ideal elastic bodies undergo reversible elastic strain when anisotropic forces are applied. In this case, the applied energy is partly stored. In case of ideal viscous body, irreversible changes can be observed, where the exerted energy is transformed. Viscous fluids generally exhibit viscosity, while solids exhibit elasticity.

The aim of fundamental rheology is trying to describe and model the physical behavior of materials by studying the relationships between molecular composition and the observed deformation. Widely applicable instruments (viscometers, rheometers, etc.) and/or specific, often purpose-built methods are used for this purpose. The resulting information, however – despite its scientific merit – does not satisfy the demands dictated by the practice: Fundamental rheology methods often do not differentiate enough among samples and, most importantly, they are not suitable for high-throughput, reasonably cheap routine application in selecting for quality in plant breeding or in case of quality control in the food industry.

During the first quarter of the last century, several empirical rheological equipments and methodologies have been developed, and the last 100 years proved that these standardized methodologies can be applied fruitfully for the comparison/rating of samples derived from the breeding or industrial operations. The collected/archived data derived from these analyses form an invaluable knowledge base based on which the new wheat cultivars and new wheat products of the future can be developed.

Traditional empiric rheological methods and instruments

As it was mentioned earlier, when wheat flour, water, and other related ingredients are mixed, the whole system undergoes a number of chemical reactions and physicochemical and physical changes during dough formation. The type and the rate of these changes highly depend on the composition of wheat flour, on the ingredients, and on the parameters of dough mixing like length mixing, energy input, and temperature. Molecular processes related to the aforementioned changes can be monitored by the continuous measurement of physical (rheological) properties of dough from the starting stage of homogenization through the formation of protein–carbohydrate–lipid–water complex (gluten) until its certain break caused by overmixing.

Wheat dough has both elastic and flowing properties; therefore, it shows a complex viscoelastic behavior. Therefore, the main challenge in the development of empiric rheological methods and instruments has been how one can apply adequate external forces on the dough to measure both elastic strain and viscous flow in one system.

Two principally different empiric rheological methodologies have been developed: *mixing methods* to monitor dough formation and *stretching* methods for the determination of dough strength and extensibility. In case of the latter process, dough is mixed to its optimum consistency in a separate process followed by a relaxation step before stretching. So, the two methods together mimic the industrial bread-making technology with one important exception: instead of a full formulation of the dough, including yeast, dough is mixed here with either water or salt solution.

Mixing methods: The traditional simple solution for detecting the physical changes in a dough is the utilization of standardized (laboratory) mixers with the recording of torque on the mixing arm(s) and/or bowl. The first recording laboratory mixers – regarded as the forerunners of the first commercial machines developed later on, the Swanson–Working

mixograph and Brabender farinograph – have been developed by the Hungarian inventor Jenő Hankóczy.

The working principle of the farinograph is to monitor the torque (energy requirement) during the continuous but relatively gentle mixing of wheat flour – added water system at constant speed and temperature (at 30 °C). The sigmoid (or Z-type) shape of the mixing blades is very unique, which is able to knead and extend the dough, periodically. The torque that arises from dough resistance against mixing was originally measured using a special balance system and replaced later with electronic recording systems. Basically, dough resistance, detected in this equipment, is determined by the rheological properties of dough, particularly viscosity, but the surface properties of the dough, sticking to the bowl walls and blades, also contribute to the measured values. The comparability of different dough behaviors (or flour quality) is ensured with the standardization of maximum dough resistance.

Beyond the mixing parameters such as mixing speed and resistance measured with this system, there is the function of the flour behavior and the amount of water added to the flour. The huge success of the farinograph spreading all around the wheat chain as early as the 1930s derived from the idea of using this direct relationship between the amount of water in the system and resistance for the determination of the most important quality attribute of the flour, *water absorption*, which is the amount of water needed to be added to the flour to reach the constant consistence (500 or 600 farinograph or Brabender units, BU) of dough.

The routine investigation on the farinograph is a two-step process: water absorption of the flour is determined through a 'titration-like' process, followed by the main mixing experiment using this amount of water to characterize the rheological properties of the dough such as dough development time, stability, and degree of softening (**Figure 1**). The detailed description of the farinograph method including the evaluation of curves is summarized in different standard methods (ICC, AACCI, ISO, etc.).

The second traditional type of recording dough mixer is the mixograph. The main difference between these two mixers is the mixing action. The mixograph equipped with pin mixers, where a pull–fold–repull type of movement is applied causing much greater mechanical stress on dough than that in the farinograph or other Z-arm-type mixers.

In case of mixing with mixograph, there is no predetermined optimum consistency of dough; therefore, other methods have to be used for measuring the optimal water absorption. Two methods are used in practice: (a) Samples are compared with a uniform amount of water added and

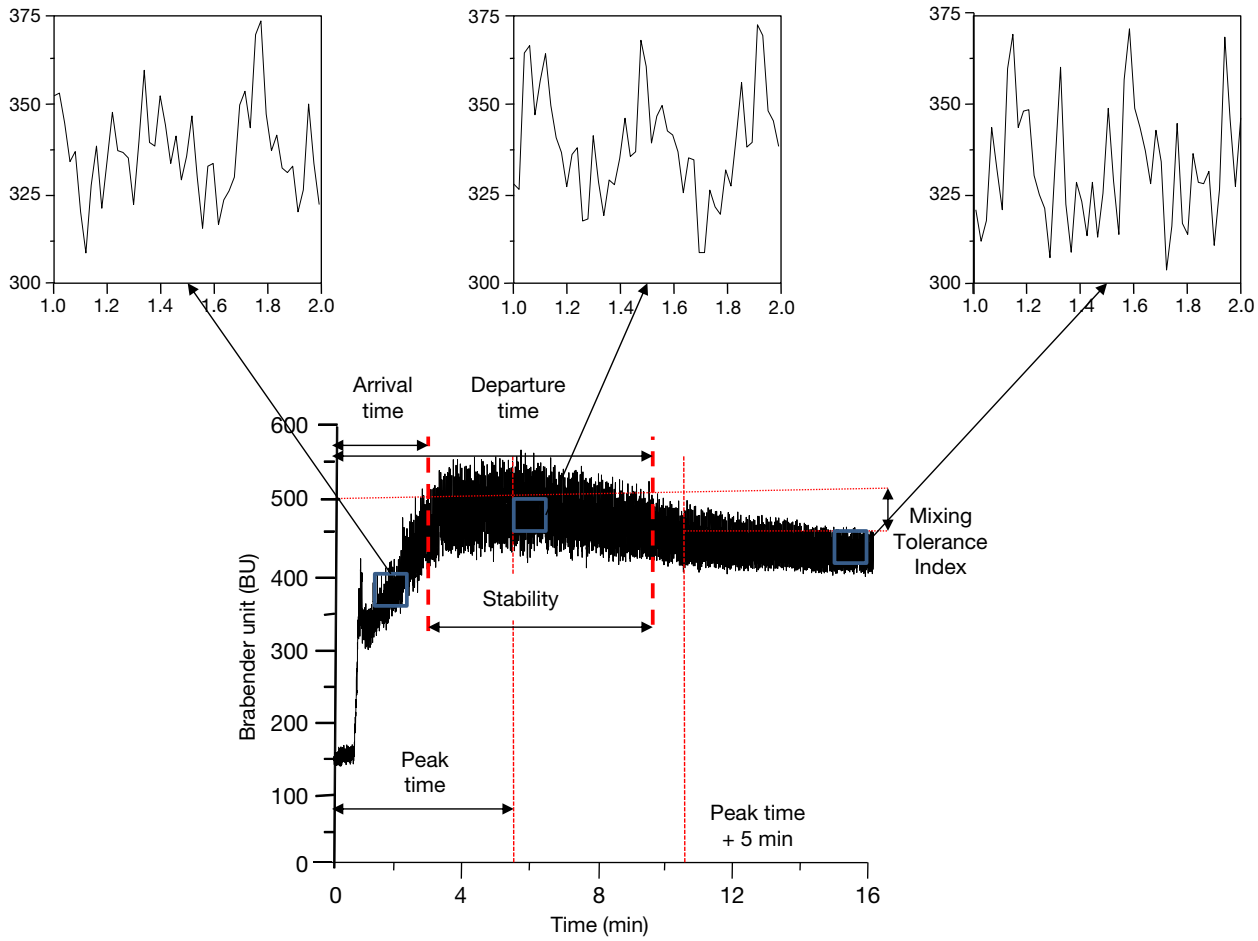

Figure 1 Important farinograph parameters.

(b) the water used in the mixing experiments is calculated based on the protein content of the investigated flours. The parameters generally determined by the evaluation of the recorded mixogram (Figure 2) are as follows: peak time (similarly to the dough development time), maximum peak height, the height of the curve at a specified time after peak (characterizing the tolerance against overmixing, similarly to the farinographic stability), the angle between the ascending and descending portions of the curve (tolerance angle, T), the weakening angle (W), and the area under the curve are defined.

High-speed recordings obtained with a 35 g mixograph equipped with a strain gage allowed the high-resolution monitoring of the mixing action. These recordings provided data essential for developing a mathematical model of dough mixing: dough mixing on pin mixers can be interpreted as a complex, periodic series of pushing and stretching the dough around the pins. Each individual peak represents one of these circles, and so, their size and shape are characteristic to the stage of dough development, and they can be used to determine dough strength and elasticity of the dough (details (a), (b), and (c) of Figure 2 illustrate three regions of the high-resolution mixing curve ((a), (b), and (c)), illustrating the hydration, dough development, and overmixing phases of the mixing). Bandwidth parameters (BWPR, BWBD, and TMBW), directly related to elasticity, in the mathematical model are also shown.

Some other instruments developed by different producers (valorigraph, doughLAB, etc.) work on the same or similar principle as described earlier, with different sizes of mixing bowls and arms for mixing 10–300 g of flour.

Stretching methods: Elasticity is the most unique property of wheat dough, and it mostly depends on the protein–wheat gluten composition and quality. Extensibility of wheat dough is responsible for the extent of expansion during leavening; therefore, it basically determines the baking performance and the quality of final products. In all stretching tests, to determine extensibility, the dough produced by one of the standardized mixing methods is then submitted to large deformations until rupture occurs and the resistance against stretching strain is recorded.

Two types of extension methods are used: in uniaxial extension test, the dough is stretched in one direction, while in case of biaxial method, the dough is extended in two opposing direction. The most traditional and commonly used equipment is the Brabender Extensograph, introduced in 1936. The operation of this instrument is based on the principle of mechanical stretching in simple tension. The investigated dough samples are prepared in the farinograph mixer with optimum water absorption, and then, aliquot pieces of the dough are molded with special tools. During the measurement, the resistance of formed dough pieces to stretching and the distance the dough stretches before breaking are recorded on the extensogram (Figure 3). The following parameters are determined/calculated: the maximum resistance (R_{max}), the resistance at a constant extension (generally at 50 mm, Rx), extensibility (the maximum length of extension before rupture, E), the ratio of maximum resistance to extension (as an indicator of the balance between elastic and viscous behaviors, R_{max}/E), and the area under the curve (as extensional work, A). In some cases, the applied methods can differ in some parameters, like constant extension and resting time of dough before measurement. The desired quality of dough means a good combination of dough resistance and extensibility.

The first device for measuring the biaxial extension character of wheat dough was also developed by Hankóczy, while the principle of dough inflation test was developed by Marcel

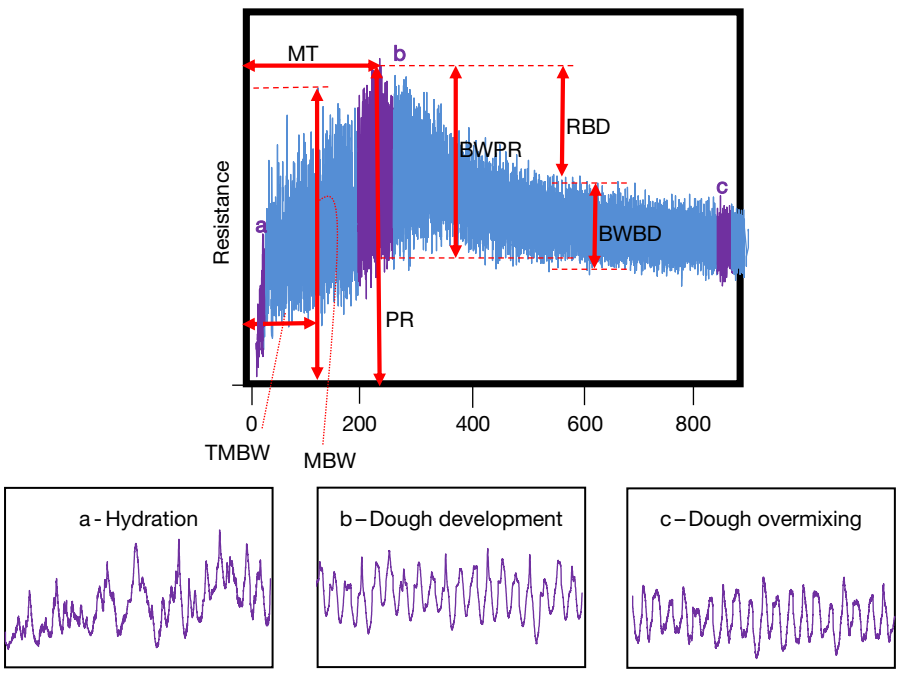

Figure 2 The most important parameters determined from the mixograph curve. MT, mixing time; PR, peak resistance; RBD, resistance breakdown; BWPR, bandwidth at peak; MBW, maximum bandwidth; TMBW, time to maximum bandwidth. High-resolution data recording of regions a, b, and c show the stages of hydration, dough development, and overmixing, respectively.

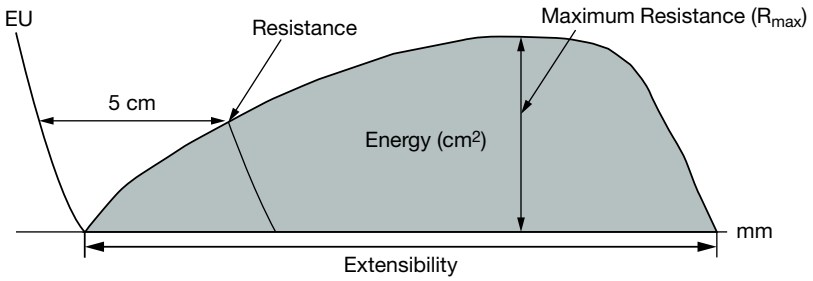

Figure 3 The determination of dough strength (R_{max}) and extensibility from the extensograph curve (extensogram).

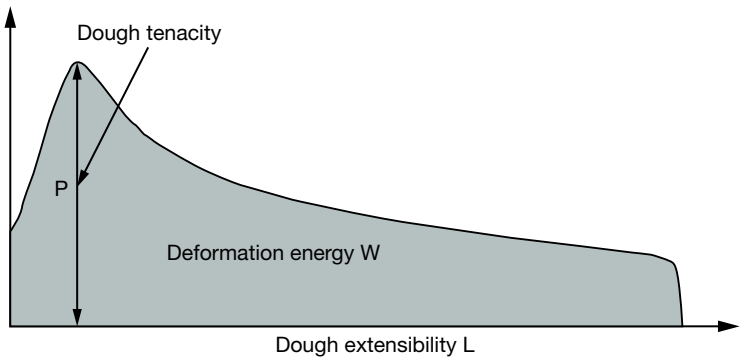

Figure 4 The determination of dough tenacity (P), configuration ratio(P/L), and deformation energy (W) and from the alveograph curve (alveogram).

Chopin in 1927. Today, the most widely known and standardized biaxial extension test is the alveograph method, which is based on the principle of dough inflation or bubble expansion technique. This procedure mimics the microprocesses occurring in dough during fermentation in macroscale, namely, the formation of thin membranes around the CO_2 bubbles. The Chopin Alveograph consists of a special thermostated, one-screw mixer for mixing and extrusion of dough, a bubble blowing apparatus, and the recording manometer. During the measuring procedure, dough disks are prepared, rested, and then inflated by constant air flow. The pressure inside the dough bubble until rupture is measured and recorded on the alveogram (Figure 4). The most generally read or calculated parameters are the maximum overpressure (an indicator of the dough tenacity, P), the average abscissa at rupture (characterizes the extensibility, L), configuration ratio (P/L), and the area under the curve (as deformation energy, W).

The extension tests are also used for investigating the effects of natural or artificial modifying agents, like bugs, enzymes, oxidants or reducing components, and lubricants. The results, recorded curves, and determined parameters of the two methods are very similar. However, because of the different mixing procedures and measuring principle, the comparability of the results is limited and depends also on the type and variety of the samples.

Viscometry as a tool for investigation of the hot phase of the bread-making process

The conventional dough rheology is mainly connected to the protein-dependent dough properties in the first, not heated phase of bread making. Starch as the main component of wheat flour also affects the quality-related properties, even the rheological properties of the dough, mostly as diluent of the proteins and as a consequence of altered hydration during gelatinization in the oven.

Additionally, starch is exposed to enzymatic breakdown, depending on the α-amylase activity of the flour and physical braking during the milling process resulting in damaged starch. An optimal level of enzymatic activity and amount of damaged starch are necessary for the optimal fermentation processes in baking. However, high enzyme activity or a high ratio of hydrolyzed starch results in a weaker water-holding capacity, resulting in serious drop in the end-product quality. Therefore, starch-related viscosity-based characterization of samples is an essential part of source material quality control in the baking industry, and the balanced amylolytic activity is part of the selection criteria during breeding.

Starch properties are usually studied at high temperatures – similar to conditions of the baking process. Generally, the starch characterization is performed by different viscometers, carrying out measurements on temperatures appearing in the technology. The most frequently used standardized method for investigation of α-amylase activity of the grain/flour is the determination of falling number on a special falling viscometer.

While the falling number is a one-point measurement, rotational viscometers are suitable for continuous measures and therefore for more complex characterization of pasting properties of cereal flours and also isolated and modified starch products. The viscometers are heated with constant heating rate, or protocols with optional heating programs are applied depending on the sample types and the goals of measurement. In the first case, Brabender Amylograph® or similar apparatuses are used, and at the beginning of gelatinization (°C), maximum viscosity value and gelatinization temperature (°C) are determined from the registered viscosity curves

according to international standards. In case of instruments working with programmable heating rates (e.g., Rapid Visco Analyser® (RVA), by Perten Instruments, or Micro Visco-Amylo-Graph® by Brabender GmbH), the pasting properties are followed continuously during heat increasing, constant heating, and heat decreasing periods. Next to the already mentioned parameters, viscosity breakdown during cooling, holding strength, and final viscosity are determined. The interpretation of the measured parameters is shown in Figure 5. These partly standardized methods allow to characterize the effects of enzymes and the hydration and viscosity development of hydrocolloids, predicting the quality of starch–protein matrices after cooling (i.e., bread crumb quality), and are applied on much wider areas than the characterization of wheat quality. The applied conditions model better the bread-baking processes in hot phases, but in all cases, the pasting properties are measured in dilute flow-water suspension. Therefore, the adaptation of the measured parameters to the real dough/bread system is not unambiguous.

Investigation of dough fermentation and real baking process

Simplified dough rheometers serve very useful parameters, but their applicability for prediction of baking quality is limited mainly because the fermentation processes, the presence and distribution of the gas (CO_2) phase, and the heating effects significantly modify the rheological behavior of the dough system.

The frequently used laboratory test for overall characterization of baking quality of wheat flour is the baking test. It is 'the ultimate' method, being the real baking process, simulating the industrial conditions in laboratory environment. However, these trials are time-consuming and labor-intensive, and the interpretation of measured parameters (volume, sensory, and texture properties) is partly subjective. Because of some critical phases of fermented dough processing (like proofing and heating), continuous and better reproducible measurements are required. The Rheofermentometer (Chopin Technologies) is suitable for measuring the dough development and tolerance, the intensity of gas production, and the rate of gas retention. The similar but more complex Maturograph® combined with Oven Rise Recorder (Brabender GmbH) is able to measure the proving and baking quality of dough, including the changes of elasticity during the whole process.

Small-scale and microscale testing

The development of very small-scale dough testing equipment and the associated automated interpretation of the resulting mixing curves has provided better reproducibility and removed operator bias, resulting in more objective assessment of the experimental variables. Several small-scale mixographs have been developed and used in different laboratories requiring 2 and 10 g of flour. The 2 g mixograph test procedure was originally designed to mimic the traditional scale methods: development of equipment and procedures included validation against the large-scale standard methods. A 10 g mixing bowl farinograph has been available since the early 1980s, while its 4 g analogous machine has been developed and its commercially available version, the micro-doughLAB, recently produced by Perten. Similar scaling-down processes have happened also in relation to the extension measurements, developing a prototype of microextension tester or the Kiefer-rig and the microdough inflation system for the TA-XT2 Texture Analyzer (Stable Micro Systems). The microextension tester has proved practical to use dough from the 2 g mixograph with micro baking facilities scaled to employ 2.4 g of dough per loaf. The traditional and small-scale dough testing methods have been found to be highly related. Essential member of the microscale machinery is the METEFEM Laboratory micro mill for supplying flour for the micro methodology. This mill is able to make flour even from one single grain and provides milling yield results from 20 g of grain, comparable to those from traditional milling tests.

Beyond applying the microscale and small-scale methodology in breeding for selection to quality in much earlier stages, these developments have facilitated a wide range of research in which either only limited amounts of test material have been available or the more objective, precise assessment of data offered extra benefits.

The spin-off of the developments of small-scale dough testing methodology has been that parallel with the development of small-scale machinery, the electronic data handling

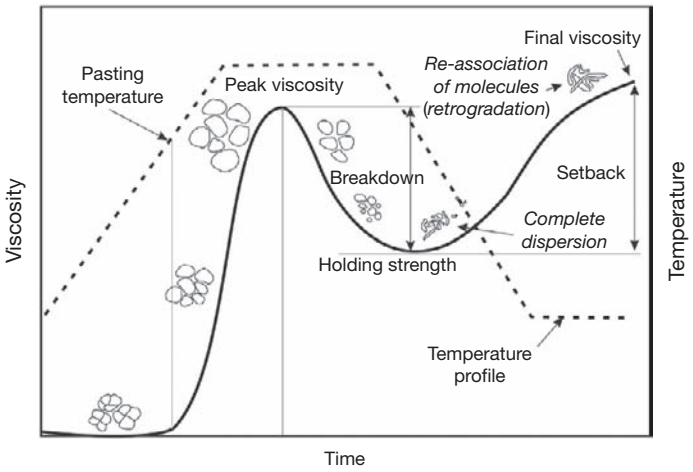

Figure 5 Characterization of the states of starch with rotational viscometers.

and processing and the specific software for calculating the mixing parameters and/or their analogous versions have been adapted for the traditional instruments; even, 'mobile' PC-based versions have been made to attach them onto industrial mixers.

New Developments

Modern bakeries employ high-energy and low-temperature mixing in the production of raw and frozen dough products. However, batch variation in mixed dough quality remains a problem. Traditional instruments used to study the mixing characteristics of doughs were unable to mimic this low-temperature mixing process. The doughLAB and the Mixolab equipments have the capabilities to alter thermal and mechanical energy inputs during mixing.

As it was mentioned earlier, different mixing procedures (straight, continuous, high-speed mixing, etc.) are applied in the baking industry. The amount and the intensity of energy input also affect the rheological properties of dough and so the final quality of baking products. In the case of the mentioned methods and instruments, constant mixing speeds are used. The recently developed doughLAB® (Perten Instruments) is a flexible recording rheometer, which can be used with both conventional z-arm and high-speed mixing actions. The latest one is able to emulate the high rates of mechanical energy input, applied in modern rapid baking systems.

A newly developed small-scale and rapid instrument is the GlutoPeak (Brabender GmbH), where a high-speed mixing action is applied in a thermostated flour–water slurry. The gluten proteins are separated and aggregated by the high-speed sharing effects; the gluten network is formed resulting to an increase in the measured torque. Further intensive mixing destroys the gluten structure; therefore, the resistance of the dough against mixing is decreasing. The time to maximum resistance and the value of peak maximum are the two most informative parameters, determined from the recorded Gluto-Peak diagrams.

The Mixolab System (Chopin Technologies) monitors the resistance of a dough during the dough formation phase and then through a heating/cooling/heating process (Figure 6) in a spiral mixer, mimicking the whole bread-making process. Phase 1 of the curve is equivalent to that of the farinograph, while information derived from phases 2–5 is similar to those of RVA. So, the Mixolab System enables the determination of the contribution of both protein and starch components of the dough in its rheological properties in a single test. Therefore, it is able to perform continuous measurement throughout a simulated baking process, which means that one can use the same instrument for several applications.

Trends and Future

Recent achievements in fundamental rheology to develop new rheological tests applying the knowledge base of modern polymer rheology principles such as the measurement of extensional strain hardening provide the basis to future developments of novel, practical equipments and methodology, suitable for routine evaluation of wheat-based end products.

Cumulative demand of the consumer for healthier, more nutritive bread is a challenge in the whole wheat chain: new quality attributes have to be considered and monitored. The best example for this trend is the effects of applying whole wheat meal and/or ingredients with higher fiber content as source materials. Besides their direct involvement in the development of protein–carbohydrate–lipid complex, altered fiber content alters drastically the water intake of the flour, changing

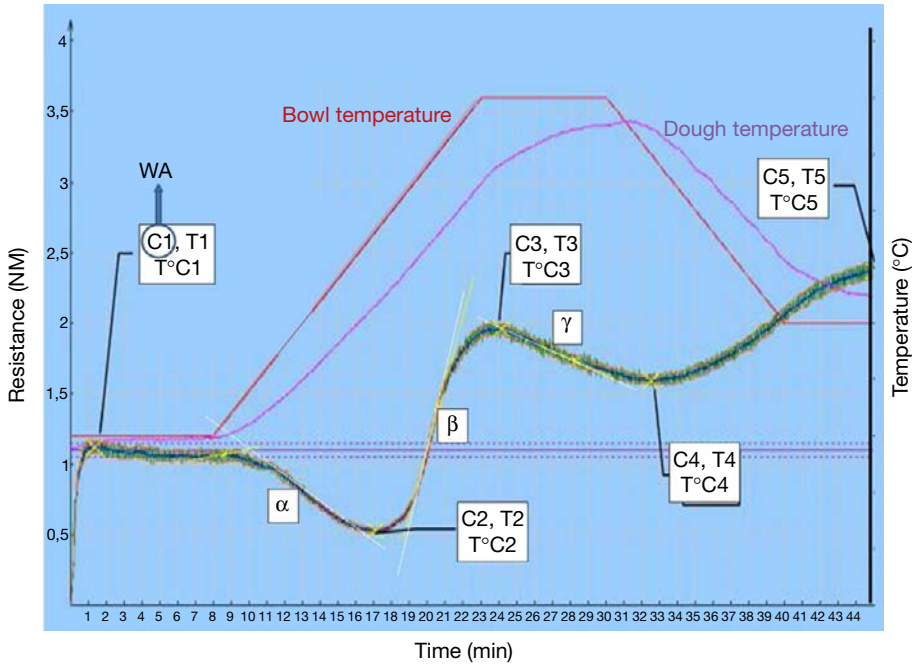

Figure 6 Mixolab parameters to characterize the mixing and heating/cooling related attributes of the dough.

the usual hydration process and therefore altering the physical and physicochemical conditions during dough mixing.

With the appearance of wheats with much more variation in starch composition (waxy wheat and high-amylase wheat), starch-related quality evaluation, largely using viscosimetric techniques, will get significantly more emphases in quality evaluation.

Similarly to milling, where the application of NIR technique to monitor the composition of source material and end products is widespread, there is a strengthening trend to utilize the advantages of spectroscopic analytic and monitoring techniques also in the baking industry, especially continuously monitoring the process of dough development in the mixer. The NIR technology has the potential to provide an invasive or noninvasive mean of probing chemical changes that occur during dough development because the absorbances in the spectra can be directly related to the chemical dough components (water, starch, protein, and fat).

Further spread of the application of indirect, high-throughput relatively cheap methods is expected in the future in prebreeding and breeding, applying small and micro methods such as the Micro Zeleny Tester, NIR, and Raman spectrophotometric techniques to estimate quality attributes and methods predicting important dough properties such as dough strength and extensibility or water absorption based on the genetic and chemical composition of the flour.

In the breeding process to select for quality, the application of traditional dough testing methodologies (farinograph and extensograph) will be the key process also in the future, because of the archived, invaluable data of previous generations of breeding material, determined on these equipments for decades. It is therefore essential to fully understand and characterize the relationships between quality attributes determined by means of traditional methods and those derived from new generation test equipments applied by the industry for process and product development and quality control.

Breeding and industrial objectives are aimed to be achieved through monitoring end-product quality rather than a set of dough parameters – a trend, appearing in the last decade that will fundamentally alter the quality control in the future. A recently developed equipment extensively used already in both basic research and developmental activities is the C-cell digital image analysis for the objective investigation of crumb structure of bread loaves, providing incomparably more insight about bread-making quality than traditional baking test determining loaf volume.

Bread: Types of Bread

C Collar, Instituto de Agroquímica y Tecnología de Alimentos (CSIC), Paterna, Valencia, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Cereals are basic, popular, and healthy raw materials, providing excellent vectors for nutrition, diversity, and innovation. Bread, made basically not only from wheat but also from other grains, is a staple food widely consumed all over the world since ancient times (10 000 BC) providing approximately half of the consumed carbohydrates. The nearly ubiquitous consumption of bread places it in a position of global importance in international nutrition. Bread was initially baked in the home using simple home-ground whole-wheat flours, and styles of bread, as well as the methods used to make them, evolved to satisfy local tastes and eating habits. Flour milling and subsequent breadmaking on a commercial scale emerged as vital components of local societies, and wheat-based foods evolved into the current diversity.

Bread baking is based on mixing flour and other ingredients with water to make dough, leavening with yeast that produces carbon dioxide, and baking to stabilize the solid protein foam formed, resulting in an elastic porous network. Bread is an excellent carrier of macro- and micronutrients and bioactive components that fulfills an increasing number of nutritional and health claims. Over the last and current decades, bread is being revisited as a key cereal-based baked goods addressed to specific targeted groups of population (low calorie density for obesity prevention and control, gluten-free for celiac patients, and high-fiber goods to alleviate the low current intake of dietary fiber), and a wide array of tailor-made bread is increasingly available.

In this article, the production and consumption of bread types across the world are presented, the role of wheat bread and nonwheat bread in nutrition and health is emphasized and updated, and the value-added bread addressed to specific groups of population is described.

Production and Consumption of Bread

A study by the European Commission in 2010 found that the European bread market was around 32 million tonnes in 27 EU countries. Across the whole of the European countries, the market share of the industrial bakers versus the craft bakers was approximately 50/50, but there were great differences in different countries. One area of continued growth throughout Europe is the market for frozen dough and par-baked products, which has transformed the market so that cooperatives and industrial baking companies are flourishing at the expense of the craft sector. In-store bakeries continue to be a growing sector. In the United Kingdom, supermarket in-store bakeries produce around 13% of the bread, with craft bakeries 7% and the remaining 80% produced by industrial bakers. Bread production is relatively stable in most countries, but there are some countries that are still showing a long-term trend of a slow decline, 1–2% per year, including the United Kingdom and Germany. Bread consumption patterns differ widely within the EU, but most countries have an average consumption of 50 kg of bread per person per year. The market structure varies throughout Europe: in the United Kingdom, the industrial sector represents 80% of production; it is 40% in Germany, 35% in France, about 81% in the Netherlands, and 19% in Spain. Germans and Austrians eat the most bread, around 80 kg per year, while the United Kingdom, Spain, and Ireland are at the bottom of the list with an annual consumption of less than 50 kg. White bread is the most commonly consumed bread (around 60%) in the UK population, although the average amount consumed as a proportion of the total bread intake was lower than those levels reported 10 years ago in the 2000–01 National Diet and Nutrition Survey (NDNS). As of 2000, the country with the largest *per capita* consumption of bread was Turkey with 199.6 kg per person. Turkish people eat more than three times their own body weight in bread annually. Turkey is followed in bread consumption by Serbia and Montenegro with 135 kg and Bulgaria with 133.1 kg. There continues to be increased demand for greater variety of bread than ever with ethnic bread becoming more popular in Europe and greater varieties of whole-wheat breads with oats, bran, seeds, etc. There is also a growing trend for increased production of sliced and wrapped bread in many countries across Europe, including Germany and France. There will be continued growth in morning goods and speciality bread with many opportunities for innovation.

With respect to product innovation and development, health trends will continue with whole grain, fiber, and omega-3, all being important contributors. There will be a continued decrease in bread consumption as alternative foods and bakery-type products are increasingly available. In North America, according to the Economic Research Service, USDA, *per capita* grain availability, adjusted for losses, increased from 43.2 to 61.7 kg per year between 1970 and 2009, which corresponds to an increase in energy availability from 432 to 619 kcal per day during this interval. *Per capita* availability of flour and cereal products varied from 199.5 to 194.7 kg per year between 2000 and 2010. The breakdown of products between 2000 and 2012 was wheat flour (146.3–134.4 kg), rye flour (0.5–0.5 kg), rice (19.2–20.4 kg in 2010), corn products (28.4–33.9 kg), oat products (4.4–5.2 kg), and barley products (0.7–0.6 kg). Consumers are interested in natural, convenience, and indulgence and growing out-of-home consumption, meaning less time spent on home food preparation and consumption. In South America, wheat-bread consumption is high only in Chile and Argentina. In other South American countries, the staples are maize and rice. In Argentina, wheat is the major source of calories and the second source of proteins after beef. Products derived from wheat supply 31% of the average Argentine's daily energy intake of some 12 000 kJ.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00085-4

Per capita bread consumption is 96 kg per year in Chile, 74 kg per year in Argentina (70 kg for craft bread and 4 kg for industrial bread), 28 kg per year in Peru, 27 kg per year in Brazil, and 24 kg per year in Colombia. After Germany, Chile is the country with the highest per capita bread consumption in the world.

Bread Worldwide

Ethnic cereal-based foods are generally defined as products that are unique to a particular geographic region or products that are produced from grains that are indigenous to a particular region. Western ethnic foods are defined as those wheat flour-based foods that initially became staples in western Europe and, with European colonization, were transported around the world.

Western Ethnic Bread

The evolution and spread of western ethnic foods can be traced back to the ages, and it is possible to identify a number of key phases in baked goods development (Figure 1). *Pita* is the oldest of known bread types indicating a range of potential countries of origin surrounding the Mediterranean Sea. Pita bread is a slightly leavened wheat bread, which is rolled flat and is either round or oval in shape and variable in size. It is commonly used as a wrap for a variety of filled pocket or rolled sandwiches and has spread throughout the world as a popular convenience food. *Sourdough* is a term used to describe bread produced where the leavening agent is a naturally occurring wild yeast or bacterium. The bread has a characteristic 'sour' flavor and is as old as the history of leavened bread itself. Natural leavens or 'starter' cultures consist of wild/natural yeast and *Lactobacilli* maintained over time and used repeatedly. They produce bread with unique flavor, texture, and keeping qualities and have been around for thousands of years. *Hearth bread* is the term used to describe the traditional baking method where a fermented dough piece is baked on the floor of an often wood-fired oven. It is still widely used in small bakeries around the world, with an almost limitless range of local shapes and styles of bread. Hearth bread should have a distinctive appearance, taste, and aroma with an open and coarse texture. *Baguette* (French bread and Vienna bread) is a hard crusty style of loaf associated with France, but developed in Vienna in the mid-nineteenth century. Baguette is whiter, lighter, and sweeter than the traditional sourdough bread that it was destined to replace. The golden-brown baguette, with its crisp crust, sweet taste, characteristic external appearance with surface cuts, and white crumb with large irregular holes, is one of the most famous of all of the world's bread styles. Many regional adaptations of the baguette have developed across the world with the pandesal in the Philippines and the popular hearth-type bread produced widely in Vietnam as examples. *Pan bread* is the term used to describe bread produced in a baking pan. It is a relatively recent innovation (eighteenth century) that originated in England and Holland, which are the only European countries that routinely produce bread on a large scale in pans. The regular shape, size, and weight of the finished loaf led to the development of the sliced and wrapped loaf. Pan bread is produced by a range of methods, varying in mixing intensity, the use of rapid-acting maturing agents, and the length of bulk fermentation. The *straight dough* method is the traditional method of breadmaking with a bulk fermentation stage of between 2 and 6 h, depending on yeast levels, dough properties, and the preferences of local consumers. This method is still widely used in small bakeries in many parts of the world. The *rapid dough method* relies on full dough development during mixing, with no need for normal bulk fermentation as in the straight dough process. Doughs are divided, molded, and deposited direct into baking pans for proofing and baking. Bread is produced in 2 h from start to finish, using medium-strength and medium-protein flour. This is the popular method of bread manufacture in Australia, and it has spread to other countries that use Australian wheat. The *sponge and dough baking* method is popular in the United States, and successful marketing programs have seen it gain popularity in many Asian countries. The finished baked product has fine, even texture and excellent flavor that has contributed greatly to its popularity. The first stage or 'sponge' is made by mixing a portion of the total flour and water together with the yeast and improver. The sponge is allowed to ferment up to 4 h before the balance of the flour, and other ingredients are added (including salt, which, if added sooner, would inhibit fermentation) and remixed to form the complete dough. The dough is then allowed to relax and then divided, molded, and baked in a conventional manner to produce bread of high specific volume. The basic recipe of *focaccia* is thought to have originated from the Etruscans or ancient Greeks. It is likely to be the early precursor of pizza and, while popular in Italy, has spread all over the world. It comprises a yeasted bread dough, often mixed or spread with oil, herbs, onion, garlic, sage, rosemary, or oregano, and cooked quickly at high temperatures. A *bagel* is a bread product, traditionally shaped by hand into the form of a ring from yeasted wheat dough, which is initially boiled for a short time in water and then baked. The result is a dense, chewy, doughy interior with a browned and sometimes crisp exterior. Bagels are often topped with seeds baked on the outer crust, with the traditional ones being poppy or sesame seeds.

Figure 1 Assorted Western-style breads.

Some may have salt sprinkled on their surface, and there are also a number of different dough types such as whole grain or rye.

Ethnic Breads

The first bread produced was probably the cooked version of a grain paste, made from ground cereal grains and water. Descendants of this early bread are still commonly made from various grains worldwide, including *lavash* (Iran and Turkey), *sangak* (Iran), *tortilla* (Mexico), *chapatti* and *roti* (India), and *pita* (Middle East). Flatbreads are a simple form of bread made from flattened dough (Figure 2). They may be leavened or unleavened, and they are still a very important staple food among the people of the Middle East and India. Their use is spreading throughout the Western world due to their versatility. Flatbreads are staples in northeast Africa (Ethiopia, Eritrea, and Sudan). They are made from a variety of different cereals, especially sorghum, finger millet, and teff, and resemble pancakes. Unlike pancakes served in the West, many of these products have a leavened texture and an acidic flavor. These characteristics are a result of a mixed lactic acid bacteria and yeast fermentation. Probably the two most well-known flatbreads are *injera* and *kisra*. *Injera* is a large (some 50 cm in diameter), spongy-textured pancake about 5 mm thick from Ethiopia and Eritrea. Its surface has a honeycomb-like appearance, very similar to a natural sponge, which is created by the escaping carbon dioxide during the steaming process. Teff is the preferred cereal for making *injera* in Ethiopia. This is due to the superior keeping qualities of teff *injera* when compared with *injera* made from other cereals such as sorghum. *Kisra*, from Sudan, is much thinner (1–1.5 mm thick) and smaller (~30 cm in diameter) than *injera*. It is more like a flexible thin wafer. These flatbreads remain almost exclusively homemade products despite the fact that there are flourishing commercial bakeries in countries such as Ethiopia and Sudan. In Kenya, wheat flour chapatis are a very popular home-baked food in all communities. It is probable that this type of flatbread was introduced by Indians who settled in the country in the late nineteenth and early twentieth centuries.

Steamed bread and buns are consumed throughout Southeast Asia but mostly in China, Japan, and Korea. The characteristics of steamed breads and buns vary from country to country and region to region. Steamed buns can be filled (*bao*) or not filled (*mantou*). *Mantou*, which is unfilled, is the only product called steamed bread. *Char siu bao*, steamed buns with barbecue pork filling, has white skin and splits open on steaming. This splitting is a positive quality characteristic. Char siu bao is very soft and cake-like and the highest quality is high in sugar (up to 30%) although low in fat. Low-sugar *char siu bao* with a low-fat filling could contribute to a healthy diet. Hong Kong-style *char siu bao* is made with low-protein soft wheat and is usually sold fresh. The buns are usually chemically leavened with ammonium hydroxide, which is released during baking when fresh. Singapore-style *char siu bao* is firmer than Hong Kong-style and uses higher-protein flour.

Figure 2 Flatbreads worldwide (clockwise from the left): *kitta*, *kisra*, *injera*, *roti* (chapati), *tortilla*, and *lavash*.

Value-Added Bread

It raises a great deal of recent interest that minor cereals, ancient crops, and pseudocereals, besides wheat, constitute highly nutritional grains with potential breadmaking applications. The concept of using South American, African, and Asian traditional raw materials and fermented foods as a template for wheat-based, wheat-free, and gluten-free foods in Europe and North America is in good accordance with the interest in westernized countries for ethnic foods with revisited value addition. Indigenous foods from different cultures and civilizations with ethnic eating habits are moving in a globalized world with strong immigration movements, encompassing the use of traditional raw materials as ingredients in novel foods. The general growing demand for novel, tasty, and healthy foods together with the increasing number of people suffering from celiac disease has given birth to a new market consisting of cereal products made from gluten-free grains. In this challenging market, oat, rice, corn, sorghum, millet, quinoa, amaranth, and buckwheat have gained a special position, as basic ingredients used singly and/or in associated blends to make gluten-free, wheat-free, and wheat composite breads with variable sensory acceptability and nutritional value (Table 1).

Moreover, the interest in leguminous flours as ingredients for bread production is growing. High-legume wheat blends appear as an efficient strategy to obtain sensorially accepted and nutritionally enhanced bread (Table 2) with no dramatic technological impairment when structuring agents (gluten/hydrocolloids) are incorporated.

Chickpea and green pea incorporation into bread formula decreased and delayed the starch hydrolysis and concomitantly reduced the expected glycemic index. The use of defatted soybean flour promoted a boost of bread antiradical activity. Structuring agents helped restore dough viscoelasticity in highly legume-replaced wheat matrices and apparently obstructed starch-degrading enzyme accessibility causing a slowdown of starch hydrolysis kinetics.

Nutritional and Health-Related Aspects of Bread

Grains are sophisticated reservoirs of macronutrients, cell wall polysaccharides (dietary fiber), and many biologically active

minor constituents. As 30–70% of daily energy according to the country income is derived from cereal-based foods, their role in nutrition is important. Cereal-based foods are an important source of carbohydrates, protein, dietary fiber, especially B vitamins, and minerals. The starchy endosperm gathered most of the scientific and technological interest for food processing until the end of the previous century. The recognition of the importance of the outer grain layers for health maintenance created the interest to reveal the types, amounts, and potential physiological significance of various vitamins, minerals, and phytochemicals in the whole grain and food made thereof. It has also been recognized that food structure at different levels, to a large extent modified in food processing, is important in controlling the rate and extent of digestion of nutrients and the bioavailability of phytochemicals. In the European Prospective Investigation into Cancer and Nutrition (EPIC) study populations, 27% of total carbohydrate intake was from bread. The majority of bread, as well as other baked goods, is made of refined white wheat flour, free of the outer grain layers rich in cell wall material and associated phenolic compounds, minerals, and vitamins. Epidemiological studies constantly show that the intake of whole grain and cereal dietary fiber protects against the rapidly increasing chronic diseases related to a sedentary lifestyle, such as cardiovascular disease and type 2 diabetes.

Energy and Macronutrients

With an energy content of around 2.2 kcal (9.2 kJ) per gram, bread is considered a 'medium'-calorie food from an energy density perspective. Most of the energy in bread comes from starch; therefore, bread is generally classified as a 'starchy food.' A medium slice of white bread typically provides 86 kcal (361 kJ). Continental breads (such as focaccia) contain oils (usually olive oil, rich in monounsaturated fatty acids) that increase the calorie content, with a 50 g serving of *focaccia* containing, on average, 180 kcal (756 kJ). An average slice of *ciabatta* (around 45 g) contains, on average, 116 kcal (487 kJ). Whole-wheat (2.2 g/100 g) and brown flours (2 g/100 g) therefore contain slightly more fat than white flour (1.2 g/100 g).

Although white flour and brown flour provide a similar profile of saturated (e.g., palmitic acid), monounsaturated (e.g., oleic acid), and polyunsaturated fatty acids (e.g., linoleic acid), the specific flours differ in their fatty acid concentration, with whole-wheat flour providing the greatest proportion of fatty acids. The amount of fat/100 g of bread is small. However, the addition of fat during the breadmaking process or in meal preparation can increase the fat content. Bread also contains considerable amounts of protein and carbohydrate.

The amount of fiber in the bread depends on the flour used to make it. A slice of 40 g of white wheat bread will deliver about 1 g of dietary fiber, and a similar slice of whole-wheat bread would deliver 3–4.5 g. During the day, the choice of bread has a large effect on the intake of dietary fiber, and six portions of whole-wheat bread would provide close to the recommended intake of dietary fiber of 25–35 g per day. A range of minerals, vitamins, and phytochemicals have been detected to be concentrated in the same grain parts as most of the dietary fiber polymers (Table 3), and there is increasing evidence about their biological activity and possible interference with various disease pathologies.

Micronutrients

Bread provides various micronutrients, including calcium, iron, zinc, copper, magnesium, manganese, selenium, and some B vitamins, such as folate (Table 3). Any food that

provides 15% or 30% of the recommended dietary allowance (RDA) for a specific vitamin or mineral, per 100 g, is considered a 'source of' or 'high in,' respectively, the named vitamin or mineral. As Table 3 outlines, bread can be considered a 'source of' and/or 'high in' many micronutrients.

Phytochemicals

The highest amounts of phytochemicals are found in the outer layers of grains and include phenolic compounds, phytosterols, and tocols (tocopherols and tocotrienols). These plant substances have been substantiated to have antioxidant properties *in vivo*. A study examining the total antioxidant capacity of various foodstuffs, including cereals (such as wheat) and 18 cereal products, found that whole wheat, buckwheat, and wheat bran had the greatest total antioxidant capacity value, while white flour showed the lowest total antioxidant capacity value, indicating that flour containing the outer layers of the wheat grain and germ has a greater potential antioxidant activity than white flour. In a recent study, the polyphenol qualitative and quantitative profile and antiradical properties of enzyme-digested extracts mimicking human gastrointestinal conditions, from single oat, rye, buckwheat, and wheat and multigrain quaternary bread at different levels of wheat flour replacement, have been investigated, and the relationships between total and individual polyphenols and kinetics of reduction of the free radical 2,2-diphenyl-1-picrylhydrazyl (DPPH) have been established. The total phenol content among the single bread extracts was significantly higher in buckwheat (808 mg gallic acid equivalents (GAE) per kg) and decreased in the following order: buckwheat > wheat > oat > rye. Mixed bread exhibited increased polyphenol content (up to 1135 mg GAE per kg) and higher polyphenol bioaccessibility (from 55% to 80%) with a higher degree of wheat replacement. Similar trends were found for antioxidant power. DPPH reduction followed two-step kinetics in all cases, where a considerable amount of phenolic acids and flavonoids corresponds to high antiradical activity and to slow kinetic rates (protocatechuic acid and ferulic acid), particularly for mixed grain bread extracts.

Role of Cereal Foods in Diet: Nutrition and Health Claims

Numerous epidemiological studies during the past 15 years have shown the protective role of whole grain foods against chronic diseases, such as cardiovascular disease, type 2

diabetes, and colon cancer. Although it has been calculated that consuming up to 50% of all grain foods as refined grain foods, when they do not contain high levels of added fat, sugar, or sodium, is not associated with increased disease risk, whole grain foods are considered to be protective for health. Cereal dietary fiber is considered to be the main contributor to the health protective effects of whole grain foods. In addition, the potential role of phenolic and other minor grain constituents in health maintenance has been emphasized.

Following reports of epidemiological studies showing the importance of whole grain, numerous actions have been taken to promote the use of cereal foods containing whole grain and dietary fiber. In 2003, the WHO/FAO expert consultation recommended that whole grain cereals, fruits, and vegetables are the preferred sources of nonstarch polysaccharides, the intake of which should be 20 g per day. Dietary recommendations in the United States (http://www.foodpyramid.com/mypyramid/) are to consume at least half of cereal foods as whole grain, and the Nordic dietary recommendations also recommend eating cereal foods as whole grain products (http://www.norden.org/fi/julkaisut/9). In Denmark, whole grain foods have been promoted by a campaign and logo (http://www.fuldkorn.dk/english/) with the aim of reaching the recommended daily intake of 75 g whole grain, and in the United States, by a stamp and communication by the Whole Grains Council (http://wholegrainscouncil.org/whole-grain-stamp) helping consumers to reach a daily intake of whole grain of at least 48 g.

In 1999, the US Food and Drug Administration (www.fda.gov) accepted a health claim for whole grain foods: "Diets rich in whole grain foods and other plant foods and low in total fat, saturated fat, and cholesterol may reduce the risk of heart disease and some cancers." The European Food Safety Authority (EFSA) has not accepted a health claim concerning whole grain foods, but some health claims can be used in connection with cereal ingredients, such as wheat and oat bran, rye fiber, and oat β-glucan. Rye fiber contributes to normal bowel function for food, which fulfills the high fiber claim with this fiber. Barley grain fiber, oat grain fiber, and wheat bran fiber contribute to an increase in fecal bulk for food, which fulfills the high fiber claim with every fiber. Wheat bran fiber contributes to an acceleration of intestinal transit for food, which fulfills the high fiber claim with this fiber with a daily intake of ≥ 10 g of wheat bran. The consumption of arabinoxylan (AX) from wheat endosperm as part of a meal contributes to a reduction of the blood glucose rise after that meal for food that contains at least 8 g AX-rich fiber per 100 g of available carbohydrates in a quantified portion. Consumption of β-glucans from oat or barley as part of a meal contributes to the reduction of the blood glucose rise after the meal for food that contains ≥ 4 g of β-glucans from oats or barley for each 30 g of available carbohydrates in a quantified portion. β-Glucans contribute to the maintenance of normal blood cholesterol levels for food that contains ≥ 1 g of β-glucans from oats, oat bran, barley, and barley bran or from their mixtures per quantified portion, 3 g needed per day. Replacing digestible starches with resistant

starch in a meal contributes to a reduction in the blood glucose rise after that meal for food with the final content of resistant starch is at least 14% of total starch.

In Europe, the nutrition and health claims directive also provides a list of allowed nutrition claims, many of which are also relevant to cereal foods, such as 'source of fiber' for products containing at least 3 g DF/100 g product and 'rich in fiber' for those containing 6 g DF/100 g product (**Table 4**).

Protein, vitamins, and omega-3 and polyunsaturated fatty acids are also among those food components where nutrition claims may be used to show a high content. In addition to AX, β-glucans and cellulose, resistant starch, lignin, and other phenolics associated with carbohydrate polymers are part of the cereal dietary fiber complex. Despite the known health effects, recommendations, labeling, and communication campaigns, the majority of cereal foods consumed are made of refined flour and contain less dietary fiber and other health-promoting compounds than are present in the whole grain raw material.

Browning: Enzymatic Browning

Y Jiang, X Duan, and H Qu, Chinese Academy of Sciences, Guangzhou, China
S Zheng, Fujian Academy of Agricultural Sciences, Fuzhou, China

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Browning that occurs widely in many fruits and vegetables, and some seafood products, is initiated by the enzymatic oxidation of phenolic compounds, resulting in the formation of brown-colored substances. Polyphenol oxidase (PPO) is a group of copper proteins that catalyzes the oxidation of phenolics to quinones, which produce a series of brown pigments. These reactions are thought to be the major cause of the enzymatic browning of many fruits and vegetables during handling, storage, and processing. The initial products of oxidation are quinones, which rapidly condense to produce relatively insoluble brown polymers (melanins). This enzymatic browning problem is of considerable importance to the food industry as it greatly influences the nutritional quality and appearance, reduces the consumer's acceptability, and, therefore, results in significant economic impact to both food producers and the food-processing industry. It is estimated that over 50% of loss in fruits and vegetables occurs as a result of enzymatic browning, and in particular, tropical and subtropical fruits and vegetables are the most susceptible to these reactions. Moreover, highly prized and economically valuable seafood is extremely vulnerable to deteriorative enzymatic browning. The millions of pounds of seafood, specifically shrimp, caught or imported into processing facilities must be treated with chemical preservatives to control and/or eliminate this discoloration process.

Owing to its tremendous economic impact to the food industry, inhibition of enzymatic browning caused by PPO in food products has been widely investigated. The most important factors that determine the rate and degree of enzymatic browning of fruits and vegetables involve the concentrations of both active PPO and phenolic compounds, pH, temperature, compartmentalization between enzymes and substrates, and oxygen availability of the tissue. Understanding the enzymatic browning process is necessary in order to control it effectively and to obtain high-quality product that is acceptable to consumers. This article reviews the browning-related enzymes, browning substrates, browning reaction properties, and control of the enzymatic browning, with an emphasis on fresh fruits and vegetables after harvest.

Polyphenol Oxidase

PPO (E.C. 1.10.3.1), a Cu-containing enzyme, is also referred to as catechol oxidase, tyrosinase, phenolase, catecholase, diphenol oxidase, or *o*-diphenolase. PPO is found in almost all higher plants, including fruits and vegetables. It is known that PPO is synthesized as preproteins and contains putative plastid transit peptides at the N-terminal region, which target the enzyme into chloroplast and thylakoid lumen in plants. In addition to its existence in higher plants, PPO is also found in some seafood products, such as shrimp and lobster. Its role in browning reactions causes deterioration in food quality by changing the nutritional and organoleptic properties and hence consumer acceptability.

The action mechanism of PPO is based on its capacity to oxidize phenolic compounds. When the plant tissue is damaged, resulting in the rupture of plastids, the cellular compartment where PPO is located leads to the enzyme contact with the phenolic compounds released by rupture of the vacuole, the major storage organelle of these compounds. It is considered that the active site of PPO contains two copper atoms and the enzyme catalyzes two different reactions in the presence of molecular oxygen: the hydroxylation of monophenols (monophenolase activity) and the oxidation of *o*-diphenols to *o*-quinones (diphenolase activity) (Figure 1). This reaction is generally followed by nonenzymatic polymerization of the quinones giving rise to the formation of melanins, pigments of high molecular mass, and dark color. Yoruk and Marshall reviewed the sequence of biochemical reactions leading to the formation of melanin from the oxidation of phenolic amino acid tyrosine. The rate of enzymatic browning of fruit and vegetables depends largely on specific activity of PPO and concentrations of phenolic compounds, the pH, and temperature. Table 1 gives some parameters of PPO from different fruit and vegetable sources with an emphasis on the optimum pH and temperature.

It is interesting to note that another phenol-oxidizing enzyme, laccase (*p*-diphenol: oxygen oxidoreductase, E.C. 1.10.3.2), appears in some higher plants. Laccase is active on both *o*- and *p*-diphenol substrates and is clearly differentiated from other PPOs by its unique ability to catalyze the oxidation of the latter. In litchi pericarp, the oxidative product of 4-methylcatechol catalyzed by PPO *in vitro* can accelerate anthocyanin degradation, resulting in the formation of brown-colored substances. Furthermore, the anthocyanase (identified now as a laccase) from litchi pericarp catalyzed the hydrolysis of sugar moieties from anthocyanin to yield anthocyanidin. Thus, it might be suggested that laccase contributes to litchi pericarp browning by rendering major phenolic constituents (anthocyanins) accessible to PPO. Properties of the laccase involved in anthocyanin degradation in combination with the oxidation of other phenolics caused by PPO require detailed elucidation. Moreover, the different contribution of laccase to enzymatic browning in some fruits and vegetables requires also clarification.

In higher plants, PPO is believed to be membrane-bound. PPO exists in soluble and membrane-bound forms. Limited activity of PPO in some fruits and vegetables such as apple, apricot, banana, pear, cucumber, eggplant, litchi, potato tubers, sunflower, and various *Prunus* fruits may be attributed to its tight binding to membranes; however, latency may not be

dependent just on membrane integrity because it persists even after release from the plastid and requires activation in broad bean, spinach, grape, mango, peach, pear, and sago palm. Activation of PPO can be induced by frost and aging, fatty acids, alcohols, denaturants, detergents, acid and alkali, protease treatment, sonication, and mild heat treatment. Removal of PPO-bound inhibitors may also result in activation of latent enzyme. It is mostly believed that endogenous proteases are involved in activation of latent PPO by cleaving a certain region. Therefore, protease inhibitors are usually used

to avoid further PPO activation by endogenous proteases during isolation. In addition, it is suggested that PPO activity may be regulated *in vivo* by oxygen concentration and pH value as the levels of both change in the chloroplast of the intact tissue. In some cases, latent PPO could be activated by pathogen attack, signifying the possible involvement of an activation process in a response to infection, which accounts for the rapid appearance of black spots when fruits and vegetables decay.

In higher plants, PPO has been described as a multiple gene family. Seven PPO genes (PPOs A, A′, B, C, D, E, and F) were identified from tomato and the PPO gene is encoded in the nucleus and translated in the cytoplasm and then the pro-PPO formed is transported to the chloroplast where it is cleaved by a protease, producing the active form. So far, PPO genes have been cloned from some fruits and vegetables, such as pear, sweet potato, grape, and apple, with their expression properties analyzed in relation to browning potential. In higher plants, predicted molecular weights range from 57 to 62 kDa. Mushroom PPO is generally thought to contain four subunits with a total molecular weight of 128 kDa. It can be expected that molecular biology techniques will help our understanding of the property of PPO and how to control enzymatic browning.

PPO exhibits a wide range of substrates in higher plants (Figure 2). Significant variations in the activities of PPOs exist from different fruit and vegetable sources. Types and relative concentrations of natural phenols vary largely for different fruit and vegetable sources (Table 2). For example, in the 'DeChaunac' grape, caffeic acid as a PPO substrate is oxidized at much faster rates than other structurally related substances, while in the 'Koshu' grape, chlorogenic acid is most rapidly oxidized, followed by caffeic acid and catechin. In addition, PPO isoforms in different fruit and vegetable tissues may also exhibit differential substrate specificities and variations in their relative activities toward monophenols and *o*-diphenols. For instance, two isoforms isolated in banana bud showed the maximum relative activity toward dopamine, but these enzymes exhibited obvious differences in their activities toward chlorogenic acid, L-dopa, and (+)-catechin. So far, all of the PPOs discovered have the ability to convert *o*-dihydroxyphenols to *o*-benzoquinones using O_2 as the second substrate, but not all PPOs hydroxylate monophenols.

Peroxidase

The relative significance of PPO activity is obscured somewhat by the presence of peroxidase (POD, E.C. 1.11.1.7), a similar oxidative enzyme. It is relatively difficult to ascribe a significant role to POD in enzymatic browning when one of its substrates, hydrogen peroxide (H_2O_2), is generally present at very low concentrations in plant cells. Recent evidence collected indicates clearly that POD could enhance browning reactions in the presence of ongoing PPO-mediated browning reactions. While the mechanism of this PPO-coupled browning is not well understood, it is possible that the PPO-mediated generation of quinones can lead to H_2O_2 accumulation, providing a higher concentration of this free radical species, thus enabling the occurrence of the POD-mediated oxidation of polyphenols. The profile and concentration of polyphenol substrates in plant tissues will also influence the potential for the POD-mediated polyphenol browning. Furthermore, the POD-related browning can be distinguished by the addition of an H_2O_2 quenching agent such as catalase, which will prevent browning caused by the POD-mediated reactions. Further work should be conducted with PPO inhibitors such as tropolone to determine whether the POD-mediated browning can occur without the existence of the PPO-associated browning. It would be premature to argue that the POD-mediated polyphenol browning is a consistently significant component in enzymatic browning of fresh fruits and vegetables after harvest, although there are sufficient questions raised by the current literature to encourage further work in this area.

Control of Enzymatic Browning

Table 3 gives the latest information about the conventional and alternative methods used currently to control enzymatic browning. The principle of the enzymatic browning inhibition involves the inactivation or inhibition of PPO activity, inhibition of the oxidation of phenolic compounds, low O_2 or O_2 accessibility, and delayed senescence in relation to compartmentalization between enzymes and substrates. Technologies to control enzymatic browning include heat treatment, PPO inhibitors, chelating agents, acidulants, reducing compounds, antiaging or signal substances, edible coatings, modified atmosphere packaging, controlled atmosphere, and cold storage.

Heat treatment is the most used method for stabilizing foods because of its capacity to destroy microorganisms and to inactivate enzymes. As mentioned earlier, PPO has a temperature range where it exhibits activity. In general, exposure of PPO to temperatures of 50–90 °C can destroy the catalytic activity, but the time required to inactivate the enzyme depends largely on the product. Thus, heat inactivation of PPO is feasible by applying temperatures of >50 °C for a short time. Temperatures of >60 °C for 3 min are sometimes used to treat red grapes before vinification, while heat shock in chlorinated water at 50 °C for 2 min inhibits effectively the surface browning of fresh-cut lettuce. However, the heat treatment may produce undesirable color and/or flavor as well as undesirable changes in texture. In general, the heat inactivation of PPO is more suitable for fresh fruits and vegetables after harvest to control enzymatic browning before they are dried or processed.

Many inhibitors of PPO have been applied for the control of enzymatic browning of fresh fruits and vegetables after harvest. The major PPO inhibitors include aromatic carboxylic acids such as benzoic and cinnamic acids and their derivatives. Strength and inhibition types follow cinnamic acid (noncompetitive) > 4-hydroxycinnamic acid (competitive) > 4-methoxycinnamic acid (noncompetitive). 2-Hydroxycinnamic acid has no inhibitory effect on the diphenolase activity, possibly due to a region different from the active site, and hinders the binding of substrate to the enzyme through steric hindrance or by changing the protein conformation. Diamine derivatives of coumarin and 4-hexylresorcinol are effective inhibitors of black spot formation in shrimp and 4-hexylresorcinol can also inhibit mushroom PPO, but they are not good inhibitors of grape PPO. Furthermore, application of 0.002% or 0.005% 4-hexylresorcinol does not inhibit enzymatic browning of fresh-cut artichokes. It is also noted that citric acid may function as a PPO inhibitor through its chelating action and ascorbic acid through its site-directed specificity toward histidine residues on the PPO protein. Application of citric acid can inhibit effectively the skin

Table 3 Treatments to inhibit enzymatic browning of fresh fruits and vegetables after harvest

Fruits and vegetables	*Treatment*	*References*
Apple	10 μl l^{-1} NO gas and 10 mg l^{-1} NO donor compound 2,2′-(hydroxynitrosohydrazino)-bisethanamine	Huque et al. (2013) and Wills et al. (2007)
Avocado	300 nl l^{-1} 1-methylcyclopropene	Hershkovitz et al. (2005)
Bamboo shoot	1.0 mM salicylic acid	Luo et al. (2012)
	0.5 mM sodium nitroprusside (a nitric oxide donor)	Yang et al. (2010)
Cauliflower	Application of an antifog shrink film	DeEll et al. (2003)
Celery	Humidified controlled atmosphere (5 kPa O_2 plus 5, 15 or 25 kPa CO_2)	Gomez and Artes (2004)
Cherimoya	0.5% L-cysteine dip	Campos-Vargas et al. (2008)
Eggplant	1 μl l^{-1} 1-methylcyclopropene for 6 h	Massolo et al. (2011)
	Exposure to 5 ml kg^{-1} ethanol vapor in a sealed container for 5 h at 20 °C	Hu et al. (2010)
Grape	0.5% burdock fructooligosaccharide	Sun et al. (2013)
	0.5% or 1% chitosan coating	Shiri et al. (2013) and Choi (2007)
	2 and 4 mM salicylic acid dip	Ranjbaran et al. (2011)
Lettuce	Heat shock in chlorinated water for 3 min at 50 °C	Roura et al. (2008)
Litchi	0.5% salicylic acid and 1% isoascorbic	Kumar et al. (2013)
	1 mM pyrogallol	Jing et al. (2013)
	2 M HCl	Salomao et al. (2012)
	60 g l^{-1} sodium metabisulfite	Liang et al. (2012)
	0.1% (v/v) *n*-butanol aqueous solution	Sun et al. (2011)
	25 μg l^{-1} methyl jasmonate	Yang et al. (2011)
	40 mM ascorbic acid and 1.0% (w/v) chitosan	Sun et al. (2010)
	0.25–2% chitosan dissolved 6% citric acid	Ducamp-Collin et al. (2008)
	Exposure to pure N_2 gas for 6 h	Liu et al. (2007)
	Plastic bag packaging	Sivakumar and Korsten (2006)
	Citric acid or tartaric acid solution at pH 0.8, 1.0, or 1.3 plus 1% (w/w) chitosan	Joas et al. (2005)
Longan	2% chitosan/30% nanosilica hybrid film	Shi et al. (2013)
	7.5% sodium metabisulfite	Hai et al. (2011)
Loquat	625 nl l^{-1} 1-methylcyclopropene followed by modified atmosphere packing	Oz and Ulukanli (2011)
	10 μM methyl jasmonate	Cao et al. (2008)
Lotus (fresh-cut root)	1.2% chitosan coating, followed by micro-perforated polyethylene packing (30 μm thickness)	Xing et al. (2010)
Mushroom	2% O_2 + 10% CO_2	Ye et al. (2012)
	An ethanolic extract from licorice roots (*Glycyrrhiza glabra*) or 1 μg ml^{-1} 3-(2,4-dihydroxyphenyl propionic acid)	Nerya et al. (2006)
Peach	80% N_2O	Nah et al. (2012)
	0.2% ascorbic acid or/and 5 M nitric oxide	Zhu et al. (2009)
Pear	0.5–1 μl l^{-1} 1-methylcyclopropene	Moon et al. (2008)
	4% calcium chloride	Mahajan and Dhatt (2004)
	0.2% diphenylamine or 0.3% ethoxyquin	Feng et al. (2004)
Persimmon	0.5% calcium nitrate or calcium chloride	Ferri et al. (2008)
Pineapple	38 °C for 60 min	Weerahewa and Adikaram (2005)
	0.1 μl l^{-1} 1-methylcyclopropene for 18 h	Selvarajah et al. (2001)
	2% $CaCl_2$ solution immersion	Goncalves et al. (2000)
Plum	0.5% ascorbic acid by vacuum infiltration	Shao et al. (2011)
Pomegranate	0.1, 0.5, or 1.0 mM acetyl salicylic acid	Sayyari et al. (2011)
Olive	3% sodium metabisulfite solution at pH 3.0	Segovia-Bravo et al. (2012)
Strawberry	60, 75, and 90 °C for 3 or 5 min	Holzwarth et al. (2012)
Sweet cherry	*Aloe vera* diluted 1:3 with distilled water and then immersed for 5 min	Martinez-Romero et al. (2006)

browning of litchi fruit and surface browning of fresh-cut Chinese water chestnut during storage. Kojic acid is found in fermented Japanese foods, and the use of kojic acid at concentrations ranging from 1 to 4 mM exhibits a significantly antibrowning effect on apple juice. This agent inhibits PPO activity and also chemically reduces brown pigments on colorless compounds.

Reducing agents are extensively used in the food industry. The application of reducing compounds is, to date, the most effective control method for enzymatic browning caused by PPO. Studies have revealed that ascorbic acid, pyrogallol, cysteine, bisulfites, and thiol compounds have a direct inactivating effect on PPO, in addition to their ability to reduce benzoquinones to *o*-dihydroxyphenols; the reducing compounds are oxidized in the process. The most widespread reducing agents used for enzymatic browning control are sulfiting agents. The reducing compound sulfite is generally used by the industry in controlled-atmosphere chambers with burning sulfur. However, in recent years, there has been increasing concern over the sulfur residue present in fresh fruits and

vegetables, particularly as some consumers are sensitive to sulfites. In the United States, sulfur is only registered as a postharvest treatment on grapes. Therefore, studies have been made to find efficient inhibitors without toxic effects. In these studies, cysteine has been shown to be an effective compound to prevent browning. It reacts with *o*-quinone intermediates to produce stable and colorless products. However, even at a low concentration, cysteine produces an undesirable odor, limiting its use in food processing. Thus, development of sulfur-free treatments to control enzymatic browning is imperative.

The use of acidulants is another approach widely used in food processing to reduce enzymatic browning. Acids naturally present in some edible food products, such as ascorbic acid, citric acid, and malic acid, shift the food pH to 3 or lower. In general, PPO present in fruits and vegetables is more active in the pH range of 4.0–8.0 (Table 1); and thus, the enzyme activity drastically decreases at a higher acid environment. Acidity may reduce the strong binding of the enzyme to its active site of copper. In fact, acidulants only partially prevent enzymatic browning of fresh fruits and vegetables compared with bisulfite; in combination with edible coatings, such as chitosan, enhanced inhibition of enzymatic browning may result.

Oxygen concentration or O_2 accessibility influences greatly enzymatic browning. A high percentage of molecular O_2 can be replaced with either N_2 or CO_2 to slow down or prevent enzymatic browning. As oxygen is required by PPO to initiate the browning reaction at the surface wound, the use of O_2-impermeable packaging, edible films, antifog shrink films, modified atmosphere packing, or controlled atmosphere may be beneficial in preventing the onset of enzymatic browning. In recent years, chitosan coatings have been extensively investigated for the control of enzymatic browning in fresh fruits and vegetables after harvest and show a potential for commercial application (Table 3). In addition, prevention of mechanical bruising during the shipping of fresh fruit and vegetables after harvest is important to avoid O_2 accessibility, while compression and vibration can be prevented by the use of soft packaging.

An alternative approach for the control of enzymatic browning involves delaying the senescence of fresh fruits and vegetables after harvest. It is well known that membrane deterioration is an early and characteristic senescence feature of fresh fruits and vegetables during storage. Although plant cells possess both enzymatic and nonenzymatic antioxidant systems to alleviate membrane lipid peroxidation and protect cellular membranes from radical oxygen species (ROS), irreversible senescence occurs, due to oxidative membrane damage induced by the imbalance between ROS and ROS-scavenging systems.

An accumulation of ROS may induce a loss of membrane integrity. Accordingly, a gradual loss of compartmentalization between enzymes and substrates could lead to the enzymatic oxidation of phenolic compounds to brown-colored polymers. As a result, application of some antiaging agents or signal substances such as calcium nitrate, calcium chloride, ethanol vapor, NO, N_2O, salicylic acid, methyl jasmonate, and 1-methylcyclopropene effectively inhibits the enzymatic browning of apple, avocado, grape, litchi, loquat, peach, pear, persimmon, pineapple, pomegranate, eggplant, or bamboo shoot after harvest by delaying senescence (Table 3). Among these applications, 1-methylcyclopropene is used commercially.

New Approaches for the Control of Enzymatic Browning

Current research on genetic engineering methods such as antisense RNA and gene silencing will help increase our understanding of the enzymatic browning caused by PPO and how to control it to improve crop quality. Molecular biology techniques have helped to explain the confusion regarding the multiple forms of PPO isolated from many fruits and vegetables. The recent work to reduce browning capacity of plants and, in turn, to improve crop quality is the control of PPO levels *in vivo* by means of antisense RNA strategy. In light of the molecular and genetic data available, it is believed that manipulation or regulation of PPO gene expression in order to diminish adverse effects of PPO on quality of fruit and vegetable crops without application of additives will be a future challenge. Antisense downregulation of PPO, for instance, in potato and mushroom has already been performed. Genetic transformation has also been conducted, and a transgenic apple (*Malus* x *domestica*) shoot with reduced PPO expression had lower browning potential than a control shoot. Furthermore, PPO activity of 'Russet Burbank' potato was inhibited by sense and antisense PPO RNAs from a tomato PPO cDNA under the control of the 35S promoter from the cauliflower mosaic virus, and tubers from five lines exhibited reduced browning correlated with low PPO activity. It appears that inhibited expression of PPO genes will be applied to prevent enzymatic browning in a wide variety of food crops without the application of various additives.

Conclusion

PPO is the key enzyme considered to be responsible for food browning. Despite the fact that the involvement of PPO in enzymatic browning has been studied for more than a century, many questions still remain about the enzyme itself as well as the enzymatic browning mechanism. The biochemical properties involved in the action of PPO in numerous fruits and vegetables have been investigated widely. Some models explaining PPO activity have provided additional insight to our understanding of the molecular structure of PPO reactions. Genes encoding PPO have been isolated and characterized from some fruits and vegetables, and all these studies verify the plastidic location of the unclearly coded protein. Current approaches to the understanding and control of enzymatic browning caused by PPO will make it possible to obtain crops of improved quality for marketing and storage. However, revealing all the complexity of PPO gene regulation to control enzymatic browning remains a prime challenge. In view of consumer concerns, products of such genetic engineering technology are not likely to be practical in the short term. Additionally, the food industry still faces the problem of how to

prevent enzymatic browning while considering food safety, regulations, marketability, and cost.

Browning: Non-enzymatic browning

JA Rufián-Henares, University of Granada, Granada, Spain

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Heat treatment is very common during the processing and storage of foods. Thus, thermal processing allows the improvement of food value attributes – such as organoleptic properties – and health attributes, getting healthier and more nutritious foods. Sterilization treatments, frying, roasting, baking, etc., reaching temperatures up to 220 °C, induce a series of food transformations leading to the formation of new compounds that affect, in general, the acceptability of the product by consumers. Some of these transformations are collectively known as nonenzymatic browning (NEB), responsible for many of the flavors and colors in foods that have undergone thermal processing.

NEB is a set of complex reactions produced in thermally treated foods giving rise to the formation of brown colors without the intervention of enzymes. This effect is desirable in many foods such as bread, breakfast cereals, candies, coffee, and chocolate, where the toasted aroma and color are expected. However, NEB produces undesirable effects during the processing and storage of different liquids or dehydrated foods – for example, milk, fruit juices, eggs, and fruits – due to the formation of undesirable aroma and/or colors and loss of nutritive value (degradation of vitamin C or essential amino acids).

NEB can be divided in three different reactions: ascorbic acid (AA) degradation, caramelization (degradation of sugars), and the Maillard reaction (MR) (sugar–amino acid reaction), although part of the compounds formed during AA degradation or caramelization can take part in the MR. The conditions where such reactions take place are reviewed in Table 1.

AA Degradation

L-Ascorbic acid (AA) or vitamin C is a highly water-soluble and strongly reducing substance with acidic properties. This chemical behavior is related to its 2,3-enediol structure conjugated with a carbonyl group (a lactone), which makes this molecule very sensitive to different forms of degradation. The decomposition of AA occurs mainly at slightly acidic pH, medium/high water activity, and moderate temperature in fruits, vegetables, and meat products, giving rise to the reversible production of dehydroascorbic acid (DHAA) and the irreversible hydrolysis to 2,3-diketogulonic acid (DKGA) (Figure 1). There are two different pathways, one oxidative and another non-oxidative. One of the main differences between them is the higher production of furfural in the non-oxidative pathway. The selection of the oxidative or the non-oxidative pathways depends on the presence of metallic catalysts such as Cu^{2+} and Fe^{3+}.

Oxidative Degradation

During the oxidative degradation under aerobic conditions, the AA molecule is oxidized to DHAA, which is the main precursor of the degradation products. DHAA is hydrolyzed to DKGA, which suffers a subsequent decarboxylation, dehydration, and/or polymerization to produce different byproducts such as brown polymers. As stated earlier in the text, the primary factors that influence the oxidative degradation of AA are the pH, oxygen partial pressure, and the presence of metal ions.

Effect of pH

The food's pH influences the oxidative degradation of AA in a nonlinear manner because of the different oxidation sensitivities of its ionic species (Figure 2): the ascorbate dianion (A^{2-}) is much more sensitive than the monoanion (AH^-), which is more sensitive than the protonated AA. In foods, at acidic pH, the predominant species are the protonated and AH^- species, due to the pK_{a1} of the C3 hydroxyl group ($pK_{a1} = 4.04$). However, at basic pH, AA is much more sensitive to aerobic degradation because the pK_{a2} of the C2 hydroxyl group is 11.4. Therefore, at a pH higher than 8.00, there is a high portion of A^{2-}.

Effect of metallic ions

The oxidation of AA can develop either catalyzed by metallic ions or not catalyzed. In the first studies on the oxidation of AA catalyzed by metals, the rate constant (first order) was thought to be relatively high ($5.87 \times 10^{-4}\ s^{-1}$). However, recent experiments under noncatalyzed conditions show that this constant is rather low ($6.00 \times 10^{-7}\ s^{-1}$) at pH = 7.0. Therefore, the noncatalyzed reaction is not spontaneous. In addition, when metals are present at concentrations of parts per million in foods, the rate constants are higher than those obtained in the absence of metals. The principle of metal catalysis is shown in Figure 3.

The oxidation speed in the presence of metals is proportional to the oxygen partial pressure (0.40–1.00 atm) under aerobic conditions. However, under low oxygen partial pressure (<0.20), the oxidation speed is independent of oxygen concentration and depends on the amount of metal catalysts. The chemical nature of the metal, its oxidative state, and the presence of chelators play an important role in AA oxidation. For example, Cu^{2+} is 80 times more reactive than Fe^{3+} while the ethylenediaminetetraacetic acid (EDTA)–Fe^{3+} chelate is 4 times more reactive than Fe^{3+}. However, in the case of copper, its catalyzing activity is almost lost when chelated with EDTA.

The chemistry behind AA oxidation

In foods and solutions, AA is in equilibrium with AH^-, which can be oxidized to the semidehydroscorbate (AH·) radical and then to DHAA by a one-electron oxidation. However, the main

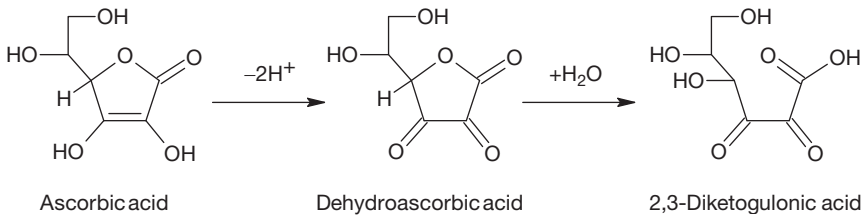

Figure 1 Oxidation of ascorbic acid (AA) to DHAA and DKGA.

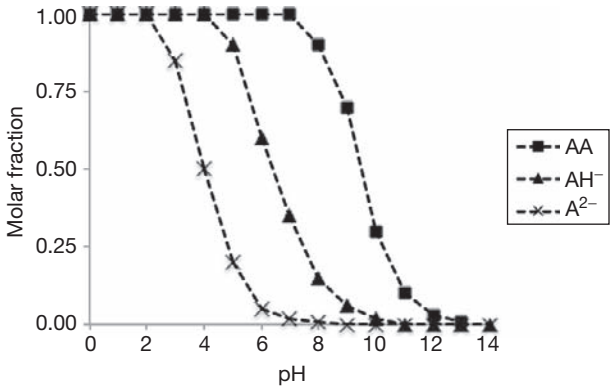

Figure 2 Effect of pH over the distribution of ascorbic acid species.

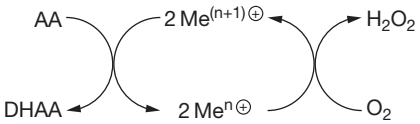

Figure 3 Principle of metal catalysis of aerobic AA oxidation.

pathway for the oxidative degradation of AA starts when a metal species, oxygen, and AH^- are linked in a ternary complex that generates DHAA. The main steps of the metal-catalyzed oxidation of AA are depicted in Figure 4. The ascorbate monoanion is oxidized to AH· due to the presence of a metal catalyst as seen. This reaction gives rise to the formation of superoxide, duplicating the reaction speed. AH· will end the radical reaction by the formation of DHAA, which will be hydrolyzed irreversibly to DKGA in the next step.

Non-oxidative Degradation

In an acidic medium under anaerobic conditions, such as canned foods like vegetables and tomato juices, the

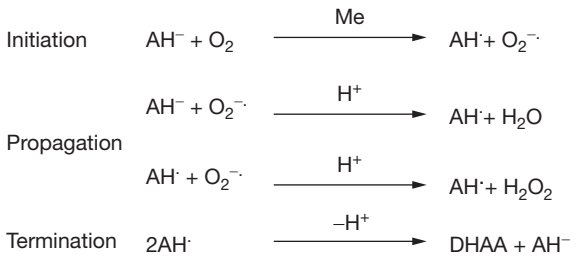

Figure 4 Metal-catalyzed oxidation of AA.

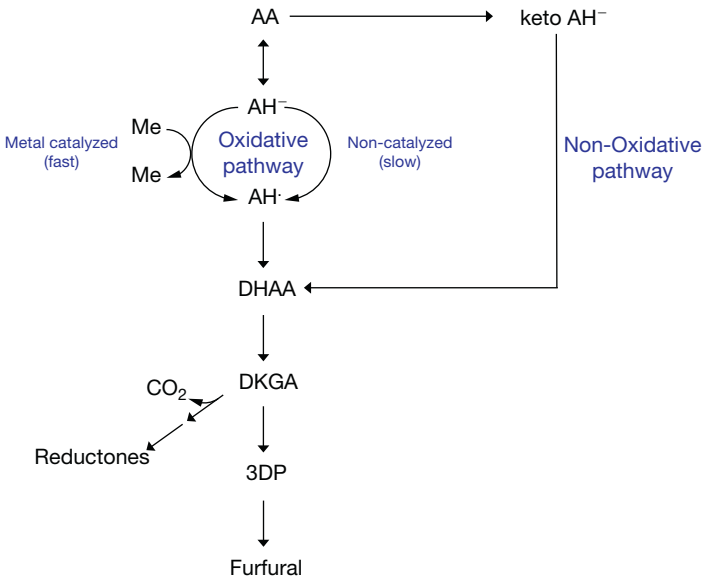
non-oxidative degradation of AA starts with the formation of the keto form of HA^- followed by the irreversible hydrolysis of the lactone group to DKGA, as in the case of the aerobic oxidation. This anaerobic degradation is negligible in fresh food, but in canned ones, it is accelerated by the presence of metal catalysts, especially copper. In addition, the non-oxidative pathway is also accelerated at acidic pH (3.00–4.00) probably by favoring the direct hydrolysis of the 1,4-lactone. The scheme of the reaction is shown in Figure 5. The next steps are shared by the oxidative and the non-oxidative pathways due to the common precursor DKGA. This chemical compound reacts by means of different chemical reactions, for example, decarboxylation, dehydration, and conjugation with other chemical species, giving rise to the formation of colored and flavored compounds. In addition, some other compounds like ethylglyoxal, 3-deoxypentosone, reductones, or furfural formed from DKGA breakdown may participate also in the MR.

Caramelization

Caramelization is another kind of NEB, obtained when sugars are heated over their fusion temperature, giving rise to an enol intermediate and final dehydration products. This is a useful method to produce color and flavor enrichment during cooking of sugar-rich foods, such as bread baking or coffee roasting.



AA: ascorbic acid. AH^-: ascorbic acid monoanion. AH^+: semidehydroascorbate radical. Me: Metal catalyzer. DHAA: dehydroascorbic acid. DKGA: diketogulonic acid. 3DP: 3-deoxypentosone.

Figure 5 AA degradation pathway.

Table 2 Main flavor compounds derived from caramelization

Heterocyclic compounds			*Carbocyclic compounds*
Furans	Furanones	Pyrones	
Furfural	Hydroxymethylfuranone	5,6-Dihydromaltol	2-Hydroxy-3-methyl-cyclopentenone
2-Hydroxyacetylfurane	Dihydroxymethylfuranone	5-Hydroxy-5,6-dihydromaltol	3-Methyl-2-cyclopentenone
5-Hydroxymethylfurfural			2,3-Dimethyl-2-cyclopenten-1-one

These thermal treatments increase the temperature at the food surface to above 120 °C. In addition, a pH range from 3.00 to 9.00 increases the development of caramelization, as well as compounds such as ammonia, sulfite, or oxidizing agents like Cu^{2+}. Therefore, the fine-tuning of these parameters allows the obtention of foods with caramellike aroma or caramellike color. For example, sucrose syrup can be heated in an acidic-buffered solution to obtain a flavored caramel, whereas the same solution when heated in the presence of sulfuric acid and ammonia gives rise to the formation of a colored caramel. Some of the compounds responsible for the caramellike aroma are included in Table 2. They produce flavor ranging from mild-sweet caramel aroma to burning bitter.

Monosaccharide Reactions

The first step of caramelization in monosaccharides comprises an intramolecular rearrangement (enolization) followed by β-elimination of water (dehydration). This is the key reaction because it initiates subsequent reactions (dicarboxylic cleaving, retro-aldol reaction, aldol condensation, and radical reaction) that give rise to aliphatic sugar degradation products, which react further to produce oxygen heterocyclic and carbocyclic compounds. These compounds, in addition to their aroma properties, possess conjugated double bonds, which in turn absorb light and produce the caramellike color. A scheme of these reactions is shown in Figure 6. At acidic pH, the enolization and dehydration allow the maintenance of the carbon chain length. However, at basic pH, there is a predominance of fragmentation by retro-aldolization reactions and further reaction of the fragments by aldol additions.

Reactivity in acidic conditions

As stated in Figure 5, during the heating of acidic foods – for example, fruit juices – enolization and subsequent dehydration are the predominant reactions. The first step involves the slow enolization to produce enediol compounds, which are important chemical species in caramelization. As shown in Figure 7, glucose can enolize to fructose, giving rise to the formation of two different enediol compounds (1,2-enediol and 2,3-enediol). They can continue the reactions by subsequent dehydrations producing different deoxyosones, which can undergo further dehydrations and cyclization, giving rise to the formation of heterocyclic compounds like 5-hydroxymethylfurfural

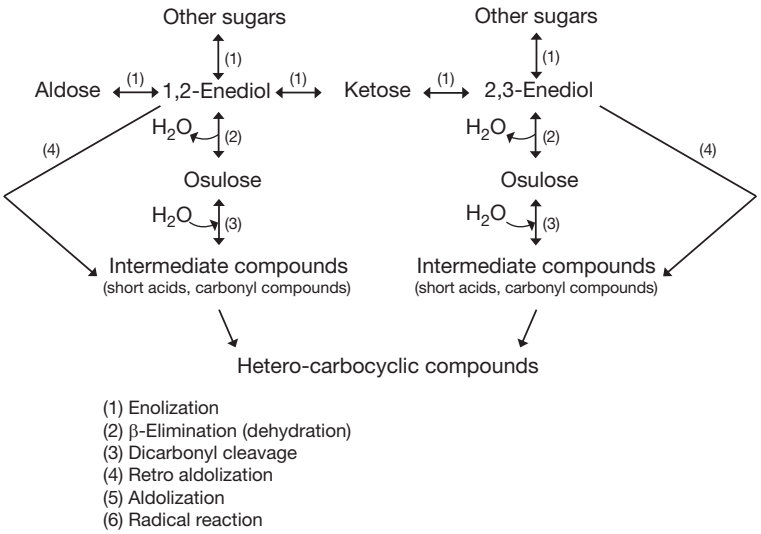


Figure 6 Main pathways of monosaccharides caramelization.

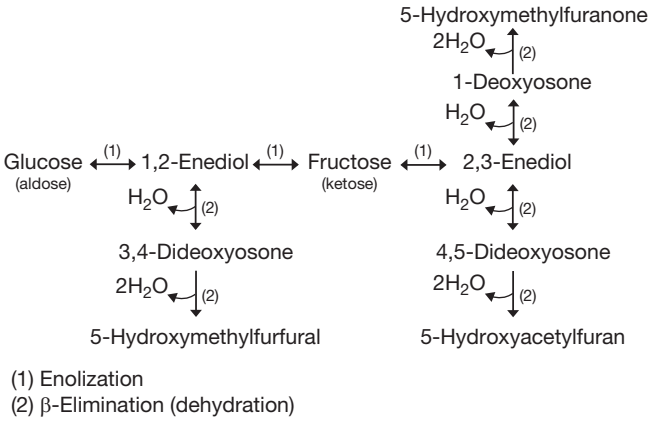

Figure 7 Caramelization of glucose–fructose.

(HMF), 5-(hydroxymethyl) furan, furfuryl alcohol, and/or 5-(hydroxymethyl)furanone. Pentoses give rise to the formation of furfural as the main degradation product, whereas hexoses produce 5-HMF. Dehydration reactions are very important, yielding a large amount of water released to the medium (up to 40% by weight). In addition, the release of short-chain fatty acids, such as formic or acetic acid, produces a drop in the food's pH. Finally, intramolecular glycosidic bonds can be formed during caramelization. For example, the heat treatment of glucose syrup above 100 °C gives rise to the generation of 1,6-anhydroglucopyranose while the heating of sucrose caramel produces 1,6-anhydroglucopyranose, 1,6-anhydroglucofuranose, and difructosedianhydride.

Reactivity in basic conditions

In alkaline foods, such as some baked goods, the enolization reactions stated in the previous sections are favored. In addition to this, there is also a degradation of the carbon skeleton. The enolization steps give rise to the generation of other sugars like mannose or psicose by the Lobry de Bruyn–van Ekenstein rearrangement. The enolization can be also favored by oxidizing reagents such as Cu^{2+}, which produces carboxylic acids and hydroxy acids. In addition, the dicarbonyl cleavage and retro-aldolization reactions produce hydroxy aldehydes and hydroxy ketones like glyceraldehyde and dihydroxyacetone. Further reactions (retro-aldolization and β-dicarbonyl cleavage) give rise to the generation of large amounts or aromatic compounds (as stated in Table 2).

Oligosaccharide Reactions

When a mixture of oligosaccharides–polysaccharides is heated over their fusion point, the first reaction taking place in acidic medium is the glycoside hydrolysis, releasing different amounts of mono- and disaccharides, which react faster than the oligosaccharides. In addition to glycosidic bond hydrolysis, the subsequent formation of glycosides – that is, transglycosidation and formation of oligomers – is also possible in an acidic medium. For example, during glucose caramelization, different amounts of the disaccharides trehalose, maltose, isomaltose, and gentobiose are found. In the case of sucrose syrup, more oligomers of fructose with a degree of

polymerization (DP) up to 25 units are also generated. So, caramelization is not only a degradative reaction. In the case of basic foods, disaccharides can suffer the Lobry de Bruyn–van Ekenstein rearrangement like monosaccharides. For example, lactose can be transformed into lactulose by the catalytic activity of sodium aluminate.

Apart from these reactions, enolization and dehydration with further aldol-like reactions also occur, to produce low-molecular-weight compounds such as HMF, like in the case of monosaccharides. However, the formation of HMF (and others) is favored in oligosaccharides because of the cleaving of the glycosidic bond between the monosaccharide residues is more efficient than water elimination by glucose. Therefore, the 4-osulose formed at the reducing end by 1,2-enolization gives rise to HMF and an oligosaccharide with one sugar less (Figure 8).

The desirable effect of caramelization development is the production of caramellike color and flavor. The caramelization of both monosaccharides and oligosaccharides generates colored compounds. Most of them are low-molecular-weight compounds such as dihydrofuranones, cyclopentenolones, cyclohexenolones, and pyrones. In addition, high-molecular-weight polymers are also produced by the fusion of reactive intermediary compounds like osuloses. These reddish-brownish colloidal polymers range from slightly acidic to basic in nature, although their exact chemical composition is not known.

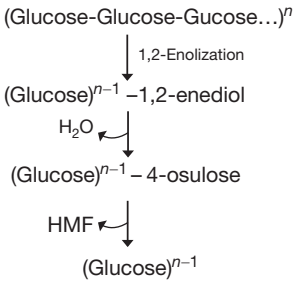

Figure 8 Fragmentation of oligosaccharides by caramelization.

Maillard Reaction

The MR is a set of chain chemical reactions that give rise to the formation of brown pigments with modifications in color, odor, and taste of thermally treated foods. It occurs most readily at low-intermediate water activity and basic pH. The general scheme of the reaction can be seen in Figure 9.

(A) The first step of the MR consists of the condensation of a carbonyl group with an amino group, and after dehydration, an unstable Schiff base is formed, which is transformed rapidly into an *N*-substituted glycosylamine. This reaction is reversible because in a strong acidic medium, the sugar and the amino acid can be regenerated. The amino group can be a free amino acid, the side chain of an amino acid (like lysine) incorporated in a protein, or the amino group of the last amino acid in each protein. In the case of the carbonyl groups, they are usually reducing sugars, although they can be also carbonyl compounds from the intermediate stages of the MR and/or lipid oxidation.

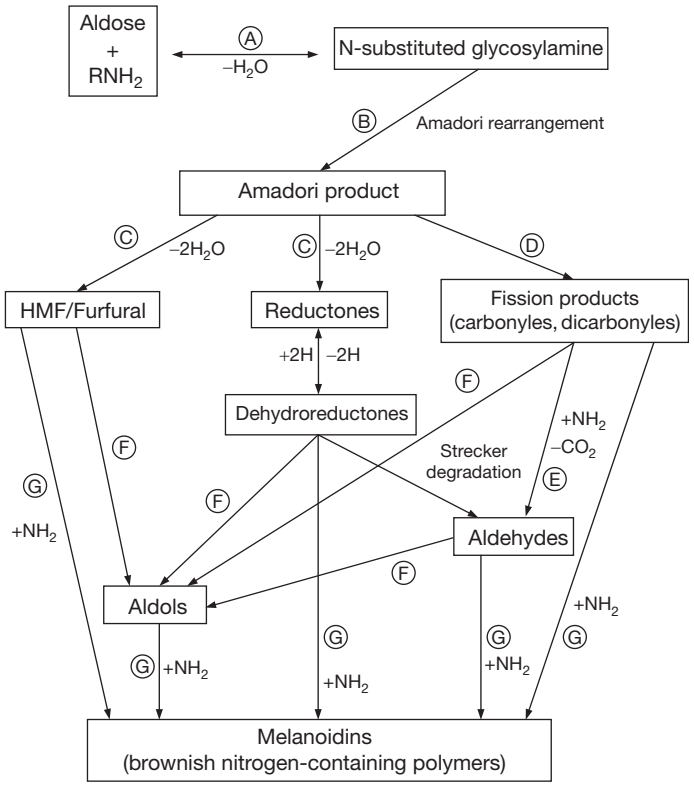

Figure 9 The Maillard reaction (MR).

(B) The next step consists of the irreversible rearrangement of the *N*-substituted glycosylamine. When the molecule is an *N*-substituted aldosylamine, by means of the Amadori rearrangement, the 1-amino-1-deoxy-2-ketose is formed. However, when the starting product is an *N*-substituted ketosylamine, a 2-amino-2-deoxy-2-ketose is formed by means of the Heyns rearrangement. The Amadori and Heyns products are decomposed, depending on the pH and temperature of the medium, giving rise to the formation of different intermediate compounds. These comprise the intermediate steps of the MR.

(C) The Amadori products can decompose by a retro-Michael reaction, removing the amino group and further dehydration. Different osuloses – named 1-, 3-, or 4-deoxyosone or reductones – are formed. At low pH, a 1,2-enolization occurs, giving rise to the final formation of HMF and furfural. A 2,3-enolization takes place at basic pH. The reductones so formed can be dehydrated again to form dehydroreductones, which form polymers by reacting with amino groups at the advanced stages of the MR.

(D) The Amadori compounds can be split into different fission products, such as acetaldehyde.

(E) The interaction of amino acids with dicarbonyl compounds, like dehydroreductones or fission products, is known as the Strecker degradation and implies the loss of amino acids in foods. As a result of this degradation pathway, new aldehydes with one carbon atom less – lost as CO_2 – are formed.

The next steps ((F) and (G)) are known as the advanced steps of the MR, where two different classes of compounds are formed: melanoidins and volatile aromatic compounds.

(F) Volatile aromatic compounds are formed directly from the Amadori compounds and do not need the mediation of free amino groups. However, 1% of the total volatile compounds produced are formed by the reaction of 2-deoxyglucose with amino acids. As in the case of the Strecker degradation, many different chemical odorants are formed, like pyrazines, pyrroles, thiazoles, and thiophenes. For example, alquilpyrazines are the main flavors of roasted meat, while boiled meat gives rise to other products like 2,4,5-trimethyl-3-thiazoline.

(G) *Melanoidins* are brown polymeric anionic compounds produced by means of the condensation of aminated products of the intermediate stages of the MR such as *N*-substituted pyrroles, *N*-substituted 2-formylpyrroles, and 2-furaldehyde. Melanoidins have a wide molecular weight and different absorbance spectra with maxima in the ultraviolet (280 nm) and visible (420 nm) ranges.

Chemical Links between AA Degradation, Caramelization, and the MR

In the previous sections, the different chemical pathways of AA degradation, caramelization, and the MR have been described. Although each set of reactions depends on a different series of variables, all of them share some chemical species that can take part in another kind of NEB. Therefore, the development of one of these pathways may lead to a higher development of a different pathway. The complete set of chemical links is shown in Figure 10.

The degradation of AA and caramelization share similarities, such as the pH influence and the formation of some chemical

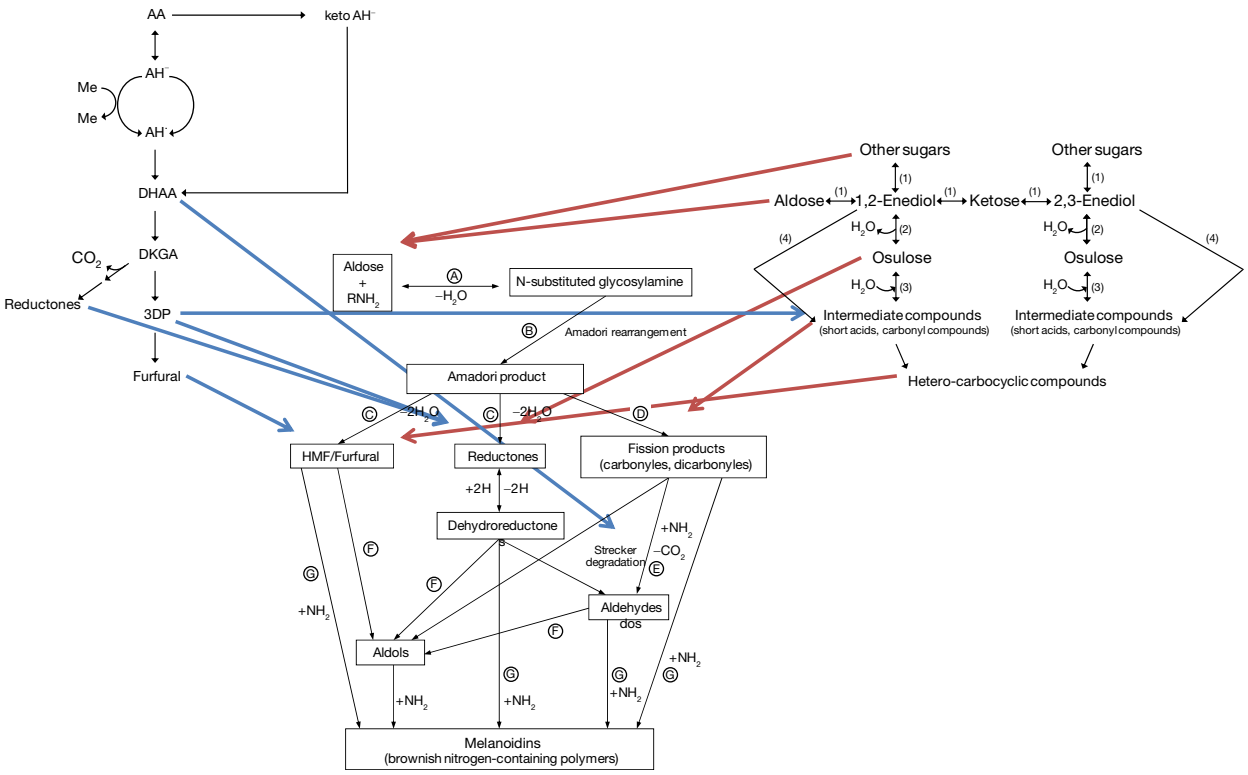

Figure 10 Chemical links among AA degradation, caramelization, and the MR.

species like furfural or reductones. These carbonyl compounds take part in the Strecker degradation and DHAA. The DHAA reacts as an amino acid to generate scorbamic acid, which gives rise to the formation of reddish–yellowish oligomers. In addition, the subsequent polymerization of these compounds and other carbonyls produces melanoidins (nitrogen-containing polymers) or nonnitrogenous polymers (caramel-like).

In the case of caramelization, the most direct link with the MR comes from the reaction of monosaccharides with amino compounds. Therefore, the enolization reactions can produce more aldoses to increase the development of the MR. Furthermore, the hydrolysis of oligosaccharides to produce monosaccharides also increases the speed of the MR. Other highly reactive species formed during caramelization – osuloses – can also take part in the MR through the formation of dehydroreductones or other carbonyl compounds. In addition, the heterocyclic compounds – such as HMF – generated during caramelization reactions can be also included in the structure of melanoidins. Caramelization can be also favored by the formation of 3 DP during AA degradation. This chemical species can react with further caramelization intermediate compounds to produce hetero- and carbocyclic compounds.

When foods are heated, the first reactions taking place are AA degradation and MR. Because of the relative low amount of AA, large amounts of furfural or reductones cannot be produced, but DHAA can readily come into the MR through the Strecker degradation. When temperature exceeds 100 °C, the surface of foods dehydrates, increasing the rate of caramelization. Furthermore, the reductones generated during the intermediate-advanced steps of the MR speed up the formation of hetero- and/or carbocyclic compounds of caramelization. Furthermore, the formation of short-chain carboxylic acids during the MR and caramelization decreases the food's pH, increasing again the development of brownish polymers from the MR and caramelization.

A good example of a MR–caramelization collaboration could be biscuit baking. The biscuit surface is covered with beaten egg and the dough goes into the oven, where the temperature increases slowly. As temperature reaches 50 °C in the inner part of the biscuit, amino compounds and sugars start to react through the MR. The inner part will never exceed 100 °C, so caramelization will never develop. At the same time, in the outer part, the MR will develop due to the presence of glucose and egg proteins. This will create a large pool of intermediate compounds that will take part in caramelization when the temperature reaches 120 °C. At this time, an extensive brownish color and flavor will develop at the surface by the combined action of the MR and caramelization.

Conclusions

The Western diet includes different heat treatments, which influence both the organoleptic and health attributes of foods. Depending on their composition and the conditions of the heat treatment, that is, temperature, time, humidity, pH, and the presence of metals, different chemical reactions take part. The degradation of AA is developed in foods like fruits or vegetables submitted to heat treatment and preservation, that is, canned vegetables or jams, while caramelization is produced mainly in foods that undergo a severe heat treatment, such as coffee or cocoa roasting. In the case on the MR, those foods rich in proteins and carbohydrates, like milk, are prone to this kind of NEB. These three reactions usually take part at the same time during heat treatment, and due to their interconnected chemical pathways, they generate a plethora of by-products responsible for the special color and aroma of heat-treated foods. Furthermore, the MR and lipid oxidation share other pathways, reinforcing the idea that food processing and storage produce alterations by many different ways. Therefore, under a technological point of view, it is complex to stimulate any of these reactions trying to keep the others stable. However, the knowledge of their shared chemical pathways allows to food producers the development of healthier and appetizing foods.

Introduction

The world has two main types of buffaloes: (1) riverine buffaloes (*Bubalus bubalis*) and (2) swamp buffaloes (*B. carabanesis*), whereas the third type known as Mediterranean buffaloes evolved from these two major types. The riverine buffalo is found in South Asia and Southwest Asia, whereas the swamp buffalo is present in East Asia and Southeast Asia. The Mediterranean buffaloes are found in Italy, the Balkan states, Turkey, and in some parts of Russia. The best buffaloes of the world are found in the Indian subcontinent, and India is the leading buffalo country, which produces 96 million tons of milk annually. Pakistan produces 27 million tons annually. Buffalo milk (BM) is ranked second after cow milk (CM) in the world as the BM produced is more than 12% of the world's milk production. About 70% of the total BM is produced by India. World milk production has doubled in the last decade, with BM production ranking second after bovine milk.

Buffalo breeds of India are known for their high production potential and high efficiency for utilization of low-quality roughages and sustaining poor-quality husbandry practices than cattle. The major population of buffalo is from rural India where farmers keep 1–4 milk animals as a subsidiary occupation for sustainable rural livelihood and nutritional security. The most important traits contributing largely toward profit are high milk-producing ability and low maintenance cost. Various compositional and functional properties render the BM eminently suitable for manufacture of dairy products such as ultra-high temperature (UHT) cream, dried ice cream mixes, dairy whiteners, edible casein, and caseinates. However, from a technological point of view, BM is often not considered an ideal fluid for manufacture of several types of cheeses, milk powders, evaporated and condensed milk, and infant formulas.

Due to several biochemical differences between BM and CM, conventional processing technologies are often unsuitable and cannot be applied directly for processing BM. Emerging R&D trends in BM processing suggest that there is an ample scope for tailoring the technology, particularly in the developing world where buffaloes enjoy a preeminent position in milk production. Several region-specific traditional milk products owe their unique characteristics to BM. The suitability of buffalo as a milk producer is now distinctly gaining importance throughout the world. A major bottleneck in the enhancement in production potential of buffaloes has been the inadequate research and paucity of information about it. It is often falsely presumed that the scientific information generated on cattle can be extrapolated to buffaloes.

Nutritional Significance of Milk

Milk is termed as the almost complete food for human diet. It is the first food of the newly born human being and other mammals. It is a food that contains all the nutrients required for the newly born baby, pregnant mothers, patients, and the old age people. There is no doubt that milk and milk products have played a key role throughout the development of human civilization and supply most of the essential nutrients in significant amounts than any other single food. It is very essential for the growth and development of a newly born child. Milk contains all the essential nutrients like protein, fat, lactose, vitamins, and mineral matter for normal growth and performing different functions for the body systems. Not only is it the most important food during early childhood, but also, in one form or another, it continues to be used for normal diet throughout the life span. It is also the most versatile of all the animal-desired food commodities, and it is a component of the diets of many physical forms like cheese, yogurt, ice cream, ghee, milk powders, and many other forms of fluid milk. The calcium content is higher in BM than in milk from cow, and it contains more colloidal calcium and phosphorus. Buffaloes are the second largest source of milk supply in the world. In India, nearly half of the milk processed by the organized dairies comes from buffaloes. The BM is richer in fat than milk from cattle. Generally, it has also higher levels of proteins, lactose, and ash, although these differences are not as high in fat. The absence of β-carotene in BM, which is present in CM, is another notable characteristic. The swamp buffalo has traditionally been regarded primarily as working animals especially in China and other rice-growing countries of the Far East. A website depicting worldwide buffalo distribution is given at the end of 'Further Reading' section of this article. It is, however, milked in many countries and yields a product rich in butter fat and similar in all respect to that of milch river breeds. It is probable that the animal has a considerable potential for milk production if managed and bred to that end.

Milk Proteins

BM proteins are complete proteins of high quality, that is, they contain all the essential amino acids in the proportions required by the body. The energy value of BM proteins is 17.2 J g^{-1}. The BM is much preferred by the consumer for its rich nutrition and is drunk or transformed into valuable products such as indigenous traditional dairy products, cheese, yogurt, and ice cream. The composition of major and minor milk constituents in BM and CM is compared in Tables 1 and 2.

BM has a higher content of fat, lactose, casein, whey proteins, and minerals than CM. All of the casein in BM is present in the micellar form, while in the CM, only 90–95% of the casein is in the micellar state and the rest is present in serum phase. The proportion of bovine casein, which is micellar, depends on the temperature range and gravitational force used to sediment casein micelles. The size of casein micelles is

bigger (110–170 nm) in BM compared to CM (range 50–500 nm, mean 120–150 nm). The voluminosity of casein micelles in BM is 2.68–3.72 ml g^{-1} compared with that of CM casein that is 4.18 ml g^{-1}. Similarly, the solvation (hydration of casein micelles) of BM is lower (2.60–2.90 g water/g casein compared to 3.48 g water/g of casein from CM). The casein micelles scatter the light, which accounts for the opacity of milk. The opacity of BM casein micelles is three times higher than that of CM casein. It is determined by spectrophotometry. The BM casein micelles contain higher levels of calcium and magnesium but lower levels of sialic acid and hexose. Lactoferrin content of BM is 32 mg/10 ml compared with that of CM that is 15 mg/100 ml. No genetic polymorphism is exhibited by either the caseins or whey proteins in BM. The presence of immunoglobulin, lactoferrin, lactoperoxidase, and lysozymes in BM makes it a good dietary and health food.

The BM and colostrum, like that from cows, also contain minor bioactive components such as peptides, hormones, and growth factors, which had advantageous intestinal effects in rat trials. The BM has slightly higher concentrations of β-lactoglobulin than CM, and it is also the major whey protein, while human milk contains no β-lactoglobulin, which contains essential and branched chain amino acids, and a retinol-binding protein, which has the potential to modulate lymphatic responses. It can yield antibacterial peptides, which are released after proteolytic digestion with trypsin and are active against Gram-positive bacteria.

Milk Fat

BM fat contains higher proportions of high-melting triglycerides (9–12%) than CM (5–6%), and as a result, it is thicker. Similarly, the proportion of butyric acid-containing triglycerides is higher (50%) in BM than in CM (37%). As a consequence of the higher proportion of butyric acid-containing triglycerides, the emulsifying capacity of BM fat is superior than that of CM fat. Fat globules are bigger in BM (4.15–4.6 μm) than in CM (3.36–4.15 μm). These are rendered chargeless at much higher pH (4.5–4.6) in BM compared with that of CM (pH 4.3).

The BM fat contains less (0.22%) free fatty acids than CM fat (0.33%). The concentration of unsaponifiable matter (392–398 mg/100 ml) is also lower in BM than in CM (414–450 mg/100 ml). Similarly, phospholipid content of BM is also less (21 mg/100 ml) compared with that of CM (37.37 mg/100 ml). The total and free cholesterol contents are 275 mg and 210 mg, respectively, per 100 g of BM ghee, which is much less than the corresponding values of 330 mg and 280 mg/100 g in CM ghee. On the other hand, esterified cholesterol of BM (64 mg/100 g) is much higher than that of CM ghee (48 mg/100 g).

The nutritive interest in BM products is also higher than that in CM because of its derived products, which could be a good source of conjugated linoleic acid (CLA) for humans, like other food products from ruminants. The CLA refers to a group of polyunsaturated fatty acids (PUFAs) that exist as positional and stereoisomers of conjugated dienoic acid (18:2). The predominant isomer in foods is the cis-9,trans-11 CLA also called rumenic acid and the trans-10,cis-12 CLA found primarily in foods containing beef or dairy products. Synthetic mixtures of CLA can also be readily purchased as nutritional supplements and are composed primarily of the cis-9,trans-11 CLA and trans-10,cis-12 CLA isomers.

Numerous potential physiological effects have been attributed to CLA including those related to its potential antiadipogenic, antidiabetogenic, anticarcinogenic, and antiatherosclerotic properties. The CLA content is much higher in foods derived from ruminants than those from nonruminants and with milk having higher content than meat, because of the ability of ruminants to biohydrogenate dietary unsaturated fatty acids with the help of bacteria present in the rumen.

In dairy products from BM, the CLA concentrations typically range from 2.90 to 8.92 mg CLA/g fat, and the cis-9,trans-11 CLA isomer makes up between 73% and 93% of the total CLA. The CLA content of cheeses typically ranges from 3.59 to 7.96 mg CLA/g fat. CLA content of cows' milk ranges from 3.38 to 6.39 mg CLA/g fat. The amount of CLA found in dairy and beef is a direct reflection of the diet the animals are fed with. It was found that CLA concentration increases linearly when animals were pasture-fed and decreases when grass intake declines.

The CLA content of BM fat can be influenced by manipulating the type of dietary supplement fed to dairy animals. Supplementing the diet with polyunsaturated oils that contain either corn oil or sunflower oil increases CLA content of milk fat substantially. The BM has better emulsifying power than that of CM because of its higher percentage of butyric acid (50%) having triglycerides as compared to CM, which has only 37%. Due to this factor, more butter and ghee is obtained from BM. The BM is also less prone to hydrolytic rancidity than CM.

Milk Salts

The concentration of calcium and magnesium is about 1.5 times higher in BM than in CM. On the other hand, the concentration of sodium, potassium, and chloride is lower in BM than in CM. The content of colloidal calcium and magnesium (160 mg/100 ml and 9 mg/100 ml, respectively) in BM is much higher than the levels 80 mg/100 ml and 3 mg/100 ml, respectively, of CM. Only about 20% of calcium and 55% of magnesium in BM are present in dissolved state compared with 33% and 75%, respectively, in CM. The Ca/P ratio in BM is much higher (1.8) than in CM (1.2).

Vitamins in BM

The BM is a rich source of most water-soluble and fat-soluble vitamins. The average concentration of vitamins in milk of buffalo, Indian cow, and Western cow is summarized in Table 3. The vitamin A content is higher in BM (340 IU kg^{-1}) than in CM (230 IU kg^{-1}). However, due to the absence of carotenoids and the high fat content in BM, its total vitamin A potency per unit weight of fat is less than that of CM. Similarly, the tocopherol (vitamin E) content of BM is slightly higher (334 μg kg^{-1}) than that of CM (312 μg kg^{-1}). However, due to higher fat content of BM, its fat is poor in tocopherol (26 μg g^{-1} fat) compared with that in CM (35 μg g^{-1}).

Pigments in BM

Biliverdin IX alpha, a latent blue-green pigment, occurs in fresh BM. This pigment is absent in CM and is considered an important characteristic of BM. The average concentration of biliverdin in skim milk of Murrah and Surati buffaloes is 51.8 and 65 μg/100 ml, respectively. The concentration of this pigment in BM varies significantly at different stages of lactation and lactation number. Biliverdin was primarily associated with α, β, and γ caseins and the proteose-peptone fraction of BM. Biliverdin is converted to bilirubin during storage and souring of BM. This pigment binds lipids and imparts the characteristic greenish-yellow appearance to BM fat and butter prepared by traditional fermentation process.

Other Constituents

The BM is rich in taurine (6 mol l^{-1}), compared with that in CM (4.0 mol l^{-1}). On the contrary, the concentration of urea in BM, 17–22 mg/100 ml, is much lower than the level, 37–40 mg/100 ml, in CM. The levels of lipase and alkaline phosphatase are lower in BM than in CM. However, the free amino acids are present at a higher concentration (0.44%) in BM than in CM (0.15%).

Factors Causing Variation in the Composition of BM

Similar to the differences in CM, changes in BM composition are due to breed, feed, stage of lactation, season, lactation number, and genetic polymorphism. These variations would strongly affect the manufacturing conditions, sensory quality, and nutritional properties of the dairy products.

Breed

The breed of buffalo has a notable effect on the milk composition and yield traits. A comparison of the composition of milk from four different breeds of Indian buffaloes revealed that Murrah was the best-performing breed for fat, total

Table 3 Average concentration of vitamins in different types of milks

	Concentration in milk		
		Zebu	
Vitamins	*Buffalo (*Bubalus bubalis*)*	*Bos indicus*	*Bos taurus*
Vitamin A (IU ml^{-1})	340	230	136–157
Thiamine (μg ml^{-1})	0.2–0.5	0.2	0.2–0.8
Riboflavin (μg ml^{-1})	1.59	2.33	1.7
Pyridoxine (μg ml^{-1})	3.25	2.6–3	–
Ascorbic acid (mg/100 g)	6.72	1.94	1.65–2.75
Tocopherol (μg g^{-1})	334.2	312.2	–

protein, and casein contents. The Mehsana breed was better for solids-not-fat (SNF) and Bhadawari for total solids (TSs). Apart from the wide differences in fat content of buffalo breeds, differences in other milk constituents were not reported.

Feeding

The quality, quantity, and composition of the diet, especially the quantity and quality of proteins, have been reported to affect the composition of BM. Feeding buffaloes on a diet containing added fats increased milk yield and fat content and, in particular, with dietary tallow. A positive correlation has been reported between the energy content of the diet and fat, milk protein, and lactose contents of BM.

Age of Animal

It is a well-documented fact that the TS, SNF, lactose, and ash content increased with the increase in the number of lactations while the fat and total protein contents were not affected.

Stage of Lactation

The fat and TSs content increased, lactose decreased, and protein and ash initially decreased before reincreasing with advanced stage of lactation.

Season

Variations in composition of BM during various seasons are reported by several workers. These variations in major milk constituents have been reported. The percentages of fat, solids, and SNF were the highest during summer. Also, the percentages of Ca, P, K, Na, Cu, Mn, and Fe were the highest in summer and the lowest in winter.

Genetic Polymorphism of Milk Proteins

The genotypes of α-s1 and α-s2 caseins had no significant correlation with milk composition except for a weak ($P \leq 0.1$) correlation being reported between α-s2 casein and TS.

Differences in Physicochemical Properties of BM and CM

Precise and in-depth information on the physicochemical and functional attributes of milk is an essential prerequisite for its automated industrial processing. Most of the prevalent processing technologies apparently originated in the Western world, where CM and milk products predominate. Therefore, processing strategies were essentially based on the knowledge of the chemistry and functionality of CM. Species-related differences in milk composition have become the subject of topical interest, as processing of milk from species other than cow is being adopted by the dairy industry in several countries of the world. With the emergence of buffaloes as a predominant milk species particularly in countries of Asia, Africa, and Latin America, coupled with rapid dairy development, efforts have been made to develop and adopt appropriate technologies for BM processing. It becomes essential to understand the unique physicochemical and functional properties of BM to overcome the various challenges encountered during its processing. BM has higher specific gravity, viscosity, curd tension (CT), pH, oxidation–reduction potential (Eh), thermal conductivity (TC), and thermal expansion than CM, but its heat capacity and rennet stability are lower than that of CM. In the fluid state, BM is as stable as CM due to various physicochemical factors. On the contrary, the heat stability of concentrated milk product is significantly lower than that of BM. Owing to differences in physical properties, milk from the two species behaves differently when processed for manufacturing of the products.

Physical Properties of BM

Specific Gravity

BM is characterized by its higher specific gravity than CM. Colostrum had higher specific gravity (1.061) than normal BM (1.037). It is also confirmed that the specific gravity of colostrum and normal BM and that of mastitic BM had a lower specific gravity of 1.014 and 1.028 in clinical and subclinical cases, respectively.

Viscosity

The viscosity of BM is generally higher than that of CM. However, the viscosity of milk from both species is largely dependent on fat content. Skim, standardized (3% fat), and whole BM (6.1% fat) showed viscosities of 1.33, 1.70, and 2.02 cP, while skim, standardized (3% fat), and whole CM had viscosities of 1.17, 1.44, and 1.66 cP, respectively. This may explain the variations in the viscosity of BM cited in different studies. A rapid decrease in the viscosity of postpartum BM from 6.80 cP for the first milking to reach the 1.64 cP on the sixth day (normal milk) was also recorded. The incidence of mastitis increased the viscosity of BM to 2.79 and 2.43 cP for milk from animals with clinical and subclinical mastitis, respectively. At pH 8.6 and 10.8, the viscosities of BM were twice as high as those of CM, which was attributed to induced changes in the interactions between water and casein micelles.

Freezing Point

The cryoscopic index of milk is related to its soluble constituents (i.e., lactose and soluble salts) and is usually used to detect water added to milk. The freezing point of BM (−0.518 °C to −0.590 °C) is less than that of CM. The FP of BM is affected by season (−0.528 °C and −0.531 °C in warm and cold weathers, respectively) and farm size (−0.532 °C and −0.519 °C in small and large farms, respectively) and between organic and conventional farming methods (-0.526 ± 0.01 and -0.537 ± 0.01, respectively). The FP of BM in Germany ranged from −0.5509 °C to −0.5146 °C.

Thermal Conductivity

Knowledge of the thermal properties of milk is essential to the design of heat exchanger, condensers, and evaporators

commonly used in dairy plants. The average TC of whole BM has been reported to be 0.5689 ± 0.00734 at 42–43 °C. Normal variations in the ranges of fat and SNF had no significant effect on the TC of BM. However, the TC of BM was higher than that reported for CM, which was attributed to the differences in the fat and fat/SNF ratio of the two milks.

Electrical Conductivity

Electrical conductivity (EC), like other milk properties, is related to the milk composition, particularly the ionized constituents. BM has a lower EC (average 9.17 ± 1.51 mmhos) in comparison to CM (11.12 ± 1.56 mmhos).

Buffering Capacity

The pH of BM decreased more slowly than that of CM during acidification due to the higher buffering capacity (BC) of BM resulting from the high casein and inorganic phosphate contents of BM. The p*Ka* of BM (pH 5.32) was higher than that of CM (pH 4.90). However, both milks showed a higher BC at the acid side than the alkali side of the titration curve.

Technologically Important Characteristics of BM

Curd Tension

Early studies have shown that the CT of rennet-coagulated BM is nearly 1.5-fold that of CM mainly due to its high casein and calcium contents. It is reported that the CT for CM and BM is 27.90 and 32.25 g, respectively. A higher CT value of 55.70 g has been reported for BM, which was attributed to differences in animal breeds and methods used for the determination of CT. However, the CT of BM was greatly reduced by heating to 85 °C, boiling, and homogenization. The addition of phosphate and citrate to heated milk further decreased the CT of BM. Lowering the pH increases the CT of rennet-coagulated BM. However, for milk containing NaCl, the CT increased when the pH was lowered to 6.0, but further lowering of the pH caused the CT to decrease.

Heat Stability

Wide variations have been reported in values for the heat stability of BM due to the heating temperature as well as in the methods used to measure the heat stability. However, most studies agreed that BM was less heat-stable than CM, which is attributed to the high fat and Ca contents, and high negative correlations have been reported between fat and Ca contents, respectively, and the heat stability of BM.

pH

Alteration in pH caused considerable changes in the heat stability of BM and exhibited type A milk with a maximum (~pH 6.7) and minimum (~pH 6.9) stability.

Acid Gelation

The acid-induced gelation of BM using glucono-delta-lactone (GDL) was monitored using thromboelastography that can separate gelation into two phases, the onset gelation time and the time to get it firm. The pH at GT ranged from 5.5 to 5.9, which was higher than that reported for CM (pH 5.1–5). The pH at GT of BM increases with increase in protein content, which may explain the higher pH at GT of BM as compared with CM. Also, the pH of BM at K_{20} was 5.40–5.65, which was higher than that of CM. Linear relations were found between GT, K20 of BM, and GDL concentration and gelation temperature.

Urea Level

The low level of urea in BM (17.5 mg/100 ml) as compared with CM (40 mg/100 ml) was considered to be a factor responsible for the low heat stability of BM. The addition of small amounts of urea has been reported to improve the heat stability of BM.

TS Content

To produce 1 kg of cheese, only 5 kg of BM is required compared with 8 kg of CM required to produce the same quantity of cheese. Similarly, 10 kg of BM is required as compared with 14 kg of CM for the production of 1 kg of butter. The BM is preferred by dairies because it is best for making Mozzarella cheese. Cheddar cheese from BM is also superior to CM cheese because of its better nutritional value and acceptability. Better calcium and phosphorus ratio and less sodium and potassium in BM than in CM make it a better nutrition supplement for infants. This very fact attracts 30–35% higher price to BM as compared to CM. Its average fat globule size is high (2.04 μm) as compared to CM, that is, 1.86 μm. Similarly, its calcium level is high and cholesterol level is low ($0.65\ mg\ g^{-1}$) as compared to CM ($3.14\ mg\ g^{-1}$). The BM has 11.42% more protein than CM. The BM also has a high level of natural antioxidant named tocopherol peroxidase. The patients allergic to CM can benefit from consuming BM.

Rennet Coagulation Time

BM is characterized by a faster coagulation than CM. Also, the rennet coagulation time (RCT) of BM was almost unchanged when the milk was diluted with an equal volume of water while a similar treatment markedly increased the RCT of CM. A close correlation was found between the RCT and the levels of colloidal calcium in diluted milk from different species. RCT increased sharply at a colloidal calcium level of <50 mg/100 ml. The RCT of BM was affected differently than the RCT of CM due to the type of milk-clotting enzyme. For example, using *Endothia parasitica* protease, both BM and CM showed similar RCT, while BM coagulated faster with the use of calf rennet. The RCT of BM is more sensitive to the addition of NaCl, H_2O_2, and Na_2CO_3 than that of CM. Storing of BM at 7 °C for up to 24 h had a slight effect on its RCT while the RCT of CM increased under the same conditions. The increase in the RCT of BM by heat treatments is less pronounced than that

of CM. These differences can be attributed to the differences in the colloidal phase of the two milks and explain the differences in the behavior of buffalo's and cow's milks during cheesemaking.

Comparison of Quality of Dairy Products from BM and CM

Edible Casein and Caseinates

Due to the higher content of casein in the form of larger micelles and presence of all of the casein in the micellar state, it is easier to manufacture edible casein and caseinates from BM. The yield of these products is also higher from BM due to lower losses in the whey because of bigger size and low hydration of the micelles.

Coffee and Tea Whiteners

Due to higher protein, fat, and calcium content in BM, the yield of whitener from BM is higher. The product is superior due to higher whitening capacity when made from BM. The bigger size and greater opacity of casein micelles from BM may be responsible for better quality product. The higher emulsifying capacity of BM fat may also be responsible for the better dispersion of whitener used in coffee or tea.

Yogurt

BM is better suited for the manufacture of yogurt, as its manufacture is easier and there is no need for prior concentration or addition of dried milk due to higher TS in fat.

Condensed Milks (Sweetened and Unsweetened)

BM behaves quite differently from CM during production and storage of condensed and evaporated milk. This is due to (1) differences in micelle composition of milk proteins, that is, casein; (2) higher levels of milk proteins (both casein and serum proteins), milk fat and lactose; and (3) higher calcium content and lower heat stability of milk.

Ice Cream

BM is considered as a better source of fat for ice cream due to higher emulsifying capacity. Further, BM ingredients produce better body and texture in ice cream.

Infant and Health Foods

Better absorption of fat due to higher emulsifying capacity; better absorption of calcium due to higher concentration of calcium, magnesium, lactoferrin, free amino acids, esterified cholesterol, and taurine; and lower concentration of sodium, potassium, chloride, urea, and free and total cholesterol in BM compared to CM are beneficial for human nutrition. These attributes make BM superior than CM as an ingredient for infant and health foods, provided its CT is reduced to improve the digestibility.

Problems in the Manufacture of Some of the Cheeses from BM

Cheddar cheese is largely manufactured mainly from CM in major cheese-producing countries. However, in India, the major share of milk production is from buffaloes. The adaptation of well-known technology for the production of various products from BM posed many problems primarily because of its qualitative and quantitative differences. CM, in general, is considered to be the most suitable raw material for cheese. The main problems encountered in the manufacture of hard-type cheese from BM have been faster renneting time, lower retention of moisture, slower lipolysis and proteolysis, and poor flavor, body, and texture development. The BM cheese is criticized for its higher fat content and hard, rubbery, and dry body and texture. The defects in BM cheddar cheese are attributed mainly to the physicochemical and compositional characteristics of milk. The high BC of BM due to its higher calcium, phosphate, and casein content is the cause of slower development of acidity. Faster renneting time may be attributed to its higher colloidal content (about 160 mg/100 ml) compared to only 8 mg/100 ml in CM. The lower retention of moisture in the curd may be the result of low solvation (hydration) of its calcium compared to CM casein. Hard, rubbery, and dry body may be due to the high CT, which, in turn, is the result of higher content of casein with bigger size of the micelle, high content of calcium and magnesium more so in the colloidal state, large proportion of solid fat with bigger size of the globules, and low voluminosity and solvation of its casein micelles compared to those of CM. The slower rate of proteolysis and lipolysis is the cause of higher CT of BM. Mozzarella cheese manufactured from BM is the most highly valued pasta filata cheese in Italy and the United States. The BM cheeses in general are becoming increasingly popular throughout the world, and its demand is rising at a rate that is among the highest for any food product. The high demand in specialty dairy products from BM is due to its high sensory quality along with the high adaptability of the animals. BM is reputed for its richness and creaminess. Certain varieties of cheese like Mozzarella and white pickled Domiati cheese are superior in quality when made from BM. The manufacture of Domiati cheese from BM is easier, as the handling of curd is easier due to more firm curd and the yield is higher.

Technology for Manufacture Cheese from BM

In view of the earlier-mentioned problems associated with the manufacture of BM cheese, research was initiated in the area of cheese in early 1960s at the National Dairy Research Institute, Karnal, India. Since a major share of milk production is from buffaloes and BM is known to be unsuitable for cheese production, attention was given to this raw material. Cheddar cheese, the most common variety made in India, does not develop proper flavor, body, and texture when it is made from BM. The main problem is the faster rate of syneresis, which results in lower moisture content in finished cheese. This, in turn, affects adversely the three most important biochemical reactions, that is, glycolysis, proteolysis, and lipolysis,

which constitute the major activity in cheese, flavor development. In order to overcome this problem, attempt should be made to develop a manufacturing technique, which would ensure greater retention of moisture and accelerated rate of glycolysis, proteolysis, and lipolysis. A presalting method was developed at this institute, which envisages the addition of 1% salt to the cheese milk that resulted in the best product. However, the addition of salt to the milk makes the whey unsuitable for utilization in food products.

Butter: Manufacture

SS Deosarkar and CD Khedkar, College of Dairy Technology, Pusad, India
SD Kalyankar, Government College of Dairy Technology, Udgir, India

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Butter is a dairy product made by churning fresh or fermented cream or milk. Conversion of milk fat into butter is a very old way of preserving milk fat. Butter accounts for a major portion of the nutritive value of milk. Butter is generally used as a spread and a condiment, as well as in cooking applications, such as baking, sauce making, and pan frying. Butter consists of butterfat, water, and milk proteins. Most frequently made from cow milk, butter can also be manufactured from the milk of other mammals, including sheep, goats, buffalo, camels, and yaks. The most dominant source for production of butter today is bovine milk. Throughout the centuries, butter was manufactured at farms in small quantities with considerable variation in quality. In the nineteenth century, industrial production of the butter started through centralization and mechanization, which resulted in substantial improvement in the quality of butter. The largest butter-producing countries are the United States, Germany, France, New Zealand, and Russia. According to the Codex Alimentarius Commission under the joint FAO/WHO Food Standards Programme, butter is a fatty product derived exclusively from milk. A 100 g portion of butter must contain a minimum of 80 g fat and a maximum of 16 g water and nonfat milk solids.

According to the USDA, one tablespoon of butter (14 g/0.5 oz) produces 420 kJ (100 kcal), all from fat, 11 g (0.4 oz) of which 7 g (0.25 oz) are saturated fats and 30 mg (0.46 g) are cholesterol. In other words, butter consists mostly of saturated fat and is a significant source of dietary cholesterol. For these reasons, butter has been generally considered to be a contributor to health problems, especially heart disease. For many years, vegetable margarine was recommended as a substitute, because it is higher in unsaturated fat and contains little or no cholesterol. In recent decades, though, it has become accepted that the trans fatty acids contained in partially hydrogenated oils used in typical margarines significantly raise undesirable low-density-lipoprotein (LDL) cholesterol levels as well. Trans-fat free margarines have since been developed. Proponents of the consumption of organic butter, such as the nutritionist Mary Enig, state that, because butter is nutritious and 'is rich in short and medium chain fatty acids,' this can have a positive effect on health and prevent disease. Butter contains only traces of lactose, so moderate consumption of butter is not a problem for lactose intolerant people. People with milk allergies need to avoid butter, which contains enough of the allergy-causing proteins to cause reactions. Butter can play a useful role in dieting by providing satiety. A small amount added to low fat foods such as vegetables may stave off feelings of hunger.

Historical Background

The art of butter making has a long history. In India, ghee has been a symbol of purity and an offering to the Gods – especially Agni, the Hindu God of fire – for more than 3000 years. References to ghee's sacred nature appear numerous times in the Rig Veda, circa 1500–1200 BCE. The tale of the Lord Krishna during his childhood stealing butter remains a popular children's story in India today. Since India's prehistory, ghee made from butter has been both a staple food and used for ceremonial purposes such as fueling holy lamps and during funeral prayer.

Manufacture of creamery butter has been confined to the 'colder' regions of the world, where gravity creaming has been successful. References to butter are found in the Old Testament. In the past, butter was an article of commerce and a sign of wealth. Up to the middle of the nineteenth century, factory butter making was unknown. Most of the butter was made on the farm from cream obtained by gravity creaming. The cream was decanted into a wooden churn and subjected to shear and mild aeration with the help of a stirrer or by rotating the vessel. Once the fat formed clumps, butter milk was removed and the fatty mass gathered and excess moisture removed. This process hardly met modern hygiene standards. In most cases, cream gets soured before converted into butter. The wooden churns were extremely difficult to keep clean. Lack of refrigeration would lead to swift growth and proliferation of putrefactive organisms. Addition of common salt to the butter grains prior to working was the only preservation methods available in those days. The presence of significant quantities of lactic acid from the sour cream would have contributed to the subsequent preservation of the butter. Butter has also been stored in containers immersed in peat swamps, taking advantage of the lower temperature and virtually anaerobic conditions.

An ancient method of butter making, still used today in parts of Africa and the Near East, involves a goat skin half filled with milk, and inflated with air before being sealed. The skin is then hung with ropes on a tripod of sticks, and rocked until the movement leads to the formation of butter. The late nineteenth century witnessed the inventions of mechanical cream separators and mechanical refrigeration. The advantages of heat treatment to improve the keeping quality of dairy products were soon realized. This led to the establishment of creameries, where milk was separated, and the availability of larger quantities of cream led to the mechanization of butter making. Initially, the churns were of wooden construction, essentially a scale-up of the barrels used for hand production, but then were slowly replaced by aluminum and then stainless steel until the technology was overtaken in the second half of the twentieth century by the development of continuous butter making processes. By the beginning of the twenty-first century, batch churning had been replaced in dairies by continuous churning processes.

Classification of Butter

Many types of butter are found in the market. These differ with the type of cream from which they are made and with variations in

the manufacturing process. Unless specifically mentioned, the different kinds of butter may or may not have been salted. A brief description of several kinds of butter is as follows:

- *Pasteurized cream butter*: Usually made from pasteurized sweet cream. Such butter has a milder flavor than that made from similar cream not pasteurized.
- *Ripened cream butter*: Made from cream in which a pleasant delicate aroma has been developed before churning by ripening (i.e., inoculating the cream with a lactic culture and holding it at a desired temperature). Properly made, ripened cream butter has a delicate flavor.
- *Unripened cream butter*: Made from unripened cream. The flavor of such butter is usually mild.
- *Salted butter*: Butter to which salt has been added.
- *Unsalted butter*: Contains no added salt.
- *Sweet cream butter*: In this case, the acidity of the churned cream does not exceed 0.20%.
- *Sour cream butter*: Made from cream which has more than 0.20% acidity.
- *Fresh butter*: Such butter has not undergone cold storage. (Usually, fresh butter is not kept for more than 3 weeks.)
- *Cold storage butter*: This butter has been stored at a temperature of about −18 °C (0 °F) for some time. (Generally cold storage butter is from 1 to 6 months old when offered for retail trade.)
- *Dairy butter* (USA): This is butter made on a farm. It is usually made from unpasteurized sour cream, which has not been standardized for acidity. This butter generally has a sour flavor due to the high acid content of the cream.
- *Creamery butter*: This is butter made in a creamery or dairy factory. It is more uniform in quality than 'dairy butter.'

Industrial Butter Making

There are two completely different methods for manufacturing butter. These are the churning method and the emulsification method. In the churning method, crystallization of the fat takes place in cream, followed by a phase inversion in which the oil-in-water emulsion of the cream is turned into a water-in-oil emulsion by strong mechanical treatment. The fat content is then concentrated by draining off the buttermilk. The butter is finally plasticized by mechanical working.

In the emulsification method, the aforesaid first three subprocesses are carried out in reverse order. First, the fat emulsion is concentrated to a fat content corresponding to the composition of the final product, then a phase inversion is carried out followed by crystallization, and finally a coherent fat mass is formed and plasticized (Figure 1).

Churning Method of Butter Manufacture

The basic principle of the churning method is that air is mixed into cream where it forms foam. Simultaneously, some of the fat globule membranes are disrupted leading to liquid fat being squeezed out of the damaged fat globules and spread at the interface of the foam making fat globules stick to the lamella of the foam. By further agitation, the foam collapses, and the fat globules are forced so closely together that they coalesce into small lumps. These lumps are further pressed into small butter granules.

A batch-type butter churn may vary in capacity from a few liters to a maximum of about 45 000 l. These churns were originally made of wood but later were replaced with stainless steel. After cleaning and disinfecting the churn, it must be specially prepared to prevent the butter from sticking to the surface. With wooden churns, this is achieved by scalding with boiling water and immediately cooling with chilled water. This treatment leaves a film of water on the surface of the wood and prevents the butter from adhering to it. All wooden equipment must be kept wet until used.

Batch butter churns may be barrel or cone shaped with fixed or rotating internal 'workers.' As the churn is rotated, the combined actions of rotating and beating cause the cream to break, forming the butter grains (fatty phase) and buttermilk (aqueous phase). During the first few turns, gases (e.g., carbon dioxide from heterofermentative fermentation) may be liberated from the cream. In order to maintain an even pressure within the churn, it is necessary to release these gases. This is done by depressing a small valve in the lid of the churn. Each churn has an indicator glass to see what is happening inside the churn. When hand churning, the cream feels heavier when it begins to thicken. This takes about 15–20 min from the beginning of churning. The cream breaks and forms small grains of butter which are clearly seen on the indicator glass. The actual size of the butter grains varies according to the type and size of the churn. For hand churning, the grains should be kept small, approximately 3 mm in diameter – traditionally stated as the size of wheat grains.

Chilled water at approximately 5 °C is used to harden and control the size of these grains, as well as to remove the traces of buttermilk. Washing reduces the yield and is not necessary if the cream is of good quality and all the necessary hygienic precautions have been observed. Traditionally, well washed butter will have a longer shelf life than unwashed and overworked butter. Salt may be added dry or in the form of brine as a final wash. The addition of brine (10% solution) to butter grains has been used to reduce the need for chilled water. This can be important during warm weather when there is a lack of chilled water. It prevents streakiness due to uneven mixing of the salt. The butter grains are 'worked' to expel excess moisture, create an even, fine distribution of water droplets, and produce a close textured, evenly colored product. During the period of working, drainage, and addition of dry salt, samples are tested to determine the salt and moisture contents. The operator determines the 'end-point' of working when the moisture content is between 15.5% and 16% and by visual assessment of the butter. At this stage, the butter is removed from the churn in readiness for packing. The moisture content of butter must not exceed the legal maximum limit of 16%. Manufacturers attempt to be as near that limit as possible to ensure the maximum yield.

Pretreatment of the Cream Prior to Churning

It is necessary to concentrate the emulsion in milk to a fat content of about 35–42 g/100 g or even higher in a centrifugal separator. The cream is heated to 85–110 °C for 10–30 s in a plate heat exchanger in order to kill any pathogens and to reduce the load

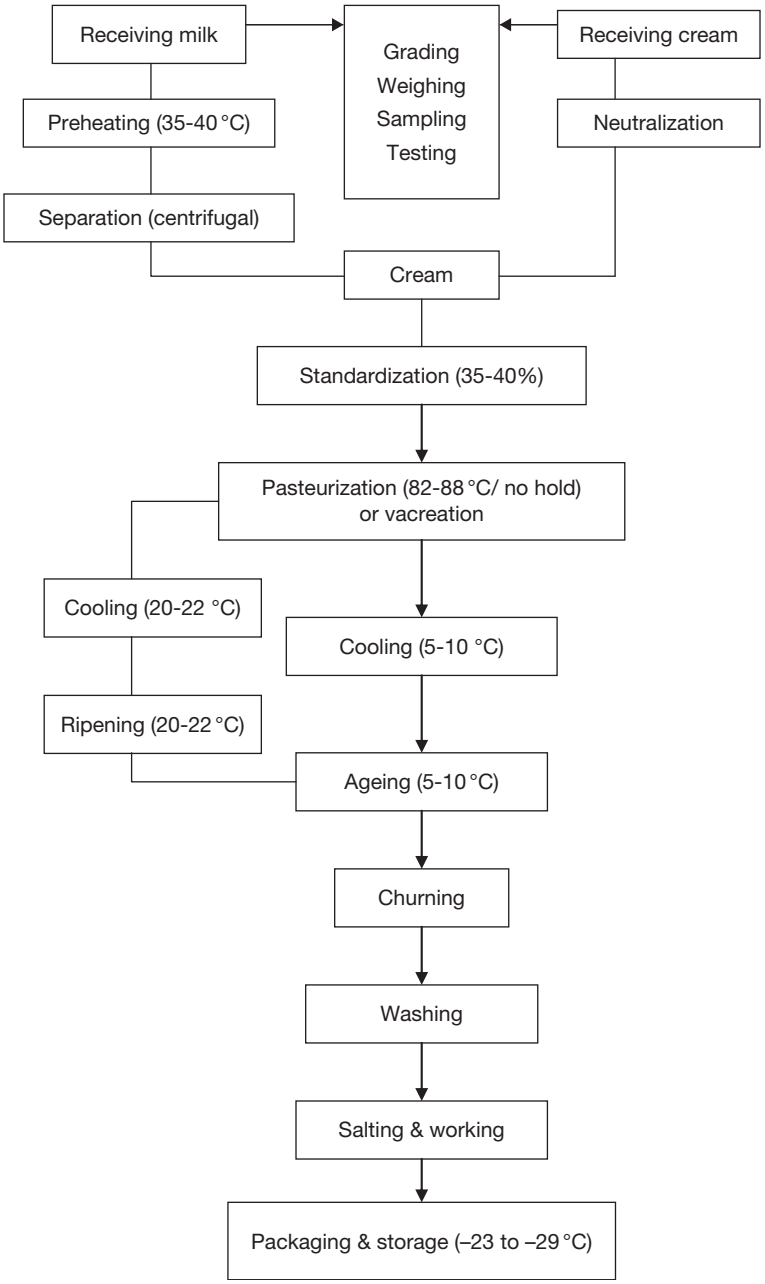

Figure 1 Process flow diagram for butter.

of spoilage-type microorganisms. It is possible to combine high-temperature-short-time (HTST) treatment with vacuum deodorization, which is termed as vacreation. A vacuum chamber could be inserted after the heating unit in the machine. Such treatment might have a fine effect on the flavor of the butter, for instance, if flavors originating from feeding of the cows occur. The system is mainly used in countries where dairy cows fed on pasture with strong tasting weeds, which cause off-flavors in the milk. The cream is cooled immediately after heat treatment as churning is impossible unless the milk fat is solidified. In one cooling procedure, the cream is cooled directly to a low temperature (4–5 °C), kept overnight, and then churned. This treatment results in formation of mixed fat crystals, also called corn crystals, in which a considerable part of the low melting triacylglycerols, due to the fast cooling, is trapped in a crystal lattice formed by high-melting triacylglycerols. Butter churned from such cream will have a lower fat content and, therefore, a very firm consistency and rather poor spreadability. When milk is converted to butter, four basic main changes – concentration, crystallization, phase inversion, and plasticizing – are necessary.

Manufacturing Process

The cream treatment has a strong effect on both the butter-making performance and the quality of the butter. It is

performed in four main stages, namely pasteurization, vacreation, cooling, and microbial and/or physical cream ripening.

Pasteurization

Cream is separated from milk by centrifugation. Normally, the raw milk is preheated to above 40 °C to ensure that all of the fat is in a liquid state so that the milk-fat globules are less susceptible to shear damage. The optimum temperature for separation is 63 °C, higher temperatures causing denaturation of whey proteins which, though not critical for butter making, may adversely affect the properties of the skimmed milk. For batch churning the cream may be separated at 35 or up to 40 g fat 100 g^{-1}, while for continuous butter makers the fat content is normally 40–48 g fat 100 g^{-1}, depending on the particular machine. In order to kill pathogens and technologically harmful microorganisms, as well as to inactivate lipolytic and proteolytic enzymes, the cream is heated to 85–110 °C for 10–30 s.

A few very small manufacturers may batch pasteurize the cream at 63–66 °C for a minimum of 30 min. The minimum treatment is at 72 °C for 15 s, though most use a slightly more severe treatment, such as at 74–76 °C for 15 s as a common practice when using the HTST treatment. Specially designed plate heat exchangers may be used to minimize physical damage to the fat globules. Severe heat treatments should be avoided to minimize the generation of a cooked flavor and to minimize the uptake of copper onto the fat globule membrane from the serum.

Vacreation

This process is applied when there are problems with taints in the milk, whether from pasture weeds consumed by the cattle or as a result of storage problems, and further treatment is needed. Undesirable flavors arising from microbial action, from high-temperature pasteurization, from the feed of the cows, or from unpleasant aromas in the milking shed, are removed. A vacreator is used for multistage vacuum treatment of cream. This equipment has now been replaced by spinning cone evaporators in which the volatile compounds are removed from a thin film under vacuum. Where less severe flavor problems may occur, the cream is heated to ~90 °C, then flash cooled by spraying into a chamber where a pressure of ~20 kPa is maintained. The loss of water on cooling is accompanied by reduction in any other volatile component. However, this treatment also has drawbacks regarding butter yield and basal moisture content.

Cooling

Following the pasteurization/vacreation stage, the cream is shock-cooled to 6–8 °C. However, if cultured cream butter from a very 'soft' cream (pasture feeding) is to be produced, cooling occurs at about 20 °C. Then, the cream undergoes physical and/or microbial ripening.

Butter from Sweet Cream

Sweet cream for butter making is potentially the simplest to prepare. The hot cream should be cooled as quickly as possible, usually within the plate heat exchanger used for pasteurization.

Milk fat contains a very wide range of fatty acids, and hence triglycerides, crystallizing as a mixture of predominantly α- and β-crystals. The continuing crystallization releases more heat, mainly within 2 h from cooling, and causes the cream to warm by about 2 °C. The extent of the crystallization will depend on the temperature and on the composition of the fat. Ideally, the cream should be cooled from 4 to 5 °C immediately after pasteurization, so that even with the release of the remaining latent heat the temperature should remain below 7 °C. When this is not possible, additional cooling should be provided, either by cooling pads on the tank wall or by circulation through an external heat exchanger. The cooled cream should be held for at least 4 h before butter making to permit adequate crystallization – at least 50% of the milk fat should be crystalline. Overnight aging is the preferred approach when butter making is carried out on a single shift.

Ripened Cream Butter

The mechanization of butter making, particularly the introduction of pasteurization and adequate refrigeration, prevented the development of acidity and associated fermented flavors in the cream. In many markets, these flavors are highly desired and steps were taken to reintroduce an appropriate microflora and carry out a controlled fermentation. Pasteurization conditions were usually more severe than for sweet cream; for example, 90–95 °C for 15 s or 105–110 °C with no hold. The increased protein denaturation reduces the redox potential, aiding growth of the culture. Cooling is limited to about 20 °C, with a typical fermentation time of 12–18 h depending on the activity of the starter.

The culture normally consists of a mixture of mesophilic lactic acid bacterial strains of *Lactococcus lactis* subsp. *lactis* and *Lac. lactis* subsp. *cremoris* providing lactic acid while citrate positive strains of *Lactococcus lactis* subsp. *lactis* biovar *diacetylactis* produce flavor compounds, predominantly diacetyl and its precursor, acetoin. The inclusion of *Leuconostoc mesenteroides* subsp. *cremoris* or *Leu. mesenteroides* subsp. *citrovorum* increases diacetyl production while avoiding a yogurt-like flavor by reducing acetaldehyde to ethanol. The fermentation must progress to a pH below 5.3 for the generation of diacetyl.

The physical ripening of the cream was originally developed in Scandinavia (Alnarp method) and it helps to optimize the consistency of butter. This process lasts several hours and includes a sequence of hot/cold levels (e.g., 'cold–warm–cold' or 'warm–cold–cold'). Without this procedure, the butter would often be too firm or sometimes too soft and tend to oil off, according to the largely varying milk fat composition. The basal moisture content and the fat losses in the buttermilk can also be influenced by physical cream ripening.

Continuous Butter Making

Continuous butter making machines began to be widely used in the 1960s. These were so successful that, within a decade, most of the batch churns used in creamery manufacture had been superseded. The important advantages of these machines are better hygiene, and control of quality and process efficiency was constantly improved. In the past 55 years, the Fritz method

of continuous butter making has become the leading technology in Western Europe and many other countries. This method is based on similar steps to that of the traditional batch method, but converts relatively small quantities (at any point of time) at a much higher rate, creating the potential for greater production capacity and process control. This method gives an hourly output of 5 tonnes and a production of more than 10 tonnes per hour is even possible.

Cream Feed to the Continuous Butter Making Machine

So as to operate optimally with a minimum of corrective action, the continuous butter making machine must be supplied with a consistent feed. It requires cream of consistent composition (fat, pH), physical characteristics (viscosity, degree of fat crystallization), temperature, and feed rate throughout the working schedule. These requirements can be met by bulking together the cream for a day's production schedule in a single silo. The cream can then be supplied within ±0.5% to the machine by a programmable-logic-control (PLC)-controlled, variable speed pump. The pipelines should be designed and constructed to ensure that the pump is neither starved nor receives excessive shear exerted on the cream during transfer. Flow rates of 0.2–0.4 m s^{-1} are satisfactory for sweet cream with slightly lower rates needed for cultured creams, depending on viscosity.

The most appropriate aging temperature is often lower than the optimum temperature for destabilization of the cream in the machine. It is expensive to introduce that energy by mechanical action. This drawback can be corrected by passing the cream through a preheater using warm water as the heating medium. Small temperature differentials of 1–2 °C should be employed to minimize the risk of overheating. The cream outlet temperature should be controlled within ±0.25 °C of the target temperature. This temperature will vary with the fatty acid profile in the cream. Higher temperatures are needed in the winter to compensate for the greater proportion of saturated fat, so that the temperature will approach that needed for 50% of the fat in the globules to be in the liquid state.

There is also a tendency for the cream feed temperature to be lowered with increasing fat content. As a general rule, all handling of cream prior to butter making should avoid damage to the milk-fat globules, because damaged fat globules will tend to agglomerate and may block the pipelines. However, controlled destabilization has been used in the past as a pretreatment immediately before the machine to increase its production capacity.

Fritz Process of Continuous Butter Making

The GEA Ahlborn (Germany), the Continab (Simon Freres, France), the Pasilac (Denmark), and the Westfalia (Germany) are the major manufacturers of continuous butter making machines. Although the design features vary with some minor differences, the basic principles remain the same. The butter maker consists of: (1) the beating section, (2) churning section, and (3) the working section. The basic sequence of operations in the Fritz process starts with the feeding of the cream into the churning cylinder. Due to the rapidly rotating beaters (about 1000 rpm) in the cylinder, this process only lasts a few seconds. Buttermilk and granules drop into the subsequent separating section. This consists of a rotating cylinder (35–42 rpm) in which after-churning takes place first, that is, the granules are built up in size. Most of the buttermilk is drained off at that stage. Chilled water circulates in the jackets of the churning sections to minimize the temperature rise in the butter. The butter granules then drop through a slide into the first working section from where they are moved with parallel contra rotating augers and start to form a continuous mass, which is forced through a series of plates with orifices.

On the downstream side of the plates, cruciform beaters contribute to the working and flow of the butter mass. There are flutes in the auger sections to assist draining of the buttermilk. The degree of working is controlled by the speed drive and the pitch angle of the beater. At the end of the first working section, salt is added, if required, as a slurry of 40–60% salt through 1–3 injection points close to the final orifice plate. If indirectly cultured butter is to be made, lactic starter cultures, acid, and flavor concentrates are injected at the same points. In this case, the remaining moisture content at these points (the basal moisture content) must not be higher than 13.5%; otherwise, the common maximum permitted water level of 16% could be exceeded when adding the culture concentrate. For this reason, the first kneader operating at low shear rates presses as much of the residual buttermilk out as possible. Before entering the second working section the butter mass is 'evacuated,' that is, exposed to a reduced pressure of 25–60 kPa, whereby its air content falls from approximately 4–7% (v/v) to approximately 0.1–0.5%. This helps avoid laminations in bulk butter and confers a smooth though firmer texture to it, which is said to be appreciated by the consumers.

Processing Variables

Butter yield and its properties, such as consistency, moisture content, and oiling-off, are affected by numerous interrelated process variables. These include the following.

Machine Variables

Machine variables include the beater speed, first kneader speed, second kneader speed, and reduced pressure at vacreation, as summarized here.

There is an optimum beater speed at which the moisture content is minimum. Higher speeds result in 'overchurning' and speeds below the optimum result in the butter moisture content causing 'underchurning.' Both overchurning and underchurning soften the butter mass, which in turn affects the working efficiency.

As the speed of the kneaders is decreased, the time for draining the buttermilk from the butter mass is extended and the butter moisture falls. In order to have the option of canceling this effect for the second kneader, a drain cock at its bottom side can be closed. Because it is generally easier to achieve low moisture content in a hard than in a soft fat, the temperature of the first kneader is reduced by injecting cooled water or buttermilk. The kneader configuration influences the amount of working given to the butter, which in turn affects the sizes of water droplets. A significant fraction of too large moisture

droplets (diameter >10 μm) allows microbial growth and affects the storage quality of the butter.

Cream Variables

Cream variables include fat content, fat composition, the cooling regime, and the salt content in cultured cream.

High cream fat contents are desirable because of higher butter yields (about 0.2% fat losses in the buttermilk vs. 0.05% in the skim milk) and the lower incidence of off-flavors. On the other hand, achievement of correct moisture content (which also depends on the process variables) relates to the fat in the cream, often at about 40–42%. At lower fat levels, the energy demand may exceed the motor capacity, and the butter tends to be underchurned. If the fat content is higher, it is difficult to reduce power to the level required, and the butter tends to be overchurned.

Proper destabilization and agglomeration of the fat occur at an optimum solid-to-liquid fat ratio. At too high or too low values of this ratio, higher beater speeds must be used. More moisture is beaten into the butter, and more fat is lost in the buttermilk. Hence, there is also an optimum cream temperature in the range of 8–14 °C yielding both a minimum basal moisture content and minimum fat losses. However, oxidative (e.g., fishy) flavors arising at higher temperatures must also be considered.

The optimum cream temperature, in its turn, is influenced by the way it has been attained, that is, by the previous temperature treatment. Because the solid to liquid fat ratio at a given temperature depends on fat composition, numerous machine and cream parameters have to be adjusted according to the fat concerned.

Vacreation tends to increase the range of globule sizes. Small fat globules are harder to disrupt than large ones, hence the fat losses in the buttermilk are higher with smaller ones. Very large fat globules, on the other hand, are easily damaged under vacreation.

The presence of salt in cultured cream butter accelerates the autoxidation, the inverse effect occurring with salted sweet cream butter. Overall, butter making depends on numerous interrelated factors which have to be carefully adjusted against each other to keep the process performance and quality parameters within their optimum ranges.

Packaging of Butter

Butter packing may be accomplished in bulk or retail packs. Because butter is relatively stable and the profitability is lower than for many other dairy products, it has been used as a balancing wheel for surplus milk fat. As such, the production has commonly been out of balance with market needs; this is particularly so in those countries where the dairy industry is geared for export rather than for supply to the domestic market. The butter is placed in bulk packs – in older and smaller butter plants, the butter, possibly batch-produced, is packed into 25-kg cartons. Originally, a loose parchment lining was used, but this has been replaced by blue-pigmented polyethylene bags, as this gives better protection.

Nowadays, freshly churned butter is collected first in a butter silo, with an auger to help feed the butter to the pump, providing a break in the product flow so that any interruption in the packing does not cause interruption. The bulk butter packing uses two-stage filling to ensure accuracy and minimum giveaway. Smaller bulk packs can be produced to comply with manual handling restrictions. The shelf-life of the bulk butter may be extended considerably by storing it in frozen conditions at below −18 °C.

Most retail butter is packed in either parchment or a parchment-aluminum foil laminate. Parchment is cheaper but is permeable to moisture vapor and ultraviolet rays so that the surface of the butter can suffer from both surface drying and oxidative rancidity, the latter being reduced by the application of pigments such as titanium dioxide to the outer surface of the parchment. Foil laminate protects the butter from ultraviolet rays and only permits moisture vapor and gas interchange at the seams, thus aiding in a longer shelf-life.

Some specialist butters may use transparent films. Though the film gives good protection against moisture loss, the risk of oxidative rancidity on the surface is higher than for parchment. Preformed plastic containers, often polypropylene, are more expensive and tend to be used for soft butters and hybrid products that would be too easily damaged in film wraps. Butter portions, typically less than 20 g in weight, for catering and institutional use, are filled either into foil laminates, where the consistency on filling can be critical, or into plastic trays with a foil or aluminum film cover, in a form-filled seal operation.

Butter Manufacturing and Butter Regulation

The use of milk fat goes back to several millennia ago, since animals started to be domesticated. However, the first written reference is around 2000 BC. Butter has been used not only as food but also for cosmetic purposes, for medical purposes, and for religious ceremonies. Butter manufacturing was first based on the separation of the cream by gravity settling, followed by a manual churning in wooden churns. The obtained butter grains were separated from the buttermilk and then manually kneaded. The continuous churning process used nowadays for the production of butter replaced most of the batch process former used. Different manufacturing technologies exist for continuous butter making; however, the most typical is the Fritz process. The Fritz process involves concentration of the cream via centrifugation, to 40% fat approximately, and then a thermal treatment of the cream is performed. The purpose of the thermal treatment is to crystallize part of the milk triglycerides, which will initiate partial coalescence, hence butter grain aggregation during the churning step. During churning, the butter grains are separated from the water phase, the buttermilk, which is subsequently removed. The butter grains are then processed in the working section; here, the excess of water is removed, and the water droplets are homogeneously distributed in the continuous fat phase. Therefore, butter is referred as a water-in-oil emulsion. The final consolidation of butter occurs during storage, in the first 2 weeks from manufacturing. Margarine manufacturing differs from butter manufacturing on the mixing and emulsification steps. During margarine production, milk fat, vegetable oils, water phase, and emulsifier are mixed and then emulsified. Cooling and an intensive mechanical working are followed.

The increase in consumers' expectations and the innovation in production technologies led to an extensive variety of spreadable-fat products available on the market. In general, spreadable-fat products are differentiated by their origin, animal or vegetable fat, and by the amount of fat. Standards and guidelines for butter are internationally designated by the Codex Committee on Milk and Milk Products, which belongs to the Codex Alimentarius Commission. At European Union level, the Council of the European Union established a classification, with annexed nomenclature, for the producers. This is laid under the Council Regulation (EC) No 445/2007. Generally, under the nomenclature of spreadable fats fall all the products with fat content between 10% and 90% (w/w), which are solid at 20 °C. However, the most known spreadable-fat products are butter, margarine, and butter blends. Butter, as quoted in the Council Regulation (EC) No 2991/94, is obtained by exclusively milk fat in which content must be between 80% and 90% (w/w), with a water content not higher than 16% (w/w) and dry nonfat milk material below 2% (w/w). Under the same condition for the amount of fat, but when vegetable and/or animal fats are used instead of milk fat for manufacturing, the obtained product is referred to as margarine. Dairy blends are referred to products obtained by combining milk fat with vegetable fats in which the amount of fat is between 80% and 90% (w/w). Spreadable-fat products that are labeled as 'reduced fat' have a fat content between 41% and 62% (w/w). For butter and blends with a fat content lower than 41%, the nomenclature of 'low fat' or 'light' is used. 'Three-quarter fat' and 'half fat' can also be used to refer to products with a fat content between 62–60% and 41–39%, respectively. For 'reduced fat' and 'low fat' or 'light' butter and blends, the member states can choose to use the term in their own language to reflect the same product. In the case of spreadable-fat products imported from non-Community countries, the same requirements as those produced in the European Union must been fulfilled. Butter production is also regulated by national legislation, brand regulation, and company specification.

In addition to conventional butter, other milk fat products are available in the market, for example, whipped butter, flavored butter, confectionary butter, anhydrous milk fat, butter oil, butter powder, and ghee. These are mainly used as ingredients in bakery and confectionary industries.

World Consumption and Distribution

In the last decade, production of butter has been increasing from 4.660 million tons to 5.202 million tons. By 2023, a 24.05% increase in butter production is expected. Europe leads in world butter production, with 66% calculated as share average in 2000–2012, followed by the Americas, Oceania, Asia, and Africa, with 16.7%, 8.3%, 7.1%, and 2%, respectively. The top five world producers, calculated as average in 2000–2012, are the United States, Germany, France, New Zealand, and Russian Federation, with 0.67 million tons, 0.44 million tons, 0.43 million tons, 0.41 million tons, and 0.26 million tons, respectively. New Zealand is the first world exporter of butter with 0.35 million tons, followed by the European Union countries. France, Germany, and Luxembourg account for the highest kilogram per capita butter consumption in the world, which is equal to 7.4, 6.2, and 6.10 kg per capita per year, respectively. Conversely, the lowest per capita consumption, indicated as below 1 kg per capita per year, is reported in Mexico, Brazil, Colombia, Greece, Spain, Iran, Israel, Turkey, Egypt, South Africa, China, Japan, Mongolia, and South Korea. This is mainly due to the higher temperature reported in most of the aforementioned countries and/or to an alternative source of fat more accessible than bovine milk fat, for example, olive oil or buffalo milk fat. The reported data illustrate the current scenario for butter manufactured from bovine milk; however, buffalo, goat, sheep, and camel milk

are also used for butter manufacturing. Buffalo butter manufacturing has been increasing in the last decade, from 0.41 to 0.83 million tons. Asia and Africa, which are characterized by the lowest consumption and production share for bovine butter, head up in the production of buffalo butter with 81.6% and 18.4%, respectively, calculated as average in 2000–2012. India is the first producer of buffalo butter, with 0.6 million tons, followed by Egypt, China, and Iraq, with 83, 8.77, and 1.45 thousand tons, respectively. At present, no data are reported on the production and trade of butter from other sources.

Milk Fat Composition and Structure

The origin of the textural and functional properties of butter must be sought on milk fat composition and structure. Milk fat composition and the stereolocation of fatty acids (FAs) in the triacylglycerol (TAG) molecules influence the crystallization behavior, which in turn affect the microstructure, hence the macrostructure and textural properties of butter. Among natural fats, milk fat is one of the most complexes, as both structure and chemical compositions. Bovine milk fats are shaped as spherical globules, the size of which is between 2 and 8 μm, and their concentration is $\sim 10^{10}$ globules ml^{-1}. A complex milk fat globule membrane, composed of lipids and proteins, the thickness of which lies in the range of 10–20 nm, surrounds the TAG core of milk fat. The primary role of the membrane is to physically stabilize the milk fat, and to protect them from enzymatic oxidation and lipolysis. The core of the milk fat globule accounts for 98.3% (w/w) TAGs of the total composition; the remaining 1.7% includes phospholipids, diacylglycerols, sterols, free FAs, and monoacylglycerols stated in decreasing order. The amount and composition of milk FAs vary considerably among breeds of cow, feeding regimes, seasons, stages of lactation, and genetic variations. Approximately 400 FAs have been identified in milk fat; among these, only 14 are present in amounts higher than 1%. The presence of short-chain FAs makes bovine milk fat a distinct fat, both in flavor and in functional properties, when compared to other natural fats used for the manufacturing of spreadable-fat products, as rapeseed, sunflower, or olive oils. Saturated FAs, with a carbon chain length varying from 4 to 18, account for 70–75% of total milk fat. Among those, palmitic acid (C16:0), stearic acid (C18:0), and myristic acid (C14:0) are predominant with 22–35% (w/w), 9–14% (w/w), and 8–14% (w/w) average range, respectively. Conversely, among the unsaturated FAs, oleic acid (C18:1 *cis*9) and palmitoleic acid (C16:1 *cis*9) account for 20–30% (w/w) and 1–3% (w/w) average range, respectively.

Textural Properties of Butter: Macro- and Microstructure

The optimal consistency of butter is smooth, slightly firm, and plastic. In addition, butter should have good resistance to cutting, being fairly spreadable, and it should be easy to melt in the mouth without leaving a greasy sensation. To study and therefore to be able to modify the mechanical and functional properties of butter, hence its macrostructure, a clear understanding of its microstructure is needed.

Microstructure

The microstructure of butter is the utmost attribute for its textural and functional properties. The microstructure of butter consists of a tridimensional fat-crystal network interrupted by intact and partially disrupted milk fat globules, water, and air droplets, which are all dispersed in a liquid fat phase. Accordingly, butter is often referred as water-in-oil emulsion. Figure 1 shows the microstructure of butter, both schematically (a) and as observed by confocal laser scanning microscope (CLSM) (b). The crystals in the network are held together by two principal types of bonds, primary and secondary bonds. Primary bonds are the cardinal bonds of the entire crystal network, due to their strength and irreversibility. On the contrary, secondary bonds that hold crystals together by van der Waals forces are weaker and irreversible, underlying the thixotropic character of butter. Sintering, which refers to the formation of strong solid bridges between crystals and crystal clusters, might also occur. In addition, stearic and electrostatic forces might be involved in the system, as milk fat globules and proteins are also present. All the elements of the microstructure, including their characteristics as size and shape, and the interactions between them, such as the forces involved between elements, contribute to the mechanical and functional properties of butter. Principal focus is given to the effect that the solid-to-liquid ratio, the crystal polymorphisms, the presence of intact fat globules, and the continuity of the crystal network, as a number of contact points between crystals, have on the microstructure of butter, hence on its textural and functional properties.

Macrostructure Textural Properties of Butter

Butter is a pseudoplastic fat, or viscoelastic product, upon application and consequently removal of stress; it is able to regain some of the original shape. Different analytic and sensorial measurements have been used to describe textural properties of butter, and different descriptors have been correlated with different measurements. The most common descriptors for butter, evaluated by sensorial and rheological measurements, are hardness, spreadability, brittleness, stiffness, elasticity, and stickiness.

How Microstructure Elements Affect the Textural Properties of Butter

Crystal Network and Milk Fat Globules

The amount of solid fat in which the optimal range at 5 °C is 30–40% has often been considered one of the main factors responsible for the textural properties of butter, in particular for hardness and stiffness. However, the size of the crystals (1–20 μm) and crystal clusters (20–100 μm), thus the amount and type of bonds between them, and the amount of fat globules contribute to the to the microstructure properties more than the solid fat content (SFC). Generally, formation of small crystals lead to a finer crystal network with more contact points,

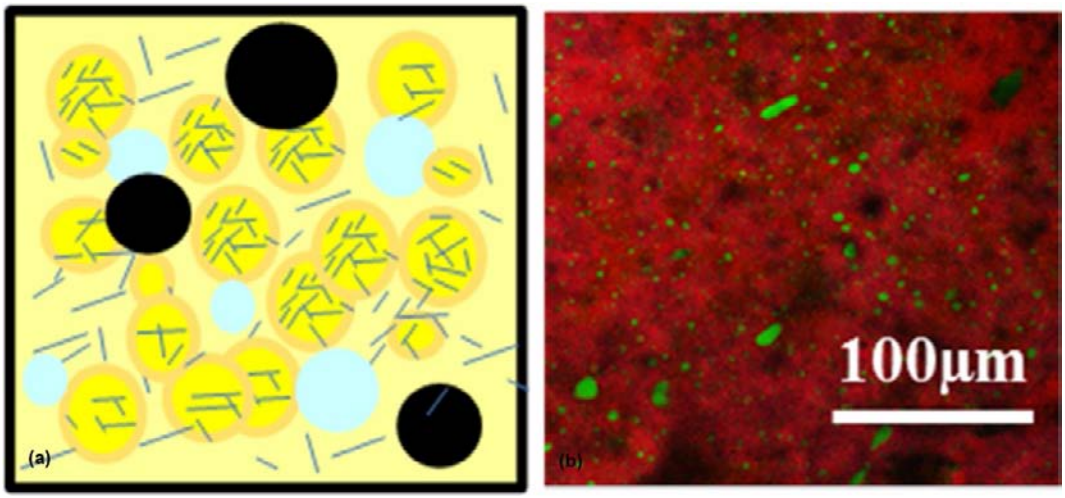

Figure 1 Microstructure of butter. (a) Schematic representation of butter as water-in-oil emulsion. The light blue area represents the water phase, the yellow area is liquid oil, the yellow circle is the fat globule containing liquid oil and crystals (petroleum bars), and the black circle is air. Not to scale. (b) CLSM images of butter after 28 days of storage. The black shadow on the image background represents the crystal network. The red area is the liquid fat of the system, and the green areas are protein/water phases. The scale bar indicates 100 μm. Adapted from Buldo, P. (2013). Crystallization of fat in and outside milk fat globules. Effect of processing and storage conditions. PhD thesis. Denmark: Aarhus University. ISBN: 978-87-92936-45-5.

which results in a firmer butter. On the contrary, larger crystals form a crystal network with few contact points that is more prone to fracture; hence, a softer butter is obtained. Yet, by increasing the amount of intact fat globules, the crystal network will be interrupted and the crystallization process will be shifted in favor of milk fat globules. The crystal network present within the milk fat globules does not contribute to the hardness and stiffness of butter. Therefore, butter with a high amount of intact fat globules has a weak structure and good spreadability. The latter is a consequence of the high melting faction of the TAGs that are inside the milk fat globules. The crystal network presents outside the milk fat globules, hence in the continuous liquid fat phase, leads to a stronger and firmer structure; therefore, it is the main element contributing to textural properties of butter. This highlights that the amount of SFC is not important as much as the ratio of solid fat present in and outside the milk fat globules for the textural properties of butter. The amount of solid fat present outside the milk fat globules is also responsible for the brittleness of butter. By increasing the volume fraction of fat crystals in the continuous phase, brittleness increases correspondingly. On the contrary, increasing the amount of intact milk fat globules will result in an increased structure deformation, hence elasticity. In conclusion, by increasing the amount of intact fat globules and thus by decreasing the amount of solid fat in the continuous phase, a more elastic and spreadable, thus less hard and brittle, butter is obtained.

Polymorphism

The polymorphism of milk fat is another element contributing to the textural properties of butter. In the majority of spreadable-fat products, including butter, β′-crystals with traces of β are found. The β′-crystals is the most desirable form in butter as it gives a smooth mouth sensation, due to its needle shape (<5 μm) and to its stability through the storage conditions. However, allowing the thermal treatment of the cream to a low cooling rate and/or the product to a prolonged storage time at refrigerator temperature, an irreversible polymorphism transition to a more stable crystal form, β, can sometimes be achieved, but only to a small extent. β-Crystals result in a sandy and coarse mouthfeel and in a poor crystal network and brittle structure, as a consequence of their large conformation (>20 μm) and platelet-like shape; therefore, they are undesirable in butter. α-Crystals are not likely to be present in spreadable-fat products, due to their metainstability. The crystal polymorphism is not a challenging factor on the microstructure and textural properties of butter, as it is fairly constant on the desired form; therefore, it is considered as a negligible element.

Water and Air Droplets

Despite their number concentration, 10^{10} ml^{-1}, water droplets do not have a significant contribution to the microstructure of butter, thus to its textural properties. This is due to their homogeneous distribution and small size (1–125 μm). However, they are relevant for microbiological safety, organoleptic properties, and chemical stability of butter. By increasing droplet size, for example, by coalescence, or if inhomogeneous distribution appears, microbiological growth, chemical instability (e.g., fat oxidation), and alteration of the organoleptic properties will occur.

Air droplets are the element that is present in the lowest share, below 5% (v/v). The size of air droplets is variable, as also is their number; however, the majority of them have a diameter of 20 μm or greater. Generally, by reducing the amount of air a harder butter is achieved, and vice versa by increasing the amount of air. Negligible consideration is given to them, as they are fairly stable through the shelf life of butter.

Alteration of Textural Properties of Butter During Storage and Handling

Butter leaves the producers at its best textural and functional properties; however, during transportation and storage, mainly during handling of butter at the consumers' place, textural changes might occur to the product. During handling, intended as temperature fluctuation, for example, from the refrigerator (5 °C) to the dinner table (25 °C) and vice versa, butter results in an increase in hardness, stiffness, brittleness, and elasticity. The changes on textural properties after temperature fluctuations, thus after melting and recrystallization of milk fat, are caused by the formation of a denser and stronger crystal network in the continuous fat phase, as a consequence of fat globule flocculation.

Butter Flavor and Color

The characteristic flavor of cultured butter is associated to the diacetyl and δ-decalactone compounds. Although sweet cream butter is associated to mild and 'nutty' flavor, this is mainly due to the presence of short-chain free FAs, aldehydes, methyl ketones, and lactones, which are depending on the feeding regime of the cows. In addition, aromatic characteristics associated to salty, cooked, grassy, and stale can also depict butter flavor. A typical rancid butter off-flavor can be caused by increased concentration of butyric and caproic acid. A conspicuous amount of volatile compounds is present in butter; however, their contribution to the final flavor is still undefined. Some aromatic compounds of butter are located in the water droplets.

Butter color varies from light to dark yellow. The color of butter is influenced by the amount of β-carotene present in the feed of the animals, hence in the milk. Generally, pasture has higher content of β-carotene than hay. The breed of the cow also influences the color of butter, for instance, milk from Jersey and Guernsey has a higher content of β-carotene than milk from other breeds.

How to Modify Butter Properties

Several approaches can be used to modify the textural and functional properties of butter. These can be classified as alteration of the composition and modification of the technological process parameters. The FAs composition can be changed in favor to the FAs more desirable in the final product. This can be achieved either by feeding regime or by fat fractionation. Increasing the amount of unsaturated FAs, for example, increasing fresh pasture or feeding encapsulated unsaturated fats, results in a softer butter. A softer butter can be obtained also by increasing the amount of low melting milk fraction through fat fractionation. However, butter with a higher melting fat fraction results in a reduced oiling off and moisture migration. To better address this topic, further knowledge is needed on the effect that TAG composition has on the textural properties of butter. The addition of minor components to the cream, for example, phospholipids, can increase the hardness of spreadable-fat products by increasing the crystal size and by promoting polymorphism transition toward a more stable form. In addition, phospholipids reduce graininess and tendency to oil off in butter.

Available Methods to Study Butter Properties

In order to fully characterize butter properties, a variety of analyses need to be performed. Table 1 shows the available methods to study butter properties.

Microscopy Techniques

As mentioned earlier, the microstructure of butter is the starting point to study the textural and functional properties of butter. Therefore, a proper visualization of the microstructure would give a first insight of the butter properties. CLSM is so far the best technique available to visualize the microstructure of butter. Images obtained by CLSM clearly identify the crystal network, the liquid fat, the fat globules, and the water and air droplets (Figure 1(b)). Yet, the resolution is low to allow a clear visualization of the single crystal or crystal cluster. The latter could be overcome by using a polarized light microscope (PLM); however, the microstructure complexity of butter makes it not suitable for this scope.

Rheology Techniques

Rheology techniques are commonly used to characterize the structure and texture of butter. In small deformation rheology, the applied stress or shear strain, at a given frequency and within the linear viscoelastic region (LVR), oscillates the microstructure without breaking it. Consequently, the time-dependent stress or strain is measured. On the other hand, by applying large deformations, a nonlinear response, which implies breakdown of the microstructure, is achieved. Outside the LVR, by applying large deformations, strength of primary bonds is monitored, whereas within the LVR, the strength of the secondary bonds is characterized. Common techniques among large deformation rheology are sectility, extrusion, compression, and penetration tests. A combination of oscillatory shear tests and compression or penetration tests characterizes the micro- and macrostructure, resulting in an accurate description of the textural properties of butter. Yet, the right technique, including test parameters and geometry used, should be carefully evaluated based on the purpose of the measurement and considering their effect on the outcoming data.

Oscillatory Rheology

In oscillatory shear tests, several geometries have been used to study the textural behavior of butter during crystallization and on the final product. Among these, parallel plate–plate, corrugated plate–plate, cone–plate, bob cup, starch cell, and vane cup, all available in different sizes and materials, have been tested. The most suitable geometry to study the microstructure of butter is the parallel plate–plate or the corrugated plate–plate, as change in structure caused by sample loading is minimized; in addition, these geometries are not destructive

Table 1 Summary of some of the methods available to study crystallization, microstructure, and textural properties of butter

Methods	*Principle*	*Applications*	*Advantage*	*Disadvantage*
Confocal laser scanning microscopy (CLSM)	Specimen is excited by a laser that is scanned in a focal plane. Fluorescence light is emitted and it is focussed as a confocal point	Observation of complex structure in a defined depth; particle size determination; fractal analysis	Detection of several component phases; 3-D images; high contrast, definition, and signal-to-noise ratio; easy and relatively fast sample preparation; emulsion stability	Low resolution
Polarized light microscope (PLM)	A polarized light is used to illuminate the sample. Due to the birefringence of crystals, they will appear bright, whereas liquid and amorphous regions of the specimen will appear dark	Observation of crystallization process and crystal structure; particle size determination	Inexpensive technique; contrast-enhancing technique	Not suitable for complex system such as butter or multiphase emulsions; limited resolution to the order of 1 μm
Oscillation rheology	Applying a constant stress or strain to the material	Measures the variation in strain as a function of the applied stress and vice versa	Determination of several parameters (G'; G'', G^*; $\tan\delta$)	Difficult sample handling and not highly reproducible with hard fat
Uniaxial compression	A sample between two parallel plates is compressed at constant load and velocity	Determination of the force needed to induce a change in a material	Easy and fast; several textural descriptor can be estimated from the data	No highly reproducible
Penetration test	A geometry is penetrated into the sample either at constant load or at constant speed	Determination of the hardness	Easy and fast, widely used	Results are dependent on parameters and geometries
Differential scanning calorimetry (DSC)	Temperatures and heat flows are associated with transitions in materials as a function of time and temperature	Determination of thermal behavior, solid fat content, and crystal polymorphism	Fast and simple; measurements performed at isothermal and nonisothermal temperature	Shape of the thermogram changes based on the cooling rate used; difficult sampling with plastic fats; shear cannot be applied
Dilatometry	Measures the change in sample volume	Determination of solid fat content	Reproducible	Laborious, time-consuming and inaccurate; measurements at constant temperature
Pulsar nuclear magnetic resonance (p-NMR) – direct method	Measures the signals from the hydrogen nuclei. Calculates the ratio between the hydrogen in the solid phase and the total number of hydrogen (solid and liquid phases)	Determination of solid fat content and crystal polymorphism	Fast, simple, and highly precise	Not accurate; measurements at constant temperature
p-NMR – indirect method	Measures the liquid part of the samples and refers it to the fully melted samples	Determination of solid fat content	Accurate	Complex sample preparation and time-consuming
x-Ray diffraction	Bragg's law is used to determine the distance between the reflections formed by the x-ray scattered from the electrons of the samples	Determination of polymorphism and lamella stacking of TAGs	Accurate	Expensive instruments, often not available

on the sample during measurements. Parallel plate–plate geometry has often been implicated of causing wall slippage; this might be the consequence of free fat on the surface of spreadable-fat products or adhesive failure of the sample, which, under normal conditions, is not the case for butter. On the other hand, special attention should be paid when using the corrugated plate–plate with plastic fat, because the sample can stick between the open spaces of the plate leading to artifact measurements. The cone–plate geometry is also not recommended for butter, due to the leakage of oil from the samples as the required gap is achieved. The geometries mounted with a cup or a cell, thus with vane, are not suitable to study the textural properties of spreadable-fat products, due to the changes in structural conformation caused by the vane; as a consequence, the measurements will be linked to a structure artifact. Crystallization behavior of milk fats during butter

manufacturing can be studied by a bob cup, since no continuous crystal network is present until phase inversion occurs. Measurements from oscillatory tests display the viscoelastic behavior of butter, with the elastic modulus (G′) always greater than the viscous modulus (G″), within the LVR and before the yield point. The elastic modulus is used to quantify the crystal network, whereas the complex modulus (G*) gives an overview of the total structure characteristics.

Large Deformation Rheology

Among large deformation rheology tests, sectility or extrusion test is often used. Briefly, during the sectility test, a cutting steel wire moves at constant speed into the butter, whereas during extrusion test, a piston with a constant speed extrudes the sample from an orifice. In both tests, the outcoming force or stress is used as firmness measurement. Penetration and compression tests are also used frequently. A wide variety of geometries are available, for example, cone, needle, cylinder, sphere, and plate, all in different sizes and materials. The most used geometry is the cone for penetration test and the plate for compression. During penetration test, the geometry penetrates into the sample either at a constant speed or with a constant load, and the response of the material, as the force needed to penetrate the material or the distance traveled by the geometry, are recorded as a function of time. The American Oil Chemists' Society official method, which uses a cone with 20° angle, is based on the distance traveled by the cone under the force of gravity. The outcoming data are often referred to product hardness or firmness. Compression test is performed in the presence of geometries larger than sample, for example, plate geometry; therefore, a uniaxial compression occurs. The outcoming data provide additional information to a penetration test, for example, brittleness. Despite that, at the moment, the cone remains the most used geometry for the study of butter texture. The interpretation of the obtained data is relative to the parameters and geometries selected. For instance, the selected speed for compression is correlated to the response of the material, as higher speed corresponds to a higher force. In addition, the recorded forces are influenced by the size and shape of the geometry and by the dimension of the sample. Consequently, the choice of the most appropriate technique and parameters and the interpretation and comparison of results might be challenging despite a simple sample preparation and performance of the measurements. For the aforementioned tests, the obtained firmness measurements have often been related to the spreadability parameter evaluated by sensorial test.

Crystallization Study: Differential Scanning Calorimeter, p-NMR, and x-Ray Diffraction

Additional knowledge for the characterization of the textural properties of butter is obtained by the study of the crystallization occurring during manufacturing and storage of butter. Crystallization in butter is often studied by differential scanning calorimeter (DSC), pulsed nuclear magnetic resonance (p-NMR), and x-ray diffraction. DSC measures the heat flow, as a function of time and temperature in a controlled atmosphere, to identify the phase transitions of the material. DSC has been widely used to study the thermal behavior of butter. The obtained thermogram is mainly used to gain information on the melting and/or crystallization temperature of butter. Milk fats have a melting/crystallization temperature's range from −40 to +40 °C. Solid fat content and crystal polymorphism of butter can also be obtained by DSC; however, literature is scarce on this topic. So far, the best available methods to measure the level of SFC are dilatometry and direct and indirect p-NMR. The dilatometry is based on the change of volume of the sample, whereas p-NMR measures the signals from the hydrogen nuclei, which are distinguished by the free induction decay. The direct NMR method calculates the ratio of the number of hydrogen in the solid phase to the total number of hydrogen. The indirect method measures only the liquid part of the sample and refers it to a calibration performed on the fully melted sample. Crystal polymorphism and lamella stacking of TAGs molecules present in butter are determined by wide- and small-angle x-ray diffraction, respectively. The distance between the intensities of the scattered light, as a function of the scattered angle and the original wavelength, is calculated by Bragg's law.

Conclusions

Butter is considered an exclusive product for its unique flavor and nutritional value; as a result, it is used nearly in all world countries. Textural and functional properties of butter are closely related to the microstructure elements and to their distribution and interactions in the system. A combination of different analyses is needed to characterize the functional and textural properties of butter. Rheological tests reflect the behavior of the microstructure elements. Oscillation rheology tests performed with parallel plate–plate geometry, together with CLSM images, contribute to microstructure characterization. Penetration and compression test are linked to butter macrostructure, thus to its textural properties. The main microstructure element affecting butter texture is the fat network outside the milk fat globules. A continuous crystal network consisting of small crystals outside the milk fat globules leads to a harder and more brittle butter than a microstructure characterized by a higher number of milk fat globules and/or by large crystals, hence with a solid phase present within the globules rather than in the continuous liquid phase.

Cadmium (Cd) is a nonessential element with chemical and physical characteristics that convert it into a toxic element for the environment and living creatures. It was discovered by a German chemist, Friedrich Stromeyer, in 1817. The name comes from the Latin word *cadmia*, meaning calamine (zinc carbonate, $ZnCO_3$), or from the Greek word *kadmeia*, which has the same meaning. Toxic trace elements, including Cd, are currently a cause of concern for the committees and agencies responsible for food safety and health. Consequently, opinions have been expressed about cadmium in recent years, providing important information about various aspects concerning this element.

Physical and Chemical Properties

Cd is a soft, malleable, blue-white metal that tarnishes in air and is soluble in acids and insoluble in alkalis. Boiling cadmium gives off a yellow-colored vapor that is extremely toxic. Its melting point is 321 °C (610 °F) and its boiling point is 765 °C (1410 °F). The density of Cd is 8.65 g cm^{-3}. It is a transition metal, belonging to group 12 in the periodic table, together with zinc and mercury. The element has an atomic number of 48, an atomic mass of 112, and one main oxidation state (+2), although a few compounds have been reported in which it is +1. It has eight naturally occurring isotopes: ^{106}Cd, ^{108}Cd, ^{110}Cd, ^{111}Cd, ^{112}Cd, ^{113}Cd, ^{114}Cd, and ^{116}Cd. Of these isotopes, ^{114}Cd and ^{112}Cd are the most common, with an abundance of 29% and 24%, respectively. It is not usually present in the environment as a pure metal, but rather combined with other elements such as oxygen, chlorine, or sulfur to form Cd oxide, Cd chloride, or Cd sulfate, respectively. Cd sulfate and Cd chloride are soluble in water, whereas elemental Cd, Cd oxide, and Cd sulfide are almost insoluble. Cd is easily complexed with some organic compounds, although these compounds have not been found in the general environment because they decompose quickly. There is some evidence that in certain foods, cadmium is bound to metallothionein-like proteins.

Cd metal has specific properties that make it suitable for a wide variety of industrial applications. These include excellent corrosion resistance, low melting temperature, high ductility, and high thermal and electrical conductivity. An interesting property of Cd is its effect in alloys. In combination with certain metals, it lowers the melting point: Lichtenberg's metal, Abel's metal, Lipowitz's metal, and Newton's metal.

Occurrence of Cadmium

The abundance of Cd in the Earth's crust is estimated to be about 0.1–0.2 ppm. It is considered the 65th most abundant element. The only important ore of Cd is greenockite, or Cd sulfide (CdS). This ore does not have a sufficient concentration of Cd to be mined profitably. Most Cd is obtained as a

by-product from the smelting of zinc (Zn), lead (Pb), or copper (Cu) ores.

Cd is released to the environment from natural and anthropogenic sources. Natural sources include volcanic activity, weathering of rocks, burning of vegetation, sea-salt spray, and mobilization of Cd deposited in soils, sediments, and landfills. Anthropogenic sources include mining and smelting of Zn ores, combustion of fossil fuels for electricity and heating, incineration of municipal waste, industrial and agricultural wastes, and manufacture of phosphate fertilizers. Figure 1 shows the changes in the emission of Cd to the environment in the years 1990–2010 in member countries of the European Environment Agency (EEA). Although emissions to the environment have decreased in recent years, they are still a cause for concern for regulatory organizations.

Once it is in the environment, Cd moves easily through soil and water and can be taken up by certain crops and aquatic organisms. In fact, for the nonsmoking population, food is the main source of exposure to this element. The latest report on Cd issued by the contaminants panel of the European Food Safety Authority (EFSA) shows that the main dietary sources of this element are cereals and cereal products, vegetables, nuts and pulses, starchy roots or potatoes, and meat and meat products. However, the highest concentrations are found in seaweed, fish and seafood, chocolate, fungi, oilseeds, and edible offal.

Maximum limits (MLs) of Cd have been established for some food groups: European Commission (Regulation (EC) No. 1881/2006), China (GB2762-2012), and Australia/New Zealand (Standard 1.4.1). The food groups considered in these standards are the ones that present the greatest problems: vegetables, cereals, pulses, meat, and seafood. MLs vary within a given food group: cereals, 0.1–0.2 mg kg^{-1}; vegetables, 0.05–0.2 mg kg^{-1}; fruit, 0.05 mg kg^{-1}; seafood and derived products, 0.1–0.3 mg kg^{-1}; crustaceans, 0.5 mg kg^{-1}; bivalves and cephalopods (without viscera), 1 mg kg^{-1}; meat, 0.05–0.2 mg kg^{-1}; liver, 0.5 mg kg^{-1}; and kidney, 1 mg kg^{-1}. For viscera, the Australia/New Zealand standard allows higher MLs: liver, 1.25 mg kg^{-1} and kidney, 2.25 mg kg^{-1}. This standard also establishes an ML for chocolate and cocoa powder (0.5 mg kg^{-1}).

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) has established a provisional tolerable weekly intake (PTWI) of 7 μg kg^{-1} of body weight. The health risk related to Cd exposure has recently been reevaluated by EFSA's Scientific Panel on Contaminants in the Food Chain (CONTAM), which has established a tolerable weekly intake (TWI) of 2.5 μg kg^{-1} body weight. Table 1 shows the intake reported for various

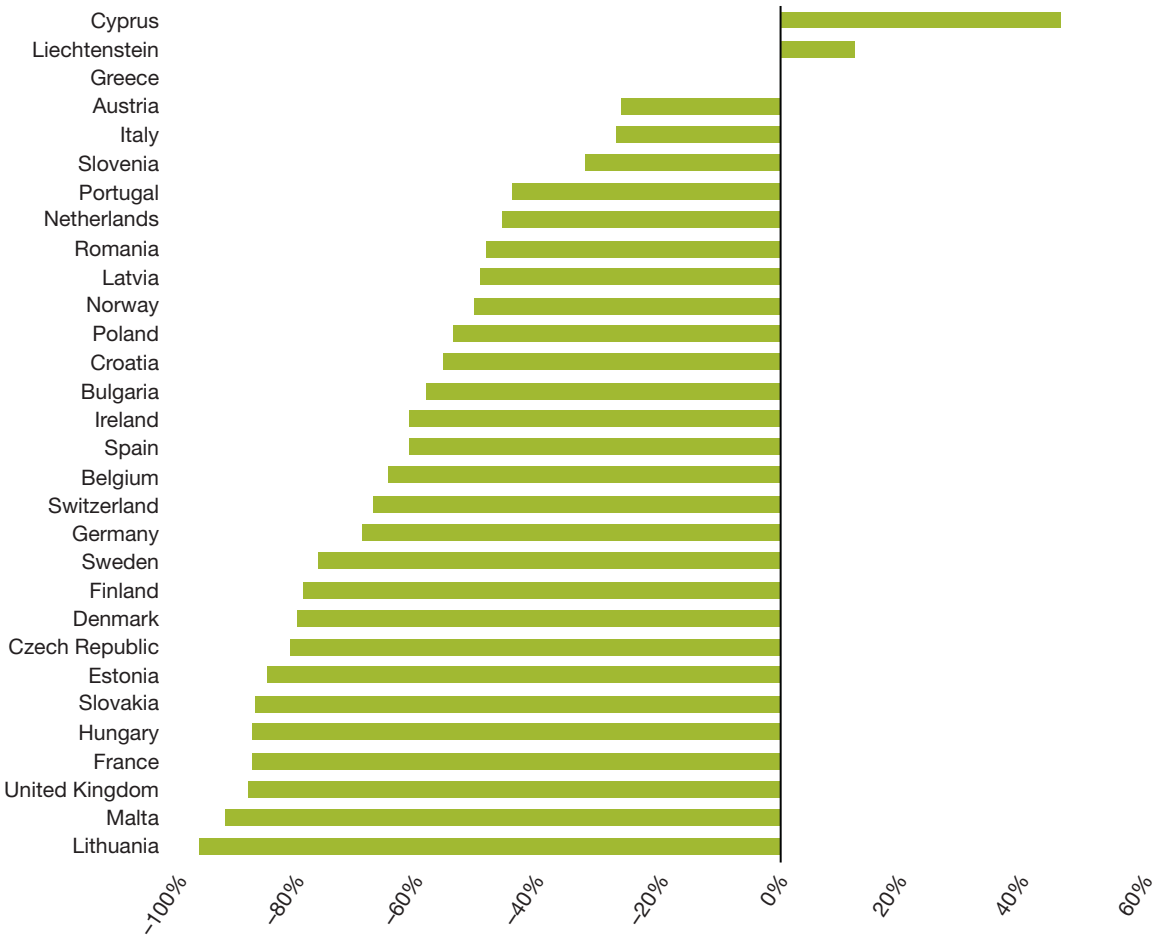

Figure 1 Change (%) in cadmium emissions 1990–2010 (EEA member countries). Reproduced from European Environment Agency (EEA) website (http://www.eea.europa.eu/data-and-maps/daviz/change-in-cadmium-emissions#tab-chart_1), with permission of European Environment Agency.

Table 1 Weekly cadmium intake in various countries

Country	*Intake ($\mu g\ kg^{-1}$ body weight/week)*	*Main food contributors*	*Year*
China	3.12 (average)	Rice, meat, and vegetables	2013
Japan	2.91–3.15 (range)	Rice	2004
Hong Kong	2.49 (average) 5.71 (high consumers)	Vegetables, fish and seafood products, cereals	2000
The United States	0.98–1.26 (average, lower to upper bound)	Vegetables, grains, and mixtures	2003
Spain (Catalonia)	1.83 (average)	Cereals, fish and shellfish, tubers	2003
The Netherlands	1.26 (average)	Wheat, potato, spinach, and carrot	1999–2002
Germany	1.4 (average) 2.35 (high consumers)	Vegetables and cereals	2014
Cyprus	4.7 (mean) 2.1–12.9 (range)	Meat and offal, cereals, vegetables	1997–2000
Sweden	0.81–3.15 (range)	Meat, potatoes, and cereals	2004–2007
France	1.12 (mean) 1.89 (95th percentile)	Bread and dried bread products, potatoes and potato products	2006–2007
Ireland	2.38–3.08 (average, lower to upper bound) 5.39–6.09 (95th percentile, lower to upper bound)	Vegetables (especially potatoes), cereals, and bread	2001
The United Kingdom	1.63 (mean) 2.8 (97.5th percentile)	Potatoes, bread, and miscellaneous cereals	1997

countries. The review that EFSA carried out indicates that the adult European population's exposure to Cd is near or above the TWI and points to vegetarians and children as populations at risk that may double the TWI. The CONTAM concludes that current exposure to Cd at the population level should be reduced.

Determination of Cadmium in Foodstuffs

When analyzing any trace element – and Cd is no exception – one must take a series of precautions to avoid mistakes and misinterpretation of the data obtained. It is necessary to work with material previously treated with diluted acid (5–10% HNO_3) to eliminate possible contamination and with ultrapure water with an electrical resistivity of 18.2 mΩ. Specific selection of reagents and purification of solvents by distillation in all-glass systems may be necessary. A more detailed description of the measures to be taken to determine trace elements in general and Cd in particular is given in the European Committee for Standardization (CEN) standard EN 13804:2002.

There are various methods for determining Cd in food, proposed by international organizations – CEN, AOAC (Association of Official Analytical Chemists), and ISO (International Organization of Standardization) – or by national organizations. Table 2 shows the methods proposed by the international organizations, which differ with regard to sample preparation and the method employed for detection.

Sample Digestion Methods

Foods are complex samples that require a preliminary mineralization treatment to decompose the matrix and dissolve the element. This mineralization is the most decisive step for obtaining quantitative determination of the element. Various methods for sample mineralization are commonly reported in the literature for Cd determination: dry ashing in a muffle furnace, pressure digestion using concentrated acid, and acid digestion by heating at atmospheric pressure.

Dry ashing

Dry ashing is done in crucibles that are first dried and then subjected to a temperature ramp in a muffle furnace. Typical ashing temperatures are 450 to 550 °C at atmospheric pressure. This step is common to all the Cd determination methods that use dry ashing; however, the method for dissolving the ash varies and may be complex. Some methods are limited to dissolving the ash in 6 M HCl and evaporating to dryness. The residue is then dissolved with 0.1 M HNO_3 for subsequent detection. This is the principle of AOAC method 999.11 and of standard EN 14082:2003 for the analysis of cadmium in foodstuffs.

Dry ashing has a series of advantages; it is possible to preconcentrate the analyte, the sample does not need much handling, and it is a method that uses a smaller volume of reagents than other forms of digestion. The main disadvantage of this method has to do with losses resulting from the formation of volatile compounds. It has been shown that losses in foods can be caused by the formation of $CdCl_2$, which depends on the matrix and the digestion temperature. A study conducted on tomato leaves showed small Cd losses (up to 7%) in dry ashing at temperatures not exceeding 500 °C. However, the losses increased to 30% when the final ashing temperature was raised to 900 °C. These losses caused by volatilization can be reduced by the use of ashing aids, which form complexes or molecules with the elements and prevent their volatilization. Another drawback of dry ashing is the time required for complete mineralization of the sample (12–24 h). Analytic instruments have been developed recently to dry ash samples using microwave heating. These devices can be programmed to remove most of the moisture initially (using relatively low heat) and then convert the sample to ash (using relatively high heat). Microwave instruments greatly reduce the time required to carry out an analysis, with the analysis time often

Table 2 Official methods for analyzing cadmium in food products

being less than an hour. The major disadvantage of the microwave heating method is that it is not possible to analyze as many samples simultaneously as in a muffle furnace.

Wet digestion

Wet digestion is performed by using combinations of oxidizing acids (HNO_3, conc. $HClO_4$, and conc. H_2SO_4), nonoxidizing acids (HCl, HF, H_3PO_4, diluted $HClO_4$, and diluted H_2SO_4), and H_2O_2. Most of the methods currently employed use HNO_3 as the primary oxidizing agent in combination with H_2O_2. Closed systems working under pressure are generally used, but systems open to atmospheric pressure (open digestion) may also be employed.

Digestion in open systems has traditionally been done in open vessels or tubes on a hot plate or in an aluminum or graphite heating block. In addition to conventional heating, it is also possible to use microwave irradiation. The most notable advantage of this technique is its low cost, especially if one is working with digestion blocks. One of the main disadvantages of working with an open system is that the temperatures are limited by the acid solution's boiling point. The boiling point of HNO_3 is 122 °C, very low for complete digestion of foodstuffs with a high concentration of fat or protein. In these cases, H_2SO_4 is added (boiling point, 338 °C), which raises the digestion temperature, although the presence of sulfates may affect determination by spectroscopic methods. Furthermore, a high temperature in an open system may bring about losses by volatilization, which can be avoided partially by working under reflux conditions. There is now instrumentation for performing open digestion, which incorporates reflux condensers and is automated. These new systems are an alternative to pressure systems, permitting digestion of a larger quantity of sample without causing overpressure problems. Although the open digestion has been used for decades, there are no official methods for the determination of Cd in foodstuffs based on acid digestion by heating at atmospheric pressure.

Pressure digestion systems can typically achieve temperatures in the 200–260 °C range. This results in a dramatic acceleration of the reaction kinetics, allowing digestion reactions to be carried out in a matter of hours (conventional heating) or in less than an hour (microwave assisted). The European Standard (EN) 13805 specifies a method for the pressure digestion of foodstuffs intended for the determination of trace elements. The mineralization method most often applied for determining Cd in foodstuffs is microwave-assisted digestion, using nitric acid as the oxidizing agent and H_2O_2. This approach is the basis for various official methods: EN 14084:2003, AOAC Official Method 999.10, and EPA Method 3051. There are also methods that leave the way in which the closed system is heated open (microwaves or pressure digestion apparatus with conventional heating): EN 14083:2003 and AOAC Official Method 2013.06.

Cadmium Quantification Methods

The most common analytic procedures for measuring cadmium concentrations in food samples use atomic absorption spectroscopy (AAS) and inductively coupled plasma atomic emission spectroscopy (ICP-AES) or mass spectrometry (ICP-MS). These three analytic methods are compatible with most of the digestion procedures described in the previous section.

Various forms of AAS have been used for the determination of Cd. Possibly the one most commonly used at present is GF-AAS (graphite furnace atomic absorption spectroscopy). There are various official methods that use GF-AAS as a detection technique for determining Cd in foods (EN 14083:2003,

AOAC 999.10, AOAC 999.11, ISO 6561-1:2005, ISO 15774:2000, and China national standard GB/T 5009. 15-2003). Most of these methods require prior preparation of the sample by dry ashing or pressure digestion, except ISO 15774:2000, developed for the determination of cadmium in animal and vegetable fats and oils, in which the sample is placed directly in the graphite furnace without prior mineralization treatment.

The principle of GF-AAS is the incineration and atomization of the samples (after digestion) in a graphite tube furnace with platform connected to an atomic absorption spectrometer. The measurement of Cd content is obtained from the absorption observed at a wavelength of 228.8 nm. Various developments have helped to improve this methodology in recent years (improved electrodeless discharge and hollow cathode lamps for increased light output). The limits of this methodology (0.03–0.08 $\mu g\,l^{-1}$) permit determination of most food samples, especially those that may be considered problematic because of their high cadmium content.

Some studies show that the determination of Cd in GF-AAS suffers from background and spectral interferences. Zn(II), Co (II), and Ag(I) ions can cause positive interferences, while Ge (IV), Cu(II), Pb(II), and Sb(III) can produce negative interferences. There have also been reports of background interference caused by the presence of iron (Fe). In order to prevent these interferences and also to avoid possible losses of Cd during the thermal treatment, it is necessary to add a matrix modifier, palladium (Pd), nickel (Ni), ammonium phosphate, and a mixture of Pd and Mg being the ones most used. There have also been improvements in the correction systems (Zeeman background correction versus D_2 correction) and the introduction of samples (use of L'vov platforms). In recent years, the high-speed self-reversal background correction (HSSR-BGC) system has been presented as a powerful background corrector to avoid background and spectral interferences in Cd determination (Figure 2).

Flame atomic absorption spectroscopy (FAAS) is a technique that has been very widely used for the determination of Cd for many years. There are some official methods that leave the choice of FAAS or GF-AAS as the detection method open (AOAC 999.10, AOAC 999.11, and ISO 6561-2:2005). FAAS requires a liquid sample to be aspirated, aerosolized, and mixed with combustible gases, such as acetylene and air or acetylene and nitrous oxide. The mixture is ignited in a flame whose temperature ranges from 2100 to 2800 °C. During combustion, atoms of the element are reduced to free, unexcited ground state atoms, which absorb light at characteristic wavelengths.

FAAS is a simple, fast determination method that costs less than other techniques, and it is very selective because atomic lines are sharp. However, its sensitivity is less than that of other detection systems used for the determination of Cd in food. The reported detection limits of this method in food are various orders of magnitude higher (4–10 $\mu g\,l^{-1}$). For this reason, the analyte is generally preconcentrated and separated prior to determination by FAAS. There are various preconcentration methods, including coprecipitation, liquid-liquid extraction, cloud-point extraction, solid-phase extraction, and dispersive liquid-liquid microextraction. After preconcentration, detection limits closer to those of other techniques used for determining Cd in food have been reported (0.60–5 $\mu g\,l^{-1}$).

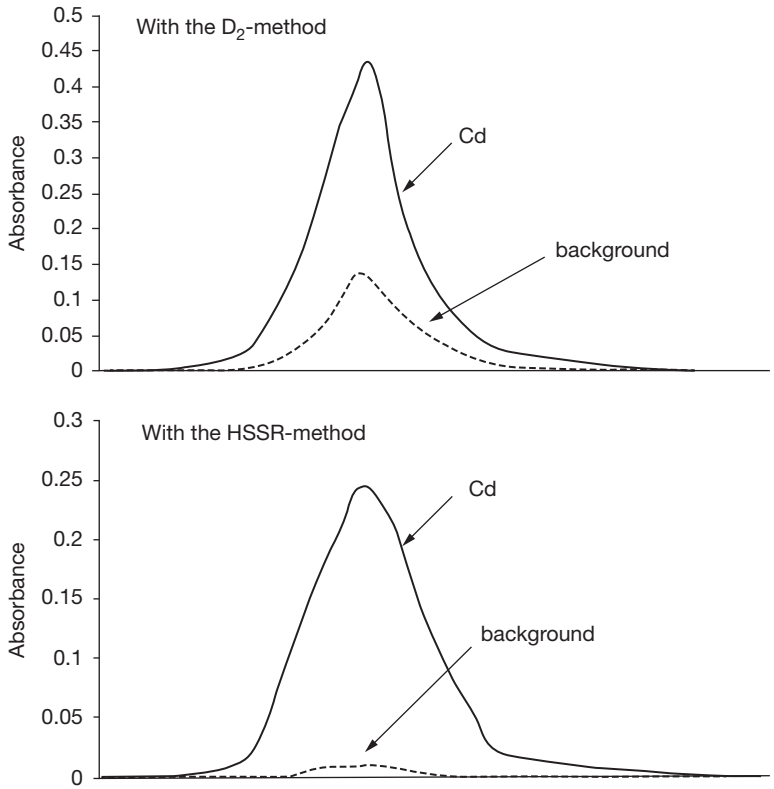

Figure 2 Background correction with D_2 and HSSR method in the determination of cadmium by GF-AAS. Reproduced from Waterlot, C. and Douay, F. (2013). *Measurement* **46**(8), 2348–2358, with permission of Elsevier.

ICP-AES is based on the generation of plasma by ionization of argon gas using the electromagnetic field created by high-frequency electric current. Initially, the liquid sample (previously digested) is converted into a stream of fine droplets (aerosol). In the spray chamber, separation of the aerosol occurs; the large droplets go to the drain and the fine droplets are carried to the plasma, which generates temperatures around 10 000°K. At this temperature, all elements become excited and emit light at their respective wavelengths. The radiation emitted from the plasma is then collected by wavelength and amplified to yield intensity measurements. The official methods established by the various organizations for the determination of Cd in food do not use ICP-AES as the detection method. Only one CEN method uses ICP-AES for analysis of animal feeding stuffs (EN 15510:2007).

This analytic technique has the same disadvantage as FAAS: its detection limit (0.1–1 $\mu g\, l^{-1}$) is approximately 100 times greater than that of GF-AAS and 1000–10 000 times greater than that of ICP-MS. In some cases, analyte preconcentration processes similar to those described for FAAS have been used. The advantages of this method are the possibility of determining a large number of elements simultaneously and the fact that the cost of acquisition and maintenance is less than that of ICP-MS. Furthermore, among all the commonly used analytic atomic spectrometry techniques, ICP-based techniques are probably the ones with the fewest interferences; however, nebulizer, chemical, and spectral interferences are all present. The chemical interferences are generally of less importance because the high temperature and the inert atmosphere of the Ar plasma help to reduce them; nebulizer interferences in ICP-AES (also known as matrix effects) can arise from physical and chemical differences between reference standards and samples or between samples, such as the inconsistent presence of matrix salts and organic compounds, or different viscosities and surface tensions of the liquid. In these cases, one can try to work by diluting the sample or using the method of additions and employing internal standards.

The most severe interferences in ICP-AES are spectral, due mainly to the excitation and subsequent emission of spectral lines for every element in the sample as well as the Ar added to facilitate plasma generation. Emission at 228.80 nm is the strongest line for Cd. If arsenic (As) is present in the sample, it can interfere with Cd measurements owing to spectral overlap from the nearby As line at 228.812 nm. Similarly, for the 214.439 nm Cd line, there is also an Fe line only 6 pm apart that can lead to severe interferences in the presence of high amounts of Fe. Spectral overlaps may be avoided by using an alternate wavelength, or high resolution (if available), or can be compensated for by the use of interelement correction (IEC) equations or multicomponent spectral fitting (MSF) (Figure 3).

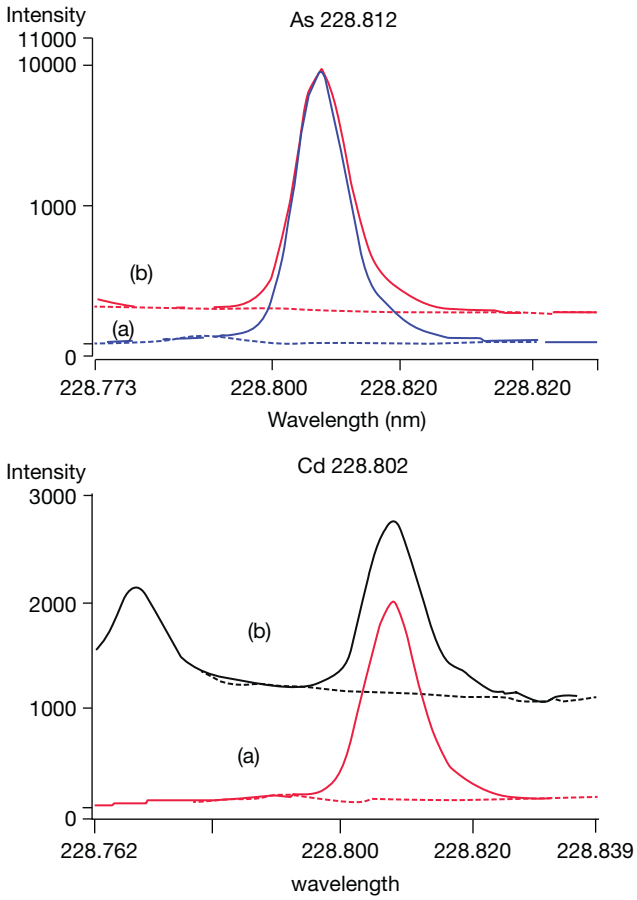

Figure 3 Line overlap of As and Cd at 228.8 nm in ICP-OES. Reproduced from Asfaw, A. and Wibetoe, G. (2009). *Spectrochimica Acta Part B* **64**, 363–368, with permission of Elsevier.

Table 3 Spectral interferences in Cd detection by ICP-MS

Isotope	*Abundance*	*Interference*
^{110}Cd	12.5	$^{39}K_2^{16}O^+$
^{111}Cd	12.8	$^{95}Mo^{16}O^+$, $^{94}Zr^{16}O^1H^+$, $^{39}K_2^{16}O_2^1H^+$
^{112}Cd	24.1	$^{40}Ca_2^{16}O_2$, $^{40}Ar_2^{16}O_2$, $^{96}Ru^{16}O^+$
^{113}Cd	12.22	$^{96}Zr^{16}O^1H^+$, $^{40}Ca_2^{16}O_2^1H^+$, $^{40}Ar_2^{16}O_2^1H^+$, $^{96}Ru^{17}O^+$
^{114}Cd	28.7	$^{98}Mo^{16}O^+$, $^{98}Ru^{16}O^+$, ^{114}Sn
^{116}Cd	7.49	$^{100}Ru^{16}O^+$

In ICP-MS, the argon plasma is also used as the excitation source; however, in contrast to ICP-AES, the plasma is used to generate ions that are introduced into the mass analyzer. The ions are separated and collected in relation to their mass-to-charge ratio. The main advantage of this method is its sensitivity, with detection limits (0.00001–0.001 $\mu g\, l^{-1}$) much lower than those of any other technique used for the determination of Cd. One disadvantage in comparison with ICP-AES and FAAS has to do with the concentration of total dissolved solids (TDS). In ICP-AES, with the proper equipment, up to 20% TDS can be run. However, in ICP-MS, TDS concentrations only range up to 0.2%, unless specialized nebulizers and torches are used. Moreover, it is an expensive technology to acquire and maintain, and it requires highly qualified operators. Currently, a considerable number of the studies that report Cd concentrations in foods use this methodology. This technique is also the basis of standard EN 15763:2010.

In ICP-MS, the determination of certain elements may be affected by spectral and matrix interferences. The spectral interferences may be due to isotopes of other elements (isobaric interferences) or to the formation of molecules or combinations of atoms among the elements present in the matrix and those that come from the air and the argon plasma (polyatomic or molecular interferences). A series of spectral interferences have been identified in the determination of Cd by ICP-MS (Table 3). The most sensitive isotope for Cd is at mass 114; however, there is also a minor isotope of tin (Sn) at this mass. This means that if there is Sn in the sample, quantitation using ^{114}Cd is difficult. Another element that can cause spectral interference is molybdenum (Mo). The formation of different species with oxygen creates interferences in the determination of all the isotopes of Cd except ^{106}Cd. This latter isotope, however, is low in abundance (1.2%) and is insufficiently sensitive to yield sub-ppb detection limits.

Various approaches can be used to try to eliminate these interferences, such as mathematical correction (a useful method for correcting interference caused by Sn) or the use of collision and reaction cells that use ion–molecule collisions and reactions to cleanse the ion beam of polyatomic and molecular interferences before entering the analyzer (used for eliminating MoO interferences). However, the best and probably most efficient way to remove spectral overlaps is the use of a high-resolution mass spectrometer.

The determination of total concentrations of Cd in foodstuffs is important because it is a way of keeping watch on food safety. In recent years, however, attempts have been made to take a further step, to identify the interactions between this element and the food matrix. The possible bonds with more complex molecules may finally be a conditioning factor affecting its subsequent intestinal absorption and arrival in the systemic circulation. In plants, there are reports of the formation of complexes with phytochelatins (PCs) as a cellular response to this toxic element. Different methods have been used in recent years to determine Cd-PC complexes: high-performance liquid chromatography (HPLC)-ICP-MS and HPLC-electrospray mass spectrometry (ESI-MS). This kind of approach is currently one of the most novel lines of research in the analysis of Cd in foods.

Sources and Production

Cadmium is a naturally occurring soft metal in the Earth's crust. It has an average crustal abundance of 0.1–0.5 parts per million and is ranked the 64th most abundant natural element on Earth.

Cadmium can be released from the rocks through natural processes such as weathering and erosion and then transported to rivers and oceans. In marine sediments, the cadmium concentration is typically higher than that on the land, with an average abundance of 1 part per million. Other natural processes resulting in cadmium emissions include volcano eruptions and forest fires.

Cadmium can also be released to the environment through various human activities. A large part of anthropogenic emission occurs during the extraction, smelting, and refining of metals, especially zinc, lead, and copper, from ores that also contain cadmium. The burning of fossil fuels such as coal, oil, and gas and the use of cadmium-containing phosphate fertilizers also contribute to the total emission. Starting from the 1930s, cadmium as the by-product of the metal processes has been found useful in many industrial products, mainly in the areas of metal coating, plastic stabilization, color pigments, and nickel–cadmium batteries. With its wide application, cadmium enters the environment during the manufacture, use, and disposal of these industrial products. High levels of cadmium have been found in the soil close to hazardous waste sites because of spills and leaks. Since cadmium does not break down in the environment, it stays in the water and soil for long periods of time and can be taken up by plants, fish, and animals.

The anthropogenic emission of cadmium used to be about ten times the amount of natural emission. However, due to the increasing global awareness of cadmium-related health and environmental issues, the traditional application of cadmium has diminished in many countries during the last 20–30 years. Today, cadmium is primarily used in the manufacture of nickel–cadmium batteries, and anthropogenic emissions have dropped significantly.

Patterns of Consumption

Route of Exposure

Humans can be exposed to cadmium from food, water, and air. Food is the major source of cadmium exposure for nonsmokers in a non-occupational environment. In unpolluted areas, the exposure from drinking water is usually less important compared with the exposure from the food because of the relatively lower levels. Though the burning of fossil fuels and cadmium-containing household waste can release cadmium into the air, the exposure from the air for non-cadmium workers is usually negligible. Cigarette smoking can be an important source of cadmium, because the tobacco plant characteristically accumulates relatively high concentrations of cadmium in its leaves. In heavy smokers, the contribution of cadmium exposure from smoking can be comparable with that from the diet. In this article, only dietary exposures will be discussed.

Levels in Food

The presence of cadmium in food results from the contamination of soil and water. Cadmium can be taken up by certain plants and aquatic organisms and accumulate in the food chain. In 2010, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) conducted a reevaluation of cadmium in food. In response to the JECFA's call, cadmium occurrence data from a total of over 155 000 food samples were submitted for review. The majority of these data were submitted by the European Food Safety Authority (EFSA), covering 19 European Union member countries. Besides, ten other countries (China, Japan, Singapore, Vietnam, Brazil, Chile, Canada, the United States, Australia, and Ghana) also submitted cadmium occurrence data. The food industry submitted cadmium occurrence data from food products distributed and used worldwide. A description of these data is given in Table 1.

For most food categories, the national mean cadmium concentrations range between nondetected (ND) and 0.04 mg kg^{-1}. Shellfish/mollusks, meat and poultry offal, nuts and oilseeds, coffee, tea and cocoa, vegetables (especially dried), and spices are among the top food categories with the highest cadmium levels (0.1–4.8 mg kg^{-1}). The food categories containing relatively low cadmium include eggs (0.0001–0.007), dairy products (ND–0.004), animal and vegetable fats (ND–0.006 mg kg^{-1}), meat muscle (0.001–0.003 mg kg^{-1}), fruits (0.001–0.007 mg kg^{-1}), and finfish (ND–0.008 mg kg^{-1}). The cadmium levels in grains usually contain medium levels of cadmium (wheat, 0.009–0.04 mg kg^{-1}; rice, 0.004–0.02 mg kg^{-1}; and oats, 0.003–0.02 mg kg^{-1}).

Dietary Exposure

The mean total dietary exposure is calculated as the sum of the cadmium exposure of all food categories; each is the product of the mean cadmium occurrences and the average consumption for the total population. Different countries and regions may apply their own methodology to assess the food consumption, normally from either a retrospective dietary history recall or a prospective dietary record. These surveys can capture an individual's food consumption from 1 day to 7 days, depending on the length of the survey. The results can be used to estimate a daily or weekly exposure. At its 73rd meeting in 2010, the JECFA committee recommended that these exposure estimates be extrapolated to a monthly basis due to cadmium's exceptionally long half-life. A daily or weekly exposure estimate can be translated into a monthly exposure estimate by multiplying 30 or 4, respectively, and expressed in μg cadmium per kilogram body weight per month (μg kg bw^{-1} $month^{-1}$).

			Shellfish	0.648
			Dried vegetables	0.330
			Spices	0.106

JECFA (2010). Cadmium, Tables 5 and 6. If data from multiple food categories are reported, only the top 5 food categories with the highest cadmium occurrence are listed.

Several countries and regions have conducted their own total diet study (TDS) to estimate the national dietary cadmium exposure. Some countries have separate survey systems to collect the occurrence data and the food consumption data. In the United States, for instance, the occurrence data come from the TDS, and the consumption data come from the National Health and Nutrition Examination Survey (NHANES). The estimated mean dietary cadmium exposures for countries with available data are listed in Table 2.

The national mean cadmium exposures in adults are estimated to range from 2.1 to 12.0 μg kg bw^{-1} month^{-1} in these countries and regions. For children 0.5–12 years old, the exposures reported by Australia and the United States range from 3.9 to 20.6 μg kg bw^{-1} month^{-1}. Dietary exposure for vegetarians, as reported by the EFSA, can reach as high as 23.2 μg kg bw^{-1} month^{-1}.

A provisional tolerable weekly intake (PTWI) for cadmium of 7 μg·kg bw^{-1} was established by the JECFA in 1988 and has been widely accepted. At its 73rd meeting in 2010, the JECFA reevaluated cadmium. Based on its adverse renal effects, the committee established a new provisional tolerable monthly intake (PTMI) of 25 μg·kg bw^{-1}·month^{-1}.

The Contribution of Food Categories to the Total Dietary Exposure

The cadmium exposure from a certain food category is calculated as the product of the cadmium concentration and the level of consumption for that food category. Therefore, the food categories with the highest cadmium concentrations may not be the categories that contribute the most to the total cadmium exposure. For instance, though the cadmium concentration in grains is not the highest among all food categories, cadmium exposure from grains may still be the main source of total dietary exposure in certain populations due to the large consumption of the staple foods. On the other hand, though certain spices can contain high levels of cadmium, the exposure from spices may not be comparable with other food sources due to the fairly low consumption.

Table 2 Dietary cadmium exposure levels in different countries

Country	Source of occurrence data	Source of consumption data	Mean cadmium exposure in adults ($\mu g\ kg\ bw^{-1}\ month^{-1}$)
Australia	TDS 2000–01	1995 Australian National Nutrition Survey	2.4,[a] 7.2[b] (males) 2.1,[a] 6.6[b] (females)
China	TDS 2007	TDS 2007	9.9[c] (range 0.5–36.5, varied by province)
Europe	EFSA 2009	EFSA 2008	9.1[c] (range 7.6–11.8, varied by country)
The United States	TDS 2004–08	NHANES 2003–06	4.6[a] (range 4.1–5.5, varied by age)
Chile	TDS 2001–02		9[d]
Japan			12[d]
Lebanon	TDS 2004		5.2[c]
Republic of Korea			7.7[b]

[a]ND = 0.
[b]ND = LOD.
[c]ND = LOD/2.
[d]ND: not specified.
JECFA (2010). Cadmium. Tables 10, 12, and 13.

The contribution of each food category to the overall dietary cadmium exposure varies by country and geographic region, primarily due to the differences in the regional cadmium occurrences and dietary habits. For example, the main dietary sources of cadmium in Japan are rice, vegetables, seaweed, and seafood, while the main sources in some European countries are cereals and grains, animal offal, and vegetables. In European vegetarians, the main contributors can be vegetables, pulses, and nuts.

The cadmium contributions of different food categories also depend on the geologic location. Taking China as an example, in Sichuan province, cereals accounted for 85% of the total exposure, and the cadmium levels in the cereals are about six times the national average. In Shanxi and Shanghai provinces, vegetables account for 62% and 69% of the total cadmium exposure, respectively. Meat is the major source of cadmium in Heilongjiang and Hubei provinces, while seafood contributes 88% of the total dietary cadmium in Liaoning province.

The Biomarkers for Cadmium Exposure

Many biomarkers have been used to reflect the level of cadmium exposure, including cadmium levels in the blood, urine, feces, liver, kidney, hair, toenail, etc. The most commonly used exposure biomarkers are blood cadmium and urinary cadmium. It has been generally accepted that urinary cadmium indicates the total body burden, while blood cadmium only reflects recent exposures. Many human studies have shown that the level of urinary cadmium is positively correlated with daily dietary cadmium exposure.

High Exposures

Foods grown in cadmium-contaminated areas can have high cadmium levels, leading to high cadmium exposures in people who consume these foods. An example is the epidemic of itai–itai disease in Japan around the 1930s, resulting from the consumption of rice grown in cadmium-contaminated fields. In some highly mineralized geographic areas, such as central Jamaica, high levels of cadmium naturally occur in the soil, resulting in high levels of cadmium in local vegetables and foods. High urinary cadmium and the incidence of kidney diseases have been reported in the local population.

Availability, Absorption, and Metabolism

In humans, the average absorption of ingested cadmium is about 5% in adults. The absorption of cadmium in newborns and infants can be higher. The factors affecting the gastrointestinal absorption of cadmium include age, gastric pH, diet type, and nutrition status. There has been evidence that zinc and iron compete with cadmium for absorption, probably through a common transporter. As a result, the bioavailability of cadmium is lower in zinc and iron-rich foods, such as oysters, and people with low body iron store can have higher cadmium absorption. It has been suggested that the generally lower body iron store in women accounts for their generally higher body burden of cadmium.

In the liver, cadmium binds with metallothionein (MT), a cysteine-rich protein that can bind metals through the thiol groups on its cysteine residues. This process reduces the amount of free cadmium, preventing free cadmium from exerting its toxic effects. However, some cadmium–MT complex is transported to the kidneys and accumulates in the renal proximal tubule by receptor-mediated endocytosis. In the kidneys, the cadmium–MT complexes are degraded by lysosomes, resulting in the release of free cadmium. Though the newly released free cadmium can induce more MT in the kidney, renal tubular damage starts to occur when free cadmium exceeds a certain level, at which the newly synthesized MT is not enough to neutralize it. This cadmium level is called the 'critical value,' commonly quoted as 200 $\mu g\ g^{-1}$ renal cortex.

Cadmium is widely distributed in the body, with the highest concentrations found in the liver and the kidneys and lower concentrations found in the brain, bone, and fat. In humans with non-occupational exposure, the majority of cadmium body burden is found in the liver, the kidneys, and muscle. Long-term exposure to cadmium leads to selective accumulation in the liver and renal cortex, such that up to 75% of the total body burden is found in these organs.

Cadmium does not readily cross the fully developed placenta or blood–brain barrier in humans. Evidence has shown that cadmium can induce MT in the placenta. The placenta retains most cadmium after low exposures, so the concentrations of cadmium in the fetuses and neonates are much lower than the corresponding concentrations in pregnant women.

Once cadmium has entered the body, it is eliminated from the body at an extremely slow rate. The most important route of elimination of absorbed cadmium, urinary excretion, normally gets rid of only less than 0.01% of the total body burden

per day. The daily urinary excretion rate is usually proportional to the level of body burden and slowly increases with age. The amount of cadmium eliminated from fecal excretion is sometimes comparable with that from urine. Other routes of elimination, such as from hair and breast milk, are insignificant. Due to the extremely slow rate of elimination, the biological half-life of cadmium in humans is very long, approximately 10–30 years.

Health Effects

Cadmium has no known biological function in animals and humans. Occupational exposure to cadmium, mainly through inhalation, can result in metal fume fever, chemical pneumonitis, pulmonary edema, and lung cancer. In this article, only health effects related to oral exposure are discussed.

The acute oral toxicity of cadmium is rarely seen in humans. Exposures to high concentrations of cadmium from heavily contaminated food or beverages can result in GI symptoms including nausea, vomiting, and abdominal pain. The no-observed-adverse-effect level (NOAEL) of a single oral dose is estimated to be 3 mg elemental cadmium per person, and the reported lethal doses range from 350 to 8900 mg.

Toxic effects from chronic oral exposure are a much greater concern than from acute exposures, because they require lower exposure levels and occur more frequently. Chronic exposures to cadmium from contaminated foods have been associated with damages of multiple organs and systems, including the kidneys, bones, and cardiovascular system. Adverse health effects in the endocrine and the neural systems and several types of cancer have also been reported.

Renal Effect

The kidneys are the major target of cadmium toxicity. Limited autopsy examinations in patients with long-term, heavy oral cadmium exposure found kidneys with granular surface, extensive tubular atrophy, and interstitial fibrosis. The molecular mechanisms of cadmium-induced nephrotoxicity are not yet clearly defined, but evidence has shown that mitochondria could be one of the earliest target organelles. Three mechanisms have been proposed: the generation of reactive oxygen species that results in apoptosis or autophagic cell death of renal tubular cells, inhibition of the Na–K–ATPase transport system, and the stimulation of calcium release from the endoplasmic reticulum, causing damage to the mitochondrial membrane.

Renal tubular damage

One of the earliest manifestations of cadmium nephropathy is the damage of the proximal renal tubule, resulting in an elevated excretion of low-molecular-weight proteins (LMWPs) due to the reduced reabsorption. This type of damage is measured by the urinary levels of LMWPs, commonly beta-2 microglobulin (β2MG), retinol-binding protein (RBP), or the activity of N-acetyl-beta-glucosaminidase (NAG). Numerous epidemiological studies have shown that the level of urinary LMWPs is positively associated with cadmium exposure, with a nonlinear dose–response curve. The overall data suggest a two-phasic response, with a rapid increase of LMWPs occurring after the exposure reaches a certain point. The JECFA estimated this transition point as U–Cd at 5.24 μg g creatinine^{-1}. Other estimates for this transition point include U–Cd at 10 μg g-creatinine^{-1} and urinary β2MG at 1000–1500 μg g creatinine^{-1}.

Urinary LMWP biomarkers serve as sensitive screening end points for early kidney damage due to cadmium exposure. In clinical labs, urinary β2MG levels that are less than 300 μg g creatinine^{-1} are usually considered 'normal,' and patients with higher levels are generally recommended for further examination. Moderate tubular proteinuria (β2MG or RBP levels in the range of 300–1000 μg g creatinine^{-1}) is indicative of early or minor tubular damage. However, due to a large functional reservoir of the kidneys, this level of exposure does not lead to clinical symptoms in most cases. In addition, tubular damage at this level is usually reversible after the exposure has ceased. Severe tubular proteinuria, that is, tubular dysfunction, occurs when β2MG or RBP levels are higher than 1000 μg g creatinine^{-1}. At this stage, more generalized biochemical abnormalities can be present, as seen in the Fanconi syndrome. Also, the tubular damage seems to be irreversible. Impairment of tubular function would be progressive even if cadmium exposure is discontinued.

Glomerular damage

Cadmium-induced glomerular damage was evident in a number of *in vivo* and *in vitro* animal studies. The generation of reactive oxygen species has been suggested as the molecular mechanism. Several animal studies and case reports have indicated that cadmium-induced renal damage could eventually progress to end-stage chronic kidney disease (CKD), which requires kidney transplant.

Cadmium-induced glomerular damage has been reported in Japanese patients with *itai–itai* disease. The association between cadmium exposure and decreased glomerular filtration rate (GFR) has been observed in polluted areas in Japan, Poland, and Thailand, but not in Belgium. In the general population, significantly reduced GFR was observed in a Swedish population of women at a mean urinary cadmium level as low as 0.6 μg Cd l^{-1} (comparable with 0.8 μg g creatinine^{-1}). Evidence from the US NHANES and the Korean NHANES has suggested an association between cadmium exposure and reduced GFR or increased albuminuria. These studies provide strong support for the role of cadmium as a CKD risk factor.

Kidney stone

Kidney stone formation has been reported as a long-term health effect among cadmium workers with tubular proteinuria. It has been suggested that calcium metabolism and citric acid uptake could be interrupted by cadmium, leading to urolithiasis. The limitation of these occupational studies is the potential confounding factors resulting from coexposure to other toxic elements, such as lead and arsenic. In the general population, relevant data are extremely limited and the effect remains inconclusive.

Diabetic nephropathy

In experimental animals, cadmium treatment caused pathological changes in pancreatic tissues and elevated blood glucose. Human studies, on the other hand, have given inconsistent

results to support a causal association between cadmium and diabetes. However, a synergistic or potentiating effect of cadmium has been observed in laboratory animals with spontaneous or drug-induced diabetes. Two European cross-sectional studies and one study in China found that diabetic-related renal tubular damage was more severe in those with high cadmium exposure than those with lower cadmium exposure.

Bone effects

Cadmium-related bone disorders were first reported among individuals with long-term, high exposure from contaminated food. In Japan, the endemic of *itai-itai* disease in the 1940s raised health concerns of rice crops grown in cadmium-polluted areas. *Itai-itai* disease is one of the most severe forms of chronic cadmium intoxication. It is characterized by severe bone pains due to osteomalacia, followed by increasingly waddling gait due to bone deformities, and progresses into more severe clinical symptoms so the patients lose the ability to walk, eventually leading to death.

Cadmium may exert its bone effects through interference with calcium homeostasis and vitamin D metabolism. In several animal and human studies, cadmium stimulated the formation of osteoclasts, leading to enhanced bone resorption. Changes in bone metabolism, bone mechanical properties, and bone mineral density (BMD) have been shown in experimental animals following long-term cadmium treatment. In humans, epidemiological studies conducted in Belgium, Sweden, China, the United Kingdom, and the United States consistently showed a negative correlation between cadmium exposure and BMD, suggesting cadmium as a risk factor for osteoporosis.

Since osteoporosis is the main cause of fractures in postmenopausal women, it is scientifically plausible that cadmium is also a risk factor for bone fracture. This hypothesis can be supported by a study in female rats, in which low-level chronic exposure to cadmium enhanced the risk of long-bone fractures. In humans, there have been very few epidemiological studies designed to investigate the relationship between cadmium exposure and the risk for fracture, and they are often different in the selection of study population, the type of fractures recorded, and the adjustment of confounding factors. The dose–response information is lacking, and a threshold dose for bone effects has not been established.

Cardiovascular effects

The cardiovascular effects of cadmium have been observed in animals with the absence of significant renal disease, primarily reported as increased systolic blood pressure. The pathological and biochemical changes have included oxidative damage, endothelial cell apoptosis, lipid accumulation, and interaction with calcium channels.

There have been a great number of epidemiological studies designed to investigate the association between cadmium exposure and hypertension in humans. Among population studies with a considerable large sample size, the results vary from significant positive relationships (in Thailand and Korea), to a weak association (in the United States), to no association (in Belgium), to a negative association (in Japan). Most studies used a cross-sectional design, making it difficult to support a causal association. It has to be noted that different cadmium exposure biomarkers (urinary cadmium and blood cadmium) were used in these studies, and different confounding factors were controlled. Examples of these factors include age, alcohol consumption, cigarette smoking, coexposure to lead, diabetes, reduced renal function, and the use of hypertension treatment medication.

The association between cadmium exposure and the risk of atherosclerosis, peripheral arterial diseases, ischemic heart disease, and stroke has been investigated in a limited number of ecological or cross-sectional studies. Because of the complicity of the etiology and diagnostic criteria for these cardiovascular conditions, the results are often inconsistent, and the overall evidence is not strong enough to support a causal association.

Cancer

Cadmium and cadmium compounds have been classified as known human carcinogens by the International Agency for Research on Cancer (IARC) and the National Toxicology Program (NTP). Most of the evidence is based on the occupational exposure through inhalation, which has been most clearly associated with lung cancer.

Cadmium does not bind directly to DNA, yet it may induce oxidative stress and act as a DNA-damaging agent. In a rodent *in vivo* micronucleus study, cadmium chloride induced micronuclei formation in bone marrow and peripheral blood. In addition, cadmium has also been found to compromise the repair of DNA adducts in an *in vitro* system. Chemical carcinogenesis has not been shown in animals except for one rat study, in which a zinc-dependent increase in prostatic proliferation was observed.

In humans, only a limited number of epidemiological studies have demonstrated an association between chronic cadmium exposure and cancers of the breast, endometrium, kidney, pancreas, and urinary bladder. Further studies are needed to confirm these results.

Other Effects

The reproductive and developmental effects of cadmium have been reported in several animal studies. In pregnant rats, oral exposure to cadmium induced the level of metallothionein in the placenta. Elevated levels of cadmium were found in dam blood, the placenta, and fetal blood and fetal brain. Other developmental effects observed in animals include reduced birth weight and skeleton malformation. In humans, the level of cadmium in maternal blood is not highly correlated with that in fetal blood, but is correlated with the level in the cord blood and the placenta.

Some neurotoxicity and neurobehavioral effects have been observed in rodents, including changes in the levels of certain neurotransmitters and abnormal behavior in offspring. In humans, the blood–brain barrier can limit cadmium's access to the central nervous system. However, infants and children may be more susceptible because the blood–brain barrier has not fully developed in the early life stages.

Caffeine: Characterization and Properties

S Oestreich-Janzen, CAFEA GmbH, Hamburg, Germany

© 2016 Elsevier Ltd. All rights reserved.

Introduction

In the minds of most Europeans caffeine is strongly associated with coffee. Indeed, this compound was first isolated in coffee 200 years ago, and this isolation led to its naming. Caffeine occurs in plants of different families, with traditional styles of human consumption. It has a mild stimulating effect on the central nervous system. Caffeine-containing coffee and tea plants are important contributors to the global economy. Since the seventies of the last century, the biosynthesis of caffeine, its in-plant transfer, and degradation have been thoroughly investigated.

Studies on caffeine's mechanism of action, stimulation, and health effects are ongoing. New fields of use have provoked increasing research. The next article in this encyclopedia is dedicated to caffeine consumption and related health effects.

Discovery and Naming

In 1819, the German poet Goethe presented some coffee beans to the chemist F.F. Runge in Jena for investigation. Runge was successful in this task. The aqueous extraction of the beans, both green and roasted, the precipitation of coffee acids, and separation eventually allowed the crystallization of the substance he called 'Kaffeebase,' the base of coffee, identifying its activity on salamanders. He published his methodology and product description in early 1820. Much later, in 1866, Runge recounted the start-up story, with his introduction to Goethe.

Concurrent research on coffee was done using similar procedures at some other centers in Europe. Within a short interval of time, multiple investigators had identified the same substance. Later in 1820, F. von Giese published his findings on coffee in present-day Estonia, calling the substance 'Kaffeestoff.' In 1821, the French senior pharmacist P. J. Robiquet verbally presented his results to the pharmaceutical society in Paris, and he used the word 'caféine,' which he had adopted from an unconvincing attribution by R. Chenevix, some years earlier. This name was accepted by scientific consensus, and in 1822, it was accepted for a short entry in a dictionary of medicine by P.J. Pelletier. The following year, the term caffeine came out at the Royal Academy of Science in Paris, in a report on alkaloids by Pelletier, in which he mentioned Robiquet's earlier note. Pelletier and his companion B. Caventou had ceased their own research on coffee in favor of Robiquet. In 1823, the latter published the details of his extraction as part of another dictionary's article on coffee, and his procedure became the standard methodology of its time, being discussed in depth in the French pharmaceutical journal (*Journal de Pharmacie et des Sciences Accessoires*) in 1826.

The community researching caffeine in Paris was open to guest scientists from all over Europe, and members communicated with corresponding societies via the exchange of letters and printed proceedings, posted per stagecoach.

Reporting to the Swedish academy about the research in France and the related notes of 1826, with all his authority, J.J. Berzelius acknowledged the seniority of Runge on the isolation of caffeine, thus disclosing his significance to the European scientific community.

In the following years, the search for the active mechanisms of other stimulating plants of human interest and use resulted in several discoveries of substances that were later identified to be identical to caffeine. In 1826, guaranine was detected in guaraná seeds by T. Martius. In 1827, V. Oudry identified theine in tea leaves, and its equivalence to caffeine was clarified by Martius in 1840 and C. Jobst in 1838. In 1836, an alkaloid was found in maté leaves by B. Trommsdorf, and this substance was identified as caffeine by J. Stenhouse in 1843. In 1865, caffeine was detected in the kola nut by W.F. Daniell, and in cocoa beans by E. Schmidt in 1883. All these researchers thoroughly described and characterized the compound, based on its physical and chemical properties, as crystalline needles, slightly bitter tasting, and soluble in hot water.

Caffeine's molecular formula, $C_8H_{10}N_4O_2$, was determined by C. H. Pfaff and J. Liebig in 1832. In the century's last quarter, the eventual structural formula of caffeine was fixed (Figure 1), first proposed by L. Medicus of Wuerzburg, Germany, based on cleavage reactions in 1875, and later confirmed via synthesis from well-known educts by E. Fischer and L. Ach in Berlin in 1898. The total synthetic pathway is shown in Figure 2.

Dimethylurea reacts with malonic acid to form the pyrimidine ring with properly placed methyl and keto groups; nitrosylation with nitrous acid, with subsequent reduction on platinum, introduces the amino group in position 5, where reaction with potassium cyanate provides the missing atoms for the imidazole part, followed by acidic ring closure to form dimethyl uric acid. Via chlorination with phosphorus pentachloride in position 8, as well as reduction with fuming hydroiodic acid, the dimethyl xanthine theophylline is produced. The last step is methylation with methyl iodide in position 7 to yield caffeine. The synthesized caffeine was checked against naturally occurring caffeine, using mixed melting point methods.

Nomenclature

In the nomenclature of the twenty-first century, the molecule caffeine is referred to as 1,3,7,trimethyl-2,6-dihydro-purin-2,6-

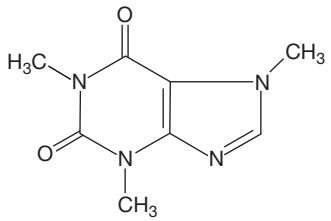

Figure 1 Caffeine – structural formula.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00098-2

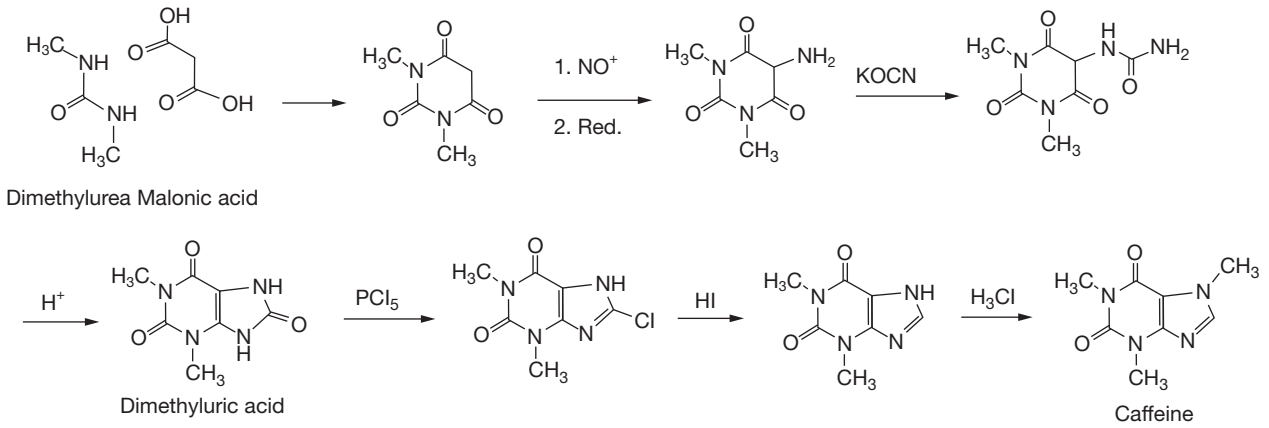

Figure 2 Reaction scheme of Fischer's synthesis of caffeine 1898 (edited from Kunz, H., (2002). Emil Fischer – unequalled classicist, master of organic chemistry research, and inspired trailblazer of biological chemistry. *Angewandte Chemie, International Edition*, 41, 4447).

dione, or by the shortened form 1,3,7-trimethylpurine-2,6-dione. Caffeine is accepted as synonymous, however. The parent skeleton is purine, a bicyclic system, which consists of two fused heterocycles, the five- and six-membered imidazole and pyrimidine, respectively. The multiplicative prefix trimethyl marks the substituents, and the suffix dione indicates the functional keto groups in caffeine. Purine is a constituent of nucleic acids.

The name purine was created by Emil Fischer in 1884. In 1897, he proposed its ring numbering, as shown in Figure 3. This customary naming and numbering was used in the standard reference works of that time, the German *Beilstein Handbook of Organic Chemistry* and in the American *Chemical Abstracts* since their first editions. In 1957, the parent name purine was declared to be a 'retained trivial name' in the rules for the nomenclature of organic chemistry established by the International Union of Pure and Applied Chemistry (IUPAC), which was based in Oxford, United Kingdom, at the time, and in the same paper Fischer's customary numbering system for purine was accepted as an exception to the systematic numbering. These naming conventions were then confirmed repeatedly. In December 2013, with a new approach in organic nomenclature, purine was upgraded to a 'preferred IUPAC name' (PIN), a decision published in the IUPAC's actual *Blue Book*. The IUPAC's naming principles continue to "allow alternatives, in order to preserve the diversity and adaptability of the nomenclature to daily activities in chemistry and in science in general," as stated in the *Blue Book*, that is Favre and Powell.

There is no doubt that this modus operandi would matter to purine (PIN) and caffeine. 'Caffeine' is allowed, without explicit IUPAC mentioning, as an alternative for the trimethylated purine dione. The more comprehensive name is 3,7-dihydro-1,3,7-trimethyl-1*H*-purine-2,6-dione. Another trivial name widely used for the unmethylated purine dione is xanthine; its subsequent methylation forms part of the well-studied metabolism involved in caffeine biosynthesis and degradation. Caffeine may also be named 1,3,7-trimethyl-xanthine. Figure 4 shows the covalent structure of caffeine – the customary skeleton numbering is marked at the locants. Classic mesomeric zwitterionic structures using the valence bond model (depicted in Figure 4(a)) have stepped down in favor of the molecular orbital view;

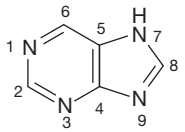

Figure 3 Purine – structural formula with customary numbering.

computational methods with software package allow calculation of partial charges (marked in Figure 4(b) and visualization of molecules.

Physical and Chemical Property and Safety Data

The chemical and physical data for caffeine are well known. It is a solid, odorless, slightly bitter-tasting, sublimating substance that crystallizes into white needles. In solution, it absorbs in the ultraviolet region, and solubility differences aid analytical separation and purification. Caffeine is both hydrophilic and lipophilic, thus easily passing through biological membranes and barriers. Its bitterness is perceived throughout the oral cavity; it is described as long lasting, and it is used as a standard for bitter-tasting calibrations. When crystallized from aqueous solutions, caffeine forms a nonstoichiometric stable hydrate. Caffeine salts, like citrate, are part of pharmaceutical compounds. Anhydrous caffeine occurs in two modifications. The low-temperature-stable form is the β modification, and at 141 °C, it is transformed to the α modification, which has a higher rate of dissolution. On cooling, the α phase converts very slowly back to the β phase, which is important for pharmaceutical preparations.

Several spectroscopic methods are available for caffeine analysis and authenticity control. The basic spectra are referenced in the analytical section.

Caffeine in solutions undergoes self-assembly: When a critical aggregation concentration is exceeded, caffeine molecules in solution cluster predominantly to dimers, with coplanar positions of the caffeine moieties, staggered at about 90°, with a distance of 3.5 Å.

The association of caffeine with the different phenolic compounds of caffeine plants follows the same principles. The

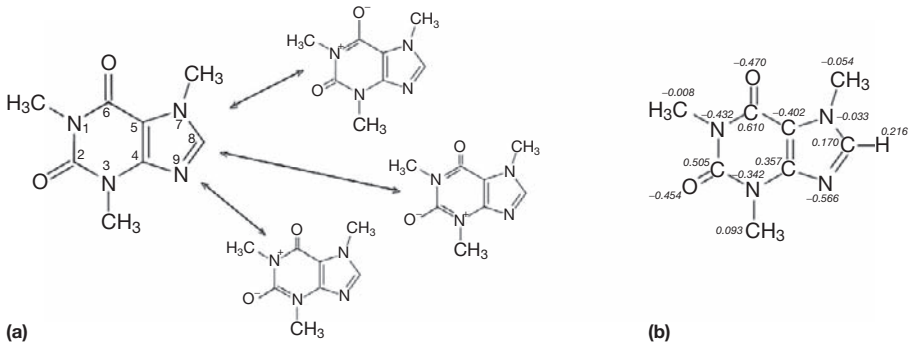

Figure 4 Caffeine – covalent structure with customary numbering, mesomeric structures (a) and atomic partial charges (b), the latter with data from Tavagnacco, L., Schnupf, U, Mason, P. E., et al., (2011). Molecular dynamics simulation studies of caffeine aggregation in aqueous solution. *Journal of Physical Chemistry B*. **115**, 10957–10966.

complexes are investigated since the fifties of the last century, inter alia by using ultraviolet (UV), infrared (IR), crystallographic, and nuclear magnetic resonance (NMR) data. With the latter method, the associates are observed by changes in the NMR chemical shift of caffeine's methyl protons, studied both in model solutions and in coffee brew.

Table 1 shows the property figures of caffeine, outlined in the *Chemical Abstracts Register*, which contains references offering additional information.

In regard to occupational health effects, the vendors of chemicals are obliged to provide a material safety data sheet for the substances in their portfolio, with property and safety data as well. For caffeine, the acute toxicity estimates on the possible route of intake reported are low, and the risk of accidental ingestion, contact, or inhalation at the worksite is minor. Thus, in the hazard classes under scrutiny, caffeine is assigned to the least hard categories. The respective labeling is at the lowest warning level. For transport, no dangerous goods marking is necessary.

Attempts to manage this information led to a compilation of International Chemical Safety Cards, a system in which caffeine is included with a peer review status, as of 1998, with partial updates in 2005. To enter the system, the substance name is requested, or its number in the registry of the Chemical Abstracts Service, CAS, in the Registry of Toxic Effects of Chemical Substances, RTECS, or the number in the Hazardous materials description of the United Nations (UN number).

Health-related property data for caffeine, with a focus on carcinogenicity, were covered by a monograph of the International Agency for Research on Cancer of the World Health Organization (IARC) in 1991. Caffeine is in Group 3, not classifiable as to its carcinogenicity to humans.

In 1958, the American Food and Drug Administration (FDA) declared caffeine as 'generally recognized as safe,' when added to cola-like beverages up to 200 mg caffeine per liter of beverage — the famous status 'GRAS,' confirmed in 1978 with a report. Since then, newly designed compositions came to the market. In November 2010, FDA sent a warning letter to producers of caffeinated alcoholic beverages, informing them, that caffeine co-consumption with alcohol would not be covered by the GRAS definition of cola-like drinks.

The scientific opinion of the European Food Safety Authority on the safety of caffeine, issued in May 2015, evaluates the published studies on the topic. The conclusion was, that single doses up to 200 mg caffeine and habitual intakes up to 400 mg per day from all sources (3 or 5.7 mg per kg bodyweight, respectively) do not give rise to safety concerns for adults. For pregnant women, the habitual consumption should be halved. For children and adolescents, a first approach is based on the bodyweight frame, until specific data for this age group will become available.

Caffeine Sources and Uptake

Caffeine is said to be the most widely consumed psychoactive substance. It is used as a stimulant in both food and pharmaceuticals, and its consumption and effects are considered in the next article in this encyclopedia.

Sources of caffeine include plants and direct chemical synthesis.

Industrial Sources

For pure caffeine, data on industrial production are rare. The Organization for Economic Cooperation and Development (OECD) in Paris has submitted summaries in a 2002 "Screening Information Data Set" (SIDS) of high-volume production chemicals. The data are repeatedly cited: "1999 the estimated world production amounted to 10.000–15.000 tons including 3.000–4.000 tons of natural caffeine" from decaffeination. Since then, a moderate increase in production has occurred. In 2011, China was the main supplier of synthetic caffeine, and the country's leading manufacturer reports a production volume of 8000 tons.

In the early 1900s, industrial decaffeination from caffeine plants was developed in Europe, with a focus on the production of decaf coffee. At about the same time, caffeine production via the decaffeination of imported tea wastes started in the United States, in response to soft drink demand. This process is still in use, as recently reported from Turkey and India, which were number 6 and number 2 in 2013 world tea production. The decaffeination of coffee pulps (i.e., the coffee waste in coffee-producing countries) is also being developed.

The changed priorities for coffee decaffeination are best illustrated by the title of a scientific article on decaf in 2012 "Which is the by-product: caffeine or decaf coffee?" In beverage

Table 1 Properties of caffeine, from the CAS Registry (if not otherwise marked); website source www.cas.org accessed February 2015, identifying the references therein

Property	*Value*		
Molecular formula	$C_8H_{10}N_4O_2$		
Molecular mass	194.19 Da		
Status at ambient conditions	Solid, dimorphic		
Appearance, taste and smell	Colorless ('white'!), bitter tasting, odorless		
Crystalline forms[a]	Hydrate 0.8 H_2O, stable up to 51.5 °C, dehydration to stable β phase		
	Anhydrous β phase		
	Anhydrous α phase (stable up to sublimation/melting)		
	Metastable α phase; on cooling down from stable α phase, back-transformation to the β phase is kinetically restrained		
Dimers in aqueous solution[b]	Self-associated caffeine dimers, coplanar, staggered, at concentrations above the solubility limit[c]		
Stability point of hydrate 0.8 H_2O	51.5° (quadrupol point)[d]		
Transformation point $\beta \rightarrow \alpha$	141 °C[a]		
Sublimation point	178 °C		
Melting point (in fused capillary)	236 °C		
Density [g cm^{-3}]	1.45 at 25 °C/α phase[e]		
	1.23 at 18.7 °C[f]		
Ultraviolet absorption maximum λ_{max} (nm)	274 (aqu.)		
Apparent molar absorption coefficient[h] ε_a (l mol^{-1} cm^{-1})	9.750 ± 75 (aqu., $c = 0001\%$), lit. average[g]		
Dissociation constant	pKa 10.4 at 40 °C (acid–base constant)		
Mass solubility aqueous (mass ratio, %)	Concentr (%)	Temp (°C)	Remarks
	2.2	20.0	pH 6.9
	46.8	83.9	
	81.0	100.3	Extrapol. value
Mass solubility, other solvents	Ethanol: slightly		
	Ether: insoluble		
	Chloroform: very good		
Dipole moment, *D*	3.7 (benzene)[i]		
Octanol/water partition ratio	−0.091 at 23 °C (log Pow)

manufacture, the eventual claim 'natural' might be a driving force, to use added caffeine obtained from a plant product.

Milestones in the development of industrially feasible caffeine synthesis include the Traube synthesis of 1900 (too many steps with low yields, but a backbone of further improvements), the Bredereck synthesis of 1950 (developed during World War II, facing the constraints of limited accessibility of educts by starting with xanthosine from yeast), and the novel Zajac synthesis of 2003, starting with inexpensive uracil. For the latter, a reaction scheme is given in Figure 5. Uracil is double-methylated with methyliodide, the 1,3 dimethyl-uracil is nitrated with a mixture of nitric and sulfuric acid, and it is then reduced with iron or hydrochloric acid in tetrahydrofuran to yield the respective amino-uracil. The latter is acylated with formic acid and nitrated again at the remaining 4-position of uracil; heating with iron in acetic acid allows simultaneous reduction and intramolecular heterocyclization to produce theophylline, which is N-methylated to yield caffeine. For almost a century, the fully synthetic caffeine could not compete economically with caffeine from decaffeination, however.

Agricultural Production

Volumes of agricultural products are published by FAO, the United Nation's food and agriculture organization in Rome, on a regular basis. Caffeine-containing plants deliver globally traded commodities of high overall economic value. For the most important caffeine products, Table 2 shows the ranking

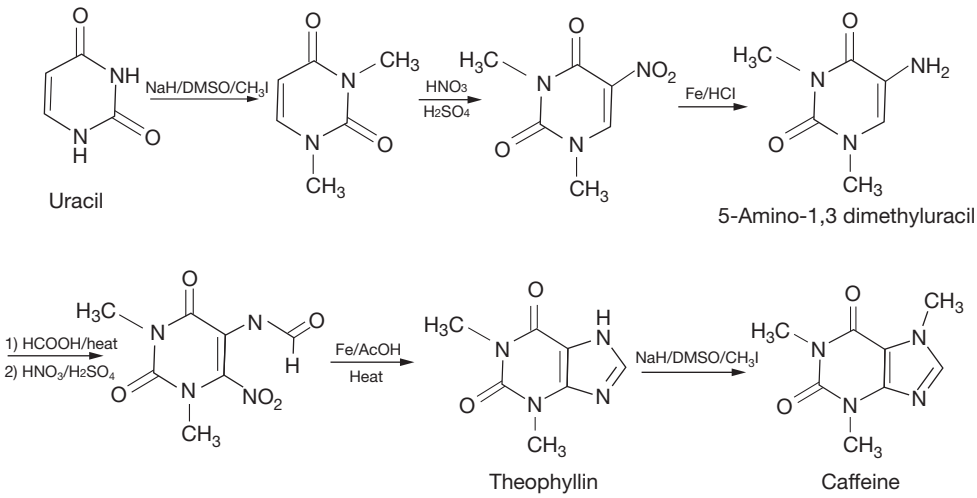

Figure 5 Reaction scheme for Zajac's novel method of caffeine synthesis 2003 (edited from Zajac, M.A., Zakrzewski, A.G., Kowal, M.G. and Narayan, S. (2003). Table 2 Caffeine sources from plants, with plant botanical naming, caffeine contents, and average production volumes of the caffeine products

Plant source	*Botanical species*	*Caffeine content (% d.b.)*	*Production average (tonnes per year)*	*Market forms, remarks*	*Use*
Guaraná seeds	*Paullinia cupana* Kunth	2.5–5%	3,900	Seeds, dried, powdered or pounded into a stick and roasted	Beverage/masticatory (caffeine supply for other products)
Tea leaves	*Camellia sinensis* (L.) Kuntze	2–4.5%	4,800.000	Black, oolong, green, and white tea from different postharvest treatments	Beverage (dust and stalks used to gain caffeine)
Coffee seeds	*Coffea canephora* Pierre ex A.Froehner	1.5–2.6%	8,600,000	Roast coffee, roast and ground coffee, instant coffee, convenience preparations	Beverage (caffeine from decaffeination used for other products)
	Coffea arabica L	0.9–1.9%			
Coffee husks	*Coffea arabica*			Arab specialty 'Qishr'	Beverage
Kola nuts	*Cola nitida* (Vent.) Schott & Endl.	1.5%	290,000	Dried	Masticatory/beverage
Maté leaves	*Ilex paraguariensis* A.St.-Hil.	0.5–1.5%	790,000	Dried, ground, and slightly roasted	Beverage
Cacao beans	*Theobroma cacao* L.	0.2%	4,500,000	Cacao beans, cocoa mass, cocoa powder	Beverage, chocolate bars

Plant source: customary name.

Botanical species: *The Plant List* (2013). Version 1.1. Publication on the Internet; http://www.theplantlist.org/ (accessed January 1st, 2015) Caffeine content: Mass percent on dry basis.

Production average: 2009-2013 data from FAOstat (web sourceww.faostat3.fao.org accessed February 2015); for Guaraná from IBGE (weweb sourcew.ibge.gov.br/home/estatistica/indicadores/agropecuaria/lspa/ accessed February 2015).

in caffeine content and the volumes of agricultural production as 5-year averages.

The data suggest that caffeine plants, roughly calculated, can provide about 300 000 tons of the biomolecule for human uptake per year. That is an order of magnitude above the amount of the chemical as derived from industrial synthetic production.

In the FAO definition of agricultural corps, coffee, tea, and maté are stimulant crops because they contain caffeine, but cacao, due to its additional nutritional value, is both a stimulant and food crop; kola nuts are separately categorized as edible nuts. Guaraná seeds, which are the highest in caffeine content, are not included in the FAO statistics, because their agriculture is negligible in volume. For the purposes of this article, guaraná data are taken from publications of the Brazilian Institute of Geography and Statistics (IBGE). Table 2 also mentions Qishr, husks of the coffee seed, traditionally used in Arabian countries to prepare a tea-like beverage; coffee husks are mentioned in the FAO commodity list, but without reported quantities; it is not a primary crop.

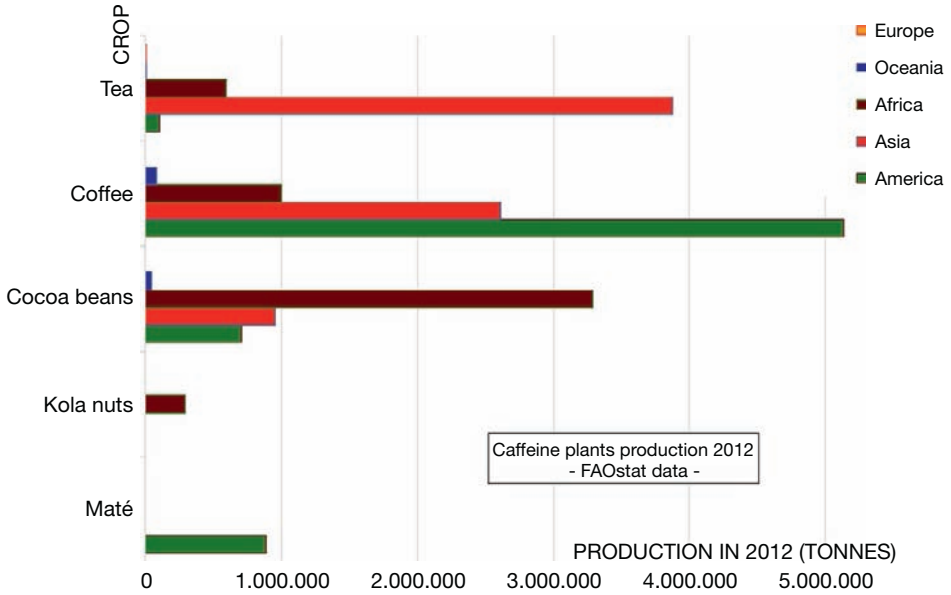

Figure 6 Agricultural production of caffeine containing plant commodities per crop and continent, 2012 volumes in tonnes, data from FAOstat (web sourcewww.faostat3.fao.org accessed January 2015).

Natural Occurrence and Volumes

In all nature, more than 60 plant species are known to contain caffeine, and coffee and tea are almost ubiquitously present to consumers. Surprisingly, up to the end of the fourteenth century, Europe was one of the few regions of the world where caffeine-containing drinks were entirely unknown.

For an outline, the 2012 crop volumes are summarized per continent in Figure 6. Tea is predominantly grown in Asia. Cocoa cultivation is centered on the African continent. Coffee production volumes are more balanced around the globe's tropic belt. Kola nut and maté are produced exclusively in Africa and America, respectively. According to the FAO, 'Oceania' comprises Australia, New Zealand, and the Pacific islands, which are fine but very small origins of some caffeine plants.

Political and economic factors influence the long-term production pattern: the FAO archives maintained since 1961 reveal an explosive coffee increase in Asia since 1995—Vietnam!—a starting coffee volume in China, and a decline of tea from Europe. The teas from the territories of the former Soviet Union are gone.

Uptake

The ways of human uptake of caffeine vary widely.

It is swallowed in beverages produced from caffeine-containing plants, such as coffee, tea, maté, and chocolate (these beverages mark the main uptake in volume), and in water-based flavored drinks, so called soft and energy drinks, to which caffeine is added. Caffeine is eaten in products such as chocolate bars, and it has been traditionally chewed, as with kola nuts. New routes of uptake arise. To facilitate on-the-go ingestion, energy drink preparations are offered as gels to swallow; some energy preparations for accelerated uptake also include chewing gums, patches with gels or microemulsions for skin penetration, and vapor sticks to imitate the idea of e-cigarettes.

Caffeine is used in pharmaceutical preparations in great volumes, primarily as an adjuvant in analgesic combinations, both in over-the counter and in prescription medicine, and in minimal volumes in orphan drugs for rare diseases such as neonate apnea. Caffeine is also part of some cosmetic formulations with transdermal uptake.

Ingested caffeine is directly absorbed in the mouth or via the stomach and intestine within 45 min, and it readily spreads into all body tissues. Caffeine clearance happens via catabolism in the liver, with successive demethylations, oxidation to uric acid, cleavage of the imidazole ring with remaining uracil, and finally the break down to ammonia and exhaled carbon dioxide. Only a little caffeine is excreted unchanged.

Dispersal

Caffeine's primary use by humans, either as a food or drink preparation or via pharmaceutical or cosmetics production, causes the chemical to enter waste waters and landfill leachates. The biodegradation of caffeine into constituent compounds requires some 3–6 weeks. Due to its biodegradability, bio- and geoaccumulation are not expected. Nevertheless, increasing dispersal in coastal waters is observed, and caffeine is found in marine fauna of coral reefs.

Caffeine-Growing

Caffeine is located in different tissues and organs within the plants that produce it; in these locations, it experiences synthesis, storage, transfer, metabolism, and degradation.

Biosynthesis

Caffeine biosynthesis in plants is well established during the last 40 years, with comprehensive overviews since 2000, notably by Ashihara. It follows a general pathway, starting with the DNA's purine base xanthosine. This is methylated at N-7 using xanthosine-methyltransferase, which depends on *S*-adenosyl-L-methionine (SAM) as a methyl donor, itself turning to S-adensoyl-homocystein (SAH). Next, the ribosyl unit is removed with the help of *N*-methylnucleosidase. The resulting 7-methylxanthine is methylated at N-3, catalyzed by another enzyme, 7-methylxanthine transferase (theobromine synthase), again with SAM as methyl donor, to produce theobromine. Further methylation with 3,7-dimethylxanthine transferase (caffeine synthase) at N-1 of the xanthine eventually leads to caffeine. The first methylation at the xanthosine level is the rate-determining stage.

The structures of the involved enzymes are known, their encoding genes have been consolidated in a multicentered work on the coffee genome in 2014 ('provides insight into the convergent evolution of caffeine biosynthesis', says the title). The main biosynthetic pathway is shown in Figure 7, which marks the involved enzymes together with their enzyme code numbers. Additionally, minor routes via theophylline or paraxanthine exist. Methylxanthines from the side pathways of biosynthesis may accompany caffeine in the composition of caffeine-plant products. They form plant-specific methylxanthine patterns, providing a useful tool for plant-source identification.

In-plant Localization

In the plant cells, caffeine is synthesized in the cytoplasm, translocated, and stored in intracellular membrane-bound compartments, the central vacuoles. It is in tight complexation with phenolic molecules of the respective plant.

These phenolics are chlorogenic acids for coffee and mate; catechins for cocoa, kola nut, and guaraná; and tannins for tea. In the respective complexes, different interactions take place. Equilibrium constants are determined. The caffeine chlorogenate complex is described as an 1:1 type, π-molecular complex stabilized by hydrophobic interactions.

The release of caffeine from its complex in plant products was an analytical challenge of the early encounters with caffeine in coffee: Runge achieved the separate preparation of Kaffeesäure (coffee acid) and Kaffeebase (caffeine) by breaking the complex via the precipitation of the acid with lead acetate and the isolation of caffeine from the filtrate. Robiquet achieved the same result with magnesium acetate.

Basic research was done, comprising the localization of xanthines in the tissues and organs of the plant, and their ways and distribution during plant development. The key aspects are similar in all caffeine plants.

Caffeine as a Secondary Metabolite

For plant biology, caffeine is classified as a secondary metabolite, that is, it is not primarily essential and active for growth and reproduction, but it is useful for adaptation to the environment. Caffeine may serve as a chemical defense against predators, or it might contribute to the allelopathic prevention of competing up-growth, or it might help attract supporters – a fashionable keyword is 'bioecology.'

As the plant accumulates caffeine in direct proportion to the risk of predation, it is synthesized in the outer parts of young leaves and fruits, and on their epicuticular waxes. On the ground surrounding the individual plant, the phytochemical is released by the seed coat of dropped fruits or from fallen leaves, which may prevent the germination of competing seeds on the same ground. On the other hand, the caffeine content of the blossom's pollen and nectar acts as an incentive to pollinators attracted by the scent; and crosspollination by bees may help to maintain the genetic diversity of caffeine-containing plants. The experimental confirmation of the presumed intention-and-effect chains requires a sophisticated study design, however. With the turn of the century, the general

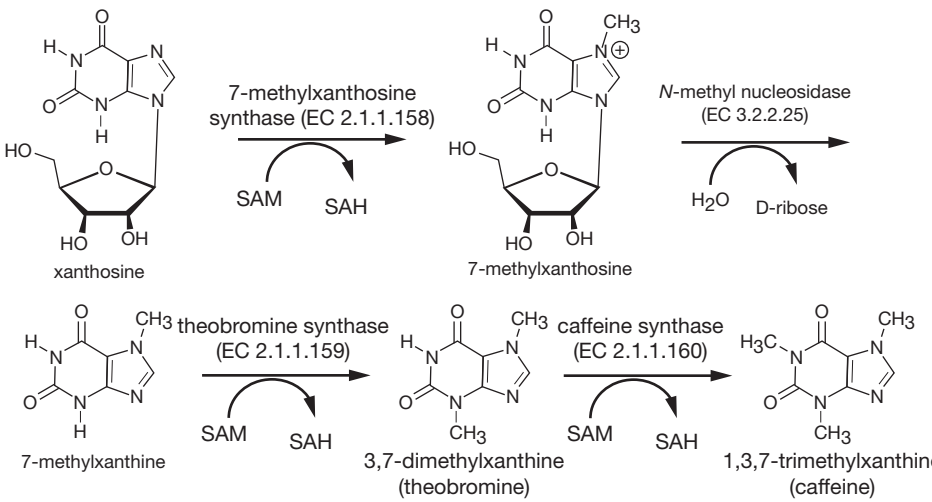

Figure 7 Main pathway of caffeine biosynthesis in plants compiled from different sources: (1) Ashihara, H., Kato, M. and Crozier, A. (2011) Distribution, biosynthesis and catabolism of methylxanthines in plants. In Fredholm, B.B. (ed.) *Methylxanthines*. p.17. Berlin: Springer. 2) Kanehisa, M., (2013). KEGG database, Pathway map Caffeine metabolism. Kyoto, Japan (web source http://www.genome.jp/kegg/ accessed June 2015).

emphasis of research changed to field studies in order to convince the producers to adopt the ideas of bioecology and moderate agroforestry. Follow-up crop management is covered in the articles on coffee, tea, and cocoa.

Caffeine-Containing Plants

The most important caffeine-containing plants are named in Table 2. Of these, coffee, tea, and cocoa are itemized in individual articles of this encyclopedia: two articles are dedicated to cocoa, four deal with coffee, and three articles describe tea.

Maté, kola nut, and guaraná are discussed in more detail in this article. They are the next most commonly produced caffeine-containing plants. In the years 2011–13, their use as herbal medicine in the European Union was assessed, with a focus on the use of maté, kola nut, and guaraná as powdered leaf or seed, all of which appear to be nontoxic preparations for oral use.

Other caffeine synthesis happens in some citrus plants, where nectar and pollen may contain caffeine.

Caffeine plants grow in the tropic zone north and south the equator. Further climatic requirements limit their cultivation to distinct environments, altitudes, and geographic regions. Weather conditions in the crop year are connected to strong up- and downturns in the outcomes of sensitive countries, with big economic impacts.

Figure 8(a)–8(d) shows the 2013 worldwide distribution of the six main caffeine crops, using the basic data from the FAO, aggregated by country, as well as Brazilian statistics.

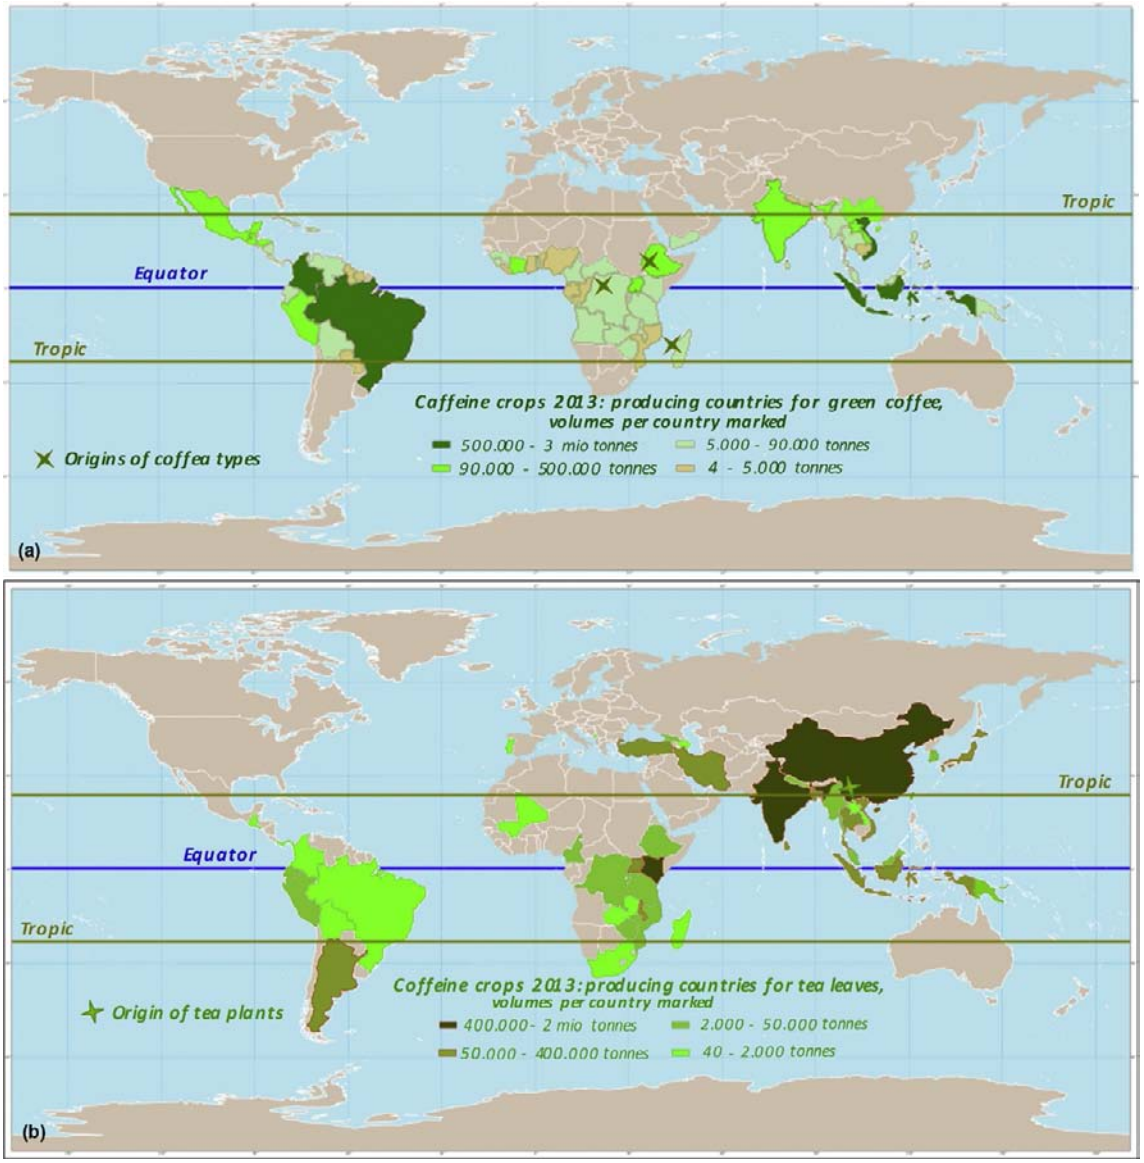

Figure 8 (a–d) Agriculture on caffeine products 2013, crop- and country wise marked on world maps, subtitles within the figures data from FAO and (for Guaraná) Brazil statistics. Web-sourcesFAOstat, http://faostat3.fao.org/download/Q/QC/E (accessed 11 Jan 2015 and 6 March 2015), and IBGE, http://www.ibge.gov.br 'Levantamento Sistemático da produção Agrícola', LSPA 2014 (accessed 6 March 2015).

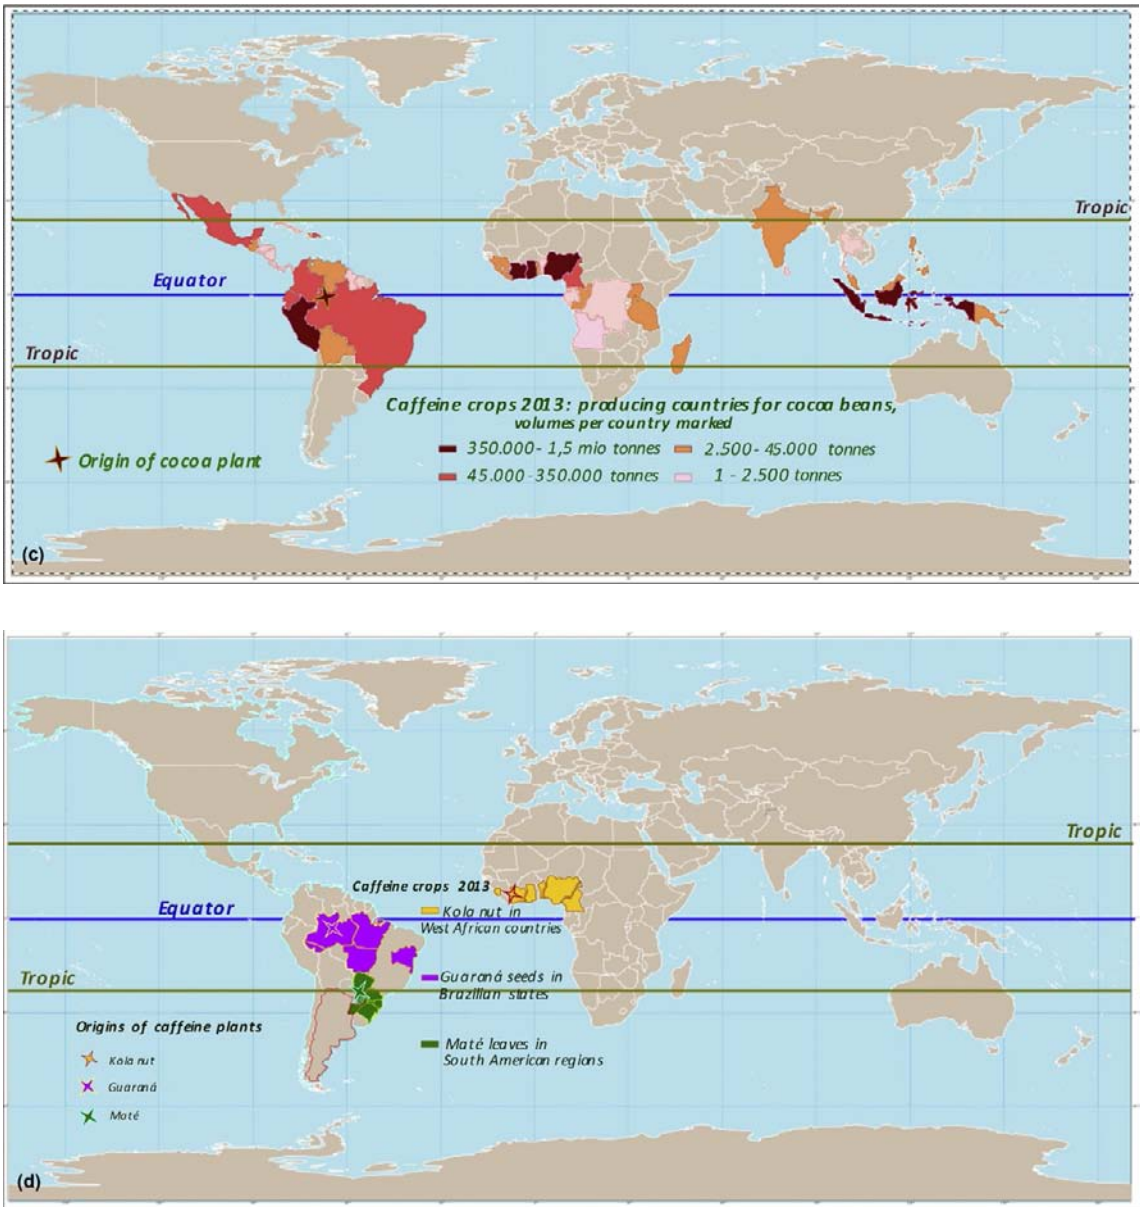

Figure 8—cont'd

The figures visualize the respective cultivation belts around the globe in four crop dedicated maps. The basic grids are world maps with political borders, with mark-ups on the surface of the countries that cultivate the respective caffeine-containing plants; the differences in production volumes are discretely implied by coloration. The place of the plants' genetic origin is indicated, as established by history and sophisticated phylogeographic analysis, lastly by Anthony for coffee in 2010.

Figure 8(a) shows the 80 countries that maintain coffee crops; Brazil is by far the biggest producer; Ethiopia, the cradle of Arabica coffee, is no. 7; on the Northern rim of the tropics, China is emerging with her Southern regions (only those are marked).

Figure 8(b): Fifty countries cultivate tea, outreaching the tropic belt to both sides; China is the top producer.

Figure 8(c): Sixty countries have cacao agriculture, with an eye-catching concentration very near the equator, in West Africa (Ivory coast!) and Indonesia.

Figure 8(d) the production sites of kola nut, mate and guaraná do not overlap, thus they are visualized together in Figure 8(d). The productions are retained at the genetic origin of the plants. Kola nut is grown in some coastal countries of West Africa. Mate is harvested in an even smaller region in the triangle of Argentina, Brazil, and Paraguay, where only the really producing districts are marked. Guarana has spread from its Amazonas origin to neighboring Brazilian states; only those are marked.

The following descriptions are in order of the product's caffeine content, as given in Table 2.

Guaraná

The seeds of the guaraná plant, *Paullinia cupana*, of South America are traditionally consumed as a stimulant beverage. Guaraná belongs to the family *Sapindaceae*, genus *Paullinia* L.; the species is *Paullinia cupana* Kunth; and the chemotaxonomy was accepted for *The Plant List* in 2012. Another *Paullinia* species has caffeine in its bark, *Paullinia yoco* R. E. Schult. & Killip, found in the frontier region of Colombia, Peru, and Ecuador. Guarana's caffeine is most concentrated in the seeds, in complexes with the phenolics catechine and epicatechine.

Guaraná is native to the tropical rainforest of the broad Amazonian basin, where it has been gathered and used since pre-Columbian times. In 1669, a Portuguese missionary described the plant and its history, and named the plant. Linné installed the genus *Paullinia* in 1753. Humboldt collected his specimen of *Paullinia cupana* further northward in present-day Venezuela in 1821, stating, "crescit in ripa obumbrata fluminis Orinoci, prope S. Fernando de Atabapo; floret Majo" or "is growing on the umbrageous banks of the river Orinoco, near San Fernando de Atabapo; it is flowering in May," cited from Bonpland and Humboldt.

In its original form, guaraná was a woody liana, as shown in Figure 9, reaching the forest canopy, at heights up to 12 m.

Figure 9 Guarana vine with fruits, scandent on a rainforest tree in East Ecuador, September 2010 (courtesy of the photographer Geoffree R. Gallice, University of Florida, Gainsvillle, USA, under collective common license by Geoff Gallice from Gainesville, FL, USA (Guaraná) [CC BY 2.0 (http://creativecommons.org/licenses/by/2.0)], via Wikimedia Commons; accessed March 2015).

Over generations of crop growing, it was domesticated to a scandent shrub, up to 2 m tall and 4 m in diameter. In their Amazonas indigenous territory, the Sateré Mawés grow these shrubs in orchards around their homes; they recruit new plants by gathering seedlings from the rainforest. Colonists in the same region cultivate the plants in plantation-style arrangements, however, propagating them by cuttings.

The guaraná plant blossoms with white corollas in clusters directly on the branches. It is monoecious with separate male and female flowering periods even on the same branch, and pollination is done by insects. The plant develops bunches of eye-catching fruits, each with a red mantle, white mesocarp flesh, and a dark seed, so that the fruit resembles an open eyeball.

The Satare Mawes have strong traditions that guide the processing of the fruit: they pick the bunches when the outer skin of the fruit bursts, and the eyes open. Immediate post-harvest treatments include roasting, and the seeds are unharnessed, separated from residual testae, and pounded with mortar and pestle. The grist is thoroughly kneaded and rolled into a cylinder. After some weeks in the smokehouse, the guaraná achieves its reliable storage form, the 'baston' or guaraná stick. For beverage preparation, the powder is obtained by grating the hard stick by means of the bony tongue of a special fish or a slab of basalt.

At the beginning of the twentieth century, guaraná was introduced as flavoring in bottled soft drinks named 'Guaraná,' with several fabrication sites and nationwide acceptance. As the use and production of Guaraná increased, an extension of the agriculture was required, as was a simplification of the many laborious stages of traditional processing, and an adaption to industrial procedures. For soft drink manufacture, guaraná was utilized as a syrup prepared via the alcoholic extraction of seeds after simple roasting and grinding.

Over the last 70 years, international demand for guaraná has grown, given its use as a natural source of caffeine. Cultivation was expanded to regions outside the Amazon, southward to Bahía and Mato Grosso, with plants provided by research institutes. Climatologic and edaphic conditions in these states are similar to the Amazon Basin, and plantations in Bahia account for some 70% of national guaraná production (Brazilian official data acquisition for 2013), with nearly 90% national use. The discussion on the ethnobotanic heritage of the crop is ongoing (see the 2013 article titled 'Who owns Guaraná?').

Tea

Tea-leaf beverages have been consumed in Asia for thousands of years, and tea is the world's second largest agricultural commodity with caffeine content by volume. The tea plant belongs to the family *Theaceae*, genus *Camellia*, and species *Camellia sinensis* (L.) O. Kuntze, with two main varieties, *C. sinensis* var. *sinensis* and *C. sinensis* var. *assamica*, as well as some minors. In 1753, Linné had installed this genus, calling it *thea* with one species, *Thea sinensis*; a separate genus was the decoratively flowering *Camellia japonica*. Later, *Thea sinensis* and *camellia japonica* were reorganized with the common genus name *Camellia*; this section deals with the species C. *sinensis*, the tea plant.

Tea was first cultivated in China, followed by Japan, some thousand years ago, with India and Indonesia starting to cultivate it in the nineteenth century. On plantations, tea is an evergreen shrub. The primary crop consists of the tender leaves. Their postharvest treatment up to the final product is done in the countries of origin.

The tradable commodities are the tea leaves; they are brewed for beverages, esteemed as stimulants for their caffeine content. The series of phenolics accompanying the caffeine in tea provokes a specific profile of caffeine release from the drink. The caffeine metabolism follows the general pathways.

Tea is explicitly treated in articles 685–687 of this encyclopedia.

Coffee

Coffee beans are the most important primary product of the caffeine-containing plants, and the second internationally traded commodity in value, following mineral oil. The coffee plant's evolutionary source is Africa and Madagascar, with west central Africa for the robusta coffee, and Ethiopia for arabica coffee, the latter being used in beverages since about one thousand years ago.

The coffee plant belongs to the family *Rubiaceae*, genus *Coffea* L., with the economically important species being *C. arabica* L., *C. canephora* Pierre ex Fröhner (the arabicas and the robustas), and some minors. In the context of the project 'World Checklist of Rubiaceae', its chemotaxonomy was elucidated and consensually accepted, cornerstones are publications by Davis 2006 and Bremer 2009.

Since the seventeenth century, coffee cultivation has expanded from its Afro-Arabian homelands into all climatically suitable regions in the tropics. Occasionally, it succeeded other tropical crops, which experienced an economic decay, including sugar in Indonesia or Hawaii. Coffee plantations are often run by smallholders. The intensity of crop management ranges from monoculture (i.e., no shade, high inputs) to polyculture (shade overstory retained, fewer inputs, agroforestry).

Coffee is a tropical shrub with cherry-like fruits. They are processed after harvest to yield the 'naked' dried beans, the trade commodity green coffee, as defined in the International Coffee Agreement between producer and consumer states. Final treatment prior to consumption is the green beans' roasting and grinding; it takes place in the consumer country. The last step is the preparation of the beverage.

The different aspects of coffee are covered in the coffee articles of this encyclopedia.

Kola Nut

The kola nut has long been known as a source of caffeine stimulation. It is native to the West African coast, very near the equator. Cultivation centers include Sierra Leone/Liberia, Nigeria/Cameroon, and Gabon. It has been domesticated in West Africa, and it has likely been cultivated in the forests of Sierra Leone since the fourteenth century. The tree is constituent of the lowland forest, requiring a hot, humid climate and capable of withstanding 3 months of dry season. Kola may be cultivated even in drier areas wherever ground water is available.

The kola plant belongs to the cacao family. The classification is in a state of flux. In 2003, it changed its place from *Sterculiaceae* to *Malvaceae*, following the angiosperm phylogeny group. The genus remains *Cola* (Vent.) Schott & Endl., with the species are *C. nitida* (Vent.) Schott & Endl., Gbanja kola, cultivated around Ghana and Nigeria, *C. acuminata* (P. Beauy,) Schott & Endl., Abata kola, which is distributed from Togo to Angola and cultivated in the tropical forests of West Africa, and some minor ones.

The phenolics, accompanying the kola nut's caffeine, are tannic acid, catechins, and, to a lesser extent, chlorogenic and quinic acids. The nuts have a bitter, astringent taste, getting milder on drying. Chewing is common in the local population, used against fatigue and hunger, and a beverage is prepared by boiling the powdered seeds in water. Exported to Europe and America, the kola nut is used as an ingredient in the production of beverages in those areas.

When grown from seed, kola needs about 3 months to germinate, but propagation from cuttings is also possible. After 4 years, when the tree has grown to a height of 2–3 m, the first fruits appear. Full maturity is reached in 10 years, with harvests up to the age of 100 years. Yields of 300 nuts per tree are considered good. Old kola trees may serve as shade trees for cocoa plantations.

The plant is an evergreen, up to 20 m high, with a rather short stem and a dense crown. It has large leaves, variable in shape and size, and its flowers are male or hermaphrodite, with wind or insect pollination. Fruits are ripe after 5–6 weeks. Botanically, they are no nuts but comprise of a set of voluminous warty follicles gathered into a star, with each follicle containing 5–10 ellipsoid seeds, about 2.5 cm in diameter and colored red or white depending on the variety. Ripe fruits are dispersed by bats, birds, and squirrels.

The kola fruits are harvested before full maturity, using knives mounted on long poles. The fruits are immediately opened, and the seeds recovered and left in heaps for fermentative decay and sun drying. After some days, the seeds are washed and put in baskets on fresh leaves to be stored under surveillance.

Kola nuts are habitually used in West Africa for social and cermenonial purposes. Without kola seeds, in Nigeria and many West African countries, traditional hospitality, cultural, and social ceremonies are considered to be incomplete.

In a 1995 document on edible nuts as non-wood forest products, the potential of kola nuts is discussed: "Considering how much cola nuts are appreciated in West Africa while being virtually unknown elsewhere, expectations for an expanding market are reasonable." (Wickens, 1995).

Maté

Maté is native in South America, in the woodlands of the Paraná River in eastern Paraguay. The leaves are used to make a tea-like beverage, and they have been collected since pre-Hispanic times. Throughout the twentieth century, maté was once again cultivated in the mountainous southern parts of Brazil, northern Argentina, and Paraguay, reestablishing the abandoned plantations that Jesuit monks had run in eighteenth and nineteenth centuries. The traditional 'extractive'

production is practiced in parallel, with leaves gathered from 'wild' forest trees, before regular postharvest treatment.

In plant taxonomy, maté belongs to the family *Aquifoliaceae*, genus *Ilex* L., species *I. paraguariensis* A. St.-H. (called yerba maté). Linné named the genus in 1753, and Auguste Saint-Hilaire gave the maté a description in 1822. Other species are *I. vomitoria* Ait. (the yaupon holly of the southern United States, archaeobotanically identified as 'black drink' from 1000 years ago) and *I. guayusa* Loes., cultivated in Ecuador, with evidence of its use for 1500 years. The decorative Christmas holly known in Europe, *I. aquifolium*, is a relative without caffeine. Maté leaves contain 0.5–1.5% caffeine, and the accompanying phenolics are the chlorogenic acids.

The maté tree is 8–15 m high, evergreen, and dioecious, flowering from October to November, fruiting from March to June, and pollinated by insects. The perennial leaves are about 8 cm long, olive-green, and leathery, with slightly crenate dentate margins. The plant needs constant, moderate rainfall and average temperatures of about 22 °C, although it can tolerate extremes down to −6 °C. The conditions are met in its region.

For harvest, older leaves and tender branches are taken. Soon after, the crop is flash-dried through direct heat for 1 min at 300 °C (blanching, zapecado). In subsequent processing stages, the leaves are dried with hot air (secado) and coarsely ground. A seasoning storage for several months can be added (aging, maturation), followed by final grinding and sieving. Modifications are developing, both with economic and ecologic aims. They have influence on the products' appearance and composition.

In 2010, an Argentine study on the bioactive compounds variation during maté processing steps revealed that these steps lead to an increased caffeine content in the product, as compared to the green leaves after harvest. The marked augmentation was observed after the zapecado step, from 0.9 to 1.5% in caffeine, with parallel increase of chlorogenic acid (1.8 to 2.1% for the mono-CQA and similar for di-CQA's). As possible reason, a degradation of nucleic acids is discussed, with release of purins for biosynthesis of caffeine.

In Latin America, the beverage is prepared in a special gourd with hot or cold water. Maté is often drunk as part of the consumption ritual in a social setting, using a metal straw called a 'bombilla'; the straw ends in a closed bulb of teaspoon size with perforations, to avoid the aspiration of fines from powdered maté leaves when the infusion is sucked up through it. The drawing in **Figure 10** incorporates maté leaves, blossoms, fruit, and the classical drinking equipment. Maté is predominantly consumed in South America, and export is preferentially done in final consumer packaging, such as individual tea bags (1–2 g). For use as an ingredient in the food or dietary supplement industries, it is also supplied as maté tea concentrate.

(1994). *Neglected crops: 1492 from a different perspective*, p.247. Rome: FAO Publications Division. Reproduced with permission of the Food and Agriculture Organization of the United Nations.)

Cocoa

Cacao beans were the first caffeine-containing plant products that Columbus encountered in 1502. At that time, they were cultivated by the Maya in Central America. Cacao is a neotropic plant, possibly originating from the lowland rainforests of the Amazon Basin. Today, it is spread within a narrow zone 10 degrees of latitude south and north of the equator around the globe. Cacao belongs to the family *Malvaceae*, genus *Theobroma*, species *Theobroma cacao* L. As with the kola nut, the classification of cacao was merged, in 2003, with *Sterculiaceae*. The reorganization was carried out by the Angiosperm Phylogenetic Group, and it is on the way to be accepted. The caffeine content of cacao in the chocolate mass (ground beans) averages 0.2%, the lowest in the series we look at here, and it is clearly overshadowed by cacao's theobromine content of 1.2%.

Cacao is an understory tree, propagated by seed or cuttings and reaching maturity with 4–5 years of age; it grows up to 10–12 m in height, with leathery leaves and small, pinkish flowers directly on the trunk and branches. Here, the fruits or 'pods' develop, each yielding 20–50 cacao beans, which equate to 20–30 pods per harvest. The beans are ground and processed to make chocolate. Pulp and pods are also used for food and forage. Cocoa has its own articles in this encyclopedia.

Analytics

Since the early seventies of the last century, the analytical characterization of caffeine is preferentially done via chromatographic separation and spectroscopic identification. This preference represents a return to the roots of caffeine research: the first to observe chromatographic separations was Runge, the caffeine man, in 1850.

As coffee and tea are globally traded commodities, their characteristics are important to international trade. They are an item governed by the International Standard Organization (ISO), with emphasis on caffeine as a main constituent. For ISO coffee, the determination of caffeine in coffee was one of the first standards, published 1983, following an American AOAC procedure of 1979, which relied on liquid chromatographic separation and ultraviolet spectrometric quantification of caffeine via UV absorption at 276 nm. The method was explicitly described in a European directive of that time, even with an illustration of the chromatographic columns.

When liquid chromatographic procedures developed toward high-performance liquid chromatography (HPLC), caffeine determination was soon affected. The standard technique is now HPLC on reversed phase columns, with quantification again via UV absorption, as suggested with Figure 11, where the UV spectrum is an insert to the HPLC chromatogram. Actually, ISO provides HPLC/UV methods both for tea and coffee, with each one applicable to the specific products on the market. Chromatograms allow separation of the other methylxanthines accompanying caffeine in the same run. The specific distribution patterns of the different caffeine plants may serve as an analytical tool for authenticity proof, and "although several detection modes have been recently proposed, UV detection is still the first choice in the liquid chromatography analysis of these analytes due to its simplicity and reliability," as emphasized in a Venezuelan research article on methylxanthines in cocoa beans in 2007. The HPLC chromatogram for this section originates there.

Other classic spectroscopic figures transport further constitutive information:

Caffeine's infrared spectrum, shown in Figure 12, provides the two C=O valence bands of C-2 and C-6, well separated at 1700 and 1650 cm^{-1}, in 2013 with molecular calculations attributed to in-phase and out-of-phase stretching vibrations of the C=O bonds respectively, and in the fingerprint region, the methyl C–H separated from the ring C–H vibrations.

The proton nuclear magnetic resonance spectrum, in Figure 13, shows the signals of the methyl proton groups, with

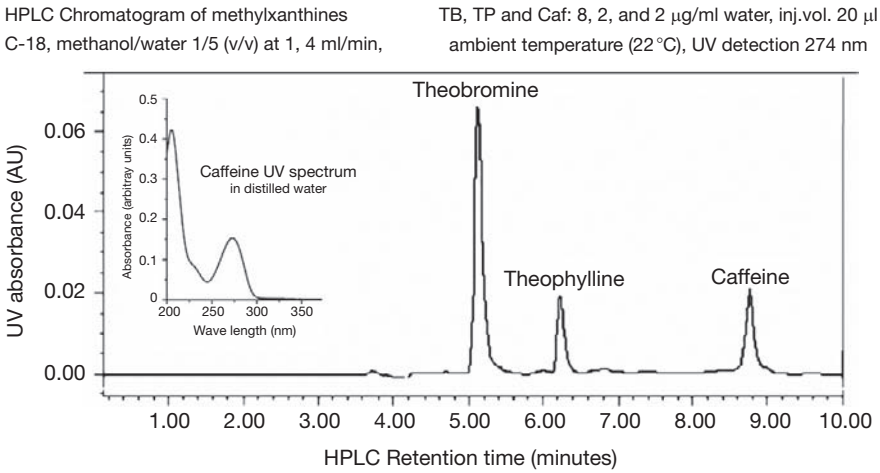

Figure 11 HPLC chromatogram of methylxanthines caffeine, theophylline, and theobromine in standard solution,[A] with UV spectrum of caffeine[B] as insert edited from several sources: [A]Brunetto, M.R., Gutiérrez, L., Delgado, Y. et al. Figure 14 Mass spectrum of caffeine, adapted from AIST spectra base, Japan; main fragments marked.

individual chemical shifts, magnetically shielded from each other. The single-ring proton, with its characteristic aromatic chemical shift, has a weak spin–spin-coupling to the protons of the adjacent 7-methyl group, reducing their signal height by splitting into a doublet, and splitting itself into a quartet.

In addition to ^{1}H-NMR, caffeine can be analyzed by ^{13}C and ^{15}N nuclear magnetic resonance, and, further on, with two-dimensional resonance techniques such as heteronuclear multiple bond coherence (HMBC) and heteronuclear single quantum coherence (HSQC), to investigate interactions between protons and distant carbons or nitrogens, including ^{13}C and ^{15}N.

In the mass spectrum, Figure 14, the last of the basic spectra, the molecular ion peak, dominates as the base signal, with only a few fragmentations. Remarkably, no methyl fragments are present: the MS-fragmentation starts with a ring cleavage at the pyrimidine part, with a cut off of methyl isocyanate (m/z 55), leading to the fragment m/z 137 and, after CO elimination, to the dominant fragment ion m/z 109. The rest of the MS are the broken bits.

Mass spectrometry is commonly used following the chromatographic separation of the analyte mixture, with GC/MS or HPLC/MS/MS as well established combinations. The mass spectrum may serve as a proof of authenticity for the caffeine origin in caffeinated soft drinks and energy drinks. A 2012 research article was entitled "Caffeine in your drink: natural or synthetic?" The isotopic composition of carbon reveals whether the caffeine in the drink is truly natural, as might be claimed, or synthetic with a carbon isotope pattern of fossil times.

Caffeine in Registries, Inventories, and Databases: Identifiers and Registry Codes

Caffeine is defined in several scientific and administrative registries. These registries have their roots in individual or corporate private initiatives or in regulatory intentions, and they are administered by either private or governmental services. The actually most accessed registers are listed in Table 3, together with the individual numerical identifiers for caffeine they provide.

By far, the most widely used is the Chemical Abstracts Service (CAS) registry, with caffeine having CAS registry number 58-08-2. The low numbers of this registry ID indicates the very early uptake of caffeine into the registry. Two later codes had to be deleted. The CAS number may often serve as an entrance to online work with elaborate regulatory listings.

The CAS has been run by the American Chemical Society since 1907. Caffeine is placed in the abstracts section "Biomolecules and their synthetic analogs." The first CAS entries of caffeine referred to German abstracts on the early caffeine synthesis by Fischer and Traube. In 1965, the service with registry numbers started. With modern tools, it may easily be accessed for pooling substance-related data and literature. The caffeine property data in Table 1 are generated from this source on-line.

Another important source, the *Beilstein Handbook of Organic Chemistry*, was started in Germany in 1881, and it incorporated papers from 1771 onward. It organized the scientific literature according to distinct chemical substances. In systematic order, caffeine had its place in Volume 26, within the nitrogen-containing heterocycles. The print version continued until the fifth multivolume supplement, covering the literature until 1979. The tradition was continued with the powerful Beilstein online database, which was taken over by Elsevier and reorganized in Elsevier's Reaxys, which integrated the older data almost completely. The Beilstein registry number is now called the Reaxys registry number, for caffeine numerically the same.

In 2011, the International Union of Pure and Applied Chemistry (IUPAC) introduced the International Chemical Identifier code (InChI). It provides structural information on chemical

Table 3 Inventories containing caffeine with registry codes

Inventory/register and reference	*Administered by*	*Short name*	*Code for caffeine*

[e]With licenses to CAS, Can. NIOSH, Elsevier and others
[f]With hazard classes for safe transportation of hazardous chemicals, based on the United Nations Recommendations on the Transport of Dangerous Goods – Model Regulations since 1957
[g]The UN number 1544 is entitled 'solid alkaloids, not otherwise specified', and 'alkaloid salts, not otherwise specified'; caffeine is dealt with in these items, but not explicitly mentioned.
[h]With common nomenclature and classification of goods (customs tariffs) since 1968 (tracing back to the principles of the former General Agreement on Tariffs and Trade GATT); actually in 2015 laid down in in Council Regulation (EEC) No 2658/87.
[i]With regular amendments; the next HS 2017 Edition was finalized in January 2015.

substances, using a string of ciphers and letters: a textual code fit for search engines. Developed in cooperation with the US National Institute of Standards (NIST), it is now held by the InChI Trust, which incorporates other relevant media organizations. The InChI code is increasingly used, replacing the earlier, less powerful SMILES code. Additionally, the shorter InChI key of IUPAC works like a registry number, providing identification and basic data for the substance requested.

The European Inventory of Existing Commercial Chemical Substances (EINECS) number follows a regulatory approach, with an inventory focused on any handling of the substances concerned. The cutoff date for 'existing' was 1981, and caffeine is included in it. The inventory was expanded step-by-step to other groups of chemicals, with an increasing volume of code numbers, and thus, a new name for the same identifier came up: EC number.

A similar approach in the United States led to the Registry of Toxic Effects of Chemical Substances (RTECS) number, established in 1971 by the National Institute for Occupational Safety and Health (NIOSH), and caffeine is included in the RTECS as well. After several transfers and mergers since 2001, RTECS was shifted from Accelrys, in 2014, to BIOVIA, which is owned by the French commercial group Dassault Systèmes. Dassault gives license other registry organizations, such as the CAS. Even though a series of other nation's analoga to EINECS or RTECS exist, these registry codes have gained remarkably broad acceptance.

Meanwhile, the EC number serves as a software key to the Europe-wide registration of chemical substances required by law. For caffeine, industry has submitted a dossier to the European Chemicals Agency (ECHA), in Helsinki, to notify it about caffeine's property and safety data, with a focus on the manufacturing workplace. In the EU, the comprehensive 'chemical index number' is included in the same regulation as the European Communities (EC) Number, again including caffeine.

The United Nations have a register with recommended coding for substances and articles dangerous to transport. Caffeine is considered part of 'solid alkaloids n.o.s. or alkaloids salts n.o.s. poisonous,' positioned in Class 6.1 Toxic, with a common four-digit code. The abbreviation 'n.o.s.' stands for 'not otherwise specified.' For caffeine, an outside marking on transport containers is not required.

In the Harmonized System (HS) of commodity description and coding, maintained by the World Trade and World Customs Organizations, 'Caffeine and its salts' have an HS

Code number identifying it as an organic chemical in the subgroup 'vegetable alkaloids' (From 2017 onwards, the subgroup will be identified as 'alkaloids.'). This classification is independent of caffeine's origin, whether from chemical synthesis or from decaffeination. The caffeine plant crops, as important internationally traded commodities under customs, are placed in the HS chapters for these vegetable products.

Table 3 is a rendering of registry codes for caffeine in several databases.

The EC Number of **Table 3** need not be confused with the Enzyme Commission's EC number, which identifies the enzymes catalyzing specific reactions. The number has been systematically designed and attributed by the International Union of Biochemistry and Molecular Biology since 1955. Enzyme numbers for the enzymes involved in the biosynthesis of are indicated in **Figure 5**.

Other mighty registers, with a history from medieval times, are the national pharmacopeias. They identify substances for pharmaceutical use and provide specifications and safety information. Caffeine is included in them. Its generic name 'caffeine' serves as pharmaceutical International Nonproprietary Name (INN) for the World Health Organization (WHO). Since 1965, the European pharmacopoeia has incorporated more and more the national texts, as laid down in the European Pharmacopoeia Convention. Under the WHO umbrella, harmonized pharmacopoeial texts are exchanged with the United States and Japanese pharmacopoeias (USP and JP, respectively).

Literature on the medical and physiological aspects of caffeine can easily be found in the Medline databases of the US National Institutes of Health and the National Library of Medicine via the search engine Pubmed. The search on 'caffeine' yields some 30 000 results.

A broad list of identification numbers is presented by the web-based information service of the Wikipedia foundation, which is authored by voluntary contributors, and has gained an increasing reputation during the last decade. Within the different language versions, the English article on caffeine dates back to 2001. Articles compile actual data, which are cross-linked intensively.

Legislative aspects and requirements belong to the part on consumption, and will be covered by the next article.

Caffeine: Consumption and Health Effects

S Gaspar and F Ramos, University of Coimbra, Coimbra, Portugal

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Caffeine is probably the most utilized pharmacologically active substance in the world. As such, due to the caffeine exposure of the majority of the population through different foods and drinks, this substance has engaged the interest of the scientific community. The effects of caffeine are dependent on multiple factors, such as the dose, contribution sources, individual responses, and body weight.

Caffeine belongs to the alkaloid family of chemicals. Prominent in this family are the methylxanthines, such as caffeine (1,3,7-trimethylxanthine), theophylline (1,3-dimethylxanthine), and theobromine (3,7-dimethylxanthine). All of them are derived from purine (the xanthine group is 2,6-dioxopurine); theophylline and theobromine have two methyl groups, while caffeine has three.

Caffeine's molecular formula is $C_8H_{10}N_4O_2$, and its molecular weight is 194.19. The chemical structure of caffeine is shown in Figure 1.

Consumption of Caffeine

Reference Levels for Caffeine Exposure

There are no European guidelines for caffeine intake for the general population. However, a conclusion that there was not an apparent justification for worries about caffeine's potential carcinogenic and mutagenic effects in humans when ingested at normal doses was taken in the eighties of the last century. In humans, moderate caffeine doses between 200 and 300 mg are frequently associated with well-being effects, such as memory improvement, increased energy, and alertness.

For non-alcoholic beverages, the maximum content of caffeine as a flavoring is 150 mg kg^{-1}. In 2012, the European Commission adopted two regulations that established a new list of authorized flavorings in the EU. The European Commission requested that the EFSA (European Food Safety Authority) deliver a risk assessment and scientific opinion about caffeine as a flavoring. However, it was not possible – through the usual procedures – to assess caffeine as a flavoring substance by the Scientific Panel on Food Additives, Flavorings, Processing Aids, and Materials in Contact with Food because data on normal and maximum levels of usage were not available. The referred panel was aware that new toxicological data on caffeine had been published in 2003, and that this data should be considered.

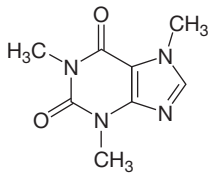

Figure 1 Chemical structure of caffeine.

Recently, the EFSA Panel on Dietetic Products, Nutrition and Allergies deliver a scientific opinion on the safety of caffeine providing advice on caffeine intakes that do not give rise to concerns about adverse health effects for the general healthy population.

Nevertheless, the main sources that currently contribute to caffeine exposure can be summarized as follows:

Tea

According to Chinese tradition, new leaves from the plant *Camellia sinensis* from the southern China mountains have been used to make tea since 2737 BC. It is believed that the Portuguese were the first Europeans to drink tea during their sixteenth-century expeditions to the Far East. In the seventeenth century, its consumption was first reported in the Netherlands and France. It was also in the seventeenth century that tea reached England; however, its generalized consumption only became established in the eighteenth century when the first teahouses appeared. Currently, tea is consumed all over the world, but mainly cultivated in China and India. *Camellia sinensis* is the scientific name of the plant. All varieties of tea are derived from this plant; the differences result from the way the leaves are processed (oxidation or fermentation). There are five main groups of tea: green tea, paocong, oolong, pu-erh (red tea), and black tea. The main difference between these products is the degree of oxidation of tea flavonoids, which are low in green tea.

The smaller the leave particles are, the greater the amount of caffeine extracted during tea preparation is. This probably depends on the bigger surface of particles in comparison to their volume. Studies show that caffeine extraction increases with the duration of fermentation. The temperature of the water used to brew the tea also affects its caffeine content: the hotter the water is, the amount of caffeine extracted increases. Another factor of the caffeine content of tea is related to the duration of the infusion. Thus, instructions about water temperature and infusion duration are usually provided on the package label by the producer.

Benefits of tea consumption are believed to be due to flavonoids that have an antioxidant effect. However, considering these positive effects, there are still many aspects related to tea consumption that need to be better understood; especially about the chemical compounds and their mechanisms of action.

It is important to highlight the difference between tea and herbal infusions made from herbs, spices, or fruits, and not from the plant *Camellia sinensis*.

Caffeine content of the leaves or commercial teabags is on average 30 mg. According to the Food Standards Agency (UK), caffeine levels in tea vary from 1 to 90 mg per dose, the average being 40 mg. However, in general, it could be considered that the caffeine content varies from 12.5 mg l^{-1} (non-caffeinated tea) to 282.5 mg l^{-1} (regular tea). Caffeine levels were tested in white, green, and black tea for different extraction time

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00099-4

periods. The caffeine contents ranged between 14 and 61 mg per cup. However, it was observed that infusion duration affects caffeine concentration in tea.

Coffee

Coffee is one of the most consumed beverages in the world. It is an infusion of roasted coffee bean grounds from plants of the *Coffea* genus. Coffee seeds are contained in berries that, once ripe, are processed (roasted) and dried. The history of coffee began in Ethiopia, and coffee has been attributed 'energizing' properties since the fourteenth century. There are two coffee species with commercial value, *Coffea arabica* and *Coffea robusta*. Coffee beans of these two species have different chemical compositions. In coffee, there are more than 1000 different compounds, many of them formed during the roasting process, which gives them their unique flavors and aromas. There are three groups of substances in coffee that stand out by their importance: caffeine, diterpenes (cafestol and kaheol), and other polyphenols. *Arabica* beans have more lipids, trigonelline, and saccharose, while *robusta* beans have more caffeine and chlorogenic acid in their products. During the decaffeination and filtration processes, some components are removed, such as caffeine and lipid fraction.

Caffeine levels in coffee vary widely. The amount of caffeine per cup is influenced by the preparation method (boiled, filtered, or espresso method). The average concentration of caffeine in ground coffee is approximately 105 mg per portion/dose with variations between samples ranging from 15 to 254 mg (espresso, filtered, and cappuccino coffee samples). The average caffeine amount per cup (150 ml) of ground roasted coffee is approximately 85 mg, but could be of approximately 60 mg in instant coffee, or only 3 mg in decaffeinated coffee. The average levels of caffeine in espresso coffee samples is 106 mg per cup, ranging from 25 to 214 mg.

Soft drinks

The expression 'carbonated water' first appeared in 1978. In the 1830s, the first attempts were made to add other ingredients, such as barks and leaves to increase carbonated water's potential benefits. As a result the first flavored carbonated drinks appeared.

Consumers are constantly searching for new flavors and formulations of soft drinks, innovation being the key to the success of the food industry. Concerns about health and lifestyle modifications have been influencing changes in soft drink consumption, primarily resulting in the increase of low calorie, or no-sugar-added varieties of the most common soft drinks. To satisfy consumer expectations, new formulations containing plant extracts, such as guarana and ginseng, have been put on the market. However, there are older formulations containing caffeine extracts. These formulations are the colas.

Colas and iced teas are the most popular soft drinks made from plant extracts. Cola is extracted from the nuts of the African tree *Cola acuminata* and *Cola nitida*. In the original formula, cola syrup also contained small amounts of cocaine. This mix became famous in 1886 in Atlanta (USA). Today, the drink is manufactured without cocaine. Its main ingredients are: water, sugar or sweeteners, caramel color, natural flavors, phosphoric acid, carbon dioxide and, of course, caffeine.

The United States had an important role in the history of tea through the invention of iced tea in 1904. Although these soft drinks are still produced using tea extracts, particularly green and black tea, they have other ingredients that separate them from plain iced tea, including high levels of added sugars. The most common iced tea ingredients are: water, sugar or sweeteners, tea extracts, flavors, juices, acidity regulators, and antioxidants.

In recent years, it was suggested that consumption of soft drinks with added sugar increases the risk of type 2 diabetes, heart disease, and other chronic diseases.

Caffeine levels in soft drinks differ by brand. However, in Europe, there is a legal limit for caffeine levels as a flavor of 150 mg kg^{-1}, or per l.

Caffeine levels in a cup of a soft drink (200 ml) vary between 20 and 60 mg. Caffeine levels range from 88 to 171 mg l^{-1} in regular cola soft drinks, and 81 to 124 mg l^{-1} in diet cola soft drinks.

Energy drinks

Energy drinks first made their appearance in Europe and Asia in 1960. In 1987, a well-known brand of energy drinks was launched in the Austrian market. This brand was launched in the United States in 1997, which contributed to the trend of high caffeine content energy drink consumption, which was enhanced by aggressive industry marketing. This kind of product usually has the word 'energy' in the product name, and contains high levels of caffeine and other additional ingredients not usually found in soft drinks. It is important to distinguish energy drinks from sports drinks. Sports drinks may have in their composition: carbohydrates, minerals, electrolytes, and flavorings. Their customary name suggests they aid in restoring water and electrolytes lost to sweating during physical activity. However, energy drinks refer to different types of beverages containing non-nutritive substances, such as caffeine, guarana, taurine, ginseng, L-carnitine, creatinine, glucuronolactone, alleged to enhance physical performance, and also high levels of sugar (glucose, dextrose, and sucrose) and small amounts of vitamins and minerals. The high variability and availability of energy drinks, often associated with being attractive, to younger generations increases the concerns about potential caffeine effects on children, and adolescents' physiology and behavior.

Plant extract soft drinks, such as cola or iced tea, usually contain flavorings, sugars and/or sweeteners, and, frequently, caffeine. However, energy drinks have more caffeine than soft drinks, and are heavily marketed to adolescents. Caffeine, as a component of energy drinks, is associated with impulsivity and the search for a new sensation in the young, promoting sexual activity, smoking, drug and alcohol abuse, and the increase of risky behavior while driving. These behaviors can be intensified with the combined consumption of energy drinks and alcohol.

Energy drink consumption is a potential health risk for the general population, but is especially alarming in younger people because of the high caffeine levels and other substances not usually found in the food chain. Therefore, it is suggested that energy drinks should not be present in the diets of children and adolescents because of the stimulant effects.

Energy drinks may contain high levels of caffeine, approximately 80 mg per 250 ml per can, equivalent to three cans of cola soft drinks, or to a cup of instant coffee.

Caffeine Consumption in Different Countries

Data on energy drink consumption in specific consumer groups in the EU was collected from the following 16 EU

member states: Austria, Belgium, Cyprus, Czech Republic, Germany, Greece, Finland, France, Hungary, Italy, Poland, Romania, Spain, Sweden, the Netherlands, and the United Kingdom. For adolescent consumers (10–18 years old), the mean exposure to caffeine from energy drink consumption is 23.51 mg day^{-1} and 0.38 mg kg^{-1} body weight (bw) per day. The mean daily exposure to caffeine from all sources (energy drinks, coffee, tea, caffeine-containing soft drinks, chocolate, and cocoa) is 184.92 mg day^{-1}, and 3.01 mg kg^{-1} bw per day for energy drink consumers. For total exposure to caffeine, the mean daily exposure from all sources is 149.20 mg day^{-1}, and 2.45 mg kg^{-1} bw per day.

In the United States the mean caffeine consumption is approximately 1 mg kg^{-1} bw per day in children and 3 mg kg^{-1} bw per day in adults. Other data from the United States, with the objective of estimating caffeine exposure from caffeine-containing drinks and cocoa and chocolate snacks, demonstrated a mean daily exposure to caffeine of 109 mg day^{-1}.

In New Zealand it is estimated that a mean exposure to caffeine in different subgroups of the population, namely, adolescents from 13 to 19 years old, is 82 mg day^{-1} and 1.2 mg kg^{-1} bw per day.

In Argentina, the mean daily exposure to caffeine by adolescents and young adults from 11 to 15 years old and 16 to 20 years old is 2.3 mg kg^{-1} bw per day and 4.1 mg kg^{-1} bw per day, respectively. Mate (an infusion of mate leaves, of which consumption is a tradition in Argentina) was the main source of caffeine.

The mean daily exposure to caffeine in France is 19.3 mg day^{-1} for the 11–14 year old age group and 33.5 mg day^{-1} for the 15–17 year old age group. This exposure is the result of the following sources of caffeine: soft drinks, energy drinks, coffee, tea, and cocoa/chocolate.

Soft drinks were identified as the main source of daily caffeine exposure for adolescents in northern countries (Finland, Norway, Denmark, Iceland, and Sweden). Daily exposure to caffeine from cola soft drinks, coffee, and tea for the 10–13 year old age group was 50.6 mg day^{-1}; and for the 14–18 year old age group the exposure was 66.3 mg day^{-1}. In Finland, 5% of all the 14–15 year old adolescents studied had a total daily exposure to caffeine from energy drinks and/or coffee greater than 2.5 mg kg^{-1} bw per day. 13-year-old Norwegian adolescents had a daily exposure to caffeine of 44.15 mg day^{-1} from the following caffeine sources: soft drinks, coffee, and tea. In Icelandic adolescents, between 15 and 19 years old, daily exposure to caffeine form soft drinks, energy drinks, coffee, and tea was 62.8 mg day^{-1}. Approximately 70% of this exposure was from the consumption of cola soft drinks.

Data from Portugal demonstrates that approximately 42% of adolescents consume energy drinks. Approximately 17% consume energy drinks combined with alcohol. The major contributors to caffeine exposure are coffee and energy drink. The total daily mean exposure to caffeine is 0.47 mg kg^{-1} bw per day. However, 3.30% of individuals exceed the daily exposure to caffeine of 2.5 mg kg^{-1} bw per day.

Effects of Caffeine on Human Health

Caffeine is a neurological stimulant, producing biological effects on a majority of body organs. Caffeine's primary cellular action is to block adenosine receptors. Blockage of these receptors by caffeine and related substances stimulates tissue and organ activity, including of the central nervous system.

Pharmacokinetics of Caffeine

After ingestion, caffeine is readily absorbed in the gastrointestinal tract and enters the blood stream. The maximal concentration of caffeine on blood is reached within 1 h to 1 h 30 min after ingestion.

The main metabolic pathway in humans (70–80%) is *N*-3-demethylation to paraxanthine, also known as 1,7-dimethylxanthine. This reaction is achieved by the liver enzyme CYP1A2, which is responsible for over 95% of primary caffeine metabolism. Beyond paraxanthine, caffeine's main metabolites are 1-methylxanthine, 1-methyluric acid, 5-acethylamine-6-formylamine-3-methyluracil, and 1,7-dimethyluric acid (17U). These metabolites are formed by secondary metabolism from paraxanthine by CYP1A2, CYP2A6, N2-acetyltransferase, and xanthine dehydrogenase. Four CYP isoforms are involved in caffeine metabolism at a concentration of 3 mmol l^{-1}, but for concentrations below 1 mmol l^{-1}, CYP1A2 and CYP1A1 are the most important isoenzymes.

After distribution, caffeine is metabolized in the liver and eliminated in urine. Caffeine's half-life in organisms varies depending on age, physiological, and pathological status, usually taking 4–5 h in human adults. However, it can be longer, up to 100 h in patients with liver disease, children, newborns, and pregnant women. Smoking enhances caffeine removal from the blood stream because of its actions on CYP1A2.

Caffeine is an adenosine receptor antagonist. Adenosine has the capacity to condition some of the effects on the central and peripheral nervous system. Caffeine has a similar structure to adenosine and acts as a competitive antagonist to adenosine receptors (A1 e A2A). It has the ability to produce effects opposite to adenosine effects, namely on the central nervous system, and on vasoconstriction. Caffeine intake causes the release of norepinephrine, dopamine, and serotonin in the brain, increasing catecholamine circulation, according to the inhibitory effects of adenosine.

The wide interindividual variability of CYP1A2 activity on its substrates, such as caffeine, is due to factors such as gender, ethnicity, genetic polymorphisms, and exposure to inducers. The metabolism of caffeine is affected by genetic determinants, age, pregnancy, diet, or life style (i.e., smoking, environmental factors, medication, including oral contraceptives, and disease types).

Pharmacokinetics of caffeine on dogs is consistent with the slow elimination of caffeine in newborns when compared with adults. The elimination of caffeine in newborns is reduced due to an immature liver enzymatic system.

Before 8–9 months of age, children have a reduced ability to metabolize caffeine. Approximately 85% of the consumed caffeine is excreted, unchanged, in their urine. In adults, this rate is only 1–5%. Caffeine's half-life is 20–30% lower in women than in men. The half-life in newborns is between 50 and 100 h, but gradually approaches the half-life of adults at approximately 6 months old. During pregnancy, the half-life of caffeine increases by 4 h through the first trimester of pregnancy, and 18 h during the third trimester of pregnancy.

General Effects of Caffeine

Caffeine, at low doses, stimulates the central nervous system and causes diuresis, smooth muscle relaxation, cardiac/heart muscle stimulation, and increased gastric secretion in adults. The consumption of caffeine is recognized for having positive effects on human health, namely in the prevention of type 2 diabetes mellitus, cardiovascular disease, cancer, and Parkinson disease. Nevertheless, this mechanism is not entirely known, and benefits are not believed to be related to caffeine because decaffeinated coffee has similar effects. However, epidemiological studies have been performed to relate caffeine consumption and the risk of bone fracture, but their results have been inconclusive.

High doses of caffeine seem to produce anxiety, nausea and nervousness. Children and women of childbearing age are risk groups that need specific recommendations about caffeine intake. Studies demonstrate that women of childbearing age should not consume more than 300 mg caffeine per day, equivalent to 4.6 mg kg^{-1} bw per day for a 65 kg individual; while children should restrict caffeine consumption to $\leq$2.5 mg kg^{-1} bw per day.

However, a maximum daily caffeine limit for children of 95 mg day^{-1} was suggested.

The northern countries have performed a caffeine risk assessment on children and adolescents to assess toxicological food risks. The following limits for tolerance and abstinence symptoms to caffeine and anxiety syndrome were defined: a LOEL (lowest observed effect level) of 1.0–1.3 mg kg^{-1} bw per day, and a LOAEL (lowest observed adverse effect level) of 2.5 mg kg^{-1} bw per day.

Caffeine tolerance syndrome is defined as the necessity to intake progressively higher doses to reach the desired objective. Currently, there is no reference value established for caffeine exposure, such as an acceptable daily intake. An exposure of 2.5 mg kg^{-1} bw per day has been suggested as a conservative upper toxicological limit, utilized as a base for risk assessment for children and adolescents, with limited evidence. For instance, Health Canada did not establish a final upper limit for caffeine intake for adolescents of age 13 or older because of insufficient data. Health Canada suggests that daily caffeine intake for this population should not exceed 2.5 mg kg^{-1} bw per day. This limit was defined for adolescents because the upper limit for adults may not be appropriate for younger adolescents with a lower body weight that are still developing. This is based on a general precautionary principle.

The structure of caffeine protein receptors is similar in children and adults. Thus, caffeine affinity to adenosine receptor is age independent. Nevertheless, differences in caffeine excretion are one of the main differences of caffeine susceptibility because the main enzyme responsible for its metabolization, CYP1A2, has different activity depending on age. Caffeine elimination is very low in newborns under 1 year old (approximately) but increases until puberty. At puberty, elimination decreases, though always with interindividual variations.

Differences in the sensitivity to caffeine among men and women were observed, which found more pronounced sleep disorders in women than in men; this difference associated with the stimulant effects of caffeine consumption.

Adolescents are a risk group for the toxicity originated by excessive caffeine intake. Caffeine metabolism decreases during adolescence because of the high natural progression of growth hormones, increasing the risk of toxic caffeine effects on this population.

Death caused by excessive caffeine intake is uncommon and only a few cases were reported. An acute lethal dose was estimated at approximately 10 g per person for adults.

Caffeine DL_{50} oral (median lethal dose) is approximately 200 mg kg^{-1}, approximately 12 g. For an adult, this would be the equivalent of rapidly consuming approximately 50 cups of coffee.

The excessive, chronic, or acute use of caffeine can result in 'caffeinism,' defined as caffeine dependency. Symptoms include restlessness, insomnia, muscle twitching, tachycardia, gastrointestinal disturbances, and sometimes the exacerbation of preexisting anxiety or panic states, depression, or schizophrenia. One of the adverse effects of its excessive intake is caffeine intoxication, classified in the WHO international list of diseases: F15.0 – mental and behavioral disorders due to the use of other stimulants, including caffeine.

Energy drinks, coffee, and soft drinks that contain caffeine can increase the risk of caffeine intoxication in abstinent individuals or in usual consumers. The potential of acute toxicity due to the consumption of energy drinks can be higher than it is from other sources of caffeine for several reasons: lack of appropriate labeling, as consumers are not entirely informed of the amount of caffeine that they will consume; advertising, because several energy drinks have 'health claims' such as increased performance, endurance and concentration; and consumer profile, by the absence of sales restriction of energy drinks to children and adolescents (which are a risk group for caffeine intoxication).

Caffeine and pregnancy

A low caffeine intake, less than 150 mg day^{-1}, during pregnancy will not affect the fetus. However, high doses, higher than 300 mg day^{-1}, equivalent to more than three cups of tea per day, should be avoided during pregnancy because they are associated with an increased incidence of congenital defects.

Caffeine intake involving pregnant women after 20 weeks of pregnancy showed a higher risk of miscarriage for women with a caffeine intake of 200 mg day^{-1} when compared with women without caffeine intake. For daily caffeine intake above 200 mg, the risk increased significantly when compared with women without caffeine intake. The fact that a high consumption of caffeine can cause adverse effects on fertility should be a concern, as well as a recommendation to women of childbearing age that an upper limit of 300 mg day^{-1} should also be avoided. Thus, moderation when consuming caffeine from any source during pregnancy should be taking into consideration.

Caffeine and cardiovascular effects

The association between coffee intake and cardiovascular risk factors was investigated. There is evidence that caffeine raises blood pressure and catecholamine levels, but reduces heart rate after acute intake.

In hypertensive patients, caffeine intake produces an acute increase of blood pressure for 3 h or more. However, recent evidence does not support an association between long-term coffee intake and the increase of blood pressure, or regular intake of coffee and cardiovascular diseases risk in hypertensive patients.

Caffeine has a minimal effect on electrocardiograms. Nevertheless, the results are inconsistent with susceptibility for arrhythmia.

Available data suggest that moderate consumption of caffeine, ≤ 400 mg day^{-1}, does not negatively affect cardiovascular health. There is not enough epidemiological data to conclude about coronary heart disease risk or death associated with an intake ≥ 1000 mg day^{-1}.

Medical recommendations advise moderation of caffeine consumption for patients with cardiovascular disorders, such as tachycardia, palpitations, and arrhythmias.

In regards to coffee, there is no clear evidence of association with hypertension risk, myocardial infarction, or other cardiovascular diseases.

Regular and moderate coffee consumption is not a hazard for health, and can even be associated with positive effects on cardiovascular health. Coffee is a complex drink that contains hundreds of biological compounds associated with beneficial health effects. For the cardiovascular system, coffee consumption may reduce the risk of hypertension, coronary heart disease, congestive heart failure, arrhythmias, and spills. However, it can negatively affect lipid profiles, depending on how drinks are prepared. In addition, possible advantages of the regular consumption of coffee should be evaluated in relation to potential risks due to high levels of caffeine.

Caffeine and bone and calcium imbalance

A minor depressor effect of caffeine on the calcium intestinal absorption and no effect on total calcium excretion in a 24-h time period was suggested. Epidemiological studies show that this negative outcome can be partially justified by the inverse relation between milk and the consumption of caffeine-containing beverages; a high caffeine intake is frequently a marker for a low calcium intake. The consumption of beverages containing caffeine is, therefore, a risk factor for osteoporosis. However, there is no evidence of a harmful effect of caffeine on the bone system for individuals who ingest the recommended daily doses of calcium.

A direct action of caffeine is increased calcium urinary excretion, because of the antagonistic mechanism of adenosine receptors. Acute caffeine intake increases urinary calcium excretion. In general, there is evidence that, in younger individuals, calcium absorption can increase to compensate for urinary losses, while elderly individuals are less adaptable.

Contrary to its predominately vasodilator effect, adenosine acts in the kidney as a vasoconstrictor.

Caffeine and human behavior

The effects of caffeine's impact on cognitive function, including alert state, surveillance, memory, and mood are not consistent. Inconsistencies may be due to the different methodologies, individual personalities, hour of the day when studies were conducted, or other uncontrolled and confusing factors, such as alcohol and smoking. In general, caffeine increases the alert state and decreases fatigue, improving the performance of surveillance and simple tasks.

However, extremely high caffeine doses may increase anxiety; but these consequences are rare with normal caffeine consumption doses. In adults with preexisting anxiety disorders, caffeine can have an exacerbating effect. Caffeine abstinence seems to be associated with negative effects; however, the studies are inconclusive.

Association between caffeine and sleep demonstrate an unwanted drowsiness reduction when the individual is working during the night, or with sleep deprivation. However, consumption patterns suggest that individuals control caffeine intake to not interfere with sleep. Thus, moderate caffeine consumption by healthy adults could not be associated with adverse effects on behavior.

Caffeine and the renal system

Caffeine is known as a diuretic substance. However, long-term studies show a decrease of the diuretic effect, leading to hypokalemia. The proposed mechanism of action includes the activation of β_2 adrenergic receptors and diuresis.

Caffeine and carcinogenicity

According to the IARC (International Agency for Research on Cancer), there is not enough evidence on caffeine to conclude about its carcinogenicity in humans. Therefore, caffeine cannot be classified with regard to carcinogenicity in humans.

Effects of caffeine on children and adolescents

In the 1990s, approximately 75–90% of children consumed caffeine regularly. Its consumption continued to grow, both in frequency and in quantity. Beneficial effects of caffeine consumption by children and adolescents are limited and restricted to athletic and short-term sports performance. However, several adverse effects have been reported in children and adolescents relating to caffeine intake. Caffeine intake has been associated with behavioral changes, hypertension, and hypercholesterolemia. However, no consistent scientific evidence is available.

Increased risk of adverse effects related to energy drink consumption can affect, in particular, children with cardiovascular, renal and hepatic diseases, diabetes, behavior and mood disorders, hypothyroidism, and specific pharmacological therapy. Physiological responses to caffeine in children and adolescents, namely increased blood pressure, were dose-dependent. Nevertheless, children and adolescents should not be considered as miniature adults because the effects of caffeine can be different from the effects attributed to adults. Additionally, child and adolescent brains are growing; thus, a healthy diet and an adequate number of sleeping hours are essential for proper child development.

Caffeine intake can compromise adolescent sleep. Moderate or high caffeine consumers have more sleep interruptions and disorders, and feel more tired in the morning. Caffeine can improve attention, but can also raise blood pressure and cause sleep disorders in children.

The relationship between caffeine consumption and drug abuse in adolescents demonstrates that consuming four or more drinks per day containing caffeine was associated with aggressive behavior, bad manners, and an increase in smoking habits.

Caffeine is frequently utilized in children and adolescents to improve school and sports performance; however, the results are not consistent. Caffeine is believed to improve sports performance by enhancing muscle contraction and decreasing effort and fatigue.

Conclusion/Final Remarks

The importance of caffeine is evident. Since antiquity, people have sought to perfect the form of their caffeine drinks. However, energy drinks currently constitute a concern because it is not possible to find a consensus in the literature and/or among regulators about the 'definition' of this type of beverage. The difficulty of distinguishing between energy and sports drinks raises concerns. In addition, there are many incorrect social perceptions, especially among young people, about the benefits and harmful effects of energy drinks. Moreover, energy drinks are easily accessible in the market; there are no age restrictions for their purchase, and costs are similar to those of common refrigerated beverages.

As such, it becomes necessary to sensitize the entities responsible for risk communication to the at-risk population, namely children and adolescents. Also, for this reason, there is strong need for regulatory entities to establish maximum caffeine content limits, and also labels with warnings about potential health risks. Moreover, European legislation determines that all beverages having $\geq$150 mg caffeine per liter must be labeled with the statement "High caffeine content. Not recommended for children or pregnant or breastfeeding women" in the same field of vision as the name of the beverage, followed by a reference in brackets to the caffeine content, expressed in mg per 100 ml.

These health warnings should be extended to advertising on television, and to the heavy marketing that the energy drink industry utilizes in the various channels of communication, sponsorship, and advertising gifts distribution.

Finally, the combination of the consumption of energy drinks and alcoholic beverages, or energy drinks and exercise should be avoided. Also, energy drink consumption by sensitive populations (individuals with cardiovascular disease, hypertension, insomnia, and anxiety, etc.) should be avoided. Moreover, at-risk population groups that are more sensitive to caffeine's adverse or toxic effects, such as children, adolescents, pregnant women and breastfeeding mothers should avoid consumption of energy drinks. Thus, the entities responsible for risk communication should provide adequate information about the risks associated with excessive caffeine intake.

Cakes: Types of Cakes

R Miller, Kansas State University, Manhattan, KS, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Cake products are found around the world and vary widely. Good quality cakes have a large volume and a crumb grain that is uniform with many small, fine cells and no large holes or tunnels. The definition of cake also varies in different parts of the world. In general, cakes are sweet baked products, which contain high levels of sugar, fat, eggs, and water. Most cakes are made using soft wheat flour with a low protein content of 7–9%. The soft wheat flour is often pin-milled to produce a very fine (small) particle size. Smaller flour particles have more surface area and are able to absorb more liquid and produce better quality cakes.

Cakes are classified by the methods used to produce them. Common classifications include layer cakes, foam cakes, and pound cakes. Layer cakes are further divided into high-ratio and low-ratio cakes and are also categorized based on the method used to prepare the batter, which includes multistage mix, single-stage mix, or continuous mix. Foam cakes can be further classified by the level and source of fat in the formula. Examples are angel food (no fat), sponge (egg yolk only), and chiffon (egg yolk and added fat). Pound cakes are typically made using the multistage (creaming) method. Pound cakes were named based on the original formula, which contained 1 lb of flour, 1 lb of butter, 1 lb of sugar, and 1 lb of eggs.

Layer Cakes

Layer cakes are quite common across the globe. They typically consist of multiple sheets of cake stacked together with some type of filling (frosting, jam, preserves, etc.) between the layers. A range of flavors, ingredients, toppings, shapes, and sizes vary enormously. At the basic level, layer cakes are produced using a batter system, which is high in sugar, water, and fat. The first step in layer cake production is making the batter. Although the procedure varies for the different methods, the objectives of mixing are the same: (1) to combine all of the formula ingredients into a smooth, uniform batter, (2) to form a stable emulsion of fat in water, and (3) to incorporate air cells. Both high-ratio and low-ratio layer cakes can be prepared using three different mixing procedures: multistage mix, single-stage mix, and mechanical mix. The three methods vary by how air is incorporated into the batter, which affects how stable the batter is during bench time (time between mixing and baking) and the texture of the final baked cake.

Multistage Mix Process

Cake batters made using the multistage mix process have excellent stability and produce cakes with a uniform, fine crumb grain (large number of small-sized air cells). In the first mixing stage, solid fat and sugar are creamed together. The wet ingredients and flour are then incorporated in two or three subsequent mixing steps. The purpose of creaming is to incorporate air into the fat. The sugar crystals help cut the fat to increase air incorporation. Because the air cells are trapped in the shortening, they are very stable and will not coalesce in the batter during bench time (holding or processing time between mixing and placement into the oven). When the shortening melts during baking, the air cells are released into the aqueous phase where the leavening gases produced by the chemical leavening reaction and water vaporization can diffuse into them to leaven (raise) the cake.

Single-Stage Mix Process

Commercial cake mixes made by home consumers and institutions are made using a single-stage mixing process. The cake mix contains the dry ingredients and fat, which are processed through a cake finisher that acts like a grinder to bind the fat onto the surface of the flour particles. This ensures that there is no free fat in the system, which would destabilize the foam generated during mixing. To prepare the cake, the consumer simply adds the liquid ingredients and mixes the batter for a few minutes. Air is trapped in the aqueous phase during mixing. This is possible because the formula contains surfactants such as propylene glycol monostearate to assist in air incorporation and stabilization.

Cakes made by the single-stage mix are simple to prepare but have poor stability and will not withstand bench time. During standing, the air cells in the batter quickly coalesce (go together) to form large bubbles, which can rise out of the batter, resulting in poor volume and poor crumb grain that is not uniform with coarse cells, large holes, and tunnels. The high level of surfactants also makes the cake delicate and tender, which is good for eating but not desirable for commercial cakes, which may be stacked and/or transported.

Continuous Mix Process

Specialized mixers are used for the production of cakes by the continuous mix process. In this method, all of the ingredients are made into a slurry, which is fed into the mixing head where the batter is mixed at high speed, while air is injected into it. Air is incorporated into the aqueous phase due to the high energy input. This method is the most expensive of the three methods. Batters made using this process are very stable and produce cakes with a firm texture. For these reasons, this production method is used for most commercial cakes.

High Versus Low Ratio

Layer cakes can be made using a high-ratio or low-ratio formula (Table 1). The main difference is the level of sugar relative to the level of flour. High-ratio layer cakes are typically

Table 1 Typical high- and low-ratio layer cake formulas

	High ratio (% flour weight)	*Low ratio (% flour weight)*
Flour	100	100
Sugar	140	100
Shortening	55	45
Milk	95	68
Whole egg	76	66
Baking powder	1.3	1.3
Salt	0.7	0.7

consumed in the United States, while many European countries prefer low-ratio layer cakes.

During baking, the high water content in the batter allows the starch to gelatinize during baking, which helps set the structure of the cake during baking and results in a uniform, aerated crumb grain and a cake with a tender texture. The ratio of sugar to flour dramatically impacts the properties of the batter during baking and affects the volume and structure of the baked cake. High-ratio cakes contain higher levels of sugar than flour. The sugar level generally ranges from 125% to 140% based on the weight of the flour. Chocolate cakes can tolerate even higher levels of sugar and may contain as much as 180% sugar on a flour weight basis. Examples of high-ratio cakes include angel food, sponge, chiffon, and layer cakes consumed in the United States. The sugar level controls the temperature at which the cake structure sets (transforms from a fluid batter to solid foam) by its effect on the temperature at which the starch gelatinizes and the egg protein denatures. In high-ratio layer cakes, the high level of sugar increases the denaturation temperature of the egg and the gelatinization temperature of the starch. The gelatinization temperature of the starch is increased to a temperature higher than the boiling point of water. During baking, the internal temperature of the cake does not exceed the boiling point of water; thus, the starch does not fully gelatinize in the interior of a cake baked with a high-ratio formula. As a result, the cake collapses during cooling. For this reason, flour used for high-ratio layer cake production is typically chlorinated. The chlorine gas reacts with the protein, lipids, starch, and other components of the flour, thereby changing their functionality. The reaction with the protein produces hydrochloric acid (HCl), which alters the pH of the flour. The change in pH does not impact the baking properties but does provide a way to measure the degree of chlorination that the flour received. Untreated flour has a pH of approximately 6.1, while highly chlorinated flour needed for production of high-ratio layer cakes typically has a pH ranging between 4.7 and 4.9. It is the oxidation of the starch that is the mechanism by which chlorine gas improves the baking performance of the flour. Oxidized starch is able to absorb water more quickly than native starch and will swell at a faster rate after gelatinization. This allows the viscosity of the batter to increase at a faster rate in the oven. As a result, the starch is completely gelatinized and the structure of the cake is fully set by the end of baking so it does not collapse upon cooling.

In low-ratio cake formulas, the sugar level is equal to or lower than the level of the flour. In low-ratio cakes, the sugar level relative to the flour level is not high enough to significantly raise the starch gelatinization temperature. Thus, it is not necessary to use chlorinated flour for the production of low-ratio layer cakes. Examples of low-ratio cakes include pound cakes and layer cakes consumed in Europe.

The viscosity of the batter is critical in order to produce a cake of high quality. Proper batter viscosity ensures the cake will have large volume and a uniform, fine crumb grain. The batter viscosity must be high enough to keep the starch and the air cells suspended. If the batter is too thin (low viscosity), the starch granules can settle to the bottom of the cake during baking. This results in a tough, rubbery, dense, gummy-appearing layer at the bottom and a fluffy, foamy-appearing layer at the top of the cake. The air bubbles will also coalesce (go together), creating large bubbles, which can become buoyant enough to rise to the surface of the batter and be lost, resulting in a cake with low volume. Large air bubbles that do not rise out of the cake will produce an open, irregular crumb grain containing large holes or tunnels.

Layer cakes are leavened by chemical leavening and steam. It is important to select the correct leavening system for the desired color, texture, volume, and crumb grain characteristics. Some varieties of cakes are leavened by steam alone and others by steam in addition to chemical leavening agents, such as baking soda (sodium bicarbonate) and baking powder. The baking powder most often used is double-acting, which contains sodium bicarbonate and two leavening acids. One leavening acid reacts at room temperature (fast-acting) to help nucleate the batter during mixing, while the other reacts in the oven (slow-acting) to expand the air cells during baking. When using baking powder, it is important to select one with the correct slow-acting leavening acid that will react at the proper time during baking. If the leavening acid reacts too early before the batter viscosity is high enough, the air cells will diffuse out of the batter, resulting in low volume and a coarse crumb grain. On the other hand, if the leaving acid reacts too late after the structure is set, the cake cannot expand, resulting in low volume, and the buildup of pressure inside the cake can destroy the crumb grain and may cause the top surface to crack.

Foam Cakes

Foam cakes are characterized by their extremely light, fluffy, and spongy texture. Eggs are the most important ingredient in the formula and play a critical role in leavening and the structure of the cake. In the production of foam cakes, the eggs are whipped into foam. The stability of the foam is critical to the final volume and texture of the cake. Fat inhibits foam formation and creates softer, less stable foams. For this reason, the stiffness and stability of foams generated using egg whites alone are the highest followed by whole egg. Egg yolk alone does not form into foam. In formulas containing whole egg, it is common to whip the egg whites into foam and then gently fold them into a separately prepared batter that contains the egg yolk later in the process. In the preparation of an egg white foam, all mixing bowls, utensils, and baking pans should be

free from grease. For this reason, it is common for egg white foams to be prepared in metal rather than plastic bowls, which can retain enough residual fat from other products to destroy the foam. Foam cakes are also commonly baked in pans, which are not greased, even if the formula contains whole egg. Foam cakes can be classified by the level and source of fat in the formula and include (1) no fat, (2) fat from egg yolk only, and (3) fat from egg yolk plus fat added in the form of butter, shortening, or oil. Examples are angel food (no fat), sponge (egg yolk only), and chiffon (egg yolk and added fat).

Angel Food Cake

Angel food cake, also known as angel cake, contains only egg whites and is an example of a no fat foam cake. Angel food cakes have a light, airy structure and a spongy or chewy texture due to their high sugar content and the absence of fat. A typical formula is shown in Table 2. The batter is prepared by whipping the egg whites with sugar and cream of tartar to produce stiff foam. The sugar helps stabilize the foam. Although cream of tartar is a leavening acid (tartaric acid), it is not added as a leavening agent but rather to reduce the pH of the egg white proteins in order to improve their whipping ability. The air whipped into the foam is the leavening agent. Once stiff foam is produced, flour and flavorings are very gently folded in. Extreme care must be taken to not stir too vigorously and break the foam.

The flour used in angel food cakes is weak soft wheat flour that has a very low protein content of about 4%. Often, wheat starch is added to dilute the flour. The function of the flour in angel food cake is completely different than in almost every other bakery good. In most baked products, the gluten protein is the most important component of the flour and responsible for the structure and quality of the baked product. In angel food cake, the starch is the most important component of the flour. When the starch gelatinizes during baking, it absorbs water, which dries the foam and causes the structure to set. Angel food cakes are typically baked in tube pans, which are tall, round metal pans that have a hollow metal tub in the center (Figure 1). The center tube helps the center of the cake bake completely. After baking, the tube pan is inverted while cooling to prevent the cake from collapsing.

Table 2 Typical foam cake formulas

	Angel food (% flour weight)	*Sponge (% flour weight)*	*Chiffon (% flour weight)*
Flour	100	100	100
Sugar	215	143	108
Egg white	277		
Whole egg		143	143
Cream of tartar	4	1	1
Oil			40
Water			80
Baking powder		4	4
Salt	1	1	2

Sponge Cake

Sponge cakes contain a small amount of fat, which comes from the use of whole eggs (egg yolk). These cakes are richer and more flavorful than angel food cakes. In general, sponge cakes are prepared using a combination of a batter and foam. The batter is prepared by beating the flour, egg yolks, and half of the sugar. Separately, the egg whites and remaining half of the sugar are whipped into foam, which is carefully folded into the egg yolk batter. In some cakes, the whole egg is whipped instead of the egg whites being whipped separately. Sponge cakes are baked in a variety of differently shaped pans. The spongy structure of the cake lends itself well to rolling; thus, sponge cake is often used to produce rolled and filled cake desserts.

Chiffon Cake

Chiffon cakes are the richest and most flavorful of the foam cakes. The texture is light and airy but denser than angel food and sponge cakes. The formula contains whole egg and added fat in the form of butter, shortening, or oil (Table 2). The fat impedes the foaming ability of the eggs, so these cakes also contain chemical leavening in order to produce expanded cakes with light and airy textures. In general, chiffon cakes are prepared using a combination of a batter and foam. The batter is prepared by beating the flour, egg yolks, fat, water, and flavorings and some of the sugar. Separately, the egg whites and remaining sugar are whipped into foam, which is carefully folded into the egg yolk mixture. The batter has a thinner consistency (lower viscosity) than the other types of foam cakes. Chiffon cakes are traditionally baked in tube pans (Figure 1).

Pound Cake

Pound cakes are rich and have a dense but tender texture. Originally, pound cakes were made using 1 lb of flour, 1 lb of butter, 1 lb of sugar, and 1 lb of eggs. Modern formulas still

Figure 1 Tube cake pan.

Table 3 Typical pound cake formula

	Percent (flour weight)
Flour	100
Sugar	100
Shortening	50
Milk	50
Whole egg	50

contain those basic ingredients but the proportions have changed and chemical leaveners have been added. A typical formula is given in Table 3. Pound cakes are typically made using the multistage (creaming) method. The cakes are usually baked in loaf or Bundt pans. Sponge cake batter lends itself well to the addition of ingredients such as cream cheese, sour cream, coconut, nuts, raisins, and other dried fruits and a multitude of flavoring agents.

Calcium: Physiology

SM Sacco, Brock University, St. Catharines, ON, Canada
MR L'Abbé, University of Toronto, Toronto, ON, Canada

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Calcium is the most abundant mineral in the human body. Approximately 99% of calcium in the body is found in the skeleton as hydroxyapatite, a crystalline complex of calcium and phosphate. The remaining 1% of calcium found in the body is found in the blood, extracellular fluid, and soft tissues. Calcium is a nutritionally essential mineral that plays a critical role in a number of processes. It provides the skeleton with rigidity, hardness, and strength to bear a variety of intrinsic (e.g., muscle contraction) and extrinsic (e.g., gravity, trauma) forces. It also plays an important metabolic role in facilitating muscle contraction, blood coagulation, enzyme activity, nerve synaptic function, secondary messengers, hormone release, and membrane permeability. Calcium is so vital in supporting physiological processes of the body that its concentration in the serum and extracellular fluid is maintained within a very narrow range. If dietary intake of calcium is low, the body mobilizes calcium from skeletal tissue, a dynamic calcium reservoir, to maintain serum calcium levels. Chronic insufficiency of calcium ultimately leads to decreased bone mass, the development of osteoporosis, and increased risk for sustaining fragility fractures.

Dietary Sources of Calcium

Calcium is naturally found in a plethora of foods; however, its richest source is dairy. A cup of milk or yogurt provides approximately 300 mg of calcium, while 50 g of cheese including Swiss, goat, low-fat cheddar, mozzarella, Gruyère, and some processed cheese slices contains 250–500 mg of calcium. Several other natural sources of calcium include green leafy vegetables, nuts, seeds, and beans (Table 1). Vegetables contain much lower levels of calcium per serving compared to dairy products. Thus, it is easier and more practical to consume dairy products to meet daily calcium requirements. Calcium-fortified foods are becoming increasingly more common in the North American market as an alternative for achieving adequate dietary calcium intake. Calcium-fortified foods include fruit and juice beverages, soy and almond beverages, rice beverages, breakfast cereals and bars, granola bars, breads, and tofu. These calcium-fortified foods may contain up to 300 mg of calcium per serving.

Patterns of Consumption

From 2007 to 2012, the consumption of dairy and, more specifically, milk has decreased among Canadians and Americans. This pattern of decreased milk intake can also be seen globally among several European countries (e.g., Belgium, France, Iceland, Italy, the Netherlands, Spain, Sweden, and Switzerland) as well as in Iran and New Zealand. In North America, calcium intake remains a concern for all age groups. According to the Canadian Community Health Survey, a federal cross-sectional survey on the health status, health-care utilization, and health determinants for the Canadian population, 65% of men and 72% of women aged 31–50 years do not consume the minimum recommended daily servings of dairy. Similarly, 83% of girls and 61% of boys aged 10–16 years do not meet the recommended 3–4 servings of dairy per day. In the United States, 85% of the population does not meet the recommendations for dairy intake. Because it is easier to meet daily calcium needs through dairy intake, strategies such as the Get Enough campaign in Canada and Milk, a Force of Nature campaign in Europe have been launched by various lobbying organizations to increase daily calcium intake through dairy and other foods. For those who cannot meet their calcium requirements with food, the medical community promotes the use of calcium supplements to achieve recommended intake levels.

Recommended Intakes Across the Life Span

The recommended intakes of calcium and vitamin D for both the United States and Canada were reassessed in 2010 by the Committee to Review Dietary Reference Intakes for Vitamin D and Calcium established by the Institute of Medicine. Dietary reference intakes (DRIs) were updated to replace adequate intakes (AIs) for all age groups, except for infants, with estimated average requirements (EARs) and recommended dietary allowances (RDAs), due to currently available data on bone health outcomes. These current data include large-scale randomized trials and calcium balance studies. Data were not sufficient to establish an EAR for infants; thus, the AI is used to reflect an intake level based on estimates that are assumed to be adequate. However, current data have facilitated the development of an upper level (UL) for infants, which was not previously specified. Table 2 lists the DRIs for calcium by life stage group in Canada and in the United States.

Bioavailability, Absorption, Regulation, and Distribution in the Blood

Bioavailability

There are several natural and fortified dietary sources of calcium as well as numerous calcium supplement products. The degree to which the body can absorb calcium can vary substantially between these sources (Table 1). Calcium is considerably bioavailable from the consumption of dairy foods. Some calcium-fortified foods and beverages also have calcium bioavailabilities that are comparable to that in dairy, while

Table 1 Calcium content and estimated absorption from various food products

Food	*Serving size*	*Calcium content (mg)*[a]	*Fractional absorption (%)*	*Estimated calcium absorbed (mg)*	*Servings required to equal 250 ml of milk*
Milk products					
Milk	250 ml	312	32.1	100	1.0
Cheddar cheese	42 g	303	32.1	97	1.0
Vegetables					
Kale	65 g	47	58.8	28	3.6
Broccoli	71 g	35	52.6	18	5.6
Spinach	90 g	122	5.1	6	16.7

Nuts and seeds					
Almonds	28 g	80	21.2	17	5.9
Sesame seeds, no hull	28 g	37	20.8	8	12.5
Legumes					
Beans, white	110 g	113	17.0	19	5.3
Beans, pinto	86 g	45	17.0	8	12.5
Beans, red	172 g	41	17.0	7	14.3
Fortified foods					
Orange juice (fortified with calcium citrate malate)	250 ml	300	36.3	109	0.9
Tofu, calcium set	126 g	258	31.0	80	1.2
Soy beverage (fortified with tricalcium phosphate)	250 ml	300	24.0	72	1.4
Soy beverage (fortified with calcium carbonate)	250 ml	300	21.1	63	1.6

[a]Based on a half-cup serving size unless otherwise noted.

Selected data from Weaver, C. M. and Plawecki, K. L. (1994). Dietary calcium: adequacy of a vegetarian diet. *American Journal of Clinical Nutrition* **59**, 1238S–1241S; 'Dairy Nutrition' www.dairynutrition.ca/.

others do not. This may be explained by the chemical nature of the calcium compound used to fortify the food or beverage product and the food or beverage matrices to which the calcium is added. The bioavailability of calcium from the consumption of some vegetables (e.g., cauliflower and broccoli) is even higher than that from dairy and calcium-fortified foods. However, vegetables contain much lower levels of calcium per serving compared to dairy products and calcium-fortified foods (Table 1). Another consideration is that some vegetables and plant foods contain other components (i.e., oxalates and phytates) that form salt complexes with calcium that render them unabsorbable by the body. Indeed, it is the amount of calcium along with its bioavailability that determines how much calcium a particular food source will provide per serving. Thus, dairy foods, and more specifically, milk, continue to serve as the major food source of calcium in Western diets. In North America, 75% of dietary intake of calcium comes from dairy. With regard to supplemental calcium, these may also vary in bioavailability. Some research suggests that differences in bioavailability among calcium supplements may be linked to the form in which the supplement is found (i.e., tablet, powder, or liquid) or the acid to which it is bound; however, these findings are mixed. Interestingly, supplemental calcium shows a comparable absorption efficiency as dietary calcium.

Absorption and Regulation

Approximately 90% of calcium absorption occurs in the small intestine with smaller amounts absorbed through the colon. Calcium absorption occurs by two major pathways, an active transcellular pathway that primarily occurs in the duodenum and a passive paracellular pathway that occurs through specialized membrane domains (i.e., tight junctions) throughout the small intestine but predominately in the more distal regions, particularly in the ileum. In active calcium transport, calcium moves across the brush border of the microvilli of the small intestine and into the enterocyte through calcium-selective channels called transient receptor potential vanilloid type 5 (TRPV5) and type 6 (TRPV6) (Figure 1). Calcium is then transported across the enterocyte to its basolateral side by a transport protein (calbindin-D) where it then gets extruded into interstitial space (lamina propria) by transport proteins (basolateral plasma membrane calcium pump (PMCA) and the sodium calcium exchanger) before making its way into the circulation. In paracellular calcium transport, specialized membrane domains (tight junctions) located between the apical and basolateral membranes of the enterocyte form a barrier to the movement of ions, proteins, and other macromolecules across the intestines. These tight junctions are driven by the luminal electrochemical gradient for calcium. Thus, when calcium levels inside the lumen of the small intestine are high, passive calcium entry into the enterocytes is stimulated by the paracellular pathway (Figure 1).

Transcellular calcium transport is almost exclusively regulated by 1,25-dihydroxyvitamin D (calcitriol), the hormonally active metabolite of vitamin D, while paracellular calcium transport is driven by a downhill concentration gradient of calcium between the luminal space and the interstitial space.

Table 2 Dietary reference intakes of calcium (mg day^{-1})[a]

Age	*AI (mg)*	*EAR (mg)*	*RDA (mg)*	*UL (mg)*
Infants

AI, adequate intake; EAR, estimated average requirement; RDA, recommended dietary allowance; UL, tolerable upper intake level.

[a]As set out by the Institute of Medicine (2011). *Dietary reference intakes for calcium and vitamin D*. Washington, DC: National Academy Press.

Even though the rate of calcium absorption through the transcellular pathway is approximately three times greater than that through the paracellular pathway, the greatest proportion of calcium absorption when dietary intake is high occurs in the ileum through the paracellular pathway. This is because the sojourn time of chyme in the lower half of the small intestine (hours) is substantially higher than that in the duodenum (minutes). Thus, when dietary intake of calcium is normal or high, the major factor that determines the amount of calcium absorbed is the quantity ingested. When dietary intake of calcium is low, a high proportion of calcium that is absorbed occurs through the transcellular pathway in the duodenum. Thus, in addition to 1,25-dihydroxyviamin D, low dietary intake of calcium also regulates the efficiency of the transcellular pathway. Other factors that affect the transcellular transport of calcium include estrogen status and age.

Distribution in the Blood

Approximately 99% of calcium in the body is stored in the skeleton as hydroxyapatite, while the remaining 1% of calcium in the body is located in the blood, extracellular fluid, and soft tissues. Calcium in the blood is found in three forms: (1) ionized or free calcium, which accounts for approximately 50% of total calcium concentration; (2) protein-bound calcium (bound mainly to albumin), which accounts for approximately 30–40% of the total serum calcium concentration; and (3) complexed or chelated calcium, which accounts for approximately 10% of the total blood calcium concentration. Ionized calcium is the physiologically active form of calcium that plays an important metabolic role in maintaining bone homeostasis, facilitating muscle contraction and relaxation, nerve synaptic function, blood coagulation, enzyme activity, secondary messengers, and hormone release. Protein-bound calcium is not usable by tissues due to its inability to diffuse through membranes. Chelates serve to bind calcium for maintaining homeostatic cytosolic concentrations.

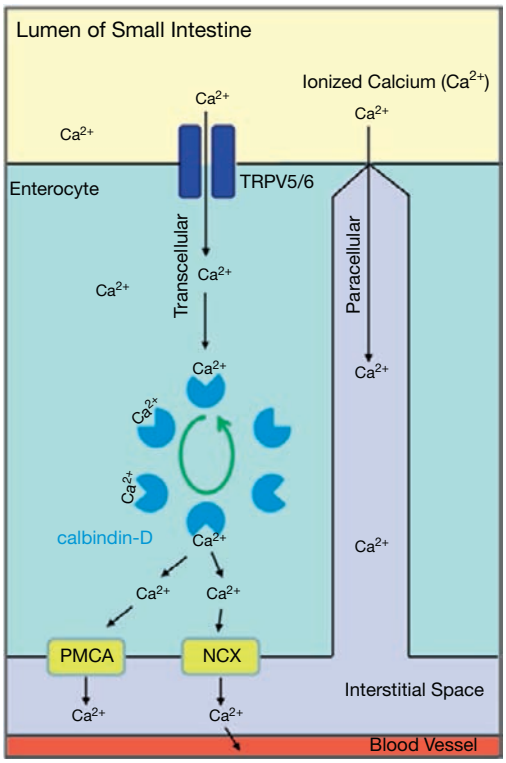

Figure 1 Active and passive calcium transport across the intestines. In active calcium transport, calcium moves across the brush border of the microvilli of the small intestine and into the enterocyte through calcium-selective channels (i.e., transient receptor potential vanilloid type 5 (TRPV5) and 6 (TRPV6)) and then is transported across the enterocyte to its basolateral side by calbindin-D. Calcium is then extruded into interstitial space via the basolateral plasma membrane calcium pump (PMCA) and the sodium calcium exchanger (NCX) before making its way into the circulation. In paracellular passive calcium transport, tight junctions located between the apical and basolateral membranes of the enterocyte form a barrier to the movement of ions, proteins, and other macromolecules across the intestines. Transport across these tight junctions is driven by the luminal electrochemical gradient for calcium. Modified from Hoenderop, J. G. J., Nilius, B. and Bindels, R. J. M. (2005). Calcium absorption across epithelia. *Physiological Reviews* **85**, 373–422.

Calcium Balance

Calcium balance is determined by its dietary intake, absorption, and excretion and is tightly regulated by the

complex interplay between the intestines, bones, and kidneys. Calcium balance is maintained when the net absorbed calcium through the intestines and kidneys (reabsorption) matches the net excreted calcium through the feces, urine, and the skin. Thus, if an adult ingests 1 g of calcium, it is estimated that approximately 0.35 g will be absorbed in the small intestine. This occurs under the tight regulation of the calciotropic hormones. Calcium balance will be achieved if the kidney excretes the same amount of calcium (0.35 g) that the small intestine absorbed. This is accomplished by a combination of filtration of calcium across the glomeruli and subsequent reabsorption of the filtered calcium along the renal tubules. Adaptations of the intestines, bones, and kidneys to various stimuli occur to compensate for changes throughout the life span (e.g., growth, hormones, injury, and disease).

Hormonal Regulation

There are three major hormones involved in controlling calcium balance. These are parathyroid hormone (PTH), 1,25-dihydroxyvitamin D, and calcitonin. Other hormones, such as estrogens, stanniocalcin, thyroid hormones, insulin, and adrenal corticosteroids, contribute to the maintenance of calcium homeostasis.

Parathyroid hormone

PTH is secreted into the circulation by the parathyroid glands in response to low blood calcium levels and acts primarily on the kidneys and bones to increase blood calcium levels. PTH acts on the kidneys by directly stimulating renal tubular calcium reabsorption, which increases circulating levels of calcium. PTH also directly stimulates the breakdown of bone (bone resorption) to increase circulating levels of calcium. The absorption of calcium through the small intestine is indirectly regulated by PTH due to the action of PTH on increasing the activity of 1-α-hydroxylase, the enzyme that catalyzes the hydroxylation of 25-hydroxyvitamin D (calcifediol) into the active hormone, 1,25-dihydroxyvitamin D (calcitriol).

1,25-Dihydroxyvitamin D

1,25-Dihydroxyvitamin D enhances active transcellular transport of calcium through the small intestine in response to decreased calcium intake. It also mobilizes calcium and phosphate from the bone and increases renal reabsorption of calcium by increasing transport proteins (i.e., TRPV5, TRPV6, calbindin-D, and PMCA). The action of 1,25-dihydroxyvitamin D in increasing blood levels of calcium occurs when adequate substrate (i.e., vitamin D) is provided, mainly through sun exposure, diet, or supplemental intake.

Calcitonin

Calcitonin is synthesized and secreted into the circulation by parafollicular cells of the thyroid gland in response to high circulating levels of calcium. Calcitonin acts to reduce circulating levels of calcium by decreasing bone resorption through the inactivation of bone-resorbing osteoclasts. It also lowers blood calcium levels by reducing calcium absorption through the small intestine and renal tubular calcium reabsorption.

Dietary Control

Vitamin D

Vitamin D must be hydroxylated in two subsequent reactions by two separate hydroxylase enzymes in order to produce the active hormone metabolite 1,25-dihydroxyvitamin D that plays a major role in increasing blood levels of calcium (see section '**Hormonal Regulation**'). Thus, through the action of its hormone metabolite, vitamin D is critical for supporting calcium homeostasis. However, vitamin D is not found naturally in most foods that are commonly consumed. Fleshy fish including salmon, mackerel, and herring are naturally rich in vitamin D (219–392 IU per 2.5 ounce serving). Other good food sources of vitamin D include egg yolk and milk. In Canada and in many other countries, vitamin D is added to foods such as milk, yogurt, soy beverages, and margarine in an effort to achieve adequate daily intakes of vitamin D. Moreover, supplementation with vitamin D is becoming increasingly more common as recommendations for vitamin D have increased substantially over the past decade.

The other major source of vitamin D for humans is synthesis by skin exposed to ultraviolet B (UVB) photons from sunlight. When UVB photons reach the surface of the skin, they are absorbed by 7-dehydrocholesterol in the plasma membrane of the epidermis, transformed to previtamin D, and then rapidly converted to vitamin D. Vitamin D is then hydroxylated into 25-hydroxyvitamin D in the liver, which is then hydroxylated in the kidneys to form the active hormone 1,25-dihydroxyvitamin D. Sun exposure can result in adequate production of vitamin D in humans. However, there are several factors that can limit the number of UVB photons that reach the surface of the skin and that contribute to vitamin D deficiency in many countries including Canada and the United States. These include the zenith angle of the sun, melanin, use of sunscreen products, and pollution in the air.

Vitamin D plays a critical role in maintaining calcium balance because balance is almost exclusively regulated by 1,25-dihydroxyviamin D, the hormonally active metabolite of vitamin D (see section '**Hormonal Regulation**'). 25-Hydroxyvitamin D concentration in the serum is the functional indicator of vitamin D status. Some research suggests that optimal calcium absorption is achieved when serum levels of 25-hydroxyvitamin D are at a minimum of 50 nmol l^{-1}. Others suggest that optimal calcium absorption is achieved when serum levels of 25-hydroxyvitamin D are above 75 nmol l^{-1} and even 80 nmol l^{-1} in certain populations such as postmenopausal women.

Phosphorus

Phosphorus is a nutrient that is easily obtained in the Western diet and is naturally found bound to oxygen as phosphate. Phosphorus is naturally found in appreciable amounts in milk, milk products, meat, beans, lentils, nuts, and grains. Phosphorus is increasing in the food supply due to the increasing addition of phosphate additives that are sources of inorganic phosphate to processed food products. Inorganic phosphorus is commonly added to processed food products to improve their taste, shelf life, and speed of preparation. In the United States, the greatest contributors of phosphorus in the diet are milk and dairy, followed by grain-based dishes, breads, poultry, pizza, vegetables, meats, and processed food

products. The absorption rate of naturally occurring phosphorus is between 40% and 60%, whereas the absorption rate of inorganic phosphorus ranges between 80% and 100%. Inorganic phosphorus has a much greater absorption rate and efficiency compared to organic phosphorus because it does not require enzymatic digestion in the stomach.

Studies have shown that the effects of phosphorus on various physiological processes are in part determined by the accompanying levels of dietary calcium. However, if dietary intake of calcium is inadequate, this balancing relationship is nullified and neither phosphorus nor calcium will support normal physiological function. In one trial, a one-time consumption of 1500 mg of phosphorus, which is over twice the RDA, showed decreases in serum calcium levels in healthy premenopausal women. Other researches reported high circulating levels of PTH in premenopausal women that consumed phosphorus at 1319 mg day^{-1} but consumed low levels of calcium (<800 mg day^{-1}). However, recent data have shown that calcium absorption and phosphorus absorption through the intestines and kidneys are independent of each other. In addition, others have shown that a 150% increase in dietary phosphorus does not alter calcium balance when calcium intakes are low, medium, or high. Indeed, phosphorus is a constituent of hydroxyapatite that makes up bone tissue. Thus, phosphorus is essential for bone accretion. Whether and under which circumstances phosphorus modulates calcium balance continues to be a subject of research interest and controversy.

Protein

The role of high-protein diets on calcium balance is complex. Dietary protein, primarily from animal sources, generates endogenous acids through the oxidation of sulfur amino acids and phosphoproteins. These acids are suspected of inducing a negative calcium balance and subsequent demineralization of the bone. Indeed, controlled feeding studies have demonstrated that an increase in protein intake by 40–60 g day^{-1} results in a 0.3–0.8 unit reduction in urinary pH. However, further studies demonstrate that other factors such as ammonia excretion and hormones (e.g., insulin and glucocorticoids) may be more involved in urinary calcium excretion from high intakes of dietary protein. Controlled feeding studies have shown that high intakes of purified proteins such as casein, dried egg whites, and wheat gluten increase urinary calcium excretion by 0.7–2.2 mg g^{-1} of supplemental ingested protein. This effect occurs from an increase in glomerular filtration rate and a decrease in fractional tubular reabsorption rate when dietary protein intake increases one- to threefold. Other studies have demonstrated no changes in urinary calcium excretion when comparing diets high in meat consumption versus those with low meat consumption. Some foods such as meat and dairy products contain components other than protein that may lower urinary calcium excretion when adequate levels of calcium intake are achieved. Thus, the effect of diets high in protein on urinary calcium excretion depends on the nature of the dietary protein.

While high intakes of dietary protein are speculated to result in a negative calcium balance, studies examining this relationship have reported mixed findings. Some studies observed negative calcium balance with high-protein diets compared to low-protein diets, while others observed no changes in calcium excretion and calcium balance. These conflicting findings may be explained by a number of factors including the difficulties in measuring whole-body calcium balance, the nature of the ingested protein, and other factors such as level of dietary intakes of calcium and phosphorus. It is possible that increased urinary calcium excretion from high intakes of dietary protein is a result of increased intestinal absorption; however, more study is required in this area. Interestingly, when adequate levels of calcium intake are achieved, increases in protein intake are positively correlated with bone mass in all age groups. Protein stimulates the production and activity of insulin-like growth factor-1 that stimulates bone formation and the regulation of bone metabolism.

Sodium

The average dietary intake of sodium in the United States and Canada is approximately 3400 mg day^{-1}, which is more than twice the AI (1500 mg day^{-1}) and significantly higher than the UL (2300 mg day^{-1}), as set out by the Institute of Medicine. Sodium and calcium compete for reabsorption in the kidneys. Thus, high dietary intakes of sodium increase urinary calcium excretion. However, adding potassium to a high-sodium diet may help decrease calcium excretion. Evidence demonstrates that for every 2290 mg of sodium ingested, an average of 40 mg of calcium is excreted, without any adaptive compensatory mechanisms. Thus, it is reasonable to expect a daily loss of approximately 60 mg of calcium among Canadians and Americans who consume approximately 3400 mg of sodium per day.

Potassium

According to the 2010 Dietary Guidelines for Americans Advisory Committee, potassium is considered to be one of the four major shortfall nutrients in the American diet; similar shortfalls are seen in the dietary intakes of Canadians. The average intake of potassium in the United States is just over half of the dietary requirements. A variety of foods are rich in potassium including bananas, papaya, dark leafy greens, avocado, milk, yogurt, various dried beans, fish, nuts, and seeds.

Studies have shown that intake of potassium improves calcium balance. In adult and elderly men and women, supplementation with potassium citrate at 0, 60, or 90 mmol day^{-1} for 6 months resulted in improved calcium balance. Net renal acid excretion and urinary calcium excretion both decreased compared to placebo, while no changes in fractional calcium absorption were observed. Other studies have also shown that supplemental intake of potassium regardless of its form (i.e., potassium bicarbonate or potassium citrate) reduces urinary calcium. The mechanism whereby potassium reduces urinary calcium excretion is unclear, but appears to be independent of net renal acid excretion.

Caffeine

Research indicates that caffeine does not affect calcium balance when dietary levels of calcium are adequate. Studies demonstrating that caffeine from coffee and tea increases urinary calcium excretion may be explained by the acute diuretic action of caffeine that does not persist past 24 h. While caffeine intake decreases calcium absorption, this effect is small and may be

counterbalanced by adding one to two tablespoons of milk to one cup of caffeine-containing coffee.

Health Effects: Bone and Cardiovascular Complications

Composition and Remodeling of Bone

The skeleton is composed by weight of approximately 60% inorganic matter, 30–32% organic matter, and 8–10% water. The inorganic phase consists of primarily hydroxyapatite, a crystalline complex of calcium and phosphate, while the organic phase is composed of primarily type I collagen and various noncollagenous proteins. The mineral complex in the bone serves to strengthen the collagen composite, providing more mechanical resistance to the tissue. It also serves as a source of calcium, phosphate, and magnesium ions for mineral homeostasis.

The bone is a dynamic tissue whereby continuous remodeling serves to maintain structural and metabolic homeostasis in the body. When the coupling action of the bone-forming osteoblasts and the bone-resorbing osteoclasts is balanced, old bone is replaced by an equal amount of new bone; thus, there is minimal net change in bone mass. Unbalanced remodeling occurs when one of the two processes (bone formation or bone resorption) is quantitatively unequal, often resulting in the loss of too much bone. This form of unbalanced bone remodeling is common in postmenopausal women resulting in an increased risk for the development of osteoporosis and fragility fractures.

Osteoporosis

Osteoporosis is a skeletal disease characterized by compromised bone strength, predisposing an individual to an increased risk of fractures. Approximately 10 million Americans and 2 million Canadians are affected by this disease. The most common sites of osteoporosis-related fragility fractures are at the wrist, vertebrae, and hip. The consequences of fragility fractures include chronic pain, decreased quality of life, loss of independence, fear of falling, development of restrictive lung disease, and increased mortality. Along with its significant consequences to morbidity and mortality, osteoporosis has an annual cost of 20 billion dollars to the American and Canadian health-care systems combined, and it is expected that this economic burden will rise due to rapidly aging populations.

Osteoporosis is considered to be a pediatric disease with geriatric consequences because the bone mass (bone mineral density, BMD) that is accrued during growth and development determines bone health later in life. BMD in later life is a function of peak bone mass and the rate of subsequent bone loss during aging. Adequate calcium intake throughout growth and development is necessary to ensure normal mineralization of the bone. Other important factors that determine bone mass include age, weight, physical activity, menopausal status, smoking, alcohol intake, and use of corticosteroid hormones. Assessment of BMD is commonly performed using dual-energy x-ray absorptiometry and provides a measure of the amount of mineral within a selected area of the bone. In humans, BMD is a predictor of fracture risk and is routinely determined to diagnose osteoporosis. However, bone weakness results from a loss in both bone quantity (BMD) and bone quality. Bone quality is determined by a number of factors such as bone microstructure, bone turnover, and material properties. In addition, there are several known risk factors for sustaining a fragility fracture that are independent of BMD. Thus, other fracture assessment tools such as the WHO Fracture Risk Assessment Tool (FRAX) and the Canadian Association of Radiologist and Osteoporosis Canada (CAROC) risk assessment systems have been developed to predict 10-year fracture risk by assessing BMD and clinical risk factors such as body weight, height, smoking status, alcohol intake, history of fracture, and use of glucocorticoids.

Relationship Between Calcium and Bone Health

Despite evidence demonstrating that calcium intake consistently reduces bone turnover by up to 20%, there are surprisingly insufficient data to draw clear conclusions about the relationship between calcium and protection against osteoporosis when examining BMD and fracture risk. This is partly due to an absence of trials that have investigated a dose–response relationship between calcium and bone health. In addition, very few studies have investigated the action of calcium alone on bone health. Rather, the combined effect of calcium and vitamin D is often included in bone trials. Other reasons for insufficient data on the relationship between calcium and markers of bone health include an absence of information on background diets, vitamin D intake, circulating levels of 25-hydroxyvitamin D, which is the functional indicator of vitamin D status, and other characteristics of study subjects such as hormonal status and physical activity levels that affect calcium balance.

Adequate calcium intake is important to achieve normal bone accretion during growth and development as it plays a role in building peak bone mass. During the first year of life, the average accretion rate of calcium is approximately 100 mg day^{-1}. This rate increases in older healthy children to about 140 mg day^{-1}. Between the ages 9 and 18 years, the accretion rate of calcium further increases, particularly in boys. BMD also increases significantly with age until approximately 17.5 years in boys and 15.8 years in girls. Thus, it is logical that AIs of calcium should be met to support normal bone accretion. Studies demonstrate that daily intake of calcium levels that are higher than needed to support normal bone accretion does not confer extra benefits to bone mineral content (BMC) or BMD. In addition, it is unclear whether bone mass gained through dairy intake or calcium supplementation is maintained post-intervention.

During adulthood, achieving adequate calcium intake is a target for supporting calcium balance and the maintenance of bone. However, little information exists on the level of calcium needed to achieve calcium balance or the maintenance of bone mass in the adult population. One study reported higher ultrasound bone mass measurements in physically active premenopausal women with higher calcium intake compared to those with lower calcium intakes, regardless of physical activity levels. Another study reported less trochanteric BMC loss in premenopausal women with high calcium intake compared to those with lower calcium intake. In men, studies have reported

that calcium intake was not related to BMD at the calcaneus, lumbar vertebrae, or femur.

During pregnancy, calcium requirements of the fetus are high particularly during the third trimester when the skeleton is undergoing mineralization. To adapt to fetal calcium requirements, intestinal calcium absorption of the mother increases early in pregnancy to result in a net positive calcium balance. During the third trimester, calcium transfer from the mother to the fetus increases substantially resulting in a maternal calcium balance that is zero or slightly negative by the end of pregnancy. Little evidence exists on the effects of calcium supplementation during pregnancy on maternal BMD. One study demonstrated that calcium supplementation during low calcium intake (600 mg day^{-1}) results in improved bone health in infants.

As mentioned earlier, calcium intake consistently reduces bone turnover by up to 20%, and this is associated with a reduction in bone loss during the postmenopause. While some trials conducted in younger postmenopausal women have not demonstrated a clear benefit to the bone in response to increases in calcium intake, others have demonstrated that calcium intake results in small increases in BMD and is associated with a lower fracture risk. This benefit has also been observed in older postmenopausal women when fracture risk is more prevalent. Given that most studies have provided calcium supplementation in combination with vitamin D, more data on the effects of calcium alone on BMD and fracture risk during the postmenopause and aging are needed. It is generally accepted that calcium may play a role in mitigating bone loss rather than protecting against osteoporotic fractures during aging.

Calcium Intake and Cardiovascular Disease Risk

As mentioned earlier (see section '**Patterns of Consumption**'), calcium intake remains a concern in the United States, Canada, and several other countries. To help achieve daily calcium requirements, calcium supplements are commonly consumed, especially by middle-aged and elderly women. However, recent evidence has suggested that calcium supplement intake, alone or in combination with vitamin D, increases adverse cardiovascular events. Studies and meta-analyses have reported opposing conclusions, highlighting the current lack of consensus for calcium supplementation recommendations for supporting bone health during aging. Inconsistencies in evidence surrounding calcium intake and cardiovascular complications may be explained by the lack of randomized controlled trials specifically designed to investigate the effect of calcium supplements on cardiovascular disease. Some inconsistencies between studies may also be explained in part by reduced power from subgroup analyses and the inclusion of both men and women in some trials. The mechanism of adverse action of calcium on cardiovascular risk is unknown. National and international osteoporosis foundations (e.g., Osteoporosis Canada) recommend reaching daily calcium requirements from all sources (food and supplements). Nevertheless, in light of the recent controversy surrounding calcium supplements and cardiovascular complications, calcium supplement use in the United States has decreased from 22% in 2011 to 17% in 2012.

Calcium: Properties and Determination

Calcium

Calcium is an essential mineral nutrient for both plants and animals. It is a soft alkaline earth metal with a shiny silver surface, which gradually reacts with the atmosphere to form a dull gray-white coating of calcium oxide and calcium nitride. Discovered by Sir Humphry Davy in 1808, calcium is the fifth most abundant element by mass in both the Earth's crust (3.5%) and the human body (1.5%). This article focuses on the basics of calcium chemistry, dietary intake and the influence of food composition, food processing and bioavailability, and methods of calcium analysis in foods and biological samples.

Chemistry of Calcium

The chemical element calcium, symbol Ca, atomic number 20, is a group IIA metal (alkaline earth metal), which does not exist as a pure element in nature. Calcium has melting and boiling points of 840 and 1484 °C, respectively, and readily reacts with oxygen and the halogens, including fluorine, chlorine, bromine, and iodine. The electron configuration of calcium is $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$, and it has two valence electrons and commonly occurs as a divalent cation (Ca^{2+}). Its reactivity results in calcium existing in the form of common mineral compounds including carbonates (e.g., limestone, marble, and chalk), sulfates (e.g., gypsum and alabaster), fluorides (e.g., fluorite), phosphates, and silicates. The name calcium is derived from 'calx,' Latin for lime (calcium oxide), which was used by the Romans in mortar for building in the first century. However, excavations at a site in Eastern Turkey have identified the use of lime as a construction material as long ago as 7000–14 000 BC.

Calcium has an atomic weight of 40.08 and a total of 24 isotopes, of which five are stable, with Ca-40 predominating at over 96% relative abundance (Table 1). In addition, Ca-48 has such a long half-life that it is also generally considered stable. The remainder are radioisotopes, with several being available for use in research, including Ca-41, Ca-45, and Ca-47. For practical reasons, Ca-45 is the most commonly used calcium radionuclide for biological investigations. The least stable radionuclide is Ca-34 with a half-life shorter than 35 ns.

Calcium as an Essential Nutrient

Calcium is an essential nutrient for all living organisms, occurring in both plants and animals in the form of solid mineral salts and also dissolved in solution. These forms allow calcium to facilitate a range of biological roles including key structural and metabolic processes such as muscle contraction, digestion, blood clotting, and cell signaling. Calcium plays key structural roles in bones, teeth, and plant cell walls and membranes. An adult contains approximately 1.2 kg of calcium, 99% of which is found in the skeleton and teeth in the form of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$], an inorganic crystalline structure consisting of calcium and phosphorus. Calcium is involved in the maintenance of the mineral composition of teeth, which undergo constant mineralization and demineralization in response to pH and dietary exposure in the mouth. In man, the structural integrity and permeability of biological membranes are maintained by calcium binding to proteins and phospholipids. In plants, calcium forms salt bridges between pectin molecules in the middle lamella, stabilizing adjacent cell walls. This stabilization is essential for cell walls to retain their structure and hold their contents, which is particularly important in developing fruits. Some plants also accumulate calcium in their tissues, thus increasing rigidity.

Many cellular processes in plants and animals rely on signaling, which involves the movement of the calcium ion, Ca^{2+}, into and out of the cytoplasm. An increase in cytosolic calcium is responsible for triggering a range of biological processes. Consequently, cellular calcium concentrations need to be tightly controlled within a narrow range in order to maintain appropriate functionality.

Overview of Occurrence in Foods

In the majority of industrialized countries, milk and dairy products, including cheese and yogurt, provide the greatest contribution to calcium dietary intake in adults. Approximately 70% of the calcium present in the food supply in the United States is in the form of milk and dairy products, with about 10% in fruits and vegetables, 5% in grain products, and the remainder in other foods. The relative importance of these food sources to an individual's calcium intake depends on the amounts consumed. However, as the main food sources of calcium for most adults consuming omnivorous diets in developed countries are milk and dairy products, this food group typically accounts for the bulk of total calcium intake at around 35–50%. Although the concentration of calcium in cereal products and vegetables is generally much lower than dairy products, the amount of these foods eaten means that foods of plant origin do make a significant contribution to total calcium intakes for most people (20–30% in the United States and the United Kingdom, with approximately 14% from bread due to calcium fortification of white flour).

In Europe, Australasia, and North America, adult dietary intakes of calcium are generally around 800–1000 mg day^{-1} compared with some areas of the developing world, such as rural Gambia, which has calcium intakes in women and children of approximately 300 mg day^{-1}. This difference reflects the lower consumption of milk and milk products in the developing world. Vegans and others who do not consume milk and dairy products may need to take particular care to ensure adequate calcium intake from their diet or may require

Table 1 Stable isotopes and selected radioactive nuclides of calcium

Stable isotopes		*Selected radioactive nuclides*				
Isotope	*Relative abundance (%)*	*Nuclide*	*Decay*	*Half-life*	*Energy (MeV)*	*Intensity (%)*
Ca-40	96.941	Ca-41	Electron capture	1.02×10^5 years	0.42	100
Ca-42	0.641	Ca-45	β^- (no γ emitted)	162.7 days	0.26	100
Ca-43	0.135	Ca-47	β^-	4.536 days	1.98	16
Ca-44	2.086				0.68	84
Ca-46	0.004		γ		1.30	75
Ca-48	0.187					

a supplemental source of calcium, particularly during periods of rapid growth. Lacto-vegetarians, who do not avoid milk and dairy products, generally have little difficulty in attaining adequate calcium intakes.

Other foods that contain considerable amounts of calcium include tinned fish such as sardines or salmon (largely due to the calcium in bones and skin), soymilk substitutes, tofu (especially if it has been processed with calcium), and certain seeds and nuts, but typical eating habits indicate that these do not contribute much to total calcium intake for most people. Leafy green vegetables are also good sources of calcium, but absorption from them is generally low.

Factors Influencing Calcium Bioavailability

Bioavailability is the degree to which a nutrient is absorbed and utilized by the body for normal metabolic functions. In the case of calcium, this generally means the amount that is absorbed and incorporated into bone. There are several physiological and dietary factors that impact calcium bioavailability. Physiological factors include calcium and vitamin D status, age, rate of growth, disease, pregnancy, and lactation. The impact of dietary factors on calcium bioavailability is often difficult to delineate from physiological factors. Bioavailability of calcium is strongly affected by the physical and chemical forms in which it is consumed. The relative solubility of calcium compounds and the degree of ionization caused by gastric acid modulate calcium absorption from the gastrointestinal tract. Calcium is also more bioavailable when consumed with food than on an empty stomach, partly due to the longer transit time through the gastrointestinal tract.

There are a range of foods, nutrients, and other compounds that either enhance or inhibit calcium absorption when consumed simultaneously. Phytate, uronic acid, and oxalate are well-established plant-based inhibitors of calcium uptake, acting through the formation of insoluble complexes in the gut.

Serum vitamin D (as calcitriol, the active form of vitamin D) concentration is positively associated with calcium absorption and accounts for approximately 25% of its variability. Intestinal calcium absorption declines with age; but treatment with 25-hydroxyvitamin D_3 (the precursor of calcitriol) has been demonstrated to enhance absorption in elderly individuals. With the exception of vitamin D, potential enhancers of dietary calcium absorption are generally less well defined than inhibitors and may have only limited influence on the intestinal absorption of calcium ingested with a meal.

Absorption from the gastrointestinal tract is not the only consideration in bioavailability; dietary sodium, fat, and protein can influence the amount of calcium excreted in urine and consequently not available for essential functions in the body.

Fat significantly influences calcium absorption in cases of fat malabsorption, such as steatorrhea. Fatty acids (particularly saturated fatty acids) bind to calcium to form insoluble soap complexes in the intestine resulting in increased loss of calcium in the feces. The effect of protein on calcium absorption is the subject of debate; some research suggests a positive correlation between protein intake and calcium absorption, which in turn leads to an increase in urinary calcium excretion. However, the impact of increased calcium turnover on bone in response to dietary calcium needs to be fully determined. Other dietary components influencing calcium absorption and excretion include caffeine and alcohol. Caffeine has a slight negative impact on calcium absorption, with no significant effect on urinary calcium excretion, while the exact mechanisms underpinning the increased risk of osteoporosis and reduced bone mass in chronic alcohol consumers require further research.

Sources of Calcium Intake

Calcium is unevenly distributed in the human diet. Some foods are rich sources of calcium, while others are relatively poor. As a result of developments in food processing and the introduction of fortification policies and practices, the increasing availability of calcium-fortified foods and dietary supplements containing calcium salts is leading to a wider range of rich dietary sources of calcium.

Foods of Animal Origin

The calcium content of cow's milk is relatively unaffected by the animal's diet, stage of lactation, or climate. Approximately two-thirds of calcium in milk is bound to the milk protein, casein, and to a much lesser extent other proteins, phosphorus, and citrate, with the remainder as unbound calcium. Removal of the fat fraction from milk leads to slight increases in calcium concentration when comparing skimmed, partly skimmed, and whole milk (Table 2). Despite processing, dried milk powder and yogurts retain virtually all their calcium, whereas hard cheeses and butter suffer approximately 20% and 80% losses, respectively. Soft cheeses and cream cheese generally contain less calcium on a wet-weight basis due to their higher

Table 2 Calcium content of selected animal source foods

Food name	*Serving size*	*Weight (g)*	*Calcium (mg)*	*Concentration (mg g^{-1} as is)*
Milk and dairy products				
Milk, whole, 3.3% milk fat	250 ml	258	291	1.13
Milk, partly skimmed, 2% milk fat	250 ml	258	302	1.17
Milk, skim	250 ml	259	324	1.25
Milk, partly skimmed, 2% milk fat with added milk solids	250 ml	260	372	1.43
Milk, condensed, sweetened, canned (Eagle Brand™)	15 ml	19	55	2.89
Milk, evaporated, partly skimmed, canned, undiluted, 2% milk fat	15 ml	16	44	2.75
Yogurt, vanilla or fruit, 1–2% milk fat	175 ml	185	227	1.23
Cheese, cheddar	50 g	50	361	7.22
Cheese, mozzarella, 22.5% milk fat	50 g	50	269	5.38
Cheese, cottage, 1% milk fat	125 ml	119	73	0.61
Meat, fish, and egg				
Egg, poached	1 large	50	27	0.54
Beef, ground, lean, crumbled, pan-fried	75 g	75	11	0.15
Beef, mechanically deboned, raw	90 g	90	436	4.84
Pork chop, center cut, lean, bone in, pan-fried	1 chop	69	16	0.23
Chicken, broiler, breast, meat, fried	75 g	75	12	0.16
Salmon, Chum (keta), baked or broiled	75 g	75	11	0.15
Salmon, Chum (keta), canned, drained with bone (unsalted)	75 g	75	187	2.49
Sardine, Atlantic, canned in oil, drained with bone	1 can	106	405	3.82

Data from Health Canada (2008). Nutrient value of some common foods. Ottawa: Health Products and Food Branch, Health Canada, Government of Canada Publications, except for meat data, which are from the Canadian Nutrient File, Health Canada, version 2010.

water content. The calcium content of cheeses also depends on the process used in preparation and whether the calcium precipitates with the milk solids or remains in the whey. Cheeses precipitated with lactic acid, such as cottage or cream cheese, contain lower calcium levels in the curd, as most of the calcium remains soluble in the acid whey. Rennin coagulation that is used in the production of cheddar or mozzarella yields cheeses with a higher calcium content as the curd is formed before significant acidification takes place.

Meat and fish are not typically rich sources of calcium (Table 2). Mechanically deboned meats can contain much higher levels of calcium due to the abrasion of bone during the deboning process. Tinned salmon provides higher levels of calcium than fresh salmon filet (Table 2), because the bones and skin tend to be consumed along with the flesh. The latter also applies to small fish consumed whole, such as sardines and anchovies. Calcium is also generally higher in crustaceans than in fin fish.

Foods of Plant Origin

Foods of plant origin are generally not particularly rich sources of calcium, and some contain significant levels of inhibitors to calcium absorption such as phytate or oxalate. However, due to the large amounts consumed, plant-based foods generally make a significant contribution to total calcium intake in developed countries. Whole grains and seeds generally provide more calcium than most fruits or vegetables (Table 3). Fortification of refined flours and breakfast cereals can significantly increase the contribution of these foods to total calcium intake. Similarly, the high calcium content of baking powder and the variety of calcium-containing food additives used (e.g., as dough conditioners or yeast nutrients – see the succeeding text) add to the amount of calcium in baked goods.

While spinach appears to contain a reasonable amount of calcium (129 mg per 95 g serving; see Table 3), its high oxalate content renders a large proportion of the calcium insoluble and therefore much less bioavailable. As a result, it has been estimated that over 15 servings of spinach would be required to obtain the same amount of absorbable calcium as one glass of milk (Table 4). Turnip greens contain a similar level of calcium to that found in spinach, but without the oxalate, consequently two servings of turnip greens provide a similar level of absorbable calcium to one glass of milk (Table 4). However, these types of calcium absorption measurements are often determined under laboratory conditions by feeding only the single food, rather than a whole diet. Calcium bioavailability from a given food source can be substantially modified by other foods eaten at the same time. Calcium absorption from milk has been shown to decrease from 33% to 27% when consumed with spinach, whereas calcium absorption from spinach increased from 3% when fed alone to 11% when consumed with milk. In a Western mixed diet, the overall calcium absorption by adults typically averages about 25–30%.

Processing Effects on Food Calcium

There are numerous food additive uses of calcium salts that may add appreciable amounts of calcium to some foods. The Food Chemicals Codex, ninth edition (2014), lists over 30 calcium compounds used as food additives or processing aids. Some of the common functions of calcium-containing food additives (and examples of the calcium compounds used) include dough conditioners such as calcium carbonate, calcium iodate, calcium lactate, calcium oxide, calcium phosphate, and calcium

Table 3 Calcium content of selected plant-based foods

Food name	*Serving size*	*Weight (g)*	*Calcium (mg)*	*Concentration (mg g^{-1} as is)*
Vegetables and fruit				
Beans, snap (green, yellow, Italian), fresh or frozen, boiled, drained	125 ml	71	33	0.46

Pinto beans	86	44.7	26.7	8.1
Kale	85	61	49.3	3.2
Rhubarb	120	174	8.54	9.5
Sweet potatoes	164	44	22.2	9.8

Selected data from Weaver, C. M. and Plawecki, K. L. (1994). Dietary calcium: Adequacy of a vegetarian diet. *American Journal of Clinical Nutrition* 59 (suppl.), 1238S–1241S, except for pinto beans, kale, rhubarb and sweet potatoes, which are taken from Weaver, C. M., Proulx, W. R. and Heaney, R. (1999). Choices for achieving adequate dietary calcium with a vegetarian diet. *American Journal of Clinical Nutrition* 70 (suppl.): 543S–548S.

sulfate; pH adjusters such as calcium hydroxide and calcium phosphate; antioxidants such as calcium ascorbate; preservatives such as calcium propionate, calcium disodium EDTA, and calcium sorbate; anticaking agents such as calcium stearate, calcium phosphate, and calcium silicate; and thickeners such as calcium gluconate and calcium alginate. The percentage composition of calcium in these compounds ranges considerably; for example, calcium gluconate is 9% calcium, calcium carbonate is 40% calcium, and calcium oxide is 71% calcium by weight. Solubility also differs considerably between compounds, with some such as calcium carbonate being relatively insoluble at neutral pH, whereas others such as calcium acetate or calcium chloride are highly soluble. Tofu set with calcium sulfate contains considerably more calcium than tofu set with magnesium chloride (Table 3). Firm tofu contains a higher concentration of calcium than regular tofu due to the lower water content (and consequently higher solids). Fermentation (including leavening of bread) or germination of selected plant foodstuffs can increase the availability of calcium due to breakdown of complexing compounds such as phytic acid. The calcium content of meat can be increased by processing or cooking in acidic solutions due to the dissolution of calcium from bone. For example, pork spare

ribs or chicken cooked with vinegar contain more calcium than the uncooked flesh.

Tap water typically contains calcium and many other elements and may make some contribution to total calcium intake particularly in hard water areas. In some parts of Europe, it is estimated that tap water contributes up to 4% of daily calcium intake. Water hardness is measured as milligrams of calcium carbonate equivalents per liter, and hard water may be over 300 mg of calcium carbonate per liter. The World Health Organization recommends water containing 80–100 mg calcium carbonate per liter as ideal. Calcium carbonate is 40% elemental calcium by weight; therefore, a 250 ml glass of water may provide 30 mg of elemental calcium in some areas. The calcium content of bottled waters varies widely from less than 10 mg l^{-1} to around 200 mg l^{-1} and up to 600 mg l^{-1} with calcium fortification. The hardness of water added during processing may also influence the calcium content of foods to some extent. However, losses through soaking and/or boiling may amount to 5–25% of the calcium content of a variety of vegetables that are commonly prepared in this way.

Foods may have nutrients added for a variety of reasons including restoration of processing losses or to provide similar nutrient levels to dairy products where they are used as a substitute, such as soy 'milk,' 'yogurt,' and other plant-based beverages, which may be fortified with calcium. Foods used for special dietary purposes such as meal replacements, formulated liquid diets, and slimming foods are generally fortified with calcium to prevent nutritional deficiency. Fortification, which in this context refers to the addition of calcium with the intent of raising the calcium content of the food for the consumer, is often undertaken in response to legislation. However, regulations and practices concerning food fortification may vary considerably between countries.

Supplements

Nutritional supplements and antacid medications can make a significant contribution to calcium intakes for some individuals. Over 40% of the US population (including almost 70% of older women) uses dietary supplements containing calcium. Calcium carbonate is found in many over-the-counter antacid preparations, which can provide up to 400 mg of calcium per day. However, calcium citrate, which is absorbed similarly when taken with or without food, is beneficial for people with achlorhydria, inflammatory bowel disease, or absorption disorders. Other forms of calcium in supplements or fortified foods include gluconate, lactate, and phosphate. Multivitamin and multimineral supplements may also contain calcium, though usually in smaller amounts. Natural source supplements include oyster shell and dolomite, although concerns have been raised concerning the potential for lead contamination in both forms, along with aluminum, arsenic, mercury, and nickel in the latter.

Analysis of Calcium in Foods and Biological Samples

The assessment of nutritional calcium status is difficult, and there are no reliable measures of status. Circulating calcium concentrations are tightly regulated via the endocrine system, varying little in response to widely differing dietary calcium intakes (see Calcium: Physiology). Consequently, deviations of calcium concentration from this narrow range are medically significant, and in this setting, the measurement of total plasma or serum calcium or specific measurement of the ionized calcium fraction is important. About half of the calcium in serum is ionized, not bound to proteins or low-molecular-weight ligands, and considered to be the active form; therefore, it is a better measure of functional levels. However, the marker is influenced by other factors such as pH and age.

Urinary calcium has been used as a marker of calcium status, but the influence of other dietary confounders (such as protein, sodium, and caffeine) on urinary calcium excretion makes it unsuitable for many applications. Urinary levels are relatively well regulated and therefore generally not sensitive to small changes in status. Total calcium in plasma or urine can be measured by atomic absorption spectrophotometry, either directly on the diluted sample or following sample mineralization ('ashing' – see the succeeding text) or by colorimetric assay (e.g., using arsenazo III or orthocresolphthalein complexone) on a clinical autoanalyzer. Ionized calcium in plasma can be assessed using an appropriate ion-sensitive electrode. Assessment of intracellular calcium levels in the research laboratory can be undertaken using fluorescent probes such as FURA 2 or QUIN.

Neutron activation measurements are considered the gold standard in assessing total body calcium content. However, its application for research is limited, and it tends to be used as a means of calibrating other methods. The method involves exposure to radiation, thus limiting its uses. It measures the proportion of Ca-49 in the body using gamma-ray counts. Calcium nutritional status is more often assessed indirectly through balance studies or by measurement of bone mineral concentration or bone mineral density, reflecting the major structural role played by this mineral nutrient. There are a variety of techniques that can be employed to measure the mineral content of bone. One of the most commonly used is dual-energy x-ray absorptiometry (DXA), which uses x-ray technology to measure either the whole body or specific bone regions. This technique can be used in all population groups (except pregnant women) but may be less accurate as a measure of calcium status in the elderly when bone degeneration occurs naturally. Measurements, however, can be influenced by fat mass and distribution and even by the methodology and machine used. Computerized tomography (CT) offers a three-dimensional assessment of bone content, but the equipment is less portable and the radiation dose significantly greater than for the DXA method. A third method of assessment is quantitative ultrasound, which is normally limited to measurement of the peripheral skeleton. Although this technique offers portable equipment with no radiation exposure, the precision of the method is questionable as results do not correlate well with DXA measurements.

Other putative measures of calcium status such as bone remodeling markers and functional enzyme measures are not specific to the mineral and therefore have limited use. A number of bone remodeling markers (such as breakdown products and enzymes) can be measured to assess calcium status in either serum, including osteocalcin and alkaline phosphatase, or

urine such as hydroxyproline, pyridinoline, deoxypyridinoline, N-telopeptide, and C-telopeptide. However, concentrations of each of these proposed markers can be influenced by a number of other factors including life stage, particularly menopause.

Sample Preparation

Most foods and biological tissue samples can be prepared for the analysis of total calcium content using either dry ashing (in a muffle furnace) or wet ashing (acid digestion) techniques or a combination of the two. Dry ashing typically involves combustion at elevated temperature (e.g., 500–550 °C) until organic matter is fully destroyed, followed by dissolution of the ash in a suitable acid for subsequent analysis. Wet ashing techniques typically involve the destruction of organic matter by heating in concentrated nitric acid until a pale straw color is attained and may feature additional oxidation steps with perchloric acid or hydrogen peroxide to clarify the sample solution. In wet ashing procedures, particularly for samples with a high calcium content such as bone meal, sulfuric acid is generally to be avoided due to the ready precipitation of calcium from solution by sulfate, forming plaster of Paris (calcium sulfate hemihydrate) or gypsum (calcium sulfate dihydrate).

Determination of Calcium Content of Foods and Tissues

Determination of the calcium content of foods and tissues is routinely undertaken using atomic absorption spectrophotometry, although a number of alternative techniques exist including titrimetric methods using EDTA or $KMnO_4$, neutron activation analysis, or inductively coupled plasma emission spectrometry. Details of sample preparation and analytic procedures for a variety of food sample types are published by the Association of Official Analytical Chemists.

Atomic Absorption Spectrophotometry

For atomic absorption spectrometric analysis of calcium, 0.1–1.0% (w/v) lanthanum is included in the analytic working solution as a matrix modifier to reduce anion interferences due to phosphate or sulfate, which otherwise can form refractory complexes and depress the absorption of light by atomic calcium.

Absorbance is measured at the 422.7 nm calcium spectral line, following atomization in a reducing air–acetylene flame, and compared with certified analytic standard calibration solutions. A reducing flame gives a higher sensitivity, though an oxidizing flame may give a higher precision where this is critical. Typical analytic working ranges are obtained up to 5 mg l^{-1} in the analytic working solution when using a standard nebulizer assembly and may be approximately doubled with the use of a high-sensitivity nebulizer (see Spectroscopy: Atomic Emission and Absorption).

$KMnO_4$ Titrimetric Method for Calcium in Wheat Flour (Method from the Association of Official Analytical Chemists)

After dry ashing and dilution of the ash to a suitable volume with demineralized water, bromocresol green indicator is added along with enough 20% sodium acetate solution to change the pH to 4.8–5.0 (blue). The sample solution is covered and heated to boiling. The calcium is precipitated by slow addition (1 drop every 3–5 s) of 3% oxalic acid solution (w/v) until pH is 4.4–4.6, as indicated by a distinct green shade. The solution is then boiled for 1–2 min and allowed to settle overnight. The supernate is filtered through quantitative paper, Gooch, or fine fritted glass filter, and the beaker and precipitate are washed with small portions of ammonium hydroxide (1 + 50). A mixture of 125 ml of water and 5 ml of sulfuric acid is added to the precipitate with heating to 80–90 °C. The solution is finally titrated at 70–90 °C with 0.01 M $KMnO_4$ to a slight pink end point, 1 ml of permanganate solution equating to 1 mg of calcium.

Campylobacter: Health Effects and Toxicity

AE Zautner and WO Masanta, Universitätsmedizin Göttingen, Göttingen, Germany

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The name *Campylobacter* was coined from two Greek words: καμπύλος (*kampylos)* meaning curved and βακτηρῖα (*bakteria*) meaning rod. The genus *Campylobacter* was initiated in 1963 by Sebald and Véron upon observing a *Vibrio*-like bacterial strain that had been isolated from abortion cases in ewes and cattle could not ferment sugar and had a different G+C content to that of *Vibrio cholerae*. Chronologically, McFadyean and Stockman who had concluded that a *Vibrio*-like bacterium was responsible for abortions in Devon longwoolled ewes in the United Kingdom reported the first case in 1906. This was closely followed by a similar report in 1918 by Smith and Taylor who had observed that a *Vibrio*-like bacterium was responsible for abortions in cattle in the United States of America. Due to the similarity between these two bacteria, Smith and Taylor had classified them into the genus *Vibrio* and collectively named *Vibrio fetus*. This bacterium was renamed as *Campylobacter fetus*, and to avoid such errors in taxonomy and nomenclature of *Vibrio*-like bacteria that were being isolated, Sebald and Véron initiated and defined the genus *Campylobacter* as comprising Gram-negative, slender, and curved bacteria, which are (a) motile by means of polar flagella (Figure 1), (b) microaerophilic with a strictly respiratory metabolism, and (c) not producing acid in carbohydrate-containing media and which have a DNA G+C content of 29–36%. This contrasted the genus *Vibrio*, which had been previously defined as comprising bacteria that ferment glucose and have a DNA G+C content between 40% and 53%. As a result of improved taxonomy methods, particularly genotypic methods, the genus *Campylobacter* presently has 25 species and 9 subspecies (see Table 1).

Unlike in sheep and cattle, the isolation of *Campylobacter* spp. from human feces before 1968 was not possible because an isolation technique had not been developed. All the *Vibrio*-like bacteria that had been isolated in humans before originated from blood samples. The first undisputable *Campylobacter* human infection was reported in 1947 by Vinzent and coworkers who identified *V. fetus* (presently *C. fetus*) to have caused abortion in two women who had been admitted to the hospital for four weeks due to fever. In 1957, Elizabeth King isolated two *Vibrio*-like bacteria from the blood of patients with diarrhea but failed to isolate any bacteria from the feces of the patients. In spite of failure to isolate bacteria from the feces of the patients, King concluded that *Campylobacter* caused the enteric infections. Dekeyser and Butzler confirmed King's conclusion in 1968. They isolated *V. jejuni* (presently *C. jejuni*) from feces and blood of a 20-year-old female who was admitted in July 1968 in St. Peter University Hospital in Brussels with severe diarrhea and fever using a filtration technique. Since then, better techniques for isolating and identifying *Campylobacter* from feces have been developed. These techniques have revealed that *C. jejuni* and *C. coli* are one major cause of human gastroenteritis. Interestingly, epidemiologic studies have constantly shown that *C. jejuni* is the leading cause of bacterial gastroenteritis worldwide and *C. coli* is responsible for a significant lower percentage of cases. Therefore, in this chapter we discuss (i) general characteristics of *C. jejuni*, (ii) epidemiology of *C. jejuni* infections, (iii) *C. jejuni* enteritis and associated postinfectious manifestations, (iv) pathogenesis of *C. jejuni*, and (v) treatment of campylobacteriosis.

Characteristics of *C. jejuni*

C. jejuni are Gram-negative, nonspore-forming, microaerophilic (5% oxygen), spiral-shaped rods measuring 1.5–3.5 μm in length and 0.2–0.4 μm in width. They possess a single circular chromosome of 1.64–1.7 million base pairs (30.6% G+C), which is predicted to encode about 1650 proteins including 52 ribosomal proteins. The bacterial cells have a unique corkscrew motility propelled by flagella located at the poles of the bacterial cell. The growth temperature ranges from 30 to 45 °C with an optimum of 42 °C. *C. jejuni* does not multiply at temperatures below 30 °C but remains viable for many months at these temperatures. Some studies have shown that *C. jejuni* cells remain viable at 4 °C for up to 7 months. They grow in a pH range of 5.0–9.0 with an optimum of 6.5–7.5. *C. jejuni* is sensitive to desiccation and heat (it can be easily destroyed above 48 °C) and is unable to grow in NaCl ≥ 2%. In contrast to many other bacteria, amino and carbon acids are the major carbon sources because they do not utilize glucose or other hexose sugars as carbon source. But particular strains are able to metabolize L-fucose. *C. jejuni* survives and thrives in a wide range of hosts.

Epidemiology

C. jejuni is the most prevalent cause of human gastroenteritis in both developing and developed countries. In developing countries, it mainly affects children below 5 years, while in developed countries it mainly infects adults. In addition, in developing countries, incidences of campylobacteriosis are not season-specific but in developed countries most cases are reported during summer.

In spite of these differences, *C. jejuni* are commensal organisms in the intestines of wild birds and farm and domestic animals including goats, sheep, cattle, swine, poultry, dogs, and cats. Also, they are found in untreated water and water bodies such as lakes, dams, and rivers. Consequently, contact with farm and domesticated animals, raw milk, milk products, untreated water, undercooked poultry, contaminated meat products, barbecue meat, minced meat, both processed and unprocessed sea foods, international travel, and restaurant eating are major risk factors. Epidemiological and

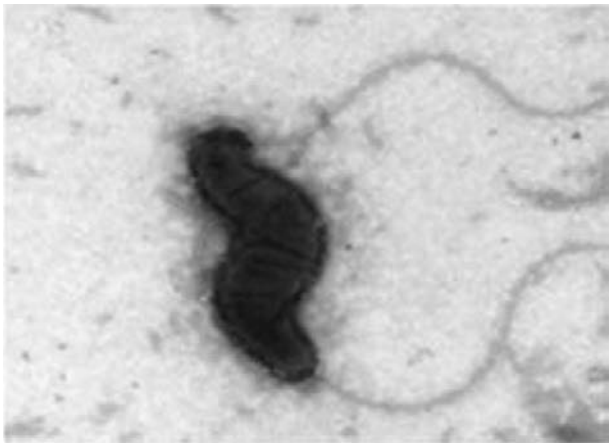

Figure 1 Electron micrograph of *C. jejuni* strain B2. The bacterial cell has at both poles a flagellum, which ensures its cellular motility. Thanks to Michael Hoppert, Department of General Microbiology, University of Göttingen for the picture.

microbiological studies have shown that poultry remains to be the major source of human infection.

According to the European Food Safety Authority (EFSA), 214 000 cases of infection were reported in the year 2012 in the European Union. It is assumed that the actual number of cases of human campylobacteriosis is at approximately nine million per year in the EU. The costs incurred by campylobacteriosis for the public health systems and due to loss of productivity in the EU are estimated by the EFSA to approximately EUR 2.4 billion per year. The disease burden of *Campylobacter* enteritis and its postinfectious sequelae is approximately 0.35 million disability-adjusted life years (DALYs) per year. Contaminated broiler meat is assumed to account for 20–30% of the cases, while 50–80% may be attributed to the chicken reservoir as a whole (laying hens in addition to broilers).

The Foodborne Diseases Active Surveillance Network, a collaboration among the Centers for Disease Control and Prevention (CDC) and 10 US state health departments, estimates the incidence per 100 000 population in 2012 to 14.30. Among these *Campylobacter* isolates with species information, 90% were *C. jejuni*, 8% were *C. coli*, and the remaining 2% belonged to other *Campylobacter species*.

C. jejuni Enteritis and Associated Post-infectious Manifestations

C. jejuni affects human health by causing an infection that is known as *Campylobacter* enteritis or human campylobacteriosis. This infection is a foodborne disease that is characterized by the following clinical symptoms: fever, abdominal pain, watery or sometimes bloody diarrhea, headache, dizziness, nausea, and vomiting. These symptoms usually start 2–4 days after ingestion of *C. jejuni* and may clear after 5–7 days. The *C. jejuni* minimal infectious dose is above 500 viable bacteria. Although this disease is self-limiting, post-infectious manifestations, namely, Guillain–Barré syndrome (GBS), reactive arthritis (ReA), and inflammatory bowel disease (IBD), can arise after recovery. Below is a brief description of each post-campylobacteriosis manifestation:

(a) *GBS*: GBS is an autoimmune disorder in which the body's immune system 'mistakenly' attacks human GM gangliosides – lipids found in the central nervous system – leading to acute neuromuscular paralysis and consecutive muscle weakness. There are four types of GBS, namely, Miller Fisher syndrome (MFS), acute motor axonal neuropathy (AMAN), acute inflammatory demyelinating polyradiculoneuropathy (AIDP), and acute motor and sensory axonal neuropathy (AMSAN). *C. jejuni* is the leading cause of GBS and has been linked to triggering MFS, AMAN, and AMSAN, but not AIDP. It triggers these autoimmune disorders because its cell wall surface contains lipooligosaccharides (LOSs) that resemble ganglioside structures on the surface of the Schwann cells and the coat of the nerve axons. As a consequence of this molecular mimicry, the immune system releases autoantibodies leading to neuritis and axonal degeneration. GBS usually develops 3 weeks after recovery from *Campylobacter* enteritis and is characterized by slow recovery and severe residual disability.

(b) *ReA*: ReA is a spondyloarthropathic syndrome characterized by inflammation of the joints and tendons occurring after gastrointestinal infections with *C. jejuni* as well as *Shigella dysenteriae*, *Salmonella enterica*, *Yersinia enterocolitica*, and *Yersinia pseudotuberculosis* or genitourinary infections especially with *Chlamydia trachomatis*. The mechanism of ReA is poorly understood. However, interleukin IL-1, IL-6, and TNF-α have been implicated in *C. jejuni*-associated ReA. In some cases, ReA occurs together with an inflammation of the eye's conjunctiva or uvea, as well as of the urethra (and rarely additionally of the uterine cervix in women). This inflammatory triad is called Reiter's syndrome.

(c) *IBD*: IBD is established when a gastrointestinal tract immunologic disorder leads to chronic recurrent inflammation of the colon and small intestine. Gut host cells and gut commensal microflora continuously communicate creating a sustained normal gut homeostasis. The diversity and load of the human normal gut microbiota are influenced by the individual's genetics and diet. It mostly comprises *Bacteroides* spp. and *Prevotella* spp. A disruption of the normal gut homeostasis by factors including smoking, diet, drugs, geography, social stress, and psychological elements leads to changes in the diversity of the gut microflora. This in turn promotes intestinal epithelial invasion by *C. jejuni* and *S. enterica* and gut commensals, which are recognized by nucleotide-binding oligomerization domain (NOD) proteins and Toll-like receptors. Sensing of these receptors stimulates the mucosa-associated immune system leading to intestinal inflammation.

(d) *Other possible C. jejuni-associated diseases*: Besides the above-mentioned clinical manifestations, campylobacteriosis was also associated with the postinfectious irritable bowel syndrome, celiac disease, and potentially with the so-called immunoproliferative small intestinal disease.

Pathogenesis of *C. jejuni*

The clinical features of campylobacteriosis are a result of the interaction between *C. jejuni* bacterial cells and the enterocytes of the host. This section looks at the *Campylobacter* virulence-associated factors and counteracting enterocytal factors: *C. jejuni* interaction with both the host microbiome and the innate immune system.

Campylobacter Virulence-Associated Factors

The environment in the lower intestinal tract is hostile for colonization with *C. jejuni*. In the process of adjusting its metabolic systems in response to this unfavorable environment, *C. jejuni* ends up secreting proteins, which lead to the disruption of the intestinal epithelium. This epithelial irritation results in clinical symptoms such as diarrhea. Also, certain *C. jejuni* surface structures interact with enterocytes contributing to their disruption. These secreted proteins and surface structures are collectively termed *Campylobacter* virulence-associated factors. They include the following:

(a) *Flagella, motility, and chemotaxis*: Motility helps bacteria to effectively colonize their environment. *C. jejuni*'s flagella and 11 different types of chemoreceptors allow it to migrate within the mucosa in search for a suitable environment. Interestingly, *C. jejuni* migrates to certain areas of the mucosa that have energy sources, like carboxylic acids, amino acids, and L-fucose. In addition to motility, the flagellin A (*flaA*) and flagellin B (*flaB*) subunits undergo phase variation, hence playing a role in evasion of the host immune response.

(b) *Toxin*: *C. jejuni* produces a toxin known as cytolethal distending toxin (CDT). This toxin is made up of three subunits: CdtA, CdtB, and CdtC. The CdtB subunit has a DNase 1-like activity; hence, it randomly cuts DNA of enterocytes to release 5′-phosphorylated di-, tri-, and oligonucleotide fragments leading to enterocyte cell cycle arrest, disrupting cell protecting structures such as the cell wall and eventually death of enterocytes. The subunits CdtA and CdtC are binding proteins for delivering CdtB into the cytoplasm of enterocytes. *C. jejuni* CDT is essential for invasion and mucosal inflammation.

(c) *Adhesion factors*: Attachment of *C. jejuni* to the epithelial cell surface is an important step in invasion of the mucosa and in some situations for evasion of the immune response. Unlike similar Gram-negative enteric pathogens

such as *E. coli* and *S. enterica*, adherence of *C. jejuni* to enterocytes is not mediated by pili or fimbriae. It is mediated by structures that are found on the cell surface of *C. jejuni*. These structures include the following: (i) CadF binds to fibronectin bound to the surface of enterocytes and is required for invasion of the epithelium. (ii) The fibronectin domain-containing lipoprotein FlpA (Cj1279c) also binds to fibronectin. (iii) The surface-exposed lipoprotein JlpA binds to heat shock protein 90 (Hsp90). (iv) Further examinations have shown that lipoprotein Cj0091; periplasmic adhesion protein Cj0268c; fibronectin/fibrinogen-binding protein Cj1349; the autotransporter proteins CapA and CapB; flagellin A (FlaA); hemolysin TlyA/Cj0588; the major antigenic peptides PEB1, PEB3, and PEB4; and p95 adhesin play a role in *C. jejuni* adherence. Their binding sites on enterocytes and the outcome of their binding to enterocytes are under investigation.

(d) *Invasion factors*: The process of *C. jejuni* internalization into enterocytes and associated factors has been a focus of research over the last 20 years. To date, it has been established that (i) internalization of *C. jejuni* into enterocytes is an energy-dependent process and (ii) the bile salt, deoxycholate, present in the lower intestinal tract stimulates *C. jejuni* to synthesize and secrete a set of proteins termed as *Campylobacter* invasion antigens (Cia) which play a role in internalization. *C. jejuni* synthesizes and excretes at least eight Cia proteins, but presently, only four, namely, CiaB, CiaC, CiaD, and CiaI, have been functionally characterized. In addition, some other *C. jejuni* proteins and host cell factors like actin have been shown to play a role in *C. jejuni* internalization.

(e) *Survival strategies within host cells*: Upon internalization, *C. jejuni* survives and multiplies within enterocytes in membrane-bound compartments that are commonly referred to as *Campylobacter*-containing vacuoles (CCV). Poor nutrition, low pH, and antibacterial molecules including superoxide, hydrogen peroxide, halogenated oxygen molecules, and lysosomal enzymes characterize the CCV. Therefore, *C. jejuni* must have strategies to survive and multiply in this hostile microenvironment. Currently, three survival strategies have been identified. Firstly, *C. jejuni* synthesizes Cia proteins, which enable it to survive within enterocytes. For example, CiaI deviates CCV from the canonical endocytic pathway, thus avoiding union of CCV with lysosomes. Secondly, within enterocytes, *C. jejuni* undergoes a significant metabolic downshift leading to the downregulation of several metabolic pathways. Thus, amino acid biosynthesis and biosynthesis pathways associated with prosthetic groups, fatty acids, lipids, pentose phosphate, purine, and pyrimidine are downregulated, as well as catabolic pathways associated with degradation and utilization of amino acids and C1 compounds and pathways involved in the transport of nutrients, metal ions, and amino acids. Thirdly, within eukaryotic cells, *C. jejuni* changes its mode of respiration from a mode that uses many terminal electron acceptors including oxygen, nitrate, fumarate, nitrite, trimethylamine *N*-oxide (TMAO), and dimethylsulfoxide (DMSO) to a mode that uses only the readily available fumarate as the terminal electron acceptor (fumarate respiration). However, its survival strategy against toxic molecules remains unclear because unlike other intracellular pathogens such as *Salmonella typhimurium*, catalase does not make a contribution to its survival within epithelial cells.

(f) *Glycolipids*: Glycolipids are lipids with covalently attached carbohydrates whose function is to provide energy and serve as markers for cellular recognition. *C. jejuni* has two kinds of glycoproteins or lipid-bound polysaccharides: lipooligosaccharides (LOSs) and capsular polysaccharides. LOSs form a major part of the *C. jejuni* outer membrane. They contain a terminal structure similar to the human gangliosides GM1a and GM2, and in response to the microenvironment in the enterocytes, LOSs undergo phase variation with the terminal β-1,3-linked galactose residue (Gla) being switched on or off creating diverse strains in a population. LOSs play the following roles in pathogenicity: (i) LOS phase variation promotes *C. jejuni's* ability to adapt to the enterocyte's hostile environment, (ii) LOSs mediate adherence and invasion, (iii) structural similarity to human gangliosides GM1a and GM2 and phase variation help in evasion of host immune response, and, (iv) as explained in the section on *C. jejuni* enteritis and postinfectious manifestations, LOS's similarity to human gangliosides GM1a and GM2 plays a role in the pathogenesis of GBS.

The polysaccharide capsule is an external structure of *C. jejuni*. Like LOSs, it undergoes phase variation, hence playing a role in adherence, invasion, and evasion of the host immune response. Also, it is important for the survival of *C. jejuni* outside its natural host.

(g) *Glycoproteins*: Glycoproteins are proteins with carbohydrate residues that are covalently attached to the hydroxyl (—OH) group of the R group of serine or threonine or the amino group ($—NH_2$) in the R group of asparagines in a process called glycosylation. The former is known as *O*-linked while the latter is known as *N*-linked. Proteins may undergo glycosylation during or after translation. *C. jejuni* has both glycosylation systems. The *O*-linked system is diverse and adds pseudaminic acid and related sugars to the immunodominant flagellin. As a result of its association with the flagella, it is essential for adaptation to changing host environment and evasion of host immune response. The *N*-linked system is conserved and adds the bacillosamine-containing heptasaccharide to over 30 proteins. It plays a role in adherence, invasion, and enhancement of the stability of virulence-associated proteins.

Host Defense

The human gastrointestinal tract poses two defenses against *Campylobacter* invasion. These are the following:

(a) *Microbiota barrier*: The human gastrointestinal tract harbors a diverse group of genetically different commensal microbial species. This group of microorganisms is collectively referred to as microbiota. The dominant species in microbiota of a healthy individual are from the following genera: *Lactobacillus*, *Veillonella*, *Bacteroides*, *Peptococcus*, *Escherichia*, *Peptostreptococcus*, *Bifidobacterium*, *Eubacterium*,

Fusobacterium, and *Clostridium*. However, these species vary from one healthy individual to another due to age, genetics, diet, and environment. These microorganisms live in the lumen, the outer mucus layer, within intestinal crypts and on the surface of the mucosal epithelial cells. Microbiota benefit the host in the following ways: breaking down complex nonabsorbable compounds into simple absorbable molecules, maturation of the immune system, and maturation of the intestinal mucosa. In addition, the microbiota plays an important role of defending the host against invasion by all invading pathogens including *C. jejuni* using the following strategies: first, competing for niches and nutrients and, second, secreting bactericidal metabolic by-products including reactive oxygen species, short-chain fatty acids, and bacteriocins. This phenomenon is known as colonization resistance or microbiota barrier.

(b) *Immune barrier*: The human gastrointestinal tract is protected with both the adaptive and innate immune systems, which complement each other. The adaptive immune system is triggered when the presence of *C. jejuni* stimulates the synthesis of interleukin 8 (IL-8). Consequently, IL-8 activates the maturation of macrophages, T-cells, and B-cells, which clear the invading *C. jejuni*. The innate immune responses are initiated when *C. jejuni*'s cell wall structures are detected by nucleotide-binding oligomerization domain-containing protein 1 (NOD1) or Toll-like receptors (TLRs). The interaction of *C. jejuni* cell wall structures and NOD/TLR activates nuclear factor kappa B (NF-κB), which stimulates the production of various cytokines that mediate maturation of dendritic cells (DCs) into antigen-presenting cells (APCs). The APCs capture *C. jejuni* and present them to the mature T-cells for elimination.

Current Model of Disease Pathogenesis

The process of campylobacteriosis establishment starts when *C. jejuni* gets an opportunity to adhere onto enterocytes upon the disruption of the microbiota barrier by diet or chemicals such as antibiotics. For instance, studies that have been carried out in humanized gnotobiotic mice to determine which commensal microorganisms promote *C. jejuni* invasion have shown that eating a typical Western diet such as pizza, cheese, French fries, and burgers elevates the dominance of *Escherichia coli*, *Clostridium innocuum*, *Eubacterium dolichum*, *Catenibacterium mitsuokai*, and *Enterococcus* spp. and reduces the levels of *Bacteroides* spp. and *Prevotella* spp. leading to campylobacteriosis. Once *C. jejuni* adheres to enterocytes, the flagellar type-III-homologue secretion system releases Cia proteins that facilitate *C. jejuni* internalization through M cells. The internalization process is unique because it shares the characteristics of both trigger and zipper mechanisms. Once internalized, *C. jejuni* survives and multiplies in vacuoles avoiding clearance by lysosomes. In response to the vacuolar environment, *C. jejuni* synthesizes several proteins that damage the host cells. During internalization, *C. jejuni* releases CDT, which damages the DNA of the host cell leading to cell death and activates the adaptive immune response. At the same time, NOD and TLR recognize *C. jejuni* and activate the innate immune response. The activities of both the adaptive and innate immune responses lead to local inflammation. While the activities of Cia damage tight junctions leading to diarrhea.

Treatment

Usually, campylobacteriosis is a self-limiting disease that requires no interventional treatment. In most cases, campylobacteriosis patients are treated with fluid and electrolyte substitution (especially potassium). However, in severe cases especially immunosuppression or HIV infection, patients should be treated with antibiotics immediately if laboratory results indicate a *C. jejuni* or *C. coli* infection. *C. jejuni* is usually sensitive to macrolides, tetracyclines, aminoglycosides, carbapenems, and chloramphenicol but increasingly resistant to cotrimoxazole and fluoroquinolones. In spite of a wide range of antibiotics available for the treatment of campylobacteriosis, the macrolide erythromycin remains the antibiotic of choice.

Campylobacter: Properties and Occurrence

SLW On and AJ Cornelius, Institute of Environmental Science and Research (ESR), Christchurch, New Zealand

Introduction

The genus *Campylobacter* was established in 1963 and comprised species that had been referred to for some time as 'anaerobic *Vibrio* species.' At this time, the main interest in campylobacters was in their role as causes of reproductive diseases in cattle and sheep. Interest in the group greatly intensified as a result of fundamental studies published by Butzler and colleagues in 1973 and Skirrow in 1977 demonstrating their involvement with diarrhea in humans. At the present time, it is widely recognized that *Campylobacter* is a taxonomically and ecologically diverse genus, with taxa found in mammalian, avian, molluscan, and reptilian hosts. Species are well established as frequent causes of gastrointestinal disease in humans, abortion, and infertility in animals and have been associated with periodontal disease too. Some are regarded as commensal organisms. This article outlines their taxonomy, distribution, associations, and core phenotypic characteristics.

Campylobacter: A Brief Taxonomic Overview

Detailed taxonomic studies of microorganisms were significantly hampered prior to the use of DNA-based methods, and the use of the G+C ratio was crucial in the initial description of *Campylobacter* in 1963 that included *Campylobacter fetus* and '*C. bubulus*.' A subsequent and more thorough study in 1973 considered additional misclassified 'anaerobic *Vibrio*' species, thereby adding *C. jejuni*, *C. coli*, and *C. sputorum*. In contemporaneous developments, seminal studies in the 1970s by Butzler and colleagues and Skirrow clearly demonstrated the relevance of *C. jejuni* as an important cause of diarrhea in humans. With *C. fetus* long established (since 1919) as an animal pathogen involved with spontaneous abortion in cattle and sheep (predominantly *C. fetus* subsp. *fetus*) and infectious infertility (*C. fetus* subsp. *venerealis*), interest in the prevalence, distribution, and significance of these organisms increased markedly. As a consequence, many new taxa were discovered and described in association with enteric, septic, gastric, reproductive, and oral diseases of humans and animals and even in the environment ('*C. nitrofigilis*,' since transferred to the genus *Arcobacter*). There are presently (November 2014) 26 species that are validly described in accordance with the Bacteriological code and one ('*C. troglodytis*') published but awaiting validation through publication in the *International Journal of Systematic and Evolutionary Microbiology*.

It is important to recognize that advances in taxonomic methods, notably those that have been applied to establish genetic and phylogenetic relationships, have had a major impact on the taxonomic structure of *Campylobacter*. Arguably, that with the greatest influence to date has been the widespread application of 16S rRNA gene sequence analysis to reveal broad evolutionary patterns. As a consequence, several species first described as *Campylobacter* species were reassigned to related, but distinct genera including *Helicobacter*, *Arcobacter*, and *Sulfurospirillum*. The differentiation of species in these genera is not trivial; although *Arcobacter* species have an ability to grow at lower temperatures and in an aerobic atmosphere, and gastric *Helicobacter* species possess a sheath around their flagellae (characteristics not found among campylobacters), many species may be found in the same habitat, making identification with all but molecular methods taxing. Notably, *C. coli* and *H. pullorum* are indistinguishable using commonly available biochemical methods alone, and both have been found in human diarrhea and poultry.

Figure 1 summarizes the phylogenetic relationships among *Campylobacter* species and related bacteria in the wider Epsilonproteobacteria class that includes *Arcobacter* and *Helicobacter*.

Campylobacter: Distribution and Pathogenicity

Table 1 summarizes the current taxonomic composition of the genus, alongside clinical significance (if any) in humans, host distribution, and foodborne vector potential of member taxa.

C. avium was described in 2009 as a novel species isolated from chickens and a turkey. Given that it shares these ecological niches with the established pathogen *C. jejuni*, it is not unreasonable to surmise that *C. avium* could be a cause of foodborne illness in humans. Indeed, given that the trait of hippuricase activity is also shared by these species (that remains the most frequently used phenotypic marker for *C. jejuni*), the potential for *C. avium* infections to be misidentified as those caused by *C. jejuni* seems credible. Nonetheless, there has been no report of human disease associated with *C. avium* thus far, even where suitable molecular culture-independent methods have been used.

C. canadensis was described in 2007, having been isolated from captive whooping cranes in Canada. There have been no descriptions of the organism in human illness as yet, and since wild birds are regarded as a low risk of human campylobacteriosis, this is unlikely to change if the host range of *C. canadensis* does not extend beyond the current domain.

C. coli is generally regarded as the second most frequent cause of classical campylobacteriosis in humans after *C. jejuni*, its closest known genetic relative. In 2003, of campylobacteriosis cases in the United Kingdom were attributed to *C. coli* infections, with a substantive (£4 million) societal cost. The host distribution of *C. coli* closely resembles that of *C. jejuni*, including many common food vehicles such as chicken, pork, and beef, with its frequency in pigs especially noteworthy. Interestingly, molecular epidemiological studies identify poultry and ruminants as the most important reservoirs of human infection. A case-to-case study in the United Kingdom conducted in 2002 suggested *C. coli* infections were more likely to be associated with the consumption of halal meats, meat pies, offal, pâté, and bottled water. The bottled water

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00107-0

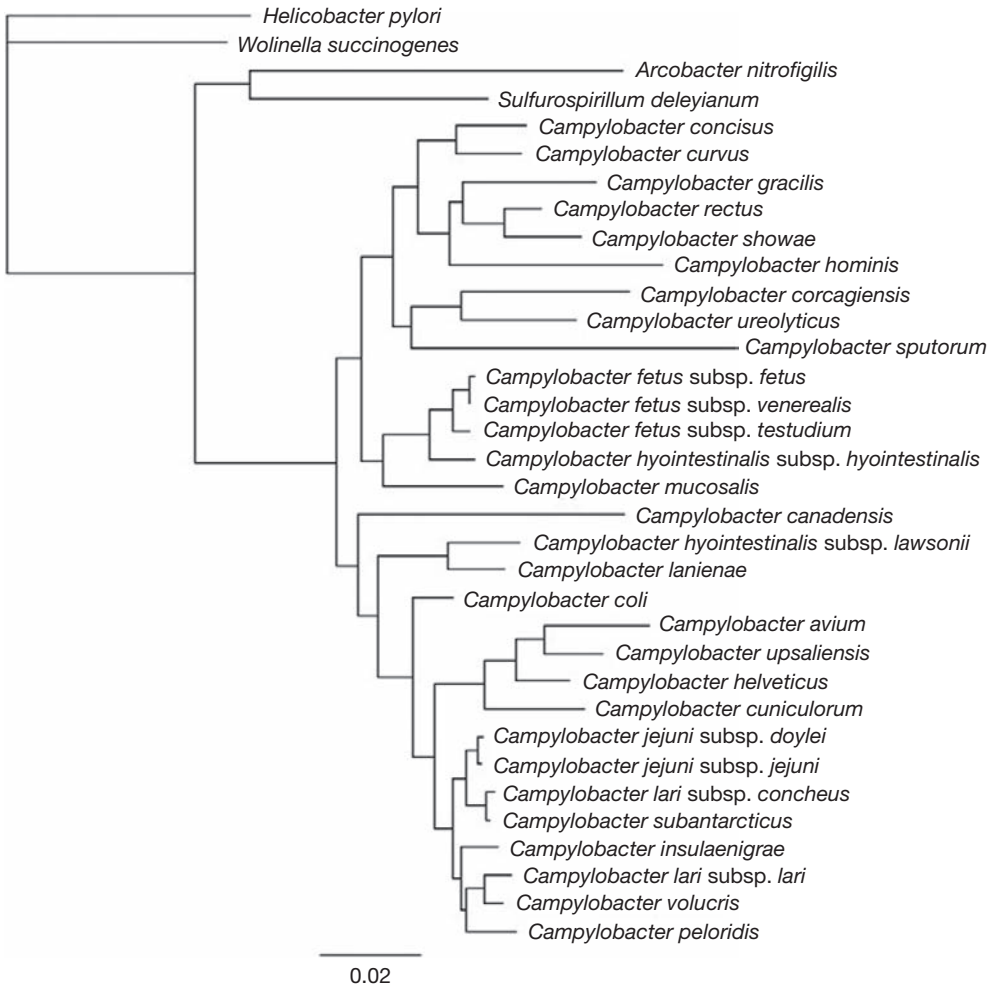

Figure 1 Phylogenetic tree for the type strains of the validly described taxa within the *Campylobacter* genus based on nucleotide sequence similarity of the 16S rRNA gene. The type species of closely related genera were also included and *Helicobacter pylori* was used as the out-group. The tree was constructed in Geneious 6.1.7 (Biomatters, available at www.geneious.com) using the Tamura–Nei genetic distance model and neighbor joining with a 70% similarity cost matrix, a gap open penalty of 12, a gap extension penalty of 3, and global alignment with free end gaps as the alignment type.

association is intriguing, given that while reported outbreaks are rare, two of the three we are currently aware of are waterborne.

C. concisus was originally described from the human oral cavity, but since this time, there have been many subsequent descriptions of its presence in human diarrheal cases. It is well known to be a genetically heterogeneous species, to the extent where analyses such as quantitative DNA–DNA hybridization and amplified fragment length polymorphism analysis indicate that at least two, and possibly up to six, genomically distinct taxa may be identified that potentially represent distinct species. However, the current lack of phenotypic markers to distinguish such taxa has led to the usage of the term 'genomospecies' to distinguish these genetically distinct but phenotypically indistinguishable groups. Two genomospecies appear dominant and a simple polymerase chain reaction (PCR) test may be used to differentiate these. It has been hypothesized that the different genomospecies have different pathogenic potentials too, yet the current evidence is conflicting. What is indisputable is that, where appropriate isolation or detection methods are employed, *C. concisus* can be found frequently not only in cases of human diarrhea and cases of inflammatory bowel disease (IBD) but also in stools from evidently healthy persons. Comparative genomic analysis of six strains revealed a range of genes associated with metabolism, adherence, and invasion that may explain the differences in patient outcomes if infected with *C. concisus*. Recent studies have identified *C. concisus* in domestic pets and various food animals including cattle, pigs, and chicken, highlighting the need to better understand the organism's pathogenic potential.

C. corcagiensis was described in 2014 resembling, but distinct from, *C. ureolyticus* and isolated from the feces of captive lion-tailed macaques. The pathogenicity of the species is as yet undetermined, as is its wider distribution. However, since we are unaware of any reports of *C. ureolyticus* in foods, and lion-tailed macaques surely being a rare exposure route, *C. corcagiensis* is an unlikely foodborne pathogen.

C. cuniculorum was first isolated from rabbit ceca in 2009 and was shown in a 2013 study to be widespread among wild rabbits in Italy. The pathogenicity of the species is as yet undetermined, but if the frequency of the organism's detection

Table 1 Distribution and human clinical significance of *Campylobacter* species

Taxon	*Human clinical associations*	*Host species*	*Foodborne illness association*
C. avium	None at present	Poultry	None reported
C. canadensis	None at present	Whooping cranes	None reported
C. coli	Gastroenteritis	Poultry, pigs, sheep, dogs, ostriches	Yes
C. concisus	Gastroenteritis, inflammatory bowel disease	Humans, dogs, cats, pigs, chicken	Potentially
C. corcagiensis	None at present	Lion-tailed macaques	Unlikely
C. cuniculorum	None at present	Rabbits	None reported
C. curvus	Uncertain	Humans, pigs	None reported
C. fetus subsp. *fetus*	Septicemia, gastroenteritis, abortion	Cattle, sheep	Potentially
C. fetus subsp. *venerealis*	Septicemia	Cattle, sheep	Unlikely
C. fetus subsp. *testudinum*	Gastroenteritis, septicemia	Turtle, skink, snake species	Potentially
C. gracilis	Uncertain	Humans	No
C. helveticus	None at present	Cats, dogs, pigs	None reported
C. hominis	None at present	Humans	None reported
C. hyointestinalis subsp. *hyointestinalis*	Gastroenteritis	Pigs, cattle, deer, sheep, hamsters, monkeys, elephants	Potentially
C. hyointestinalis subsp. *lawsonii*	Gastroenteritis	Pigs	Potentially
C. insulaenigrae	Gastroenteritis, septicemia	Seals, sea lions	Potentially seafood
C. jejuni subsp. *jejuni*	Gastroenteritis, septicemia, polyneuropathies	Poultry, cattle, pigs, sheep, dogs, cats	Yes
C. jejuni subsp. *doylei*	Gastroenteritis, septicemia, gastritis	Humans, chicken[a]	Unlikely
C. lanienae	None at present	Pigs, cattle	None reported
C. lari subsp. *lari*	Gastroenteritis, septicemia	Wild birds, chickens, horses, dogs	Potentially
C. lari subsp. *concheus*	None at present[b]	Humans, shellfish, seagulls	None reported
C. mucosalis	None at present	Pigs	None reported
C. peloridis	None at present[b]	Humans, shellfish	None reported
C. rectus	Periodontal disease	Humans, dogs[d]	None reported
C. showae	Periodontal disease	Humans, dogs[d]	None reported
C. sputorum[c]	Abscesses, gastroenteritis	Humans, sheep, cattle, pigs	Potentially
C. subantarcticus	None at present	Wild birds	None reported
C. troglodytis	Gastroenteritis	Chimpanzees	None reported
C. upsaliensis	Gastroenteritis	Cats, dogs	None reported
C. ureolyticus	Wound infections, urethritis, gastroenteritis	Humans, cattle	None reported
C. volucris	None at present	Black-headed gulls	None reported

[a]The identification of strains from chicken samples is controversial. See text.
[b]Some strains have been isolated from human feces but no pathological association was described.
[c]Comprises three biovars differentiated by catalase and urease production: bv. sputorum, bv. faecalis, and bv. paraureolyticus.
[d]May represent as-yet undescribed novel, but closely related species.

in rabbits in Italy is echoed in other countries, *C. cuniculorum* may be of interest to study in more detail, in nations that have a known appetite for the consumption of rabbit meat.

C. curvus was originally described as '*Wolinella curva*' and recovered from the oral cavity of humans. An extensive polyphasic taxonomic study reclassified the organism into the genus *Campylobacter* at which point the specific epithet was also emended. *C. curvus* is not regarded as a cause of periodontitis, but there are rare reports of its involvement with hepatic abscesses, premature birth, and pediatric IBD. The role of *C. curvus* in these conditions has not been established. The use of a sensitive culture method recovered *C. curvus* from both bovine and porcine sources, indicating the potential for foodborne transmission.

C. fetus was one of the two taxa (the other was '*V. bubulus*,' since reclassified as *C. sputorum*) that formed the genus *Campylobacter* in the original taxonomic proposal. It remains the type species of the genus. Subsequent to inception, *C. fetus* has been divided into three subspecies. *C. fetus* subsp. *fetus* may be found in the intestine of cattle and sheep and may also cause abortion in these animals if the reproductive tract is contaminated. In humans, *C. fetus* subsp. *fetus* may cause septicemia, abortion, and gastroenteritis. To date, there has not been a definitive link of human illness to the consumption of contaminated food, but the organism has been recovered from meat and liver samples from sheep, cattle, and pigs; chicken meat; turkey carcasses; vegetables; and milk. Thus, human consumption of contaminated foods is a risk for *C. fetus* infection, as is direct animal contact.

In contrast to *C. fetus* subsp. *fetus*, *C. fetus* subsp. *venerealis* appears highly adapted for colonization of the bovine genital tract; such infections may lead to abortion, but more importantly infertility, where the venereal nature of infection may be associated with substantial economic losses to breeding

programs. Reports of human infections are extremely rare and limited to cases of vaginosis and septicemia.

C. fetus subsp. *testudinum* is the most recently described subspecies and its natural hosts are a range of reptiles including turtle, skink, and snake species; it has also been recovered from clinical cases of septicemia, diarrhea, and pulmonary edema. Several human cases described consumption of Asian speciality dishes, some of which contained ingredients including turtle, frog, and eel. These data imply *C. fetus* subsp. *testudinum* infections in humans may be foodborne, where reptiles and perhaps eels are used as ingredients. It should be noted that the evidence to definitively link infections to foodborne consumption is presently circumstantial and that eel species are not a proven host for *C. fetus* subsp. *testudinum*.

C. gracilis was first described as '*Bacteroides gracilis*' and in association with human periodontitis. A polyphasic taxonomic study formally assigned the organism to the *Campylobacter* genus. The role of *C. gracilis* in periodontal disease is unclear. The organism has been detected in stool samples from both healthy and diarrheic dogs and humans using culture-independent methods. To our knowledge, detections in food animals have not been reported. Current evidence indicates *C. gracilis* is not a foodborne cause of gastroenteritis.

The principal hosts of *C. helveticus* are domestic pets (cats and dogs), from which this species was first described. Strains have been identified in porcine cecal and carcass swab samples, but not on pork meat. There are as yet no reports of *C. helveticus* infections in humans, but it should be noted that the close phenotypic and genetic similarities between this species and *C. upsaliensis* (a known human pathogen) do not preclude the possibility that historical cases of human *C. upsaliensis* disease may have been misidentified episodes of *C. helveticus* infections. Nonetheless, there is currently no evidence to support that hypothesis.

C. hominis was first detected in human feces using a PCR approach in 1998 and subsequently isolated in 2001 using an anaerobic growth protocol, suggested by the close phylogenetic association with *Campylobacter* species for which culture conditions of anaerobiosis appear to be preferred. There are presently no reports of *C. hominis* in animals, or with diseases in humans, and it is generally believed that this bacterium has a commensal role.

C. hyointestinalis is divided into two closely related but distinct subspecies with substantive phenotypic, genotypic, and ecological differences. *C. hyointestinalis* subsp. *hyointestinalis* has been found in fecal and intestinal samples of pigs, cattle, deer, sheep, hamsters, monkeys, and elephants; in many of these animals, there has been an association with diarrhea. Cases of gastroenteritis in humans have also been reported, including an outbreak for which the implicated (but not proven) source was raw milk. The relatively wide spread of host animal species in which *C. hyointestinalis* subsp. *hyointestinalis* is found and its presence in human gastroenteritis are indicative of foodborne pathogenic potential. The other subspecies, *C. hyointestinalis* subsp. *lawsonii*, was first isolated in 1995 from the porcine stomach. Since then, a 2002 report linked isolates from a case of human diarrhea and pigs in the same household with genetic typing has been published. Furthermore, *C. hyointestinalis* subsp. *lawsonii* has been detected in 2014 in 26.7%, 55.6%, and 65.4% of infant stool samples from Bangladesh, Peru, and Tanzania, respectively. Other studies published in 2011 and undertaken in Ireland and Canada have detected *C. hyointestinalis* in human diarrhea, but were unable to identify to subspecies level. The data thus far suggest each *C. hyointestinalis* subspecies may be an agent of foodborne non-*jejuni*, non-*coli* illness, with prevalence rates varying markedly between countries. However, further work is needed to substantiate this and the role that *C. hyointestinalis* plays in human gastroenteritis.

C. insulaenigrae has been recovered predominantly from marine mammalian species including sea lions, a porpoise, and several seal species. To date, there is one formally published report of human infection, an Australian case of enteritis and septicemia in a 60-year-old female with end-stage renal failure. While this patient was clearly compromised, there was no known prior contact with marine mammals and the route of infection must remain speculative. A second report was presented at the 2014 New Zealand Microbiology Society conference, a case of bacteremia and enteritis, which *may* have been associated with the consumption of mussels (T. Blackmore, personal communication). It should be noted that seals are native to New Zealand. These cases suggest both direct contact and exposure to or consumption of contaminated water or food may be transmission routes for *C. insulaenigrae* to humans, where marine mammal species are extant.

C. jejuni comprises two subspecies, of which *C. jejuni* subsp. *jejuni* is by far the better studied, most widespread, and most important from a foodborne illness perspective. This is substantiated from a review of outbreaks worldwide where, when species-level identification was performed, *C. jejuni* subsp. *jejuni* was far more frequently found to be the cause compared with the closely related species *C. coli*. The organism is extensively distributed among production animals and domestic pets, with consumption of contaminated food, water, and milk and direct animal contact all establishing transmission pathways. The infectious dose appears comparatively small, the incubation period ranges from 18 h to 8 days, and post-infectious complications can include polyneuropathic disorders including Guillain–Barré and Miller Fisher syndromes and reactive arthritis. It has been suggested that the pathogenic potential of individual strains may vary. Suggestions of host specificity or at least host preference of certain strain types have been made from genotyping studies, and differential survival rates between strains has also been used to argue the 'successful clone' hypothesis, first proposed to the best of our knowledge in 2006. Equally, it has been suggested that the absence of host-associated phenotypic or genetic markers among multilocus sequence type 21 strains from different sources may argue for generalist rather than specialist adaptation. Strain NCTC 11168 was the first *Campylobacter* spp. genome to be sequenced and publicly released; while there are a further 15 *C. jejuni* subsp. *jejuni* strain genomes completed and published as of 12 November 2014, decreasing costs and increased access to genome sequencing infrastructure are resulting in many more being made available for study.

In contrast, *C. jejuni* subsp. *doylei* is reported only rarely in human disease and has been found in cases of gastritis, diarrhea, and septicemia. Its scarcity may in part be related to a key phenotypic difference between the two subspecies; *C. jejuni* subsp. *doylei* is unable to grow at 42 °C, a common component

in methods for the isolation of enteric campylobacter. This trait would also explain the absence of *C. jejuni* subsp. *doylei* in poultry, given that this is also the core temperature of the host birds. The report of *C. jejuni* subsp. *doylei* in 19 of 31 chickens examined by Kaakoush and colleagues in 2014 is questionable from this ecological perspective as well as the use of the 16S rRNA gene sequence for speciation, since this does not possess sufficient resolution to distinguish such closely related taxa. Aside from this single report in chickens, no animal host has been identified for *C. jejuni* subsp. *doylei*. Additional distinctions between *C. jejuni* subsp. *doylei* and *C. jejuni* subsp. *jejuni* include the inability of the former to reduce nitrate and produce cytolethal distending toxin, both of which have been shown to be the result of gene deletion.

C. lanienae was first recovered from fecal samples of asymptomatic abattoir workers, with subsequent studies demonstrating its presence in pigs, cattle, sheep, wild boar, and red deer. Although the presence in pigs and cattle and detection in humans suggest zoonotic transmission from direct contact or consumption of contaminated meats, the absence as yet of any reported disease symptoms in humans currently indicates *C. lanienae* may be of limited concern, although clearly, it deserves close monitoring.

C. lari is another species known to be genetically and taxonomically diverse and is currently divided into two subspecies. *C. lari* subsp. *lari* was first described in 1983 as '*C. laridis*' with the species epithet corrected to *C. lari* later. Strains have been described from diverse sources, including seagulls, ducks, cows, shellfish, dogs, and horses, and reports of human infection have included gastroenteritis, abdominal pain, septicemia, and infections associated with surgical implants. Outbreaks associated with contaminated water have been described. *C. lari* subsp. *concheus* is more recently described (2009) with strains thus far recovered from human feces and shellfish. Its pathogenicity has yet to be determined but, given the sources from which it has been recovered, should be regarded as a potential enteropathogen that can be transmitted from the consumption of contaminated food; shellfish are as yet the only verified animal host. The diversity of *C. lari* extends to a third, genetically diverse group referred to as urease-positive thermophilic campylobacters on the basis of their most discerning phenotypic trait, urease production. Strains have been recovered from human diarrhea, marine and river waters, and shellfish and on this basis should be regarded as potential human pathogens that may be transmitted by contaminated water or food, notably shellfish.

First described in 1975 as a subspecies of *C. sputorum* but elevated to species status in a later polyphasic taxonomic study, *C. mucosalis* was initially recovered from pigs in association with lesions of porcine intestinal adenomatosis, necrotic enteritis, regional ileitis, and proliferative hemorrhagic enteropathy. The role of *C. mucosalis* in such diseases is questionable given the identification in 1995 of the intracellular *Lawsonia intracellularis* as the predominant pathogen. Two cases of enteritis in humans described in 1993 attributed to *C. mucosalis* were subsequently shown to be misidentified *C. concisus* strains in 1994. More recently, the use of sensitive isolation methods has recovered *C. mucosalis* from beef and pork products. Genetic methods have detected strains in canine feces and at low frequency in healthy and diarrheic human stools. Current evidence casts considerable doubt on *C. mucosalis* being an important foodborne pathogen.

C. peloridis was described in 2009 following a taxonomic study of bacteria resembling *C. lari*. This study refined the taxonomic structure of *C. lari* (see earlier) and also determined that some strains from human stools and shellfish were distinct enough to warrant recognition as a distinct species, namely, *C. peloridis*. Its pathogenic potential has yet to be determined, but its close resemblance to the established enteropathogen *C. lari* and occurrence in shellfish suggest it would be prudent to maintain an awareness of the organism.

C. rectus was first described (as '*Wolinella recta*') in 1981 in association with human periodontal disease, where it remains as one of several bacterial species that may be involved with this condition. There have been several reports (most recently using culture-independent molecular tools) of the organism in human diarrhea and in dogs. While the role of *C. rectus* in periodontal disease is substantiated, its role as a potential zoonotically transmitted cause of gastroenteritis is far less clear.

C. showae is another species that was first identified in 1993 to play a role in periodontal disease. As with *C. rectus*, *C. showae* has also been detected in cases of human gastrointestinal disease, and in dogs, and the pathogenic and zoonotic potential of these species may be considered to be equivalent at this time.

Along with *C. fetus*, *C. sputorum* was one of the first 'anaerobic *Vibrio* spp.' to be reclassified as *Campylobacter*, although here it was referred to as '*C. bubulus*' and was subsequently reclassified as a biovar of *C. sputorum*, which was later rescinded in 1998 since the defining phenotypic tests were found to be irreproducible and invalid. *C. sputorum* is divided into three biovars based on their ability to produce catalase and urease, with bv. sputorum negative in both traits, bv. faecalis catalase-positive only, and bv. paraureolyticus urease-positive. *C. sputorum* can be found in cattle, pigs, and sheep as host species and has been reported in humans as an oral commensal, in diarrhea, and in abscesses. Its pathogenic potential is largely undetermined, but the body of evidence thus far suggests it to be a possible risk to immunocompromised persons, with foodborne transmission being a credible, if presently unsubstantiated, pathway.

C. subantarcticus has so far only been recovered from wild birds in the subantarctic. While this species is closely related to the pathogenic *C. lari*, there are currently no reports of human infections, and wild birds are generally regarded as a low-risk exposure route for human campylobacteriosis.

'*C. troglodytis*' was first described in 2011 from fecal samples of wild chimpanzees in national parks located in Tanzania. A 2014 study of *Campylobacter* spp. in infant diarrheal samples in developing countries including Tanzania, and also Peru and Bangladesh, revealed '*C. troglodytis*' in 18 of 53 representative samples examined for emerging campylobacters. These limited studies suggest (but do not prove) pathogenic and zoonotic potential, or contamination via a common source.

C. upsaliensis was first isolated in 1983 from canine feces and described as the 'catalase-negative or weak campylobacter' in light of its (at that time) quite distinctive phenotype. Domestic cats and dogs remain the host species that are most commonly associated with *C. upsaliensis*; recent exemplar studies have found it in 37% of dogs and 44.6% of cats. In addition, three of 31 samples (9.7%) in commercial broiler

chickens in a 2014 Australian study harbored *C. upsaliensis*; a separate 2013 Swedish study in which 2% of rodents were positive suggests that vectors other than domestic pets potentially pose an exposure pathway and, with rodents especially, a possible contamination route for animal husbandry. In humans, *C. upsaliensis* is considered to be pathogenic, with diarrhea and septicemia being recognized outcomes. *C. upsaliensis* is less frequently reported from human disease compared with other enteropathogenic species such as *C. jejuni* and *C. coli*, although its more pronounced sensitivity to antibiotics commonly used in routine isolation protocols may contribute to underdetection.

The taxonomic status of *C. ureolyticus* had remained unclear for some time, given its original (1978) classification as a *Bacteroides* species was questioned with the advent of phylogenetic analyses; a more detailed polyphasic taxonomic examination in 2010 reassigned the organism to the genus *Campylobacter*. The first reports of clinical associations encompassed abscesses, non-gonococcal urethritis, and soft tissue infections, with more recent studies implicating the species as a cause of gastroenteritis, ulcerative colitis, and Crohn's disease. The status of *C. ureolyticus* as a primary pathogen is, however, unproven and controversial, given that it can be detected in healthy and diarrheal patients. Infraspecific differences in virulence properties have been proposed to explain this. Recent studies suggest cattle may be a reservoir for *C. ureolyticus*; thus, contaminated meat or milk may represent foodborne infectious sources of note, if subsequent studies prove organismal pathogenicity.

C. volucris is a *C. lari*-like species isolated from black-headed gulls. The pathogenic potential of the species is undetermined, and thus far, no association with human illness has been reported.

Campylobacter: General Properties

The genus *Campylobacter* represents a distinct phylogenetic group within the class Epsilonproteobacteria that includes *Arcobacter*, *Sulfurospirillum*, *Helicobacter*, and *Wolinella* (**Figure 1**). Nonetheless, species within the genus exhibit some remarkably diverse properties. Cells may be spiral (e.g., *C. fetus* and *C. jejuni*), curved (e.g., *C. concisus*), or rod-shaped (e.g., *C. gracilis* and *C. hominis*) and either aflagellate (*C. gracilis*, *C. hominis*, or *C. ureolyticus*) or with one or more polar flagella (other species). They have a preference for nutritionally complex media, but many species can be cultured on blood-free media and some species will grow on a minimal medium. One important unifying feature is their particular atmospheric gaseous requirements. Historically, taxa have been considered to require microaerobic (3–5% O_2 content) conditions (e.g., *C. jejuni* and *C. fetus*); microaerobic conditions, but with a H_2 requirement (e.g., *C. concisus*); or anaerobic conditions (e.g., *C. rectus* and *C. ureolyticus*). However, recent studies in 2011 have indicated that all species can be cultured in a single specified microaerobic atmosphere comprising 3% O_2, 7% H_2, 10% CO_2, and 88% N_2. This atmosphere, combined with the use of blood agar media and 0.60–0.65μM filtration, has successfully recovered a wide range of species from food products. This approach was derived from 'the Cape Town protocol' used in Professor Lastovica's laboratory for many years to examine clinical samples, with a remarkable recovery rate of an extensive range of *Campylobacter*, *Arcobacter*, and *Helicobacter* species.

Campylobacter: Incidence and Significance

Campylobacter species are widely regarded as the most frequent bacterial cause of acute gastroenteritis worldwide; reports of campylobacteriosis often do not differentiate the various enteropathogenic species (*C. jejuni* subsp. *jejuni*, *C. coli*, *C. lari*, and *C. upsaliensis*) that together have been reported at rates per 100 000 population varying from 42.6 across the 27 European Union (EU) member states in 2013, to 44 in the United States, to 383.5 in New Zealand. The rate of campylobacteriosis in New Zealand has since dropped to 156.8 following a range of interventions in poultry production. It is widely recognized that these reported rates represent only a fraction of the actual disease burden as a consequence of underdiagnosis and underreporting; for example, the true incidence of campylobacteriosis across EU states has been estimated at 1860 cases per 100 000 population in 2013, representing an average underreporting rate of 43.6. In low-to-middle income countries, campylobacter infections are estimated to cause 8.4% of the total burden of diarrheal disease.

As high as these figures are, it should be noted that they represent reports of species such as *C. jejuni* for which isolation methods have been predominantly designed. With some studies demonstrating essentially equivalent numbers of taxa such as *C. concisus*, the burden of disease may be even higher and perhaps accounting for some of the majority of acute gastroenteritis cases for which routine analyses fail to identify a pathogen. Although much progress has been made in understanding *Campylobacter*, there is much that remains to be understood.

Campylobacter: Species Detection

K Rantsiou and LS Cocolin, University of Turin, Turin, Italy

Introduction

The genus *Campylobacter* comprises Gram-negative, non-spore-forming, microaerophilic microorganisms. Cells are slender, spirally curved rods often motile by means of a single polar flagellum at one or both ends. It encompasses microorganisms of human and veterinary medicine interest; most species are pathogenic for humans and/or animals, and they are commonly found in the reproductive organs, intestinal tract, and oral cavity of humans and animals. A phylogenetically related genus that is an important human pathogen as well is *Arcobacter*. In general, campylobacters can be differentiated from arcobacters by the higher optimal growth temperatures (25–30 °C for arcobacters compared with 30–42 °C for campylobacters) and the aerotolerance of arcobacters. Taxonomy of the *Campylobacter* genus has evolved in the last 30 years and presently contains 16 species. Five of them, namely, *C. upsaliensis*, *C. helveticus*, *C. lari*, *C. jejuni*, and *C. coli*, are established or possible enteropathogens for humans, are found in food and water, and are thermotolerant.

The two subspecies of *C. jejuni*, *C. jejuni* subsp. *jejuni* and *C. jejuni* subsp. *doylei*, are currently recognized as the first causative agent of foodborne infection in developed and developing countries. In contrast to the well-known foodborne pathogen *Salmonella*, which is also the second causative agent of foodborne disease in developed countries, *Campylobacter* is responsible for sporadic cases rather than structured disease outbreaks. *C. jejuni* asymptomatically colonizes chickens and other avian species, and chicken meat is recognized as the most common food vehicle that causes intestinal disease in humans. *C. jejuni* infection in humans is symptomatic as the microorganism invades the intestinal epithelial layer resulting in inflammation and diarrhea. The basis for the different outcomes of infection in humans versus chicken is not well understood. Human campylobacteriosis is a self-limiting disease. However, a correlation exists between human *C. jejuni* infection and the development of Guillain–Barré syndrome (GBS), an autoimmune disorder of the peripheral nervous system. It is now recognized that GBS is a severe, potential sequel of *Campylobacter* infection.

The role of *Campylobacter* in human foodborne infection has only recently been recognized, and this is partly due to the difficulties of detection of this microorganism in foods. Such difficulty hinders proper epidemiological studies to assess the burden of disease caused by *Campylobacter* spp. Additionally, the lack of harmonized sampling and analysis procedures limits the efforts directed toward determining *Campylobacter* prevalence in foods and eventually proposing preventive measures to control foodborne infections. This article describes the currently available *Campylobacter* detection methods, with particular emphasis on the *C. jejuni* species, due to its significance for the food safety.

Detection Methods Based on Culture Media

Culture media for the detection of *Campylobacter* were initially developed for microbiological analysis of feces (medical samples) and are based on the use of a basal medium, supplemented with antibiotics. Furthermore, increased temperature of incubation (42–43 °C) facilitates the detection and isolation of thermotolerant campylobacters. The use of these culture media subsequently has been extended to the detection in food and water (food samples). As for the detection of other foodborne pathogens, an enrichment step is commonly performed for *Campylobacter*. Furthermore, a pre-enrichment is often employed in order to recover sublethally damaged cells of *Campylobacter*, common in samples as a consequence of food processing/preservation technologies employed. The microaerophilic nature of *Campylobacter* is taken into consideration in culture media development. In particular, ingredients need to be added in media, which neutralize the toxic effects of substances that are formed in the presence of oxygen and light. Neutralization can be achieved by the addition of ferrous sulfate, sodium metabisulfite, and sodium pyruvate, in some cases also combined with blood, or alternatively by the addition of charcoal. It should be highlighted that the addition of blood in the media used for enrichment can greatly influence downstream molecular biology applications since it is a renowned inhibitor of PCR amplification. Furthermore, the atmosphere of incubation greatly influences the recovery of *Campylobacter*; therefore, it needs to be adjusted accordingly. Usually, conditions of 5–7% O_2, 10% CO_2, and 80% of N_2 and/or H_2 are employed.

Apart from the increased temperature, antibiotics are the main selective agents employed in enrichment and plating media. Common antibiotics used are polymyxin, trimethoprim, and colistin, active against Gram-negative bacteria; vancomycin, rifampicin, cephalosporin, and bacitracin, active against Gram-positive bacteria; and cycloheximide, amphotericin B, and nystatin, which are employed as inhibitors of yeasts and molds.

Preston and Bolton broths are used for enrichment purposes, while Preston agar and mCCD (modified charcoal, cefoperazone, deoxycholate) agar are the most common plating media. On such media, the typical appearance of *Campylobacter* colonies is flat, glossy, and moist, with a tendency to spread.

Figure 1 presents an outline of the EN ISO 10272-1 method for the detection of *Campylobacter* spp. in food and feedstuff. Common tests performed on suspected colonies for confirmation are Gram staining and cell morphology, motility, and microaerobic growth tests at 25 °C (negative for *Campylobacter* spp.), aerobic growth test at 41.5 °C (negative for *Campylobacter* spp.), and oxidase test (positive for *Campylobacter* spp.). The identification of confirmed colonies as *C. jejuni* is mainly based on hydrolysis of hippurate; among *Campylobacter* spp., only *C. jejuni* is positive for this test. Furthermore, identification can

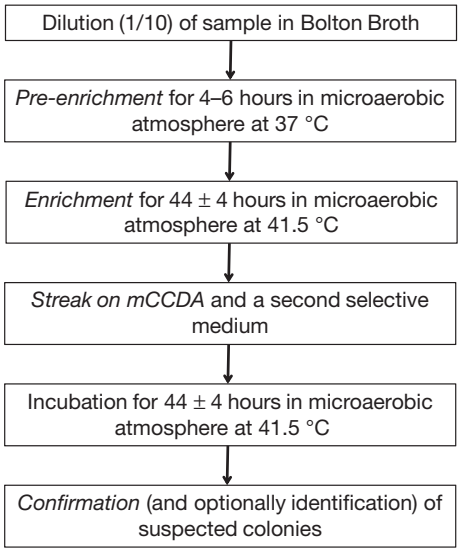

Figure 1 Outline of the ISO 10272-1 method for detection of *Campylobacter* spp. in food and feed.

be performed by commercially available latex agglutination assays with polyclonal antibodies raised against antigens of main *Campylobacter* species. Alternatively, identification can be performed by molecular methods, as described in the succeeding text.

It is widely recognized that recovery of *Campylobacter* from food samples (especially chicken meat) is highly dependent on the choice of enrichment broth and selective plating medium. This is due to (i) varying sensitivities, within the *Campylobacter* spp., to the antibiotics added in the media, (ii) difficulties in recognizing *Campylobacter* spp. on the plating media because often they form atypical colonies, (iii) the presence of sublethally injured cells in the samples, and (iv) outgrowth of *Campylobacter* during enrichment, especially when present at low concentrations, by competing bacteria. Under certain conditions, direct plating is preferable to plating after enrichment. Such an approach, however, is inadequate for samples with a low number of *Campylobacter* or when cells are sublethally injured and there is a need for resuscitation prior to plating. The difficulty in recovering *Campylobacter* from a food sample increases the risk of obtaining false-negative results. Despite significant efforts in recent years, monitoring of *Campylobacter* in foods and risk assessment still suffer from the lack of reliable and standardized culture-dependent protocols.

Species Identification by PCR

As reported in the preceding text, *Campylobacter* species identification may be performed by phenotypic tests. Such an approach presents certain limitations. First, it should be underlined that all members of the *Campylobacter* genus can be considered fastidious microorganisms; therefore, any test that is based on growth in culture media displays inherent disadvantages. Second, discrimination of the closely related members of the genus can be problematic due to the increased phenotypic relatedness or atypical results by some representative members. Alternative methods for identification have been developed that are based on PCR. These methods have mainly focused on human pathogenic campylobacters and are proposed as single species-specific PCR or multiplex PCR (mPCR) for simultaneous identification of different species in one reaction. Various genes have been used as targets, and **Table 1** summarizes the wealth of PCR protocols developed for the identification of *Campylobacter* species of food safety interest.

Typing

Typing refers to the process of identifying isolates of one species to the strain level. It allows the classification of clonally, and epidemiologically, related isolates and their differentiation from unrelated isolates. Typing of an isolate usually follows the identification of the species level, and it is indispensable for the epidemiological investigation of a foodborne outbreak or for tracking foodborne pathogens through the food chain. Ultimately, typing may allow better control and prevention–intervention measures to limit the prevalence of pathogens in food. Clearly, typing of *Campylobacter* isolates is an important task in microbiological analysis of foods, and it can be based on phenotypic or genotypic methods. Among phenotypic methods, serotyping (Penner scheme serotyping of heat-stable antigens detected by passive hemagglutination and to a lesser extent Lior scheme serotyping of heat-labile antigens detected by bacterial agglutination) is widely accepted and has been broadly applied for typing. With the advent of application of molecular biology methods in food and medical microbiology, different genotypic methods have been proposed and are discussed in the succeeding text.

Genotypic Methods

(i) Sequence polymorphism of the genes encoding for flagellin proteins in *Campylobacter* has been exploited for typing purposes. The *flaA*, or both *flaA* and *flaB* genes, can be amplified by PCR and subsequently subjected to restriction fragment length polymorphism. Alternatively, a *flaA* PCR product can be analyzed by denaturing gradient gel electrophoresis. Typing based on the *fla* gene (s) represents a simple and quick method, and the results correlate with heat-labile serotyping results (at least for some serotypes).

(ii) Pulsed field gel electrophoresis (PFGE) is considered the method of choice for typing of different pathogens, particularly during investigation of foodborne outbreaks. It should be highlighted that an international network of laboratories (PulseNet International) detects and defines foodborne outbreaks by applying PFGE as a fingerprinting method. Standardized protocols and a well-structured database of electrophoretic profiles for different foodborne pathogens (including *C. jejuni*) allow comparison of results between laboratories and facilitate the detection of outbreaks. The main disadvantage of the PFGE method is the lengthy and labor-intensive preparation of the samples for electrophoresis. This aspect renders the method impracticable in routine analysis or if a large number of isolates need to be typed.

(iii) Ribotyping essentially consists in digestion of genomic DNA, separation in agarose gel electrophoresis, and southern blot hybridization with probes targeting the rRNA-encoding genes. This method may be used for

Table 1 Summary of published PCR protocols for the identification of various species of *Campylobacter*

Method developed	*Species identified*	*Gene target*	*Additional features*	*Reference*
Single PCR	*C. jejuni*	*ceuE*, encoding a siderophore transport protein		Gonzalez et al., *Journal of Clinical Microbiology* **35**, 759–763
Single PCR	*C. coli*	*ceuE*, encoding a siderophore transport protein		
Single PCR	*C. jejuni*	*omp50*, encoding a porin	A scheme based on *omp50* amplification and hippurate hydrolysis is proposed for the identification of *C. coli* and *C. lari*	Dedieu et al., *Journal of Clinical Microbiology* **42**, 2301–2305
Multiplex PCR	*C. jejuni* *C. coli*	*mapA*, encoding a membrane lipoprotein *ceuE*, encoding a siderophore transport protein	*Campylobacter* genus identification by 16S rRNA gene primers	Denis et al., *Letters in Applied Microbiology* **29**, 406–410
Single PCR	*C. jejuni*	*hip*, encoding a hippuricase	A set of primers targeting the 16S rRNA gene was proposed for the differentiation of *C. jejuni* and *C. coli* from all other *Campylobacter* species	Linton et al., *Journal of Clinical Microbiology* **35**, 2568–2572
Single PCR	*C. coli*	Primers targeting partial aspartokinase coding gene and a downstream ORF		
Multiplex PCR	*C. jejuni* *C. coli* *C. lari* *C. upsaliensis*	*lpxA*, gene involved in lipid A biosynthesis		Klena et al., *Journal of Clinical Microbiology* **42**, 5549–5557
Multiplex PCR	*C. jejuni* *C. coli*	Gene encoding a putative oxidoreductase subunit *ceuE*, encoding a siderophore transport protein	*Campylobacter* genus identification by primers *cadF* gene (encoding an outer membrane protein) primers	Nayak et al., *Molecular and Cellular Probes* **19**, 187–193

typing of different bacterial species and it has also been applied for *C. jejuni* and to a lesser extent for *C. coli*, *C. upsaliensis*, and *C. lari*. Ribotyping for *Campylobacter* showed a low discriminatory power (i.e., ability of the method to discriminate two strains that are unrelated). It can be considered a complicated method with low throughput capacity, and therefore, an automated protocol (i.e., riboprinting) has also been proposed.

(iv) Random amplified polymorphic DNA is basically a PCR performed with short primers in low-stringency conditions. The resulting electrophoretic band patterns are used as fingerprints of the isolates. This method has been applied for *Campylobacter* sp. typing. It is a method that is easy to apply and fast but has the major disadvantage of low reproducibility.

(v) Amplified fragment length polymorphisms (AFLPs) are differences in restriction fragment lengths that occur within a genome and are the consequence of the presence/absence of restriction enzyme recognition sites. AFLP analysis is a typing method that is based on selective amplification of restriction fragments from total genomic DNA digested with restriction enzymes. It has been used as a typing method for *C. jejuni* with good reproducibility results. It is a rather complicated and laborious method but offers the advantage of analyzing a random portion of the whole genome of a microorganism without the need for prior sequence knowledge.

(vi) Multilocus sequence typing (MLST) consists in PCR amplification and sequencing of a number (usually 6–8) of housekeeping genes and comparison of the sequences obtained from different isolates. It is a very powerful typing method extensively used for strain identification of foodborne pathogens, including different members of the *Campylobacter* genus. Typing by MLST has proved useful, and its application has expanded with the availability of high-throughput sequencing platforms. The method is reproducible and has a high discriminatory power. Furthermore, it offers an additional advantage compared to the methods described in the preceding text: since typing is based on DNA sequences (and not some form of electrophoretic profile), direct comparisons between laboratories, as well as unambiguous database construction, are facilitated. MLST may be considered currently the 'gold standard' for typing of different *Campylobacter* spp., including *C. jejuni*.

It should be noted that *C. jejuni* and *C. coli* show significant intraspecies biodiversity and are characterized by genetic instability. This is partly due to the fact that both microorganisms are naturally competent and, therefore, prone to horizontal genetic exchange. Consequently, an essential characteristic of the typing method to apply for *Campylobacter* is the stability of the marker. MLST is not affected by genetic instability since it is based on the study of variation that slowly accumulates within a population and it has allowed the description of *Campylobacter* population structure. It is expected that whole-genome sequencing of multiple isolates will further contribute to the understanding of the diversity of *Campylobacter*.

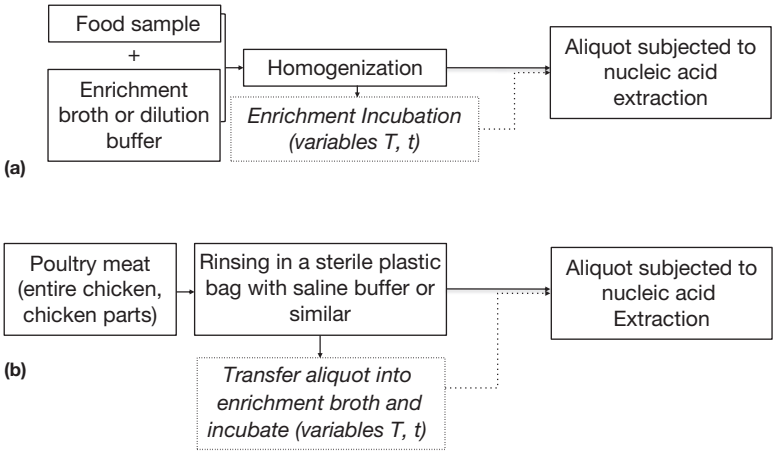

Figure 2 Work flow of microbiological analysis by a culture-independent approach. (a) The first step in the analysis involves a homogenization of the sample; after this step, it is possible to extract nucleic acids directly or after enrichment. (b) For poultry samples rather than homogenization, rinsing can be performed, and the subsequent analysis can be performed on the rinse, either directly or after enrichment. Abbreviations: *T*: temperature, *t*: time.

Direct Detection and Quantification

As evidenced in the preceding text, detection of *Campylobacter* spp. by the use of culture media is problematic. Currently, no universal enrichment and/or plating medium exists. This can be related not only to the fastidious nature of the microorganism but also to the physiological state of the cells in the various food matrices. Apart from stressed or sublethally injured cells, the viable but nonculturable (VBNC) state has been described for *Campylobacter* spp. Cells in the VBNC state by definition do not grow on culture media. Entry into the VBNC state seems to be a survival mechanism when cells encounter unfavorable conditions. It has yet to be determined if VBNC cells are/may become virulent and eventually cause disease to humans. Independently of the fate of VBNC cells, a method should be able to detect them in order to accurately describe the prevalence of *Campylobacter* in foods. Another nonnegligible inadequacy of detection based on culture media is the long time to result, considering the various steps of microbiological analysis, that is, pre-enrichment, enrichment, and selective media incubation. To overcome these specific limitations of culture-dependent microbiological analyses, that is, incomplete and possibly biased recovery and determination of *Campylobacter* and length of analysis that does not coincide with timely corrective actions, food microbiologists are increasingly investigating alternative approaches that are based on molecular biology methods. Application of molecular methods has the advantage of bypassing at least some of the culturing steps, thereby circumventing these limitations. Figure 2 summarizes the work flow of a microbiological sampling and analysis by means of molecular methods applied in a culture-independent approach. As shown, for poultry samples, it is possible to perform the analysis on homogenates or on rinses of whole carcass or parts. The most commonly employed culture-independent approach involves extraction of nucleic acids (usually DNA) and quantitative PCR (qPCR) amplification.

qPCR can be considered the best alternative to traditional culture plating for the detection (and if possible quantification) of pathogens in foods. It is currently recognized as the molecular method of choice when a culture-independent approach is employed for foodborne pathogen detection. Important parameters of the developed qPCR protocols that need to be taken into consideration are specificity, limit of detection, and, in case where the protocol is intended for quantification, the linearity range. Specificity is determined by testing the qPCR protocol with a large number of nontarget species, and no amplification should be obtained. This is a parameter that strictly depends on the choice of the target gene and subsequently on the primer/probe design. The limit of detection and the linearity range are strongly dependent on the quality of nucleic acid that can be extracted from a given food sample. Calibration curves can be constructed in order to determine these parameters. Calibration curves correlate cell concentration (usually expressed as log CFU (colony-forming units) per gram or milliliter of food) to threshold cycle (C_t), determined as the cycle number of the PCR when amplification is detected (the output of qPCR). Such calibration curves are commonly constructed by artificially inoculating serial dilutions of the target microorganism in the food sample of interest and subsequently extracting and amplifying the DNA by qPCR to recover the C_t value for each cellular concentration. Each calibration curve is characterized by a linear regression equation, a coefficient of linearity that indirectly indicates the linearity range, and a detection limit. The equation can be used for the quantification of the target microorganism in a naturally contaminated food sample.

As mentioned in the preceding text, DNA is commonly employed in qPCR. This choice is based on the easiness of extraction and manipulation of this nucleic acid as compared to RNA. It should be underlined that DNA is a stable molecule and can persist long after cell death. For this reason, the use of DNA in qPCR has been criticized as it can result in positive amplification from dead cells. Alternatively, RNA can be used as a target since it is an unstable molecule and generally is considered to have a short half-life. This characteristic of the RNA renders it a good indicator of vitality; that is, the RNA of dead cells is rapidly degraded and is not being detected. The choice of the RNA molecule to target in a qPCR is also important. It is recognized that rRNA is more stable with respect to mRNA and differences in stability have also been observed among mRNA molecules. For this reason, the suitability of an RNA molecule to serve as an indicator of vitality needs to be verified.

So far, no suitable RNA vitality target has been proposed for *Campylobacter*. When RNA is used as a target, alternatively to qPCR, the nucleic acid sequence-based amplification (NASBA) can be used. This is an amplification method that is performed at isothermal conditions with RNA as a target. NASBA protocols for detection of viable *Campylobacter* spp. have been proposed that employ both rRNA and mRNA as targets.

As shown in Figure 2, an enrichment step before nucleic acid extraction is sometimes required. An enrichment step is deemed necessary when the detection and/or quantification limit of the method is not compatible with the purpose or the needs of the microbiological analysis. For foodborne pathogens, it is essential to determine the presence or absence in a certain quantity of sample. If this detection limit cannot be achieved, an enrichment step is performed. Such enrichment step can be considered a double-edged sword. On the one hand, after enrichment, it is no more possible to quantify the initial population present in the sample; on the other hand, DNA amplified after enrichment can be attributed to live cells.

qPCR protocols have been optimized for detection and/or quantification of *Campylobacter* in food. Protocols mainly address thermophilic *Campylobacter* detection, and several target genes have been used. These include the *cadF* gene (encoding a membrane protein involved in adhesion), part of the 16S rRNA-encoding gene, the *hip* gene (encoding the hippuricase), and the *rpoB* gene (encoding the β-subunit of the RNA polymerase). Performance of the developed qPCR protocols has been tested with artificially contaminated samples. Such protocols represent potentially valuable tools for the determination of the prevalence of *Campylobacter* in foods. So far, there has been limited application of the qPCR directly in food samples for the detection and quantification of *Campylobacter*. In the studies conducted so far, two important observations have been made. First, an underestimation of the *Campylobacter* prevalence in the food samples can result from the sole application of culture-dependent methods; that is, when both culture-dependent and culture-independent methods are applied in parallel, there are a higher percentage of samples that result positive by the latter as compared to the former. Second, a higher prevalence is determined in the samples without enrichment; this observation has been made also by the culture-dependent methods and can be due to the presence of stressed or injured cells that are not able to propagate in the selective medium used for the enrichment. Further application of the qPCR in food and environmental samples that will provide quantitative data of prevalence of *Campylobacter* and that can be used for quantitative risk assessment is urgently needed. In order to obtain robust quantitative data regarding *Campylobacter* prevalence in foods, standardized and validated procedures have to be developed and adopted. The lack of standardized procedures regarding type of sample, employment of enrichment broth and relative details (type of broth and time and temperature of enrichment), DNA (and/or RNA) extraction and qPCR amplification, is currently hindering efforts of determining the true prevalence of *Campylobacter* spp. in food samples, particularly in poultry.

Conclusions

In order to perform quantitative risk assessment, tools must be available that can accurately determine the *Campylobacter* prevalence in food and determine the contamination level. At present, *Campylobacter* is the leading cause of human gastroenteritis in developed countries. The advancement achieved in just a few years regarding molecular identification and typing of *Campylobacter* has been important in determining the role of poultry meat in the transmission of disease to humans. Although it is widely recognized that the main risk factor that leads to *Campylobacter* infection is manipulation and consumption of poultry meat products, available microbiological data regarding prevalence and contamination load do not allow for a valid risk assessment. Improved and standardized application of culture-independent methods will permit accurate quantification of *Campylobacter* in foods and will allow a quantitative estimation of *Campylobacter* risk related to consumption of various foodstuffs. Such estimation can also be used for proposing preventive measures in the food chain.

Cancer: Diet in Cancer Prevention

PA Tsuji, SE Galinn, and J Hartman, Towson University, Towson, MD, USA

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Cancer remains the second most common cause of mortality and accounts for about 20% of all deaths in industrialized countries. Carcinogenesis, the process from initiation with a mutagen through promotion and tumor formation, usually occurs over a long period of time. Patterns of cancer rates in various countries point to environmental influences including diet as important contributors to both initiation and prevention of cancer. The unifying characteristics among cancer cells include their ability for uncontrolled growth and replication, the avoidance of apoptotic signals, and their capacity to increase invasiveness and angiogenesis. Nutrients that may interfere with any one or more of these aspects are viewed as potentially anticarcinogenic or chemopreventive. Given the complex nature of the collection of diseases we call cancer, it is unlikely that a single compound will be identified as the ultimate chemopreventive agent. Rather, bioactive nutrients may interact synergistically or antagonistically with other food components and influence the expression or activity of more than one gene product. Thus, a very complex nutrient–gene environment is created, potentially leading to an effective chemopreventive strategy. Most of the supporting data for chemoprevention with dietary nutrients are derived from preclinical cell culture (*in vitro*) or animal model (*in vivo*) experiments, studying a single nutrient in relation to selected gene products in carcinogenesis. Epidemiological human studies are usually case–control or prospective cohort studies, frequently relying on food frequency questionnaires and extrapolation of nutrient content from databases. Randomized clinical trials with single nutrients or single foods have mostly shown conflicting results. This article principally deals with the role of diet in the prevention of cancer rather than dietary components implicated in contributing to tumorigenesis (e.g., aflatoxin and alcohol) or treatment of established cancers. It also should be noted that often several dietary factors are associated with effects on carcinogenesis at more than one organ site. Finally, the importance of a balanced diet in health and cancer prevention needs to be stressed. Supplementation with supranutritional doses of any given nutrient may lead to potentially harmful effects, especially in individuals who are already nutrient-replete or who are oxidatively stressed (e.g., smokers). To this day, neither the American Institute for Cancer Research (AICR) nor the National Institutes of Health (NIH) recommends dietary supplements in supranutritional levels for the general population as a cancer-preventive strategy.

Maintaining a Healthy Weight

Body fatness, or obesity, and a progressively sedentary lifestyle appear to be an ever-increasing problem in many developed countries. Rates of overweight and obesity are now more prevalent than they have ever been. Correlation with hundreds of cohort and case–control studies has provided convincing evidence that body fatness is associated with a host of diseases and increases risk for developing esophageal, pancreatic, colorectal, breast, endometrial, and renal cancers. Frequently, the correlation between caloric restriction and cancer prevention relates to decreased inflammation – a prime contributor to tumor promotion. Therefore, maintenance of a healthy weight throughout a person's life is regarded as one of the most important ways to protect against cancer. Several phytochemicals, including the polyphenols curcumin, daidzein, epigallocatechin gallate, genistein, and resveratrol, have been reported to exhibit potential effects against adiposity and thus obesity and against obesity-related cancers. Their cancer-preventive effects are further described in the succeeding text.

Dietary Fiber

The definition of fiber appears to vary depending on the organization and manufacturer. Both naturally derived and synthetically manufactured dietary fibers are now ubiquitously present in the food market and mostly present a collective term to describe a spectrum of nondigestible, unrefined carbohydrates, including nonstarch polysaccharides, oligosaccharides, lignin, and analogous polysaccharides. Legumes, minimally processed cereals, and various fruits and vegetables are considered to be good sources of natural fiber, and a vast number of dietary supplements have flooded the market with soluble/insoluble fiber products.

Experimental animal studies consistently have suggested that dietary fiber plays an important role in cancer prevention. In epidemiological studies, the protective benefits of fiber intake in terms of cancer prevention remain somewhat controversial. For colorectal cancers, the evidence appears stronger. A recent meta-analysis of case–control and cohort studies, which included 20 trials involving 10 948 subjects with colorectal adenoma, supported the hypothesis that high dietary fiber intake is associated inversely with colorectal adenoma risk. Furthermore, in the recent 11-year follow-up analyses of the European Prospective Investigation into Cancer and Nutrition (EPIC) study, inverse associations of total dietary fiber intake with colorectal cancer regardless of age, sex, or anthropometric and lifestyle variables were described. The beneficial role of dietary fiber in the reduction of colon cancer risk may relate to the ability of fiber to reduce the contact time of carcinogens within the intestinal lumen and to promote healthy intestinal microbiota, thus enhancing bile acid deconjugation and production of short-chain fatty acids and modulating inflammatory bioactive substances. Intestinal bacteria ferment fiber into short-chain fatty acids such as butyrate, which has been shown to function as a histone deacetylase inhibitor, thus

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00108-2

epigenetically regulating gene expression to inhibit cell proliferation, induce apoptosis, and therefore suppress tumorigenesis. For other types of cancer, the evidence remains controversial. However, during the 11.6-year follow-up of the 825 men newly diagnosed with prostate cancer in a population-based prospective study in 43 435 Japanese men, total fiber and insoluble fiber intake were associated with a decreased risk of advanced cancers. These results suggested that consumption of dietary fiber was associated with a decreased risk of prostate cancer.

Inorganic Nutrients

Among the micronutrients, trace minerals are inorganic substances that are frequently essential components of enzymes and other proteins. Specifically, the trace mineral selenium has been implicated in cancer prevention. Selenium, which is found in the active site of selenocysteine, the twenty-first amino acid, is incorporated into selenium-containing proteins (selenoproteins). Selenoproteins appear to be the primary responsible connection in selenium's role as a cancer chemopreventive agent. Whereas animal models convincingly demonstrated beneficial effects of selenium supplementation, the evidence from human clinical cancer prevention trials remains controversial. Early trials in populations with relatively low levels of serum selenium demonstrated decreased incidence of prostate, colon, and lung cancers with dietary selenium supplementation. However, the 2008 Selenium and Vitamin E Cancer Prevention Trial (SELECT), which investigated prostate cancer incidence in a selenium-replete population of over 35 000 men, found no positive health benefits. Considering the recent evidence that certain selenoproteins not only prevent but also can promote cancer, it may not be surprising that the 2014 follow-up analyses of SELECT found that those men who started the trial with a high selenium baseline, compared with those with low levels, increased their risk of developing high-grade prostate cancer twofold. The AICR and the NIH currently do not recommend dietary selenium supplementation for cancer prevention.

Phytochemicals

Phytochemicals include tens of thousands of nutrients and secondary plant metabolites, and many are involved in the plant's defense against aggression by pathogens or ultraviolet radiation; some serve as pigments. Upon consumption of vegetables, herbs, seeds, nuts, and fruits, a diverse range of these nutritive and nonnutritive and potentially pharmacologically active phytochemicals are ingested. Mechanistically, phytochemicals may interfere with the cancer process at various stages and through diverse modes of action. Additionally, many of these phytochemicals lack toxicity, making them potential agents for cancer prevention.

Phytochemicals may help protect against lipid peroxidation through their antioxidative abilities, where free radicals are prevented from removing electrons from membrane lipids, thus averting cellular damage. More intriguingly, *in vitro* and *in vivo* studies have shown many phytochemicals to prevent environmental mutagens, to which we are principally exposed through the food and water we consume, from binding to DNA, thus inhibiting cancer initiation. This may be accomplished by suppression of either expression or catalytic activity of carcinogen-activating enzymes, also known as phase I enzymes, such as the cytochrome P450 (CYP) enzymes and epoxide hydrolases. Without endogenous activation, the ingested exogenous carcinogen is impeded from binding to DNA, thus preventing potential mutations. The chemopreventive process via the reduction of phase I enzyme activity is aided by stimulus-induced activation or increased expression of phase II enzymes, which include various isoforms of glutathione *S*-transferases (GST), uridine 5′-diphosphoglucuronosyltransferase (UDP-glucuronosyltransferase, UGT), NAD(P)H dehydrogenase (quinone)-1 (NQO1), sulfotransferases (SULT), *N*-acetyltransferases (NAT), and methyltransferases (e.g., *S*-methyl transferase and catechol *O*-methyl transferase, COMT). These phase II enzymes attach polar groups to the CYP-activated carcinogen to enable efflux and subsequent excretion of the potentially harmful molecule, and risk of cancer initiation will have been reduced. It should be noted that human genetic polymorphisms exist for several phase II enzymes, in which case phytochemicals may have increased or decreased effects on the expression or activity of these enzymes.

Several phytochemicals also have been shown to interfere with tumor promotion, inhibiting the survival and expansion of established cancer cells. The suppression of cell proliferation and induction of apoptosis has been shown for a variety of dietary compounds. Induction of cell cycle arrest through upregulation of the tumor suppressor P53 or inhibition of signaling pathways involving the oncogenes Akt and Ras may result in decreased cell proliferation, thus restricting tumor growth. Tumor progression and invasiveness may be inhibited by phytochemical-induced inhibition of enzymes involved in the regulation of inflammation, such as cyclooxygenase-2 (COX-2), or those that regulate angiogenesis, the process by which new blood vessels are formed to provide nutrients to the growing tumor, such as the vascular endothelial growth factor (VEGF). Lastly, phytochemicals and other exogenous compounds have been shown to elicit epigenetic alterations, including DNA (de)methylation and histone (de)acetylation, impacting microRNA expression, all of which influences gene expression. The epigenetic mechanisms of many dietary components are not well understood and are the subject of intense investigations.

Vitamins

Dietary vitamins are important to consider in cancer prevention because of their ability to stop reactive oxygen species (ROS) and reactive nitrogen species (RNS) by accepting electrons from free radicals thus neutralizing their damaging effects on polyunsaturated fatty acids, proteins, carbohydrates, and DNA. Therefore, dietary antioxidative vitamins have the capability of counteracting harmful effects of otherwise carcinogenic chemicals. Case–control studies have frequently demonstrated that increased consumption of foods correlating

with increased vitamin consumption results in decreased cancer incidence.

Vitamin A and Carotenoids

Vitamin A is fat-soluble and is found in preformed and provitamin forms. Preformed vitamin A, which includes retinol and related compounds, is acquired from animal sources, whereas provitamin A, such as β-carotene and related carotenoids, is acquired from plant sources; both forms of vitamin A have antioxidant properties and thus may contribute to free radical scavenging. Because vitamin A is important for cell-mediated immunity and humoral immunity, a vitamin A deficiency may contribute to cancer susceptibility. Retinoids and other vitamin A species have been shown to have cancer-preventive properties *in vitro*, because of their influence on epithelial proliferation and differentiation. However, among the various human clinical trials, greater exposure to retinol was not associated with decreased prostate cancer risk and in some cases appeared to modestly increase the risk of cancer.

Carotenoids' main function in plants appears to be as accessory photopigments, thus providing fruits and vegetables their red and yellow colors. Observational studies in humans previously found an inverse correlation with carotenoid intake and cancer risk. Of the many carotenoids, β-carotene and lycopene have received the most research interest. A 2001 study examining serum β-carotene levels and breast cancer risk in women found an inverse association. However, clinical cancer prevention trials have been unable to support these observations. The Physicians' Health Study found no effect of β-carotene on lung cancer, and in two other major clinical trials, high doses of β-carotene showed a significant increase in risk of developing lung cancer in study participants, who were current or former smokers. While the relationship between vitamin A and cancer prevention in nonsmokers remains unclear, the lack of consistency among the various cancer prevention trials with β-carotene led the AICR and NIH currently to not recommend β-carotene supplementation to those who are current or former smokers or those who have been exposed to asbestos.

Lycopene, a carotenoid found in diets rich in tomatoes and tomato products, is a very powerful antioxidant, with about twice the antioxidant activity of β-carotene. In various cell-based and animal studies, lycopene targeted antioxidant/detoxification enzymes and the Ras signaling pathway. Among the various observational studies in humans, some reported that consumption of tomato products appeared to lower risk of certain types of cancers, including prostate cancer, and lycopene preferentially accumulates in the prostate tissue. Because tomato products also contain a variety of minerals, vitamins, and other phytochemicals, it was unclear whether the beneficial effects were due to lycopene itself. This was further put into question when experimental studies demonstrated that rats that consumed tomato powder had a much lower cancer risk, compared with rats receiving lycopene supplements. Several human case–control studies using lycopene supplements gave conflicting results: whereas some studies indicated a protective effect against prostate cancer, other studies found little to no effects. The association between lycopene and prostate cancer is rather complex, and a 2006 study suggested that the association between lycopene and prostate cancer may be modified not only by other dietary antioxidants but also quite possibly by the gene encoding for the DNA repair protein XRCC1. Even though there appears to be insufficient evidence to support lycopene as a (prostate) cancer-preventive agent, increased consumption of tomato products as part of a healthy diet may be beneficial.

Vitamin B Complex

The B vitamins are a group of eight water-soluble vitamins, which are important as parts of coenzymes. As such, they are essential for cell and organismal growth and development and other physiological functions. Vitamin B_1 (thiamine), vitamin B_2 (riboflavin), vitamin B_3 (niacin), vitamin B_5 (pantothenic acid), vitamin B_6 (pyridoxine), and vitamin B_7 (biotin) have not been shown to act as cancer-preventive agents. Vitamin B_{12} (cobalamin) is required for proper red blood cell formation, neurological function, and also DNA synthesis. Vitamin B_{12} has been shown to help increase genetic stability and DNA repair and, like vitamin B_6, is involved in homocysteine metabolism. In terms of cancer prevention, very few randomized clinical prevention trials have been completed with individual B vitamins, and there appeared insufficient scientific evidence to support supplementation with B vitamins. However, in the recently (2013) analyzed data from the Women's Health Initiative Observational Study, vitamins B_2 and B_6 intakes from diet and supplements were associated with a decreased risk of colorectal cancer in postmenopausal women. New cross-sectional case–control and intervention trials with vitamin B_6 in colorectal and other cancers are currently underway.

Folate (vitamin B_9) is the generic term utilized for both the naturally occurring folate in food and folic acid, which describes the oxidized monoglutamate form that is used in dietary supplements and fortified foods. Much of the supplementation has focussed on folic acid's hitherto unexplained ability to reduce the risk of fetal neural tube defects. Potentially important for cancer prevention, the conversions of homocysteine to methionine in the synthesis of the methyl donor *S*-adenosyl methionine and the methylation of deoxyuridylate to thymidylate in DNA synthesis are folate-dependent. Thus, epigenetic regulation of gene expression through DNA methylation using folate supplementation has been proposed. A number of epidemiological studies suggested that folate might inhibit development of cancers of the urogenital system and of the gastrointestinal tract. A number of clinical trials examined the effects of folic acid supplementation on colorectal cancer risk. However, the results were controversial and did not support the early findings. In at least one study, the risk of adenoma development increased with folic acid supplementation and secondary analyses demonstrated an increased risk of prostate cancer. A prospective study in 2011, however, found an inverse association between folate intake and risk of the early pre-adenoma stages of colorectal cancer. Thus, folate, like some other nutrients (e.g., selenium), may play a dual role in cancer, whereas dosage and timing of exposure may determine whether this nutrient will prevent or promote cancer. Furthermore, common ethnic differences in genetic variations (polymorphisms) in the gene encoding for the enzyme methylene tetrahydrofolate reductase exist,

influencing its enzymatic activity and subsequent individual dietary folate needs. For those reasons, the NIH strongly caution against consumption of high doses of folic acid.

Vitamin C

Vitamin C, L-ascorbic acid, is an essential nutrient for humans and other primates and, beyond its role in collagen synthesis, is a very strong, water-soluble antioxidant. The molecule donates electrons to intra- and extracellular free radicals, therefore being oxidized to dehydroascorbic acid. Dehydroascorbic acid is then converted back into ascorbic acid, and the process can be repeated. Epidemiological studies have suggested that consumption of foods with high vitamin C content is inversely correlated with most types of cancers. However, even though vitamin C is known to limit formation of carcinogens, evidence from human clinical trials and prospective cohort studies has been inconsistent. Most clinical prevention trials have failed to establish a link between vitamin C, alone or in combination with other micronutrients, and cancer incidence or mortality. While it remains unclear whether vitamin C may be cancer-preventive, the tight regulation of plasma and tissue vitamin C levels in humans may not allow an increase above saturation levels, even with supplementation.

Vitamin D

Vitamin D is produced endogenously when skin epithelial cells synthesize this lipophilic vitamin in response to ultraviolet rays from sun exposure. Additional, albeit small, quantities may be consumed through dietary sources such as oily fish, meat, egg yolks, and fortified products such as milk or margarine. Because of moderately successful sunscreen/protection strategies to reduce UV-related skin cancer incidence, vitamin D synthesis may be declining. Calcitriol is the physiologically active vitamin D metabolite (1,25-dihydroxyvitamin D). Vitamin D promotes calcium absorption, thus enabling normal bone mineralization, and plays important roles in the reduction of inflammation and modulation of immune function. Epidemiological and many preclinical studies indicated that vitamin D played a role in the prevention of colorectal, prostate, and breast cancers. *In vitro* evidence suggested that vitamin D inhibits genes involved in apoptosis. Conversely, vitamin D inadequacy was thought to increase cancer risk. However, clinical prevention studies remain inconclusive, partially because vitamin D intake and serum 1,25-dihydroxyvitamin D concentrations may not correlate. Therefore, while vitamin D is an essential nutrient and important for general health, studies do not support excessive vitamin D intake for the purpose of cancer prevention.

Vitamin E

There are eight naturally occurring forms of vitamin E found in plants: α-, β-, γ-, and δ-tocopherol and α-, β-, γ-, and δ-tocotrienol; α-tocopherol (vitamin E) is the biologically active form. Vitamin E has distinctive antioxidative properties and plays an important role in the protection of lipoproteins from free radical damage. Furthermore, vitamin E enhances the immune system and plays a role in anti-inflammatory processes. Several clinical trials have investigated whether vitamin E intake or supplementation may benefit in the prevention of colorectal, prostate, or other forms of cancer. Some early studies found promising results, indicating that vitamin E supplementation was associated with decreased risk of population-specific cancer mortality. Many subsequent studies, however, showed no association between vitamin E intake and prostate or colorectal cancer risk, and one study in 2004 pointed to vitamin E plus β-carotene supplementation increasing mortality. Recently, the study SELECT, which investigated the supplementation of selenium and/or vitamin E in men, found a statistically significant twofold increase in high-grade prostate cancer incidence in men who had low baseline levels of selenium and took the vitamin E supplement. Thus, insufficient data exist to support vitamin E supplementation as a cancer-preventive agent, and the NIH caution against daily use of large doses of vitamin E (400 IU), because of a potential increased risk of cancer.

Vitamin K

Vitamin K describes a group of related, essential nutrients: vitamins K1, K2, and K3. Acute vitamin K deficiency is life-threatening due to the liver's requirement of vitamin K for synthesis of coagulation factors to promote blood clotting and to prevent abnormal bleeding. Vitamin K can be obtained through consumption of foods, including green leafy vegetables, okra, asparagus, prunes, and avocado. Importantly, humans also obtain vitamin K from their intestinal microbiota. Preclinical investigations suggested that vitamin K inhibited proliferation and induced apoptosis in liver cancer cells. Since then, some small human clinical prevention trials indicated that vitamin K supplementation lowered the risk of developing liver cancer among Japanese women with hepatitis C-induced cirrhosis. However, the results were not statistically significant. Another clinical trial in 2006 suggested that a subtype of the vitamin K2 group might reduce recurrence of liver cancer after surgery. Even though follow-up studies failed to show an effect, vitamin K is now being tested along with other drugs after liver cancer surgery. Available scientific evidence thus far does not support the use of vitamin K supplements for primary cancer prevention.

Glucosinolates

Glucosinolates, which groups the bioactive isothiocyanates, thiocyanates, and indoles, are found in the plant family Brassicaceae, which includes vegetables such as broccoli, cabbage, and mustard. Epidemiological, preclinical, and clinical studies have demonstrated that dietary glucosinolates in amounts achievable in a normal healthy diet help in slowing down carcinogenesis or risk of cancer without toxic effects. The most intensely studied glucosinolate in cancer prevention, by far, is sulforaphane, the bioactive metabolite of glucoraphanin, a compound found in high concentrations in broccoli sprouts. Sulforaphane is a very potent inducer of the transcription factor nuclear factor (erythroid-derived 2)-like-2 (NFE2L2 or Nrf2) and thus increases expression of the phase II enzyme NQO1. Administration of high glucosinolate

concentration containing beverages has very eloquently been demonstrated to decrease the amount of carcinogen-DNA-adducts, and the cancer preventive and other health effects of glucosinolates are covered in great detail elsewhere in this encyclopedia.

Lectins

The plant secondary metabolites chlorophyll, phthalides, and phytic acid (including inositol phosphates) make up the lectins, which are commonly found in legumes and grain products. Phytic acid, in its bioavailable inositol form, has been shown to be a beneficial cancer-preventive agent in cell and animal studies, especially in breast, prostate, and colorectal cancers. Several human clinical intervention trials with inositol are currently ongoing or have recently been completed and are awaiting analysis. In animal models, chlorophyll inhibited carcinogen uptake and tumorigenesis. Few randomized, clinical trials with lectins have been conducted. Even though chlorophyllin (commercially available mixture of synthetic chlorophyll derivatives) has been shown to inhibit aflatoxin–DNA adduct formation in Chinese, to date, there is not enough evidence to suggest effectiveness in cancer prevention with chlorophyll.

Omega-3 Fatty Acids

In epidemiological studies, consumption of fish and fish products, including fish oil supplements, has been associated with decreased cardiovascular risk and cancer incidence. The health benefits of omega-3 versus omega-6 fatty acids were based on the evidence that omega-6 fatty acids, which predominate in the typical US diet, may stimulate tumor growth through prostaglandin-E2 synthesis, whereas omega-3 fatty acids, particularly eicosapentaenoic acid and docosahexaenoic acid, may suppress tumor formation. However, studies in humans have provided conflicting results. Even though strong evidence exists that omega-3 fatty acids may be helpful in cardiovascular disease, a 2006 meta-analysis of 38 studies conducted over the past 40 years on the effects of omega-3 fatty acids on cancer found no effect overall.

Organosulfurs

The thiol-containing organosulfur compounds of garlic, onion, and some other bulbous plants include diallyl sulfide, diallyl disulfide, and diallyl trisulfide, as well as the dithiole thiones found in cruciferous vegetables such as the cabbages. Among the various beneficial health effects attributed to the organosulfur compounds, antibacterial and anticancer activities have received much attention. Diallyl sulfide increased apoptosis in cancer cell lines and in animal models. Diallyl disulfide and diallyl trisulfide increased expression of phase II enzymes and inhibition of cancer initiation in preclinical models. Only few human clinical trials have been conducted with organosulfur compounds, and a 2006 randomized trial on long-term garlic supplementation showed no beneficial effects on the prevalence of precancerous gastric lesions or on gastric cancer incidence in a Chinese population.

Phytosterols

Plant seeds, nuts, grains, and unrefined vegetable oils and margarine are good sources of phytosterols. Because of structural similarity, plant phytosterols can inhibit uptake of dietary cholesterol. Observational data in humans suggested that consumption of dietary phytosterols correlates with a reduction in colon, breast, and prostate cancer risk. Phytosterols appear to interfere with tumor promotion and progression through influencing hormone-dependent growth of endocrine tumors, slowing of cell cycle progression, and boosting of immune recognition of cancer cells. For example, β-sitosterol aided in cell cycle arrest and prevented cell proliferation. However, even though some epidemiological studies have inferred that higher intakes of plant foods containing phytosterols were associated with a decreased risk of stomach and breast cancers, it remains to be elucidated whether phytosterols were the active components and whether these potential cancer-preventive activities can be replicated in humans.

Polyphenols

Polyphenols, which are found in abundance in spices, herbs, seeds, nuts, vegetables, berries, many beverages, and fruits, are the most abundant antioxidants in the human diet. Structurally, they are defined by the presence of large multiples of phenol rings, many of which contain various active groups, such as hydroxyl or meth(ox)yl groups. Much like the endogenous radical scavengers (e.g., glutathione), polyphenols donate one of their electrons to the ROS, leading to neutralization and efflux in a nontoxic form. In addition to being direct antioxidants, polyphenols have also been shown to be indirect antioxidants and to induce antioxidant enzymes, including glutathione peroxidase, catalase, and superoxide dismutase. Current experimental evidence strongly supports a contribution of polyphenols to the prevention of cancers, and polyphenols reverse epigenetic alterations and inflammation. However, because doses much higher than achievable in the human diet are usually utilized in these models, uncertainty persists regarding applicability to cancer prevention in humans. Within the structurally diverse polyphenols, molecules are grouped into classes primarily based on the number of phenol rings.

Flavonoids

Flavonoids are benzo-*c*-pyrone derivatives and thus share the common structure consisting of two aromatic benzene rings, which are separated by an oxygen-containing pyran ring. Based on the degree of oxidation of the pyran ring and their position of functional groups, the over 5000 naturally occurring flavonoids and their glucosides are divided into six subclasses: flavonols, flavones, isoflavones, flavanones, anthocyanidins, and flavanols. A seventh subclass, the proanthocyanidins, which consists of polymers of flavonol units, is often added.

Flavonoids are found in a variety of plants. In cell and animal models, many individual flavonoids have been shown to affect a variety of biological activities, many of which may interfere with carcinogenesis. Several epidemiological studies have supported evidence for an inverse relationship between flavonoid intake and cancer risk, but human studies remain difficult to interpret. This may be partially explained by the low oral bioavailability of many flavonoids and the significant inter-individual variability in metabolic enzyme expression and activity as a result of genetic and environmental factors.

Flavones and their 3-hydroxy derivatives (flavonols) comprise the largest subgroup among all polyphenols. Their many functional groups, including glycosides, methoxides, and other acylated products, can attach to their three rings. The most common flavonol aglycones are quercetin and kaempferol, and they both have an estimated 279 and 347 different glycosidic combinations, respectively. In human cancer cells, quercetin, kaempferol, and many methoxylated flavones have been shown to induce apoptosis and inhibit cell proliferation and/or angiogenesis. The flavones chrysin and galangin inhibit the activity of the enzyme aromatase, thus resulting in anti-estrogenic effects, important in hormone-related cancers. Luteolin, a flavonoid found in parsley, inhibited COX-2 and VEGF expression, thus preventing tumor progression and angiogenesis in preclinical models. However, a 2009 human prospective cohort study with over 38 000 women, which assessed intakes of quercetin, kaempferol, myricetin, apigenin, and luteolin with food frequency questionnaires, has not supported a major role of these flavonoids in cancer prevention.

Isoflavones are mostly found in the leguminous (beans) family of plants. Genistein and daidzin are almost exclusively found in soybeans, and high consumption of soy products is associated with decreased breast cancer risk in Asian populations. Isoflavones are able to bind to the mammalian estrogen receptors and thus are often referred to as phytoestrogens, even though human estrogen still has a 1000-fold higher effect. Similar to some flavones, genistein inhibits aromatase activity. Genistein can also aid in the induction of phase II enzymes, thus preventing cancer initiation. Whereas animal studies provided convincing evidence for a role of genistein and daidzin in cancer prevention, human studies have been unable to replicate these findings. This may be partially explained by the differential isoflavone metabolism in rodents and humans, but not enough human studies have been conducted to verify.

The polymers of proanthocyanidins are responsible for the astringent characteristic of many fruits and beverages. Anthocyanidins, primarily responsible for the red, blue, and purple pigments of most flowers, fruits, and vegetables, mainly exist in glycosidic forms, which are commonly referred to as anthocyanins. Even though anthocyanidins and anthocyanins have been effective in preclinical cancer prevention studies, human trials have not correlated intake of specific anthocyanidins and anthocyanins with decreased cancer incidence.

Lignans

Our intestinal microbiota metabolize plant-derived lignan precursors into enterolignans, enterodiol, and enterolactone. The latter two are classified as phytoestrogens because of their ability to mimic some of the effects of estrogens. Therefore, research on lignans in cancer prevention has primarily focussed on hormone-associated cancers, such as breast, endometrial, ovarian, and prostate cancers. Studies have reported conflicting results. Several prospective cohort studies found no association between lignan intake and breast or other cancers. In contrast, a 2009 meta-analysis limited to postmenopausal women showed a 15% reduction in risk of breast cancer with high lignan intake. In a 2013 data analysis of a multisite phase II randomized controlled clinical trial, 147 patients with prostate cancer who participated in a presurgical trial of flaxseed supplementation were investigated. Significant inverse correlations between total flaxseed-derived urinary lignan metabolites and the nuclear cellular proliferation marker, Ki67, in tumor tissue were observed. Furthermore, enterolignans hindered cancer cell proliferation via VEGF-associated pathways. Analyses of the EPIC study in 2014 showed significant inverse associations with lignans and bladder cancer risk. However, at present, it is not clear whether high intakes of plant lignans offered significant protective effects against any cancers or if other phytochemicals present in the diet were involved.

Stilbenes

Many stilbenes, including resveratrol, are found in red wine and other dark berries and possess anticancer activity in animal and *in vitro* models. Resveratrol has been shown to inhibit the proliferation of many different human cancer cell lines. Although absorbed by enterocytes, resveratrol has limited bioavailability and is quickly metabolized. Thus, many of the early studies investigating resveratrol in the diet failed to find any correlation to cancer risk. Recently, smaller human studies with very large daily doses of supplemented resveratrol have found inverse correlations to breast and colon cancer incidence, whereas resveratrol levels achieved with a normal Western diet have not been associated with cancer prevention.

Other Important Polyphenols

Curcumin, a strong antioxidant from turmeric, prevented weight gain (obesity) and cancer in animal models. The molecular mechanism in cancer prevention remains to be elucidated but likely involves induction of apoptosis in cancer cells and inhibition of cell proliferation through upregulation of the tumor suppressor P53. Because of the poor intestinal absorption, new delivery strategies are being developed to improve curcumin's bioavailability.

Ellagic acid and its derivatives, which are found in berries and nuts, promoted apoptosis and cell cycle arrest in bladder, breast, cervical, pancreatic, and prostate cancer cell lines, as well as those of the aerodigestive tract. This polyphenol also exerts antiangiogenesis effects in breast cancer cells. Ellagic acid appears to accumulate in epithelial cells and has been shown to irreversibly bind to cellular DNA and protein. In animal models, ellagic acid was shown to inhibit the incidence of chemically induced small intestinal adenocarcinomas and to reduce intestinal inflammation. While ellagic acid has been suggested as support in chemotherapy-induced toxicity, clinical trials with the single compound have not been conducted thus far.

Rosmarinic acid, which is a dimer of caffeic acid, showed anti-inflammatory, antioxidant, and antimutagenic characteristics. It inhibited angiogenesis through inhibition of VEGF and interleukin-8 *in vitro* and significantly reduced the levels of ROS in endothelial cells. Whereas studies with rosmarinic acid have been successful for allergy studies, the effect of this compound in cancer prevention in humans remains to be investigated.

Capsaicinoids, polyphenolic amides found in chili peppers, induced apoptosis and inhibited CYP 3A4 and 3A5 in cell and animal models. Information regarding the metabolism and bioavailability of capsaicin in different tissues and organs and its potential cancer-preventive effects in humans is limited. A prospective study investigating capsaicin as a chemopreventive agent for prostate cancer is currently planned.

Future Directions

There is little doubt that diet influences carcinogenesis and can be employed as a cancer-preventive strategy. Investigations into individual genotypes of nutrient- and carcinogen-metabolizing genes will become essential in order to understand and measure outcomes. The complex gene–nutrient interactions will need to be further investigated before individuals or diseases can be identified that will benefit from intervention with specific phytochemicals in cancer prevention. Still, a pill will unlikely be able to offset an unhealthy lifestyle or replace the established benefits of a healthful lifestyle with a primarily plant-based diet.

Candies and Sweets: Sugar and Chocolate Confectionery

MA Godshall, Consultant, New Orleans, LA, USA

© 2016 Elsevier Ltd. All rights reserved.

Candies and Sweets: Sugar and Chocolate Confectionery

Candies and sweets, collectively known as confections, are defined as foods whose main characteristic is sweetness. It is typically understood that a candy is a rather small, defined food item. Confectionery products are divided into two categories:

Sugar confectionery: Sugar is the main ingredient.
Chocolate confectionery: Chocolate is the characterizing ingredient, either as entirely made up of chocolate or as a coating or inclusion.

Patterns of Consumption

Globally, sugar confectionery accounts for about 39% of candy consumption and chocolate confectionery about 61%. This ratio can vary widely among countries. Confectionery consumption is increasing in countries with a growing middle class, such as Brazil and India, and in countries with traditionally low sugar consumption, such as China and Japan. As populations become more prosperous, chocolate consumption tends to increase. In more developed countries, confectionery consumption shows little growth from year to year and has declined in some nations.

Table 1 shows candy consumption for a few countries on a yearly and daily basis. Northern and Western European countries are the highest consumers of chocolate confectionery in the world.

In 2013, the global confectionery market was estimated to be worth $171 billion, with chocolate representing $110 billion. US candy sales for the same period were $33.9 billion.

In Asia and Latin America, sugar confectionery tends to predominate. In parts of Asia, less sweet confections are preferred. In Japan, candy must be aesthetically pleasing. Kit Kat bars are wildly popular in Japan, and there is a tradition of constantly introducing new and unusual flavors, such as wasabi, green tea, soy sauce, miso, and sweet potato. Throughout Asia, gummy candies with fruit flavors are preferred.

The Nordic countries are among the top global consumers of confectionery. Sweden has a high consumption of sugar confectionery and Switzerland has the highest chocolate consumption.

In a number of countries (India, China, and Mexico), candies are thought of as mainly for gift-giving occasions or for children. With cultural changes caused by globalization, candy consumption begins to be considered for everyday snacking. Chocolate was traditionally considered an expensive luxury, but with smaller sizes and lower prices, consumption has increased rapidly in Asia and Latin America.

Large spikes in confectionery consumption occur during Easter, Halloween, and Valentine's Day, when confectionary is traditionally gifted. Each holiday has its own set of traditional treats.

Ingredients

Sugar and Other Nutritive Sweeteners

The single most important ingredient in confectionery is sugar. Along with sweetness, sugar provides structure, bulk, and preservative properties in candies. Sugar confectionery is made from a mixture of sucrose and glucose syrup in various proportions. Chocolate production uses only sucrose. Molasses, brown sugar, and honey are used for specific flavor effects in various confections. Demerara sugar is a special type of golden-brown sugar made from cane juice used in some high-cocoa-content chocolate bars.

Sugar, chemically known as sucrose, is a disaccharide made up of one molecule of glucose and one of fructose. Unlike most other monosaccharides and disaccharides, sucrose is a non-reducing sugar, which confers a high degree of stability, so it can be cooked to a high temperature without breaking down or undergoing browning reactions. Under temperate storage conditions, sucrose does not pick up moisture and can remain stable for years. Sucrose sets the standard for sweetness and functionality in candy making, and all other sweeteners are compared with it.

The two commercial sources of sucrose are cane sugar and beet sugar, with cane sugar representing 78–80% of world sugar production. Production methods differ between cane sugar and beet sugar, but the sucrose from each is chemically identical.

Sugar refineries produce several types of sugars:

- Granulated white sugars, with a range of defined crystal sizes obtained by screening
- Confectioners' sugars of various particle sizes and cornstarch content
- Brown sugars of various grades – light, medium, dark, agglomerated, and liquid
- Liquid sugars of various concentrations of dissolved sucrose that may contain invert sugar
- Specialty sugars, which have added ingredients or may be colored

Within these categories is a wide range of products. Since there are no standard definitions, the names companies use for the same product can be different. Screened sugars have been sieved to give specific crystal size ranges. The smaller crystals dissolve more readily and are preferred for confectionery. Coarser crystals, called sanding sugar or decorating sugar, can be used for dusting the surface of jellies and other confections to give surface sparkle and a mild crunch. Sugar used in confectionery must be highly refined and of the highest quality.

Confectioners' sugar is produced by pulverizing white sugar and then screening it to 75 or 45 μm size. To prevent caking, 3% cornstarch is added. Some is also available without cornstarch. Confectioners' sugar is recommended for fondant production.

Table 1 Sugar and chocolate confectionery consumption per capita per year and per capita per day

	kg per capita per year			*g per capita per day*		
Country	*Sugar*	*Chocolate*	*Total*	*Sugar*	*Chocolate*	*Total*
Japan	1.73	2.23	3.96	4.74	6.11	10.85
Brazil	1.83	2.16	3.99	5.01	5.92	10.93
France	3.50	6.50	10.00	9.59	17.81	27.40
The United Kingdom	5.26	10.29	15.55	14.41	28.19	42.60
Germany	5.95	11.60	17.55	16.27	31.78	48.05
The United States	6.15	5.46	11.61	16.85	14.96	31.81
Denmark	8.64	7.65	16.29	23.67	20.96	44.63

Invert sugar is a mixture of glucose and fructose produced by acid or enzymatic hydrolysis of liquid sucrose.

Glucose syrup is the other essential ingredient in sugar confectionery production. Its most important function is to control or prevent crystallization in hard candy production; it also provides humectancy, helps maintain texture, and stabilizes the product. Glucose syrups are about 40–50% as sweet as sucrose.

Glucose syrups are produced from cornstarch (the United States) or wheat starch (Europe) by acid or enzymatic hydrolysis, which produces different grades. Standard glucose syrup, also called confectionery syrup, is 42 DE syrup. DE stands for 'dextrose equivalent' and is a measure of the degree of hydrolysis and the amount of reducing sugar present. The two types of 42 DE syrup used in confectionery are glucose syrup and high-maltose syrup.

Labeling sugars

On labels in the United States, the quantity, in grams, of all carbohydrates is listed and then broken out as dietary fiber and 'sugars.' Sugars include all nutritive sweeteners, including corn syrups, sugar, lactose, and brown sugar. The different types of sweeteners are listed separately in the ingredients list.

Sugar-Free Candies: Sugar Alcohols

Candies labeled 'sugar-free' contain sugar alcohols or artificial sweeteners or a combination of both. Sugar alcohols, also known as polyols, are carbohydrates, but they are not sugars. Sugar alcohols include erythritol, xylitol, glycerol (glycerin), hydrogenated starch hydrolysates (HSH; polyglycitol), isomalt (isomaltitol), lactitol, maltitol, mannitol, and sorbitol. Xylitol is about as sweet as sucrose and maltitol about 90% as sweet. The other sugar alcohols are 40–60% as sweet as sucrose. Some sugar alcohols – xylitol, erythritol, and mannitol – have a pronounced cooling effect, similar to mint. Isomalt and maltitol have a less cooling effect. Sugar alcohols are noncariogenic (do not promote tooth decay). They contain 2–3 calories per gram. Erythritol has only 0.2 cal g^{-1}. They do not raise blood glucose, so they are suitable for diabetics. However, they have a laxative effect if consumed in excess.

Other Ingredients

Acidulants provide the tart flavors in sour candies, enhance fruit flavors, and provide preservative properties. Common acidulants include citric acid, potassium citrate, malic acid, fumaric acid, lactic acid, calcium lactate, sodium citrate, tartaric acid, and ascorbic acid. Different acids can be blended to obtain a desired level of sourness and taste duration.

Confectionery fats contribute to the tenderness, structure, and texture in candy. Cocoa butter, the fat in chocolate, is considered the 'gold standard' of confectionery fats. Its sharp melting curve, close to body temperature, allows it to melt in the mouth, and the proper alignment of its fat crystals provides the desirable snap of chocolate when it is broken. Because of its expense, cocoa butter is not used in other types of confectionery; other fats are used instead, including butter and vegetable fats, the most important of which are coconut oil and palm kernel oil, usually in a partially hydrogenated form, designed to have similar properties to cocoa butter. Other fats include partially hydrogenated soybean and cottonseed oils and fully hydrogenated palm kernel oil and coconut oil. The FDA has recently proposed revoking the GRAS (generally recognized as safe) status of partially hydrogenated oils, which presents a challenge to confectioners to find alternatives that provide the same functions in candies. Many hard candies and jelly/gummy candies do not contain any fat.

Dairy: A wide range of dairy products are used in confectionery – fluid whole milk, skim milk, cream, evaporated milk, sweetened condensed milk, evaporated milk, milk protein concentrates, butter, anhydrous milk fat, whey, a range of milk powders, and lactose (milk sugar). Milk is a significant ingredient in milk chocolate, fudge, caramel, toffee, and pralines. Milk used in chocolate must be in dry form, as water will prevent chocolate from flowing properly and ruins its texture.

Emulsifiers have many important functions in confectionery: viscosity reduction, lubrication, control of sugar crystallization, aid in dispersion of ingredients, stabilization of structure, and prevention of sticking. The most widely used emulsifier is lecithin, derived from soy. Commercial lecithin is a mixture of phosphatides and sterols. Other emulsifiers include polyglycerol polyricinoleate, sorbitan esters, polysorbates, mono- and diglycerides of lactic and tartaric acids, sucrose esters, and propylene glycol monoesters. In chocolate confectionery, emulsifiers prevent the separation of cocoa butter from cocoa solids and slow the development of bloom.

Flavors: Sometimes, an ingredient's flavor profile is very complex, with many different chemicals contributing to the odor, such as coffee and chocolate flavors. Sometimes, one chemical characterizes a flavor, for example, benzaldehyde in almonds, eugenol in cloves, and vanillin in vanilla. If only the

characterizing chemical is used, as in less expensive candies, the flavor profile may be one-dimensional; other flavor compounds present, for example, in vanilla extract, round out and add complexity to the flavor.

Some flavors are developed during cooking or roasting. Sugar heated with proteins or bicarbonate will produce an array of pleasant flavors that are described as 'browned,' brown sugar, or caramelized, in a reaction known as the Maillard reaction.

Dairy ingredients provide milky, creamy, and buttery flavors; heating produces cooked cream, browned butter, and butterscotch flavors.

The complex flavor of chocolate is developed through a series of processes, from fermentation of the cocoa beans to roasting the nibs and conching.

Flavors used in confectionery can be artificial or natural or a combination of both and must be able to withstand the candy making process. The FDA maintains a list of flavor compounds that are GRAS. Over 3000 compounds have been listed to date.

Food coloring: The most common colorants used in confectionery are artificial colors that are either oil- or water-soluble. There is a growing trend toward using natural colorants, but these are more expensive and tend to be heat-sensitive and fade.

Fruits are used as inclusions in many candies, the most popular being raisins. Other fruit products used in confectionery include dried fruits, pastes, juice, and juice concentrates.

Glazes, coatings, and polishing agents; *antistick and release agents*: Coatings and glazes improve the appearance and stability of candies, providing gloss, increased shelf life, adhesion of sugar crystals to encapsulate acidulants on the surface of jelly candies, fat barrier, moisture resistance, and antistick properties. The common confectionery glazes are carnauba wax, shellac, beeswax, and gum arabic. Shellac is extracted from the *Laccifer lacca* insect. Carnauba wax is extracted from the leaves of a Brazilian tree, *Copernicia prunifera*. Beeswax is secreted by bees. Gum arabic is used to give chocolates a brilliant shine. A less common coating is made from a corn protein, known as zein, which provides a vegetable-based glaze that competes with shellac.

Gelling agents provide body, texture, and structure to chewy, jelly-type candies. The gelling agents used in candy making are gelatin, pectin, modified starches, and egg albumin (egg whites). Gelatin, derived from cows or pigs, is widely used in gummy candies, fruit jellies, and gumdrops. Egg whites produce a structured foam and are used as a gelling or whipping agent to provide a characteristic flavor and an airy, open texture in marshmallows, nougat, and divinity. Pectin and modified starches are used as vegetable substitutes for gelatin and egg whites. Each gelling agent confers different properties to a candy, and they are often used in combination to achieve desired effects.

Nuts, seeds, and coconut: The tree nuts used in candy making are almonds, pecans, walnuts, hazelnuts, and pistachios, available whole, broken, and finely chopped or as meal, flour, butter, or paste. Peanuts and peanut butter are among the most popular candy ingredients. While peanuts function like tree nuts, they are a legume. Nuts are roasted or pasteurized before use in confectionery for both flavor development and microbiological safety. Seeds used in confectionery include sesame and sunflower. Spice seeds such as fennel, caraway, and anise are used sparingly for flavor. Halva, an ancient confection popular in the Middle East, is made from sesame seed paste. Marzipan is made from almond paste.

Botanically, coconuts (*Cocos nucifera*) are classified as a fruit. The coconut is made up of a fibrous outer husk and a hard inner shell. When immature, coconut water fills the shell; as the coconut matures, the coconut kernel or 'meat' is formed as a pure white layer on the inner surface of the shell. In mature coconuts, the water is absorbed and the meat is about one-half inch thick. This meat is the source of coconut oil. The meat (full fat or partially defatted) is dried and shredded or powdered for use in candies. Coconut candy is very popular in Latin America, where it is known as *cocada*.

Preservatives are used to prevent rancidity in fats and oils. The most common preservative is tert-butylhydroquinone. Safe usage has been set to an upper limit of 0.02% of the fat and oil contents by the FDA and the European Food Safety Authority. Another common preservative is citric acid. Not all commercial confectionery products contain preservatives.

Salt is used to enhance sweet flavor and to round out and blend complex flavors. Sodium levels are required on labels and are in the range of 10–45 mg per serving (equivalent to 25–114 mg of sodium chloride). Salt flavor in confectionery is popular in chocolate and caramel. Salt sprinkled on the surface of chocolate and caramel confections enhances flavor and provides a subtle crunch. Sea salt is often used because it adds a certain cachet to the confection and is perceived to have a different taste than regular salt.

Asian ingredients not found in Western-style confectionery are red bean paste, glutinous rice flour, and rice malt syrup. Red bean paste is made from cooked, mashed, and sweetened adzuki beans. Rice malt is considered to be healthy.

Methods of Production

The production of candy depends on boiling sugar and corn syrup in various proportions in water or milk to specific temperatures, sugar concentrations, and moisture contents and controlling the crystallization of the sugar. Within these constraints, a wide range of confections are produced. The two general categories of sugar confectionery include soft-boiled and hard-boiled (hard candy) production. Soft-boiled confections have a higher moisture content and a creamy texture. Hard candies can be hard and dense, brittle, or crispy and crunchy. The process of crystallizing sugar in soft-boiled confections, such as fudge and pralines, is known as graining. Sugar cooked and solidified to the point where crystals are no longer present, as in brittles and hard candy, is considered to be in a glassy state. Water content in sugar confectionery is typically low, ranging from 1.5% to 6.5%. Hard candies have the lowest moisture content. Candies with higher water content include jellies, marshmallows, fondants, and creams.

In both commercial and home cooking, a series of cooking stages are used as a shorthand way to determine when the sugar mixture has reached the proper temperature and sugar concentration to produce the desired texture. For home cooking, a small dollop of the cooked syrup is dropped into cool water, and the form the quickly cooled syrup takes is an indicator of

Table 2 Temperature ranges for boiling sugar confections

Type of confection	*Cooking stage*	*Degrees C*	*Degrees F*	*Sugar conc %*
Syrup	Thread	101–112	215–233	80
Fudge, pralines, fondant	Soft ball	112–116	234–240	85
Caramels	Firm ball	117–120	242–248	87
Nougat, gummies, divinity, marshmallows	Hard ball	121–131	250–268	92
Taffy, butterscotch	Soft crack	132–143	270–290	95
Lollipops, toffee, brittles, hard candy	Hard crack	149–154	300–310	99

the cooking stage. It is both a visual and tactile test. Table 2 shows the various cooking stages for different types of candies.

Fondant and Frappé

Fondants and frappés form the base of many confectionery recipes. Fondant is prepared from a mixture of sucrose and corn syrup concentrated with cooking to about 86–90% solids and 10–14% moisture and worked until smooth and pliable. It is a soft to firm white mass consisting of microscopic sugar crystals ($\leq$20 μm) dispersed in a saturated sugar solution. The corn syrup helps to keep the fondant hydrated and prevents the crystals from growing larger. Fondant is a confection in its own right such as filling in chocolate candies with or without added flavors and colors, as well as an ingredient in other confections, to add grain to caramels, fudge, and nougats and to make creams.

Frappé is a mixture of egg whites or dry egg albumin and sugar whipped into boiled corn syrup. Frappé is an aerating ingredient added to fondants and creams to lighten their texture and to make nougats. Nougat can be hard or soft. Soft nougat is a common filling in many popular candy bars, such as Three Musketeers, Baby Ruth, and Milky Way.

Panning

Panning is the process in which a confectionery center is coated with a sugar or chocolate shell. The centers are placed in a round, tilted pan, called a dragée pan, with an opening for adding ingredients and air for drying. The pan is filled with syrup and rotated until the centers are evenly coated and the syrup dries. The process can be repeated several times depending on the nature of the desired shell. Sugar is added to aid drying. Soft panning refers to shells that are soft, such as for jelly beans. Hard panning refers to shells that are hard; M&M's and Jordan Almonds are examples. Examples of chocolate panning include malted milk balls, nuts, and raisins.

Another process for coating confectionery with chocolate is called enrobing, which is akin to dipping the center into molten chocolate to cover it. Today, enrobing machines carry out the process.

Aeration of Hard Candies

Aeration is the process of injecting air into a hard-boiled candy mass. It is an important process for lightening the texture of hard candies and providing crispiness. Aeration is done in one of four ways.

Pulling is the most common method. The candy mass is repeatedly stretched and folded to incorporate air bubbles, producing a silky, fibrous appearance. Taffy is an example. Adding bicarbonate releases carbon dioxide, which puffs up the mass, resulting in a porous, low-density, crispy candy. Vacuum expansion produces a low-density honeycomb structure. In the vacuum process, pulled candy pieces are placed under vacuum causing the incorporated air bubbles to expand rapidly. Lastly, there is continuous cooking with air injection, which produces a consistent product.

Production of Chocolate and Chocolate Confectionery

Chocolate production is a complex and lengthy process. After harvesting ripe cocoa pods, the beans and surrounding pulp are removed and fermented, during which time the beans turn brown, the pulp disappears, and flavor precursors develop. The beans are dried, often in the sun but sometimes in kilns, and transported to the factory where chocolate is produced. The dry beans are cleaned, roasted, and winnowed. Roasting continues the development of the chocolate flavor. Winnowing causes the roasted shells to crack, and the nib (kernel) inside is removed. The nibs are ground and liquefied to produce chocolate liquor, which is composed of cocoa solids and cocoa butter.

Cocoa solids and cocoa butter are separated and blended in the required proportions with sugar and milk powder (for milk chocolate). The chocolate mixture is put into a machine called a conche. During the conching process, the chocolate mass is continually ground and scraped from the sides to create a smooth consistent texture and to reduce particles to a size that can no longer be sensed on the tongue. Conching produces frictional heat that helps to develop, blend, and mellow the chocolate flavor.

After conching, chocolate is tempered by repeated, controlled heating and cooling cycles to produce the desired crystal structure of the cocoa butter fat. The fat molecules in cocoa butter can crystallize into six different polymorphic crystal forms: I, II, III, IV, V, and VI. Each form has a different melting point, stability, gloss, and hardness. Only one form, known as V crystal, gives the desired texture, shiny appearance, melt in the mouth sensation, smoothness, snap when broken, and keeping qualities. When cocoa butter is allowed to cool naturally, it produces a mixture of crystal forms and lacks the desired qualities. Proper tempering allows the melted chocolate to cool very slowly, producing the highest proportion of V crystal. Crystal forms I–IV have lower melting points, so a continued process of melting these without melting V crystals, with subsequent slow cooling, eventually produces a majority

of V crystal. Crystal form VI has an even higher melting point; it forms from V crystal after several months of storage at room temperature, which then causes a drop-off in quality and the phenomenon known as fat bloom.

There are many types of chocolate ranging from dark, bittersweet, semisweet, and milk. The United States and other countries have standards of identity for chocolate types. The typical milk chocolate bar contains 25–30% cocoa, while a sweet dark chocolate bar contains 30–40%. In recent years, chocolate bars with up to 85% cocoa content have come on the market due to perceived healthy qualities of dark chocolate.

Ganache is a mixture of heavy cream and semisweet chocolate used as the basis of the truffle center. Couverture chocolate is a very high-quality chocolate with added cocoa butter that is used by professionals for dipping, coating, and molding.

Compound coating or confectionery coating (compound chocolate) is made from a combination of cocoa, vegetable fat, and sweeteners and is used to enrobe some candy bars. Since it contains no cocoa butter, it does not need to be tempered. It is a lower-cost alternative to chocolate coatings. According to FDA regulations, if a product contains no cocoa butter, it cannot be called 'chocolate' on the label but may be referred to as 'chocolate-flavored.'

White chocolate contains no chocolate solids other than cocoa butter. According to the FDA, it must contain at least 20% cocoa butter, at least 14% total milk solids, and no more than 55% nutritive carbohydrate sweeteners. White confectionery chips that are sometimes erroneously referred to as 'white chocolate' have substituted vegetable fats for cocoa butter and are considerably less expensive.

Shelf Life of Confectionery

Shelf life refers to the amount of time a food product will retain its quality prior to consumption. 'Best before' dates on labels are intended to inform the consumer of the shelf life of a product. This label does not indicate that the candy is no longer safe to eat after that date, just that the quality may not be up to standard. Candy quality can deteriorate in several ways. The sugar in a hard-grained confection, such as toffee, can crystallize, making it grainy. Moisture can migrate out of a candy to the surface, making it sticky. In layered candies, there can be bleed-through from one layer to the other, affecting texture, taste, and color.

Chocolate can develop white spots on the surface, known as bloom or fat bloom, which looks like mold but is actually an indication that the cocoa butter crystals are converting to less stable forms and leaching onto the surface of the chocolate. It could mean that the chocolate was not properly tempered, but this also happens when chocolate is stored for a long time. Formation of bloom is speeded up if the chocolate is subjected to fluctuating temperatures. The texture of the chocolate can be adversely affected, becoming dry and crumbly. These are all quality issues; the candy is still safe to eat.

Health Effects

The main health concerns about consuming confectionery are contributing too much added sugar and calories to the diet and the risk of dental caries. Consuming a small amount of candy in a well-balanced diet is acceptable. However, diabetics must watch their sugar intake. For some individuals, there are concerns about allergens and gluten content. Sugar is known to lead to dental caries/cavities when dental hygiene is not optimal.

Candy manufacturers have responded to concerns about obesity by decreasing serving sizes and developing smaller bars and packages, often called 'fun size' or 'snack size.' Miniaturized 'bite size' candy bars are also coming to market. The National Confectioners Association recommends a daily consumption of candy not exceeding 50–100 calories a day. The data in Table 1 show that Americans' average daily consumption is less than 32 g, but this amount exceeds 100 calories.

In attempts to have a more favorable label (known as a 'clean label') and a healthier product, confectioners are exploring ways to reduce or substitute fat, salt, and sugar. In 2012, Nestlé announced it would remove all artificial colors, flavors, and preservatives in all their confectionery products sold in the United Kingdom.

Functional Confectionery and Healthy Ingredients in Nuts and Chocolate

A functional ingredient is one that confers a health benefit when added to a food. Examples include vitamins, probiotics, omega-3, resveratrol, taurine (for energy), and fiber. A small but growing confectionery niche has added functional ingredients, sometimes blurring the boundary between food and food supplements. Consumers are eager to find foods that will solve their health problems.

Nuts and chocolate have been shown to possess numerous healthy constituents. A growing body of research shows that chocolate has many benefits for cardiovascular and cognitive health, due to the presence of antioxidant compounds, such as flavanols, polyphenols, and proanthocyanidins. While polyphenols constitute 12–18% of the dry weight of whole cocoa beans, it has been shown that the various chocolate processing states, such as fermentation, roasting, and alkalization, contribute to some loss of these compounds. Research is still needed on which specific ingredients are the most important and what the effective dose is to achieve a benefit. Nuts are rich in antioxidants and good fats.

Health Effects of Selected Ingredients

Allergens. According to the FDA, major food allergens include milk, eggs, tree nuts, wheat, peanuts, and soybeans, all common ingredients in candies. Allergens must be listed on the label.

Artificial dyes. A recent study from Purdue University found that some candies had 29–33 mg of artificial dyes, which is of concern because levels in this range can affect behavior in a small percentage of children.

Black licorice. Glycyrrhizin, the sweet agent in licorice, is alleged to have many health benefits but is also known to cause high blood pressure and arrhythmia if consumed in large quantities and can cause potassium levels to fall. The FDA has warned against heavy consumption of black licorice but has not set a daily limit and lists it as GRAS, with usage

Figure 1 Sugar confectionery in Seville, Spain.

amounts for certain foods: up to 16% glycyrrhizin in hard candy and 3.1% in soft candy.

Caffeine. Caffeine, as much as 50 mg, is added to a few candies, such as some jelly beans, marshmallows, and chocolate bars, for its energy-imparting qualities. In May 2013, the FDA announced it will investigate the safety of caffeine being added to food products, especially its effect on children.

Gluten. Gluten will be present in a candy if the starch used as a gelling agent comes from wheat. Candies with barley malt and any confectionery with wafers or cookies included will also contain gluten. In August 2014, the FDA issued a final rule to define the term 'gluten-free' for voluntary use in the labeling of foods. For a food to be labeled gluten-free, it must contain 20 ppm of gluten or less. The Hershey Company provides a list of all their gluten-free confectionery on their website.

Zein. Zein, a prolamin protein derived from corn gluten meal, is gluten-free and safe for those with celiac disease or gluten intolerance. The term 'corn gluten' causes confusion, and many people think that zein is a gluten protein. There is no gluten in corn, and, according to Wikipedia, the term arose colloquially. Zein is preferred by vegans and others who object to the use of shellac, an insect product, in confectionery glazes, but the consumer has little knowledge or control over this.

Kidney-friendly candy. People with chronic kidney disease or on dialysis need to restrict their intake of phosphorus, potassium, and salt, which are found in some confections. Phosphorous and potassium are not required on labels. The DaVita company has a list of permissible candies on their website.

Metallic dragées. Dragées are small hard spheres of sugar, about 4 mm diameter, coated with a colored or metallic glaze, used for decorating cakes and cookies. There is concern about the metallic content, especially of the silver ones, and although claimed to be safe by the manufacturers, the state of California banned them in 2003. The FDA declares that dragées are nonedible and require jars to carry labels saying 'for decoration only.'

Salt. Most commercial candies contain salt, and the amount of sodium per serving is required on the label. Confectionery sodium levels are in the range of 10–45 mg per serving, with some confections as high as 100–145 per serving. This amount of sodium constitutes from 0% to 6% of the % daily value. Not all sodium in commercial candies comes from sodium chloride (table salt). Other sources of sodium include sodium salts of acidulants.

Sugar alcohols. Sugar alcohols can cause a laxative effect if too much is consumed, and foods are required to have a warning label to that effect. However, excessive consumption of sugar alcohols can cause a laxative effect, and the maximum safe daily amounts are in the range of 20–50 g depending on the sugar alcohol. The FDA mandates that foods with 20 g or more of mannitol and 50 g or more of sorbitol must carry the warning label 'Excess consumption may have a laxative effect.'

Vegan considerations. Many candies are not vegan because of the presence of milk, egg, or gelatin. Confectioner's glaze made from shellac is an animal product from insects. Beeswax may also be considered nonvegan.

Perspective on Confectionery in Food and Health

By mixing sugar with a few other ingredients, an almost infinite variety of candies and confections can be created. They are colorful, pretty, and tasty. Candy and confections are small packets of food, meant to provide pleasure and to be eaten in moderation. Behavioral studies suggest that pleasurable foods can help to achieve and sustain a healthy diet. Chocolate, in particular, is associated with producing a sense of well-being, which is attributed to the many natural compounds it possesses. However, even though many ingredients in candies are healthy or have healthy ingredients, the amount present in a piece of candy or chocolate is far too small to have an effect, and moderate consumption is key to maintaining a healthy diet (**Figure 1**).

Canning: Process of Canning

FT Vergara-Balderas, Universidad de las Américas Puebla, San Andrés Cholula, Mexico

Introduction

Canning process was introduced about two centuries ago, and for long time, it has been one of the main means of food preservation, together with chilling and freezing. The food canning history began in the late eighteenth century in France when Nicholas Appert discovered that the application of heat to food in a sealed glass container prevented food spoilage. Later, Peter Durand developed a method of sealing food in tin containers; this idea was improved by Bryan Dorkin and John Hall who installed the first commercial cannery in England. Some years later, L. Pasteur gave a reasonable explanation for canning's effectiveness when he demonstrated that microorganisms were responsible of food spoilage. Gradually, the production of canned foods became mechanized and the developments associated to food canning continue today.

Conventional canning is a method of food preservation in which a food is placed in hermetically sealed containers and heated to destroy microorganisms. The main objective of heat application is to destroy pathogenic and spoilage microorganisms, and at the same time, the hermetic container prevents contamination by new microorganisms. Although the use of metal containers is common, there are other alternatives as glass jars, plastic cans, and retort pouches. The level of heat applied to a food depends on several factors: acidity of processed food, density, composition, resistance to heat transfer of food, heat resistance of microorganisms of interest in food, initial load of microorganisms, container, heating medium, equipment, processes, etc. After heating, canned foods are cooled and then handled at room temperature maintaining container integrity and preventing recontamination of product.

Some Concepts Related to Canning

In order to evaluate the suitable amount of heat for the canning process, several concepts must be studied. Among these concepts, the following are considered:

pH

pH is one of the most relevant factors when designing canned foods; the pH of the food plays a key role in determining the extent of heat processing needed to insure a safe and stable final product. The pH value of a food represents the molar concentration of hydrogen ions (in other words, the acidity level of a product); this concentration decreases as the pH value of the food increases. So a low pH value means a higher concentration of hydrogen ions. The range of pH values is between zero and 14. A pH of 7 is neutral (corresponds to pure water), while values less than 7 are acidic and those greater than 7 are basic or alkaline.

In the canning industry, a low-acid food is defined as a food having a pH higher than 4.6, while an acid food is defined as a food with a pH value equal or lower than 4.6. This simple classification of foods considers a reference pH value of 4.6. This value is based on *Clostridium botulinum* spores. *Clostridium botulinum* spores are very resistant to several conditions, including heating; if these spores survive, they have a chance to germinate and grow. However, *Clostridium botulinum* spores will not grow if the pH of a food is 4.6 or less. These spores in low-acid foods must be killed by heating during the canning process, and low-acid foods must receive a severe thermal process, so they are pressure-cooked at high temperatures (around 120 °C) during long periods of time. Examples of low-acid foods include fish, meat, poultry, and most vegetables and their products. On the other hand, acid foods are processed with less heating because *Clostridium botulinum* spores are unable to germinate and grow at pH 4.6 or less. In canning processes for this kind of foods, no pressure cooking is required and pasteurization temperatures are used (temperatures under boiling point of water). Pasteurization temperatures are suitable to inhibit most microorganisms, including vegetative cells of *Clostridium botulinum*. Bacterial spores can survive these processes; however, these spores will not grow at low pH, and the food will remain stable at room temperature (commercially sterile). Examples of acid foods include most fruits and their products.

In addition to low-acid and acid foods, another category of foods is used: acidified foods. Acidified foods are containing a significant amount (over 10%) of naturally low-acid ingredients. The pH of the low-acid ingredients is lowered by the addition of acid in the formulated food. This acid may be added directly or by the use of naturally acid ingredients. No matter how the acidification is achieved, all the low-acid components must take up enough acid to drop their pH below 4.6 within 24 h. Acidified foods are thermal processed at moderate temperatures, similar to those of acid foods.

Commercial Sterility and Microorganisms

The condition of commercial sterility is reached when a product that has been processed will neither represent a danger to consumer's health nor spoil. In the case of conventionally canned low-acid foods, the processes are designed to destroy spores of *Clostridium botulinum* and reduce chances of survival of spores of spoilage microorganism. Bacterial spores are more resistant to heat than vegetative cells. The concept of commercial sterility implies to render foods free of microorganisms capable of growing in the product at room temperature at which the finished product is intended to be held during storage, distribution, and trading. The thermal destruction of microorganisms generally obeys a first-order reaction kinetics. That is, the destruction rate of microorganisms is dependent on the concentration of microorganisms. Mathematically, the first-order kinetics of microbial destruction can be expressed as follows:

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00110-0

$$-\frac{dN}{dt} = kN \quad [1]$$

where $-\frac{dN}{dt}$ is the rate at which microbial concentration decreases, N is the microbial concentration, and k is the first-order reaction rate constant.

Integrating eqn [1] between limits, N_0 at $t_0 = 0$, and N at time t results

$$-\int_{N_0}^{N} \frac{dN}{N} = k\int_0^t dt \quad [2]$$

$$-\ln N + \ln N_0 = k(t-0) \quad [3]$$

$$\log N = \log N_0 - \frac{kt}{2.303}. \quad [4]$$

The expression of eqn [4] describes a straight line with slope $-\frac{k}{2.303}$ and y-intercept $\log N_0$. Also, D-value is defined as $D = \frac{2.303}{k}$. The D-value is the time to destroy 90% of a microbial population when it is heated at a lethal temperature. D-value is a measure of microbial thermal resistance; it is specific for each microorganism under given conditions. At a given temperature, greater D-values are related to higher thermal resistance of a microorganism.

On the other hand, the minimum sterilization level for *Clostridium botulinum* during canning process when the concept of commercial sterility is used is expressed as 12 log cycles or decimal reductions (12-D). It means that if hypothetically a container would have a microbial load of 1×10^{12} cells of *Clostridium botulinum*, after this thermal process, only one cell would survive. If a particular food cannot support the growth of *Clostridium botulinum*, another microorganism of interest can be used to monitor the condition of commercial sterility.

Clostridium botulinum has been chosen as the reference microorganism in the canning industry because it has several useful characteristics that make it suitable for this task. It is a rod-shaped anaerobic bacterium that forms very resistant spores; it can grow in foods with a pH value greater than 4.6. This microorganism is responsible for botulism, a mortal disease caused by the ingestion of a neurotoxin generated by the vegetative form of *Clostridium botulinum*. This neurotoxin is one of the most potent poisons in nature. The vegetative form of *C. botulinum* is not resistant; however, its spore is highly resistant to heating. These spores can be found in several raw foods; under definite conditions, they can germinate, grow, and generate the toxin. Among the suitable conditions to germinate the spore, pH above 4.6, anaerobic environment, and room temperature are found. Potentially, these conditions can be found in low-acid canned foods. So destruction by heating is required in these products.

Although other microorganism may be present at raw materials used to prepare canned foods, they are less important than *C. botulinum* because they show less resistance to heat or they do not endanger the consumer's health.

On the other hand, *Clostridium sporogenes* (PA 3679) is significantly more resistant to heat than *C. botulinum*; it is a nontoxic obligate anaerobic sporeformer mesophilic microorganism, and it is used to determine safe thermal processes for low-acid foods. For acid foods, thermal processes are based on facultative anaerobes, such as *Bacillus coagulans*, *Bacillus macerans*, and *Bacillus polymyxa*; these microorganisms are more sensible to heat.

Preparation of Foods for Canning

In order to obtain wholesome canned foods, good manufacturing practices must be used during storage, handling, and preparation of raw foods and ingredients. Some problems can appear because of unsuitable handling of foods previous to thermal process. It is important to minimize the microbial contamination of food in each operation prior to heat treatment; otherwise, the microbial population increases and designed thermal process could be insufficient to reach the condition of thermal sterility.

Depending on the characteristics of foods, different preparative actions are taken to process a product.

Fruits and vegetables are usually peeled, pitted, destemmed, and seeded. Some leafy vegetables (like spinach) are heated (blanching) before canning to remove air and facilitate the packing of leaves in containers; in other cases, the heating inactivates enzymes to prevent some changes in product, or it can increase the initial temperature of food. High-acid fruits or vegetables can be thermally processed before they are placed in containers.

Usually, meats are precooked, boned, and compacted before thermal processing.

In the case of seafood, most fish and shellfish are boned or shelled before packing; however, some smaller fish, like sardines, are packed with their bones, considering that they will soften during the thermal process.

Thermal Process

Essentially, there are two categories of thermal processes in the canning industry. One is based on the use of retorts (or autoclaves: conventional canning), and the other is the aseptic processing of foods. In processes using retorts, containers are filled with food, followed by sealing them and then heated using steam under pressure until both container and food become sterilized together. In aseptic processing, a liquid food is sterilized outside the container by means of heat exchangers, and then it is cooled in the same equipment. The cooled sterile food is then filled and sealed in a container that has been previously sterilized; these operations are carried out in a sterile environment at room temperature. Summarizing, the retort processing is an 'in-container' sterilization, which can be applied to all types of foods, while aseptic processing is an 'out-of-container' sterilization used for liquid foods. Additionally, a third category of thermal processes can be considered; it is the atmospheric processing or pasteurization, applied to acid and acidified foods that require only a mild heat treatment.

The thermal process must be specific for each product, container type and size, and type of sterilization equipment. The thermal process is obtained by combining information about thermal destruction of microorganisms and product heating data in the proposed sterilization equipment. The amount of heat needed to destroy an expected number of microorganisms can be determined according to information on thermal resistance of microorganisms of interest in the product and the level of microbial destruction planned with the thermal process. On the other hand, the product heating

data usually are obtained from heat penetration tests that measure the temperature/time profile in containers during the thermal process. It is a good practice to obtain heat penetration data under the 'worst-case' conditions likely to be encountered during the thermal process to be sure that a suitable process is achieved. This is the reason why the tests are made with temperature sensors located at the slowest heating point inside the container. In some cases, the use of inoculated packs with microorganisms of known heat resistance can be helpful to design a thermal process. Product heating data are affected by intrinsic (product characteristics) and extrinsic (related to heating equipment) factors. Several mathematical methods have been developed to use the aforementioned information to design or analyze a thermal process.

Equipment

Sterilizers of different types are used on conventional canning. Both batch and continuous systems are available. In batch retorts, cans are loaded in crates and introduced into the retort; they are heat-treated and then unloaded. Examples of batch retorts are the vertical and horizontal steam (or water) still retorts; in this equipment, crates of containers are loaded into the retort, closing the vessel, and heating the containers; then the cooling is carried out by cutting off the steam and adding cool water. In addition, agitating batch retorts are also available. On the other hand, in continuous retorts, filled sealed containers are automatically and continuously moved from atmospheric conditions to a pressurized steam environment, held during the process time, and then moved again into an atmospheric condition for further handling. Examples of continuous retorts are the continuous rotary cooker and the hydrostatic sterilizer. It is common to use steam or hot water as the heating medium or, less usually, a mixture of steam and air. Food containers may be held stationary or rotated.

Most aseptic systems consist of heaters, a holding tube, and coolers. Equipment used for heating during aseptic processing of foods includes several types of heat exchangers; among these are the scrapped surface, the plate, and the tubular heat exchangers; these are indirect heat exchangers because heating medium does not mix with food. Also, there is equipment using direct steam injection in the food.

Pasteurization is normally carried out at temperatures under 100 °C, and it can use hot water baths. At the end of the thermal process, cold water is used for cooling. During the cooling stage of metal and glass containers, it is advisable to remove them at temperatures around 38 °C, so surface water evaporates, preventing corrosion problems. Pasteurization of bulk liquids can be accomplished in heat exchangers; they use as heating medium steam or hot water.

Each type and size of heating equipment (sterilizer) has its particular characteristics and must be known to establish a specific thermal process. With this information, the limits of accuracy of both time and temperature given to the food container can be known.

Postprocess Handling of Canned Foods

Achievement and maintenance of container integrity are essential for microbiological safety and to minimize spoilage. It is important to take appropriate measures to prevent leaker contamination. Among factors involved in control of container leaks are inspection of seam formation, care in seam abuse during passage of containers throughout the handling equipment, disinfection of water used to cool the containers, avoiding wet handling of containers, etc.

On the other hand, canned foods are commonly intended for long storage periods at ambient temperature, so containers must be kept dry. Also, during distribution, the use of sharp knives to open shrink-wrapping and cardboard cases in store may be a problem.

Nutritional and Health Concerns of Canned Foods

The main objective of thermal processes for canned foods is to achieve the condition of commercial sterility. However, as a consequence of thermal treatment, several components in the food can be affected, changing its characteristics, including sensorial and nutritional attributes. So thermal processes must be optimized in order to guarantee that stable and safe products are obtained and that they are quality foods with the suitable retention of sensorial and nutritional characteristics.

Nutrients

In canned foods, the nutrient retention varies depending upon the process, the product, and the nutrient, among other conditions. For a long time, there were canned products in which a significant amount of vitamins was lost during heating, but other nutrients remained in high levels, like protein and calcium. During storage, nutrient losses were less evident. According to new trends in thermal processing, canned foods provide at least the same nutritional value as fresh produce and their frozen counterparts when prepared for a table dish; inclusive, in some cases, canned products can provide higher nutrient levels than fresh produce. This is because fresh produce are exposed to several detrimental conditions (intrinsic enzymes, environmental factors, microorganisms, deleterious reactions, etc.).

Principles that can be applied to describe the effect of heating on microbial destruction also can be applied to other changes occurring in foods, that is, nutrients, quality factors, and enzymes.

Hazards

Most operations in canning processes are oriented to ensure the safety of canned foods. Frequently, the canning industry uses the principles of a system called hazard analysis and critical control points (HACCP) to achieve this goal. Among others, HACCP specifies control points (operations) during food processing to prevent health risks with canned foods. The following are some health concerns associated with canned foods that are commented:

In the case of troubles of microbial origin, it is important to consider that naturally acid foods and acidified products will not support the growth of food pathogen microorganisms, so mild thermal treatments (like pasteurization) are enough to destroy microorganism in the food. Food processors are most

concerned about low-acid foods, like meats, fish, mushrooms, and vegetables; in these products, *Clostridium botulinum*, which causes botulism, must be destroyed by thermal processes, which also destroy other microorganisms that may poison or spoil the food. In addition to thermal process, a suitable and sanitary handling of food before and after heating to prevent the manufacture of unsafe foods is important. There are reports involving other microorganisms different from *C. botulinum* that had the opportunity of growing before thermal process or recontaminating the heated product yielding a dangerous product. This is why systems like HACCP are helpful to obtain safe products.

Another point of interest related to health involves potentially hazardous or toxic substances in container materials that may migrate into the food inside the container. One example of such substances is lead, which was used to solder the metal parts of a can. In the three-piece cans, the lead-soldered side seam has been replaced by a welded side seam. The welding process uses electrodes that apply pressure and electric current to form the side seam. In the welded seam, the problem of lead leaching into the canned food is eliminated. At present, practically lead-soldered cans are not in use. Another example of hazardous substance in container materials is bisphenol A (BPA). This substance is used as an ingredient in the manufacture of internal can coatings, which are used to prevent or retard the interaction between metal cans and their contained food substances. Currently, there are dispute statements that suggest potential risk from BPA exposure; some chemical companies have begun developing BPA substitutes, but on the other hand, more information about BPA impact on consumers' health is required.

Containers for Canned Foods

Historically, the first canning processes used glass containers, with the inconvenience that they were bulky, brittle, and expensive. However, glass containers are still widely used in different sizes and shapes, because they present several desirable properties (glass is inert, transparent, resistant, etc.).

Immediately, the tin cans appeared. Despite the use of metal cans for almost two centuries, innovations in can manufacture have been made up to present days. For example, currently, metal cans are made of recyclable metals (steel and aluminum); additionally, the inside of cans is coated to prevent interaction between metal and food components. The use of the three-piece can is common, but the use of the two-piece can is continuously increasing, and this is justified because the manufacture of two-piece cans (drawing and redrawing (DRD) and drawing and ironing (D&I) methods) is more efficient and economical in comparison with the conventional production method of welding three-piece cans. Also, there are savings with the continuous gauge reduction in manufacture of metal cans. Other innovations in metal cans are the use of ring pulls to open a can and the system of easy-open ends.

On the other hand, the concept of a can ('a container that can store and protect foodstuffs for long periods at room temperature') must be reevaluated since this concept has led to a number of interesting and important developments in other materials and formats. The following are some examples:

(1) Aseptic carton, like the one used by Tetra Pak for milk and other liquid foods is subjected to aseptic processing. This special carton is made with several laminated materials including plastic, aluminum foil, and cardboard.
(2) Cardboard bottles made from recycled paper and low-density polyethylene liner; it has been proposed for milk packing.
(3) Paperboard cans combining paperboard and plastics.
(4) Aluminum foil lamination pouches that can show some advantages compared to traditional metal cans.
(5) Barrier plastics combined with structural polyolefins in can or can-like shapes represent a type of container that could provide all the food protection properties required.

In addition to the traditional cylindrical shape of a can, there are other shapes in use, like trays, cups, pouches, bowls, and bricks.

Future Trends

Traditionally, the analysis and design of thermal processes to achieve commercial sterility are based on mathematical models that assume that inactivation of bacterial spores and vegetative cells, including those of *Clostridium botulinum*, follows first-order kinetics; with this information, thermal resistance parameters (D and z) are evaluated. This approach has provoked that thermal processes evaluated by these means yield safe foods from the microbial point of view; however, these products are probably overprocessed. At the present time, there is evidence that microbial inactivation by heat has a different behavior. In addition, today, better mathematical and computational resources are available to analyze and evaluate thermal processes and generate improved mathematical models, which have been validated experimentally for specific microbial populations. According to this information, theories of thermal processing must be reexamined to guarantee not only safe foods but also quality products.

Related to the last point, food processors are concerned about optimization of thermal processes looking not only for safe and stable foods but also for a reduction in costs and energy in the operation. On the other hand, consumers are demanding nutritional value, chemical safety, sensorial attributes, and, in general, overall quality in their products. To reach these objectives, the canning processes must be reexamined and optimized taking into account the availability of new materials, equipment, and tools to analyze the processes.

Another point of interest is the availability of new sterilization technologies. In canning, sterilization is accomplished by heat and in some cases by a combination of heat and acid. However, nowadays, alternative processes, such as microwave heating, or nonthermal processes such as ultrahigh pressure or UV radiation, are available. These late processes have been used in combination with heat to generate canned foods. Foods processed with these alternative technologies are reported to have minimal quality and nutritional loss as compared to those obtained by conventional thermal processing methods.

Caramel: Methods of Manufacture

P Tomasik, Cracow College of Health Promotion, Cracow, Poland

© 2016 Elsevier Ltd. All rights reserved.

Introduction

The term caramel has three meanings, that is, (i) solid or semisolid mass for making candies and decoration of cakes pastries and other desserts; (ii) syrup for flavoring sauces, gravies, and some beverages; and (iii) liquid colorant for food and selected pharmaceuticals. All of them are available by burning sugars, and the properties and applications of resulting products depend on the temperature and duration of the burning.

Solid or Semisolid Caramel

Solid or semisolid caramel is a beige to brown color mass resulting basically from burning sugar at temperature depending on the source applied. For fructose, galactose, glucose, sucrose, and maltose, it is 110, 160, 160, 160, and 180 °C, respectively. The process proceeds stepwise. When it begins from aqueous solution of sugar, first, evaporation of water has to take place at 100 °C. Otherwise, the solid source can be thermally liquefied. When sucrose is taken as a source, the material for semisolid (soft) candies is formed at 129 °C. Making hard candies takes heating to 165–168 °C. Light, medium, and dark caramels are formed at 180, 180–188, and 188–204 °C, respectively. The so-called black Jack caramel with burnt odor results from burning sugar at 210 °C.

That kind of caramel is standardized on the level of particular manufacturers who use their own compositions of ingredients. There are several more or less complex methods of making caramel. They are based on caramelization of sugars with some additives. One of them is making traditional Middle East sweet kaimak from sugar and milk fat or cream at elevated temperature. Milk provides a softness of the product, which distinguishes the caramel from hard candies. Corn or maple syrup is added to increase the sweetness and prevent aggregation into grains usually resulting from too high level of sugar in the product. Fat is frequently added to provide a taste. Among fats, butter is superior but it is also the most expensive. Therefore, commonly, a blend of various fats is in use, and in good-quality products, butter is an indispensable component. Other ingredients being in use are whey, calcium hydrogen carbonate, salt, flavor, molasses, and corn starch.

There is a patent for producing caramel of a high content of fructose oligosaccharides. Thus, either mono-, oligo-, or polysaccharides, eventually some sugar alcohols together with sugar syrups, wheat gluten, eventually deaminated, an oil, and lecithin are initially treated in a ball mill, followed by 5–15 min caramelization at 130–160 °C. In other patents, the same procedure is carried out with the addition of an organic acid, for instance, citric acid.

Caramel is hygroscopic. Thus, it should be stored in tightly closed nonmetal containers. The hygroscopicity of the caramel decreases with a content of the noncaramelized saccharide.

Caramel Syrups

Caramel syrups are usually homemade although they are also commercially available. House ladies burn sugar, chiefly sucrose, and use resulting syrup *in situ*. The process begins from melting sugar, and then, due to dehydration, initial bubbling increases, producing massive foams. Simultaneously, decomposition reactions generate brown color and acrid smoke. Usually, at this stage, the process is stopped. Temperature of the process at this stage provided formation of furan-2-aldehyde from pentoses or 5-hydroxymethyl furyl-2-aldehyde from hexoses. Under conditions of burning, their low-degree polymerization occurs. The products being low-molecular-weight furan derivatives do not dispose with any extended chromophore system. Simultaneously, some part of monomers still resides in the syrup, making it suitable for flavoring rather than for coloring.

Caramel syrups can be stored in closed glass containers for 2–3 weeks at room temperature and for 2–3 months in refrigerator. The shelf life of caramel syrups even at room temperature can be significantly extended by blending on five hot volumes of a sugar base holding syrup containing granulated sugar, water, corn syrup, and glucose with three volumes of a burnt sugar syrup. The caramel syrups are used for flavoring some dishes, particularly sauces, but since they are alcohol-soluble, they are applicable for flavoring and coloring liquors. They have specific bitter taste and slightly burnt odor.

Caramel Colors

Sources

Mono- and disaccharides are common sources for manufacturing caramel colors. The source has some impact to the course of the caramelization and properties of the final product. Reduced sugars caramelize more readily than nonreducing sugars. Since some residual sugar is left in the product, the caramels have slightly different organoleptic properties and different stability. Caramel colors manufactured from molasses have poor quality, and they are rich in potassium. Fruit juices and extracts have also been considered as a stock for caramelization.

For economical reasons and availability of mono- and disaccharides, in some parts of the world, oligo- and polysaccharides and even starch waste have paid attention as the source for the caramel manufacture. They were first subjected to either acid-, base-, or enzyme-catalyzed hydrolysis into starch hydrolyzates containing 70–85% reducing sugars (DE

30–58). Caramels from the stock prepared by enzymatic hydrolysis have a greater tendency to crystallize. They are more hygroscopic and less viscous as they contain more low-molecular-weight dextrins. Also, malt and soybean carbohydrates can yield caramel.

Caramel Classes

Caramels are the colloidal species, and retaining this property when applied as a colorant is a necessary condition for their effectiveness. As every micellar system, they discharge and precipitate as brown floccules at an isoelectric point. For that sake, there is no one universal caramel color for all types of food. The caramel colors spread into four classes as shown in Table 1 taking color intensity and binding to diethylaminoethyl cellulose (DEAE cellulose) and phosphoryl cellulose as criteria.

Catalysts and Additives

Several additives have been used to stimulate the caramelization and add some flavor and aroma. The use of α-hydroxy carboxylic and proteogenic α-amino acids and their salts could be rationalized in terms of the formation of secondary food aromas on the thermal reactions of those acids with saccharides. Usually, caramels of the III and IV classes are contaminated with neurotoxic 4(5)-methylimidazole (MeI) up to the level of ~200 mg kg^{-1}. The decrease in the content of MeI was an additional argument for the use of such catalysts. In order to provide the stability of the color of the caramels, some inhibitors such as magnesium sulfate or chloride, potassium metabisulfite, and sodium sulfite, sulfate, or polysulfate may be added.

The additives and catalysts in use are subjected to some limitations according to local regulations. The US federal law accepts the following acid additives: acetic, citric, phosphoric, sulfuric, and sulfurous acids. Ammonium, calcium, potassium, and sodium hydroxides are the accepted alkaline additives. Ammonium, sodium, or potassium carbonates, bicarbonates, phosphates (including dibasic phosphates and monobasic phosphates), sulfates, and sulfites are accepted salts. The use of polyglycerol esters of fatty acids as antifoaming agents in amounts not greater than that required to produce the intended effect is also legal.

Table 1 Classes and types of caramel colors [44]

Class	*Sort*	*Color intensity (ε_{max} at 560 nm)*[a]	*Characteristics*
I	Plain caramel E 150a	0.01–0.02	Not more than 50% of the color is bound by DEAE cellulose and not more than 50% of the color is bound by phosphoryl cellulose
II	Sulfite caramel E 150b	0.06–0.10	More than 50% of the color is bound by DEAE cellulose and it exhibits an absorbance ratio of more than 50
III	Ammonia caramel E 150c	0.08–0.36	Not more than 50% of the color is bound by DEAE cellulose and more than 50% of the color is bound by phosphoryl cellulose
IV	Sulfite ammonia caramel E 150d	0.10–0.60	More than 50% of the color is bound by DEAE cellulose and it exhibits an absorbance ratio of not more than 50

Each class of caramel is prepared using a different catalyst suitable for manufacturing caramel of different isoelectric point, thus suitable for coloring products of different acidities (all caramel colors are acidic). Typically, all (i) ammonium, sodium, and potassium carbonates/bicarbonates, (ii) sulfites, (iii) ammonia, and (iv) ammonia/sulfite combination are used to prepare caramel of I, II, III, and IV type, respectively.
[a]The parameter is expressed in terms of a product having a color intensity of 0.10 absorbance units taken at 560 nm in 10 mm quartz cell.

Caramel Manufacture

The whole process proceeds usually batchwise in entirely stainless steel, preferably 316 stainless steel, installations that include either open or pressure kettles, lines, agitators, fillers, and storage tanks. In the case of pressure kettles, at up to 160 °C, the typical gauge pressure is 483 kPa (70 psi, 5 atm). The selection between processes involving either the open or pressure kettles depends on the type of caramel required. There are some contradicting opinions on the role of atmosphere under which caramelization takes place. The caramelization in the open but under oxygen-free atmosphere provided products of higher tinctorial strength.

The process requires thorough maintaining the reaction parameters. They are adjusted accordingly to the caramelized source and the desired product and then strictly controlled throughout the process. Modeling approaches to the caramelization are available. Composition of resulting caramel depends on reaction temperature and time and the concentration of the reagents. On batchwise production, in-process controls are crucial for making uniform product. The tinctorial strength of the product is proportional to the time of heating. The initial setting-up isoelectric point is essential. Its corrections throughout the process are complicated and sometimes impossible. It is selected depending on the required class of caramel. Then, the course of the process is monitored through regular checking the tinctorial strength and viscosity of the samples. The latter is a function of the rate of dehydration of the source. That rate influences the properties of the final product. It can be corrected by manipulating with temperature and mutual contact of reagents. The final stage of the processing involves killing heat. It is also very important. It involves decreasing temperature of the reaction mixture to ~30 °C. Spraying with water through nozzles is not recommended as such caramel is fairly unstable. Instead, spraying caramel in large volume of 4:1 mixture of ethanol and diethyl ether is proposed as providing stable product of high tinctorial strength. There are also other methods for killing heat. Perhaps, employing heat exchangers is now the most common approach.

Caramelization can be performed without any catalyst. This process takes heating the substrate to 190–250 °C under atmospheric, reduced, or elevated pressure. The latter method

was recommended for caramelization of starch syrups to initiate reaction. Caramels from the process run above 200 °C dispose with low tinctorial strength and they are acrid.

Catalysts provide decreasing temperature of caramelization. For technological reasons, among all catalysts in use, ammonia is superior as it provides the lowest temperature (130 °C) of caramelization at the shortest time of the process and the caramel of the highest tinctorial strength. However, the level of MeI in resulting caramel is the highest. Considerable amount of MeI is also formed in the caustic sulfite-/ammonia-catalyzed process. Caramels of both those classes containing MeI as low as 25 mg kg^{-1} are available in modified processes. The manufacture of ammonia caramel in continuous process involves pumping a heated stream of corn syrup through a reaction zone under pressure to which preheated ammonia is injected. It accelerated the formation of the caramel, whereas the rate of the formation of MeI is lower. In such manner, the concentration of MeI in caramel decreases. Class IV caramel of reduced MeI content is manufactured in close vessel applying the ammonium bisulfate catalyst blended with acid to afford $pH < 5$.

The use of mineral acids and alkali also offers manufacture of caramels at lower temperature. Compared to ammonia and caustic sulfite/ammonia caramels, they have a higher content of 2-furaldehyde from pentoses and 5-(hydroxymethyl)-2-furaldehyde from hexoses and higher content of components from dehydration and condensation. On selection of the catalyst and the burning parameters, resulting Linner hue index (H_L) describing the caramel redness should be taken into account. H_L is defined as $10 \log(A_{510}/A_{610})$ where A denotes UV–vis absorbance taken at 510 and 610 nm, respectively.

The tinctorial strength of caramels can additionally be enhanced applying some physicochemical methods. They involve ultrafiltration. This method helps to remove some MeI. Another approach combines size exclusion chromatography with centrifugation (10–2000 *g*).

Solid caramels are also available. To meet the goal, viscous caramel at 120 °C is treated with ammonium carbonate, sucrose and orthophosphoric acid added, cooling to 100 °C and finally treating the blend with citric acid and sodium bicarbonate. In another solution, caramel is thickened with cereals such as rye flour and conditioned at 80–85 °C and pH 3.5–5.5. Alternatively, a blend of starch with dextrins can be used as a thickener. Ajinomoto has patented caramelizing extrusion of mono- and disaccharides at 150–300 °C. In contrast to liquid caramel colors, solid caramels may have $pH > 7$.

The caramelization can be stimulated by UV light and γ-radiation. Sonication ruins caramel micelles and causes flocculation.

Caramel Stability and Storage

Caramel colors are unstable, and on storage, the caramelization progresses. It is manifested by gradual increase in its tinctorial strength. Cooling slows down but does not eliminate this process. After prolonged storage, caramels irreversibly resinify yielding amorphous gel. When stored at low temperature in plastic-lined drums or barrels, it can withstand the storage for up to 5 years. When stored at ambient temperature, their shelf life reaches hardly 2 years.

Caramel: Properties and Analysis

N Kuhnert, Jacobs University Bremen, Bremen, Germany

© 2016 Elsevier Ltd. All rights reserved.

General Introduction

Watching white crystalline sugar turning brown into caramel, producing an enticing and appetizing aroma, must be one of the first childhood exposures to chemistry for most humans. Caramel constitutes one of mankind's oldest and most important dietary materials. Despite the high profile of this dietary material, due to its familiarity and due to its economic importance, with around one-third of the total 150 Mt of sugar produced annually processed by heat treatment to form caramel and related products, an understanding of the chemistry of caramelization remains in its infancy.

Caramel refers to a material obtained from carbohydrates, in particular mono- and disaccharides, at elevated temperatures. The products of this thermal transformation are referred to as caramelization products. The term caramel is synonymously employed as well for caramel coloring used as a food additive in many food products and beverages. This will be described separately later in this article. Caramel is furthermore used as a synonym for certain kinds of candies with caramel as the main ingredient, which is not described further here.

The process of caramelization has been known since the early days of cooking, when sugar-rich products were heated. Indeed, whenever carbohydrate-rich food raw materials are heated, products of caramelization will be formed. Carbohydrates have been treated thermally by humans since ancient times. Mankind began cultivating wheat around 12 000–10 000 BC, with archaeological evidence from central Turkey (e.g., Göbekli Tepe or Çatalhöyük sites), when a genetic mutation in wheat resulted in a nonshattering rachis suitable for harvesting. The most definite archaeological evidence of early thermal treatment of carbohydrates originates from an illustration in the ancient Egyptian tomb of Ramses III displaying a royal bakery. The earliest records of a material we now would consider as caramel date back to recipes from the Arabian Peninsula using honey as the raw material for caramelization around AD 900. In the eighteenth century, recipes using caramelization became more widespread due to the wider availability of sucrose obtained from sugarcane (cross-reference sugar/sucrose). In the nineteenth century, caramel, in particular caramel color, obtained commercial significance once again due to a wider availability of sucrose with sugar beet cultivation starting in Europe and the rise of industrial food production.

Chemistry

The onset of the caramelization process varies with the type of mono- or disaccharide used. Sucrose **3**, for example, starts melting at 135 °C without color change. Development of color and caramel aroma starts around 143–160 °C. On cooling, a brittle glass-like material results. E150a, a standard caramel color, is obtained at temperatures above 160 °C resulting in a dark brown to blackish color accompanied by a bitter aroma. Other monosaccharides start the caramelization process at lower temperatures, such as fructose **2** at 110 °C, glucose **1** and galactose at 160 °C, and maltose at temperatures above 180 °C (for chemical structures, see Figure 1).

Analytic Methods

Purity

A series of analytic procedures exist for defining purity standards of caramel. Just to give one example, the US Pharmacopeia requires a specific gravity lower than 1.30 g cm^{-3}, an ash content below 8%, and a simple purity check involving the absence of a precipitate upon the addition of 0.5 ml phosphoric acid to a 20 ml sample. Furthermore, threshold levels for arsenic, lead, and mercury have also been defined.

Color Index by Colorimetry

Color is the most important property of caramel. The color strength of caramel is typically defined as its tinctorial power, K_{560}. This is the absorbance of a 0.1% weight/volume solution measured through a 1 cm light path at a wavelength of 560 nm (nm) using a spectrophotometer. The higher the value of the absorbance, and consequently, the tinctorial power, K_{560}, the darker the caramel color.

The color tone of the caramel color is also important. This is defined by the hue index, which is the measure of the color hue or red characteristics. It is a function of the absorbance at 510 and 610 nm. Generally, the higher the tinctorial power, K_{560}, the lower the hue index and the lower the red tones. Various other indices are in use around the world.

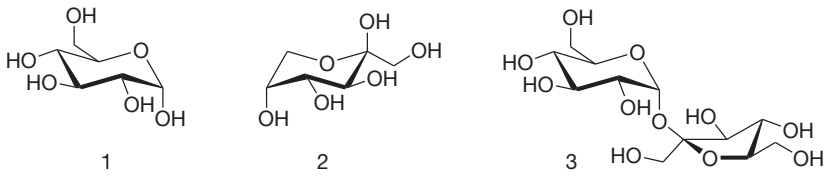

Figure 1 Chemical structures of typical saccharides used in caramel production.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00112-4

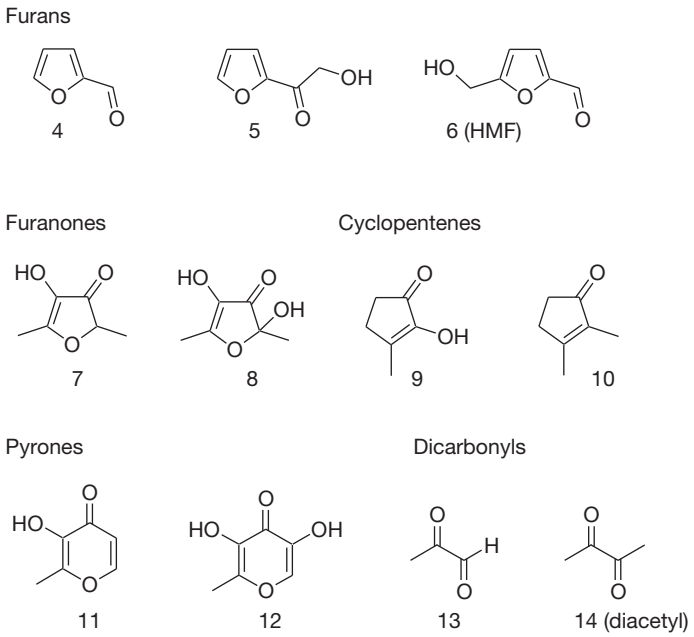

Figure 2 Chemical structure of typical volatile compounds from caramel.

Gas Chromatography

For analysis and characterization of volatiles in caramel, gas chromatography (GC) methods have been traditionally employed for separation. As detectors, GC-FID, GC-nose, and GC-MS (gas chromatography–mass spectrometry) are used. For the majority of caramel volatiles (for structures, please see Figure 2), GC-MS data are contained in commercial spectral libraries such as NIST and allow straightforward identification of caramel volatiles from GC-MS data. It should be noted that other aroma volatiles not formed in caramelization also possess an aroma classified as caramel-like in sensory evaluation panel testing.

Liquid Chromatography–Mass Spectrometry

In the last years, high-resolution MS has evolved as a powerful technique to study complex mixtures. Due to its unsurpassed resolving power, combined with tandem MS methods for structure elucidation and innovative data interpretation strategies developed recently, a comprehensive characterization of the chemical composition of caramel was possible.

Reaction Mechanisms

In caramelization chemistry, it is advisable to separate caramelization reactions, which occur under simple heat treatment in pure mono- and disaccharides from Maillard reaction products, which require the presence of an amine base, most frequently amino acids.

The following reaction types dominate caramelization chemistry summarized by Krohn and Golon et al.:

- Enolization
- Dehydration
- Dicarbonyl cleavage
- Retro-aldol reactions
- Aldol reactions
- Glycosidic bond formation
- Hydration

Volatile Compounds

Within the volatile fraction of caramel, a series of heterocyclic and carbocyclic compounds are formed including furans **4–6**, furanones **7** and **8**, cyclopentenes **9** and **10**, and pyrones **11** and **12** (see Figure 2). Retro-aldol reactions of saccharides yield dicarbonyl compounds such as **13** and **14**. Diacetyl **14**, associated with a butterscotch-type flavor, is one of the best-characterized aroma compounds in caramel, which is accompanied by several hundreds of other identified flavor compounds. The mechanism of formation has been discussed in detail by Blank and Krohn.

Nonvolatile Fraction

Within the nonvolatile fraction, caramelization leads to a significant reduction of the starting material saccharides (90% and more) and yields several ill-defined products as a complex mixture. The scientific investigation of caramel started around 1860 with a seminal paper by French chemist A. Gelis, who noted that upon heating of sucrose, dramatic chemical changes occurred. He named the products originating from heated sucrose as caramelans and caramelins depending on their molecular weight. In 1967, Kitaoka classified the reaction products of caramelization into three distinct classes: caramelans, tetramers of hexoses ($C_{24}H_{36}O_{18}$); caramelens, hexamers of glucose ($C_{36}H_{50}O_{25}$); and caramelins, polymers of glucose ($C_{125}H_{188}O_{80}$). Although this classification is reported on many websites and even in food chemistry

textbooks, with an added hint that caramelization is accompanied by loss of water from carbohydrates, this early classification has never attracted the attention of other research groups or has ever been further substantiated, probably due to a lack of analytic methods able to unravel the complexity of the product mixture formed in caramelization.

Recent work by Golon and Kuhnert using liquid chromatography in conjunction with high-resolution and tandem MS could first of all show that in a typical caramelization reaction, around 1000 analytes with different m/z ratios can be detected. The number of actual reaction products is due to the presence of isomerism in carbohydrate chemistry and is impossible to estimate. The observed reaction products could be classified according to reaction types encountered in their formation.

Using a domino tandem MS approach, the products formed in caramelization of the most important dietary carbohydrates including monosaccharides, disaccharides, and polymeric carbohydrates, such as starch and cellulose, were investigated by Golon and Kuhnert.

In typical high-resolution MS spectra of caramel, around 300 intense signals could be observed on average (see Figures 3 and 4). The total number of signals resolved in an MS experiment is around 1000. A combination of van Krevelen and Kendrick analysis (see Figures 3 and 4) revealed that the products formed fall into four distinct compound class categories: (1) oligomers of sugars (up to dodecamers); (2) dehydration products of sugars mainly of oligomeric nature; (3) polyaromatic heterocycles; and (4) minor lipid-like redox products.

Kendrick analysis with normalization of water addition revealed that several homologous series of dehydration products were formed with a loss of up to eight water molecules starting from a given oligomer (shown in Figure 4).

Targeted tandem-LC-MS measurements showed that all compounds formed existed as multiple isomers, and in some cases, close to the theoretical number of isomers were resolved chromatographically. Tandem MS could confirm the structure of carbohydrate oligomers in most cases, although all issues of stereo- and regiochemistry remain open due to a lack of reference materials. For dehydrated products, tandem MS data revealed that dehydration always starts at the reducing end of the oligosaccharide leading to, after loss of the first three water

molecules, a furanoid moiety at the reducing end (either 5-hydroxymethylfurfural or acetylfuran derivatives). Selected tentative structures **15–17** are shown in Figure 5.

When comparing the reactivity of various carbohydrates, Golon and Kuhnert observed that galactose moieties are most reactive, probably due to their axial 4-OH group, which allows the formation of reactive bicyclic hemiacetal intermediates.

Caramel Coloring

Caramel color is produced by thermal treatment of carbohydrates, in pure form or after addition of selected reagents. A wide range of raw materials are used as carbohydrate source, including fructose, glucose, invert sugar, sucrose, malt syrup, molasses, starch hydrolysates, and fractions thereof. Acids used include sulfuric, sulfurous, phosphoric, acetic, and citric acid; alkaline reagents include ammonium, sodium, potassium, and calcium hydroxide; and the salts used include ammonium, sodium, and potassium carbonate, bicarbonate, phosphate, sulfate, and bisulfite. Antifoaming agents, such as polyglycerol fatty acid esters, are added as processing aids during manufacture. Its color ranges from pale yellow to amber to dark brown. The resulting caramel color bodies are found to be either anionic or cationic in nature depending upon the reactants used in their manufacturing.

Table 1 Classification and application of industrial caramel colors

Class	*E number*	*Description/synonyms*	*Application*
Class I	E150a	Plain caramel, caustic caramel, and spirit caramel	Whiskey and other high-proof alcohols
Class II	E150b	Caustic sulfite caramel	Vegetable extracts, cognac, sherry, and vinegars
Class III	E150c	Ammonia caramel, baker's caramel, confectioner's caramel, and beer caramel	Beer, sauces, gravies, baking goods, and confectionery
Class IV	E150d	Sulfite ammonia caramel, acid-proof caramel, and soft drink caramel	Soft drinks

Source: Wikipedia: http://en.wikipedia.org/wiki/Caramel_color.

Internationally, the United Nations Joint Food and Agriculture Organization recognizes four classes of caramel color, differing by the reactants used in their manufacture, each with its own INS or E number, shown in Table 1.

Caramel coloring is developed as a result of heating several commercially available carbohydrates, including glucose, fructose, sucrose, and starch, in the presence of acidic (e.g., sulfuric

acid, phosphoric acid, acetic acid, and citric acid) or alkaline reagents (e.g., hydroxides, carbonates, and bicarbonates of ammonium, sodium, or potassium), which lead to caramel color compounds that are cationic or anionic in nature. In some case, phosphate, sulfate, and bisulfite salts can also be used. In general, four groups of caramel colorings, identified by their E number, have been internationally recognized and are presented in Table 1. The choice of caramel color depends on the requirements of a given application and therefore on the color intensity required. Additionally, stability factors for the food matrix used, including stability in aqueous ethanol, stability in the presence of salts (adjustment of the net charge of color bodies plays a role here), stability at pH 3 or 2, and stability in the presence of tannins, also need to be considered.

It should be noted that slight variation of manufacturing process parameters (starting material, temperature, and time) allows the production of a large range of different qualities of product within each caramel category and also results in differences in chemical composition and physical properties. This is further evidenced by variation in 4-methylimidazole (4-MEI) **18** and 2-acetyl-4-tetrahydroxybutylimidazole (THI) **19** concentrations in E150c and E 150d, respectively (see section 'Toxicology'). Variations in chemical composition in industrial caramel color have not been systematically studied, and no published material is available on the composition of the nonvolatile caramelization products other than for E150a caramel. It must, however, be assumed that the presence of ammonia compounds in E150c and E150d caramels will lead to Maillard chemistry and hence a chemical composition completely different if compared to E150a caramel.

Dietary Burden

The EFSA panel on food additives and nutrient sources added to food provided figures for the average intake of caramel from different classes. These data mainly originated from food questionnaires from the UK population and are divided into intake from adult and children population. Table 2 provides data on the average daily intake of E 150a–d, whereas Table 3 provides a summary of the different classes of foods that contribute to the intake of E 150 a–d.

From the data, in particular from the children population, it becomes obvious that minimum and maximum daily intakes vary dramatically by a factor of 5–10. A total intake for an average person of 70 kg bodyweight can be calculated from these data resulting in an intake of ~35 g day^{-1}. The maximum figures clearly exceed the recommended daily intakes. Interestingly, the types of food contributing to caramel intake vary dramatically if adults and children are compared. In the adult population, alcoholic drinks are the main contributors, whereas in the children population, sweet goods such as confectionary, fine bakery goods, and desserts are the main contributor.

Table 2 Estimated dietary intake of caramels in UK population

	Children population		*Adult population*
Class	*Minimum intake (mg kg^{-1} body weight per day)*	*Maximum intake (mg kg^{-1} body weight per day)*	*Average intake (mg kg^{-1} body weight per day)*
E150a	76.9	427.2	136.6
E150b	8.7	34.6	21.7
E150c	21.7	302.4	295.0
E150d	23.2	506.2	89.4

Toxicology

Generally in caramel, polycyclic carbocycles and heteroaromatics potentially form in thermal treatment and heterocycles 4-MEI **18** and THI **19** are under scrutiny for their adverse health effects. All four classes of caramel colors have been previously evaluated by the EU Scientific Committee for Food (SCF), by the Joint FAO/WHO Expert Committee on Food Additives (JECFA), and by the Nordic Council of Ministers (TemaNord). Both JECFA and SCF concluded that an acceptable daily intake (ADI) figure was not required E150 a, considering that it contains no chemical reagent used in manufacturing and therefore resembles caramel formed in normal cooking processes. For E150b, an ADI of 0–160 mg kg^{-1} body weight per day and, for E150b and E 150d, an ADI of 200 mg kg^{-1} body weight per day were established. These threshold values are based on information indicating that its chemical composition was similar to and intermediate between E150a plain caramel and E150d caramel. For E150c caramel, an ADI of 200 mg kg^{-1} body weight per day with the stipulation that THI **19** concentration should not exceed 10 mg/kg color on a color intensity basis was set. In 2010, the International Programme on Chemical Safety (IPCS) concluded similarly that commercially produced caramel color has the same toxicological properties as caramel produced by cooking or heating sucrose, except for those prepared using ammonium (E150c and E150d) (Figure 6).

The US Food and Drug Administration classifies and regulates caramel color in Title 21 CFR § 73.85 as a generally recognized as safe color additive exempt from certification. The IPCS has concluded that caramel color does not exhibit carcinogenicity or mutagenicity, referring to the available literature.

Data on the toxicokinetics of the caramel colors are very limited and show little uptake of the high-molecular-weight fraction of the color bodies from the gastrointestinal tract, with the bulk of the material being excreted in the feces. Animal studies on E150c ammonia caramel have shown evidence of lymphocyte depression and other evidence of immunotoxicity, which are considered to be due to the presence of THI, a potent immunosuppressant, in this caramel.

Caramel colors have been extensively tested for genotoxic potential in a variety of assays *in vitro* and *in vivo*. The results in *in vitro* systems were generally negative, with a few marginally positive findings, and no positive findings have been reported in *in vivo* assays.

Long-term toxicity studies carried out on E150c/d caramel were similar to and did not reveal any pattern of toxicity in addition to available 90-day oral toxicity studies. No evidence of carcinogenicity was seen in 2-year studies in rats on E150c/d.

Table 3 Estimated dietary intake of caramels according to food type in UK population

	Children population		*Adult population*

18 19

4-methyl-imidazole THI (2-acetyl)-4- tetrahydroxybutyl imidazole

Figure 6 Chemical structures of imidazoles 4-MEI (**18**) and THI (**19**) from E150c and E150d.

In a complementary study in mice, there was as well no evidence for a carcinogenic potential of E150d. In 2007, the National Toxicology Program issued a report summarizing the results of toxicological testing conducted on 4-MEI **18** in rats and mice. A 2-year study in rats was inconclusive regarding carcinogenicity, however, a mouse study of equal length revealed an increased incidence of certain lung tumors. These studies were conducted in rodents at levels of 4-MEI that far exceed current estimates of human exposure to 4-MEI from the consumption of E150c/d in food products and beverages. The latter level is higher than the current maximum level for THI required in the specifications for E150c.

According to the Food Chemicals Codex, 4-MEI in caramel color is allowed up to 250 ppm on a color-adjusted basis, which means 250 ppm maximum for every 0.100 color absorbance of a 0.10% solution at 610 nm.

In conclusion, the use of caramel colors can at the current stage be considered as safe if ADI values and maximum concentrations for 4-methylimidazole and THI are met.

Digestion

Mouth and Stomach

Digestion of polysaccharides, namely, starch, begins in the mouth. Salivary α-amylase, also known as ptyalin, hydrolyzes the α-(1-4) glycosidic bonds in linear glucose polymers. This enzyme is unable to hydrolyze α-(1,6) linkages in branched polymers, terminal α-(1-4) linkages, and α-(1-4) linkages near branch points; thus, the primary end products of amylase digestion are oligosaccharides, maltose, maltotriose, and α-limit dextrins (small and branched glucose polymers). Digestion by salivary α-amylase is brief and incomplete as the enzyme is inactivated by the acidic gastric juices in the stomach.

Smaller carbohydrates, such as trisaccharides and disaccharides, are not enzymatically digested until they reach the small intestine.

Small Intestine

As food passes from the stomach to the small intestine, bicarbonate (HCO^{3-}) is released to neutralize gastric juices and pancreatic α-amylase is released to resume the enzymatic digestion of starch that began in the mouth. Similar to salivary α-amylase, this enzyme is only able to hydrolyze linear portions of glucose polymers. The end products of maltose, maltotriose, and α-dextrin are then further hydrolyzed by enzymes contained in the microvilli of the small intestine, often referred to as brush border enzymes. These glycosidases are also responsible for the digestion of disaccharides such as sucrose and lactose.

The major brush border enzyme complexes responsible for carbohydrate digestion are glucoamylase, sucrase–isomaltase, and β-glycosidase (lactase). Table 1 describes the enzyme activity for these different complexes and their primary location in the small intestine. Glucoamylase continues to hydrolyze the larger end products of starch digestion, such as maltotriose and α-limit dextrins. Unlike α-amylases, which are endoglucosidases (can only hydrolyze α-(1,4) bonds within a linear glucose polymer), glucoamylase is an exoglucosidase that can begin hydrolyzing α-(1,4) linkages at the nonreducing end of a glucose polymer to release individual glucose moieties. However, this enzyme is still unable to hydrolyze α-(1,6) glycosidic bonds so the end products of digestion from glucoamylase are primarily glucose and isomaltose (a disaccharide of glucose bound by an α-(1,6) linkage).

Sucrase–isomaltase is a single brush border enzyme with two catalytic subunits that have different substrate specificity. The sucrase–maltase subunit is responsible for the digestion of sucrose to glucose and fructose and maltose to two glucose moieties. The isomaltase–maltase subunit is responsible for the digestion of isomaltose and maltose into two glucose moieties. This enzyme complex is critical as it accounts for 100% of sucrose digestion and almost all of the small intestine's ability to hydrolyze an α-(1,6) glycosidic linkage.

The β-glycosidase enzyme complex is also made up of two subunits, thus the reason this complex is often called lactase–phlorizin hydrolase. The lactase subunit hydrolyzes the β-(1,4) bond of lactose to release glucose and galactose. Glycolipids are the predominant substrate for the phlorizin hydrolase subunit, resulting in the release of a monosaccharide (glucose or galactose) and ceramide.

Large Intestine

The end products of carbohydrate digestion are monosaccharides, which are quickly absorbed in the small intestine. However, any carbohydrates that escape digestion and absorption in the small intestine, such as dietary fiber, pass into the large intestine where they are then fermented by microbes residing in the intestine. For more information on dietary fiber and the role of large intestine microbes on health, see elsewhere in this Encyclopedia.

While the presence of polysaccharides, such as dietary fiber, may be beneficial for the health of the large intestine, the presence of small carbohydrates, such as oligosaccharides, disaccharides, and monosaccharides, in the large intestine can lead to intestinal discomfort, such as bloating, gas, and diarrhea. Small carbohydrates are generally highly osmotic and will bring a large amount of water into the large intestine, often resulting in diarrhea. Smaller carbohydrates polymers are also rapidly fermented by the microbes in the intestine, resulting in the formation of gas and possibly feelings of bloating and flatulence.

Sugar alcohols, or polyols, are small monosaccharides and disaccharides that generally escape digestion and absorption in the small intestine. While some sugar alcohols occur naturally in fruits and vegetables, they are also frequently used in the food industry as noncaloric sweeteners for sugar-free and reduced-sugar foods. Since most of these polyols escape digestion and absorption, they pass into the large intestine and are fermented by the microbiota. These polyols are also highly osmotic so overconsumption can cause symptoms such as diarrhea, gas, and bloating. In fact, in the United States, some foods containing polyols that may be consumed in amounts that would cause discomfort carry a warning label that 'excess consumption may have a laxative effect.' For more information on sugar alcohols, see elsewhere in this Encyclopedia.

Absorption and Transport

Intestinal Absorption

Once carbohydrates are digested, the resulting monosaccharides are quickly absorbed by the cells of the small intestine (enterocytes). Because monosaccharides are polar molecules,

Table 1 Primary enzymes involved in carbohydrate digestion

Enzyme/enzyme complex	*Enzyme action*	*Location*	*Substrates*	*End products*
Salivary α-amylase	Hydrolyzes internal α-(1-4) glycosidic bonds in linear glucose polymers	Mouth	Starch (amylose, amylopectin) Glycogen	Oligosaccharides Maltose Maltotriose α-Limit dextrins
Pancreatic α-amylase	Same as salivary α-amylase	Small Intestine Secreted by the pancreas into the duodenum	Starch (amylose, amylopectin) Glycogen	Oligosaccharides Maltose Maltotriose α-Limit dextrins
Glucoamylase	Hydrolyzes α-(1-4) glycosidic bonds at the nonreducing end of linear glucose polymers	Small intestine Activity extends entire small intestine with highest activity in the ileum	Oligosaccharides Maltose Maltotriose α-Limit dextrins	Glucose Isomaltose
Sucrase–isomaltase	Sucrase–maltase subunit hydrolyzes (α-1) → (β-2) glycosidic bond in sucrose and the α-(1-4) glycosidic bond in maltose Isomaltase–maltase subunit hydrolyzes the α-(1,6) glycosidic bond in isomaltose and the α-(1-4) glycosidic bond maltose	Small intestine Activity highest in the jejunum	Sucrose Maltose Isomaltose	Glucose Fructose
β-Glycosidase	Lactase subunit hydrolyzes the β-(1,4) bond of lactose Phlorizin hydrolase subunit hydrolyzes the bond between monosaccharides and ceramides	Small intestine Activity highest in the jejunum	Lactose Glycolipids	Glucose Galactose Ceramide

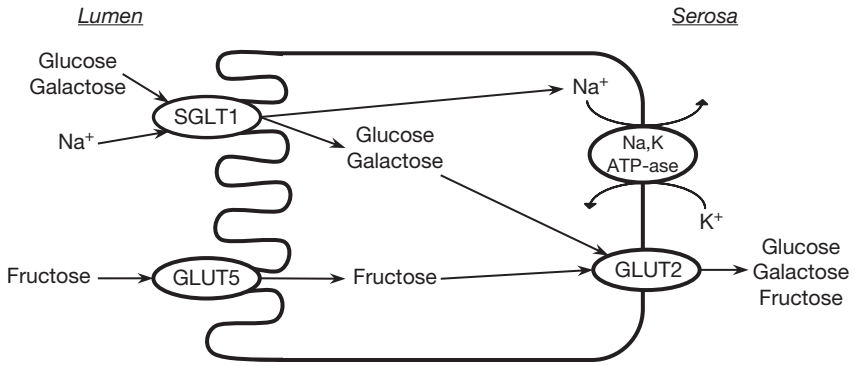

Figure 1 Absorption of monosaccharides.

transporters are required to carry them across the cell membrane. The specific transport mechanisms differ for the different monosaccharides.

Glucose and galactose are absorbed via the sodium-dependent transporter, SGLT1, located on the luminal side of the small intestinal cells. The monosaccharides are transported from the lumen to the enterocyte against a concentration gradient while the sodium is cotransported into the cell down a concentration gradient (Figure 1). In order to maintain the sodium gradient between the lumen and the enterocyte, sodium is pumped out of the enterocyte by a sodium–potassium ATPase in the basolateral membrane. Fructose transport into the enterocyte is facilitated by the GLUT5 transporter that is not sodium-dependent. This transporter can also facilitate the transport of glucose across the membrane, but the affinity for fructose is much greater. Once inside, the enterocyte monosaccharides are transported through the serosal side of the cell by GLUT2 transporters.

Transport into the Tissues

After being absorbed, monosaccharides are carried through the bloodstream to the tissues of the body. Virtually every cell in the body contains one or more types of GLUT transporters, signifying the importance of carbohydrates, particularly glucose, as a major fuel source for the body. As many as 14 different isoforms of GLUT transporters have been discovered; however, GLUT1–5 transporters have been the most thoroughly studied. Table 2 describes the functions of the different GLUT transporters and where they are found throughout the

avoidance of specific carbohydrate triggers or minimizing or eliminating starch from the diet.

Congenital disorders in carbohydrate absorption are also quite rare, and treatment can be more difficult. In glucose–galactose malabsorption, a mutation in the gene for SGLT1 leads to the inability to absorb glucose or galactose in the diet. Symptoms include diarrhea, dehydration, bloating, and abdominal pain and can begin as early as the first day of life. The primary treatment is to remove most carbohydrates from the diet with the exception of fructose. In some cases, individuals with this condition improve as they age and develop greater glucose tolerance. A mutation in the gene for the GLUT2 transporter leads to a condition called Fanconi–Bickel syndrome. As discussed previously, the GLUT2 transporter is the primary monosaccharide transporter in the intestine, but it is also expressed in the liver, kidney, and pancreas. Therefore, in addition to carbohydrate malabsorption, individuals with this condition will also have systemic effects, such as renal nephropathy and hepatomegaly.

Food Factors

There are several properties of foods that can impact digestion and absorption of carbohydrates, including physical structure, processing, and the presence of other macronutrients in the food. There is considerable research interest in this area as controlling the rate of digestion and absorption of glucose may have an important impact on health conditions, such as type 2 diabetes.

Alteration in the physical structure of carbohydrates, particularly starch, within foods has been shown to change the digestibility of the carbohydrates. For example, ground rice has been shown to be digested and absorbed more rapidly than whole, unground rice. Similarly, carbohydrates from pureed beans are more rapidly absorbed than those from whole beans. It is likely that the process of grinding or pureeing breaks down the semicrystalline structure of starch, thereby increasing the available surface area of the carbohydrate to digestive enzymes and thus the rate of digestion and absorption.

Other types of processing can also impact carbohydrate digestibility, particularly starch. Most of the starch contained in cooked foods is gelatinized. Starch gelatinization is the hydration of starch during cooking and is an essential process to make baked goods and pasta. During gelatinization, the starch granule swells and bursts, making the starch much more accessible to digestive enzymes. In foods where there is incomplete gelatinization of the starch, such as in pumpernickel bread, that often include intact grain kernels, digestion and absorption of the starch carbohydrates tend to be slower. Also, as gelatinized starch cools, it can undergo the process of retrogradation where the starch molecules attempt to recrystallize. Often, this process can result in the formation of resistant starch. As the name suggests, these recrystallized starch molecules are generally more resistant to digestive enzymes and either escape digestion or are more slowly digested and absorbed.

The presence of other macronutrients and food components, such as protein, lipid, fiber, and antinutrients, can also change the digestion and absorption rate of carbohydrates. When carbohydrates are consumed along with protein and/or lipids, the digestion and absorption rate appears to be slower, as evidenced by a lower glycemic response compared to consuming the carbohydrate alone. This may be due in part to the formation of a protein matrix around starch granules, as is often seen in grains. However, there may also be interactions between starch and protein that occur after ingestion as the addition of protein-based foods, such as fish and cheese, to breads or pasta can change the digestion and absorption of carbohydrates. Complexes can also form between starch chains and fatty acids that can slow the digestion and absorption of carbohydrates. The complexes may be more resistant to digestive enzymes, but starch–lipid complexes can also change the solubility and gelatinization temperature for starch, which could also impact digestibility. Dietary fiber has probably been the most-studied food component for impacting carbohydrate digestibility. The fibers that have shown the greatest impact on carbohydrate digestion and absorption are viscous dietary fibers because of their ability to slow transit in the intestine and interfere with enzyme accessibility to carbohydrates. Antinutrients, such as phytic acid and α-amylase inhibitors, have also been shown to interfere with carbohydrate digestion. Inhibitors of α-amylase can occur naturally in foods such as beans and grains. The impact of these inhibitors as they exist in the food seems fairly small; however, when isolated and concentrated, these inhibitors can have a significant impact on blood glucose levels.

Metabolism of Carbohydrates

Catabolism for Energy

The primary fate of absorbed carbohydrates is to be catabolized for cellular energy in the form of ATP. The energy value of carbohydrates is typically estimated to be 4 kcal g^{-1}. This value was determined by Atwater's calculation of the heat of combustion of various food carbohydrates. However, the true caloric value of carbohydrates can vary significantly. Some insoluble fibers, such as cellulose, have practically no caloric value since they are minimally digested and absorbed. Some soluble fibers, as well as sugar alcohols, can be partially digested and easily fermented, which makes their caloric value, on average, around 2 kcal g^{-1}. Most mono- and disaccharides have a caloric value ranging from 3.75 to 3.95 kcal g^{-1}, while highly digestible starches can yield as much as 4.2 kcal g^{-1}.

Glycolysis

Once taken into the cells, glucose is phosphorylated by a hexokinase to glucose 6-phosphate. This helps retain glucose within the cell and maintain a concentration gradient for continued entry of glucose into the cell. Glucose 6-phosphate is the precursor for several metabolic pathways, including glycolysis, pentose phosphate pathway, and glycogen synthesis. Hexokinase activity can differ in tissues with liver cells having a lower affinity (higher K_m) than hexokinases in other tissues. This ensures that active tissues get the glucose they need for metabolism, and when glucose levels rise, more is taken up by the liver for storage. Hexokinase in the liver (known as glucokinase) also has no feedback inhibition from its product,

glucose 6-phosphate. This is essential for the liver to be able to control blood glucose levels and generate glucose 6-phosphate for glycogen storage when excess glucose is present. In other tissues, excess glucose 6-phosphate can inhibit hexokinase, which then allows the concentration of free glucose in the cell to rise, eliminating the concentration gradient and stopping further transport of glucose into the cell.

To enter the glycolytic pathway (Figure 2), glucose 6-phosphate is isomerized to fructose 6-phosphate. Fructose 6-phosphate is then phosphorylated by phosphofructokinase-1 (PFK-1) to form fructose 1,6-bisphosphate. This is the committed step into glycolysis; thus, PFK-1 is highly regulated by the energy status of the cell with high ATP/AMP levels inhibiting the enzyme and low ATP/AMP levels activating the enzyme. Fructose 1,6-bisphosphate is cleaved by aldolase to form two 3-carbon units: dihydroxyacetone phosphate and glyceraldehyde 3-phosphate. Dihydroxyacetone phosphate is isomerized to glyceraldehyde 3-phosphate, and these two molecules are again phosphorylated to form 1,3-bisphosphoglycerate. This step also generates NADH, which can be utilized to produce energy in other aerobic metabolic pathways. Through a series of additional steps, both three-carbon units are eventually converted to two pyruvate molecules and all four phosphate groups are removed to yield four ATPs. However, since two ATPs were utilized by hexokinase and PFK-1, the net energy yield of glycolysis is two ATPs.

Fate of pyruvate and NADH from glycolysis

The fate of pyruvate and NADH generated during glycolysis will depend on the presence of oxygen in the cellular environment and the presence of mitochondria. If oxygen is available, both NADH and pyruvate can be further oxidized to produce more ATP. However, if there is a lack of oxygen in the tissues, such as skeletal muscle during anaerobic exercise, or in tissues lacking mitochondria, such as erythrocytes, pyruvate and NADH cannot be used to generate more ATP.

In aerobic conditions, pyruvate can enter the mitochondria where it is oxidized to acetyl-CoA and enters the TCA cycle. The TCA cycle metabolizes pyruvate completely to CO_2 and in the process donates electrons to NAD^+ and FAD. These electrons are then passed through the electron transport chain in the mitochondrial membrane to generate ATP. The NADH molecules generated by glycolysis cannot enter the mitochondria, but under aerobic conditions, shuttle systems between the cytosol and the mitochondria can ensure the electrons from NADH get inside the mitochondria and into the electron transport system to generate ATP. These two shuttle systems are the glycerol 3-phosphate shuttle and the malate–aspartate shuttle.

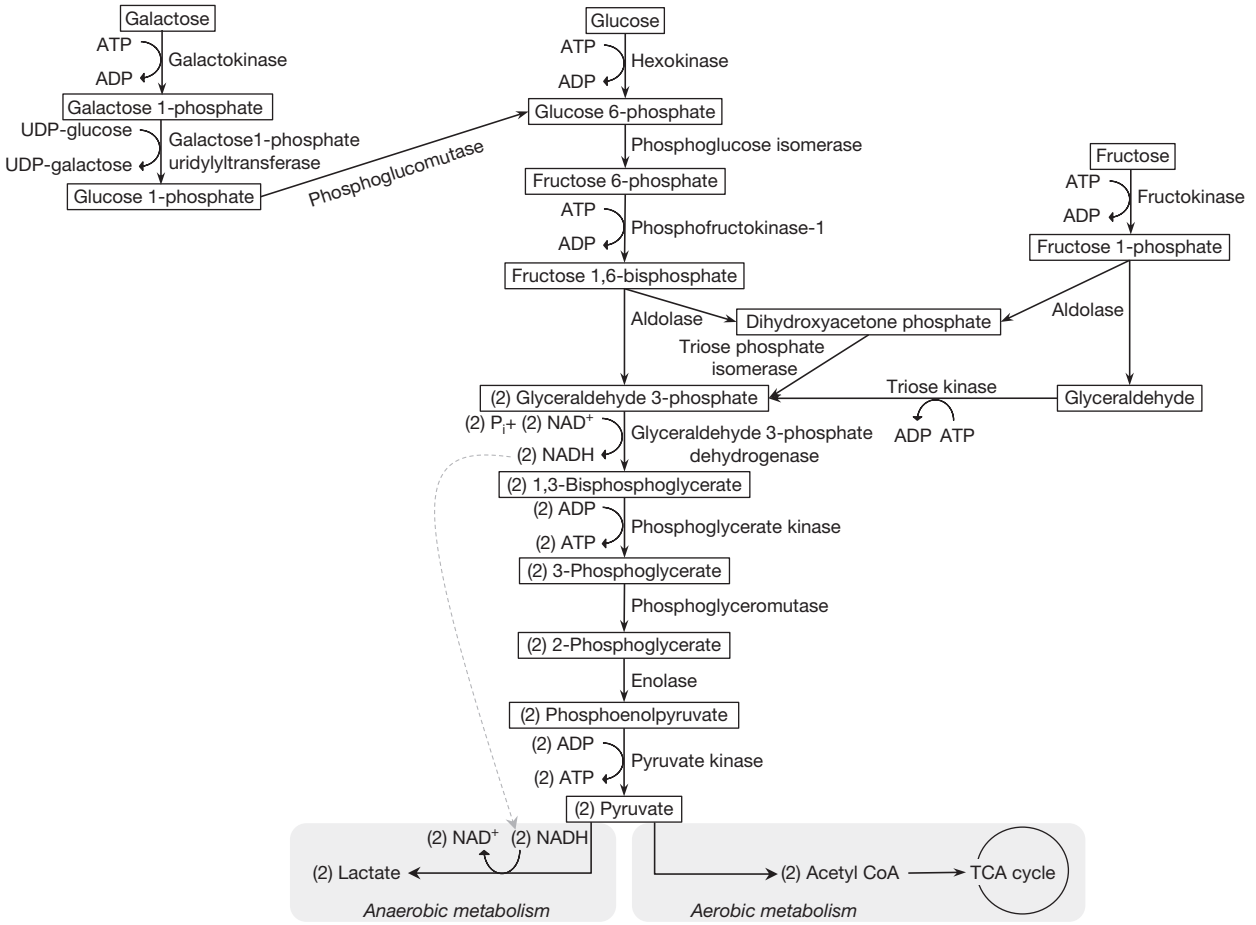

Figure 2 Aerobic and anaerobic glycolysis and entry points for fructose and galactose.

The glycerol 3-phosphate shuttle transfers electrons from NADH to dihydroxyacetone phosphate to form glycerol 3-phosphate, which can pass through the mitochondrial membrane. Similarly, the malate–aspartate shuttle transfers electrons from NADH to oxaloacetate to form malate, which can then enter the mitochondria.

In anaerobic conditions, or when there is a lack of mitochondria, the fate of pyruvate and NADH is closely linked. Pyruvate is converted to lactate by lactate dehydrogenase, a process that requires NADH. The conversion of pyruvate to lactate ensures that NAD^+ is regenerated for glycolysis to continue and prevents a buildup of pyruvate in the cell. Lactate can be released by cells into the bloodstream and taken up by other tissues as a fuel source or converted back to glucose by the liver in a process called the Cori cycle.

Fructose and galactose metabolism

The preferred carbohydrate source for cellular metabolism is glucose. Therefore, fructose and galactose are converted to intermediates in glycolysis. Fructose is metabolized in the liver to form glyceraldehyde 3-phosphate and dihydroxyacetone phosphate, both intermediates in glycolysis. Galactose is also metabolized primarily in the liver to form glucose 6-phosphate, which can enter glycolysis. Figure 2 summarizes fructose and galactose metabolism and the entry of the metabolites into glycolysis. As we will discuss more in the succeeding text, since these monosaccharides can contribute intermediates in glycolysis, they may also contribute to the production of glucose through gluconeogenesis.

Maintenance of Glucose Homeostasis

Because of the importance of glucose as an energy source for the body, it is critical that tissues always have an available source of glucose, even during times of fasting. Gluconeogenesis, which occurs primarily in the liver, is the process by which glucose is generated. Most of the steps of glycolysis are reversible, and this is the primary means by which the liver will synthesize glucose.

Gluconeogenesis

Gluconeogenesis (Figure 3) is essentially a reversal of glycolysis, and the primary substrates for gluconeogenesis are pyruvate, lactate, glycerol, and amino acids. Each of these substrates can be converted to intermediates in the gluconeogenic pathway. Lactate can be oxidized to pyruvate to enter the gluconeogenic pathway. Glycerol is an intermediate of lipid metabolism and can be converted to dihydroxyacetone phosphate, while alanine is converted to pyruvate through alanine aminotransferase.

Since cellular energetics favor glycolysis, ATP is required to drive gluconeogenesis, and there are four key enzymes that enable the reversal of glycolysis to favor the production of glucose. The conversion of pyruvate to phosphoenolpyruvate requires two enzymes in gluconeogenesis even though the reverse reaction in glycolysis required only one. The enzyme involved is pyruvate carboxylase, which requires ATP and converts pyruvate to oxaloacetate. Oxaloacetate is then converted to phosphoenolpyruvate. The next several steps are a reversal of glycolytic enzymes and result in the conversion of phosphoenolpyruvate to dihydroxyacetone phosphate and glyceraldehyde 3-phosphate, which then condense to form fructose 1,6-bisphosphate. To reverse phosphofructokinase-1 to return fructose 1,6-bisphosphate to fructose 6-phosphate requires another unique enzyme for gluconeogenesis, fructose 1,6-bisphosphatase. Likewise, the removal of a phosphate to convert glucose 6-phosphate back to glucose requires a unique enzyme, glucose 6-phosphatase. Once glucose is formed, it can be released by the liver to provide fuel to cells.

Similar to the enzymes in glycolysis, the enzymes in gluconeogenesis are also regulated to ensure a steady supply of glucose. Because of the similarity of the glycolytic and gluconeogenic pathways, generally, the activation of an enzyme in one pathway results in the inhibition of the 'paired' enzyme in the reverse pathway. For example, AMP is an activator of phosphofructokinase-1 to favor glycolysis and the generation of ATP. Conversely, AMP is an inhibitor of fructose 1,6-bisphosphatase, which favors gluconeogenesis rather than glycolysis. The enzymes in gluconeogenesis and glycolysis are also subject to hormonal regulation. During the fed state, insulin is released, which inhibits gluconeogenic enzymes, such as phosphoenolpyruvate carboxykinase. Alternatively, during fasting, glucagon levels rise, which induces gluconeogenic enzymes.

Storage of Glucose

The importance of glucose for energy is again demonstrated in the ability of the body to store glucose in the readily available form of glycogen. Most of the glycogen is stored in the liver and skeletal muscle with the purpose of maintaining blood glucose and providing a quick energy source for active cells, respectively. For greater depth into glycogen, see elsewhere in this Encyclopedia.

Glycogenesis

Glycogen is a glucose polysaccharide composed of α-1,4 linked glucosyl units with occasional branching created by α-1,6 linkages. This branching allows for more rapid breakdown when glucose is needed since there are many chains for enzymes to begin degrading. Glycogen synthesis begins with glucose 6-phosphate, the result of the phosphorylation of glucose by hexokinase (the first step in glucose metabolism). Phosphoglucomutase then catalyzes the conversion of glucose 6-phosphate to glucose 1-phosphate. UTP is then utilized to form UDP-glucose, which is necessary for glucose to be added to the glycogen chains. Glycogen synthase then transfers UDP-glucose molecules to the glycogen chains.

Glycogen synthase is the key regulatory enzyme of glycogenesis and is regulated by blood glucose levels as well as insulin and glucagon levels. As expected, elevated blood glucose and insulin will trigger glycogenesis, while fasting and elevations in glucagon will inhibit this pathway. Since skeletal muscle glycogen is primarily for rapid energy needs rather than the maintenance of blood glucose, skeletal muscle glycogenesis is also regulated by the energy state of the cell, with AMP inhibiting glycogenesis and triggering glycogenolysis.

Glycogenolysis

Different enzymes control glycogen degradation and glycogen synthesis. The main enzyme involved in glycogen degradation is glycogen phosphorylase, which catalyzes the removal of glucose 1-phosphate from the terminal end of a glycogen chain. A debranching enzyme is also required as glycogen phosphorylase cannot cleave glucose molecules near a branch

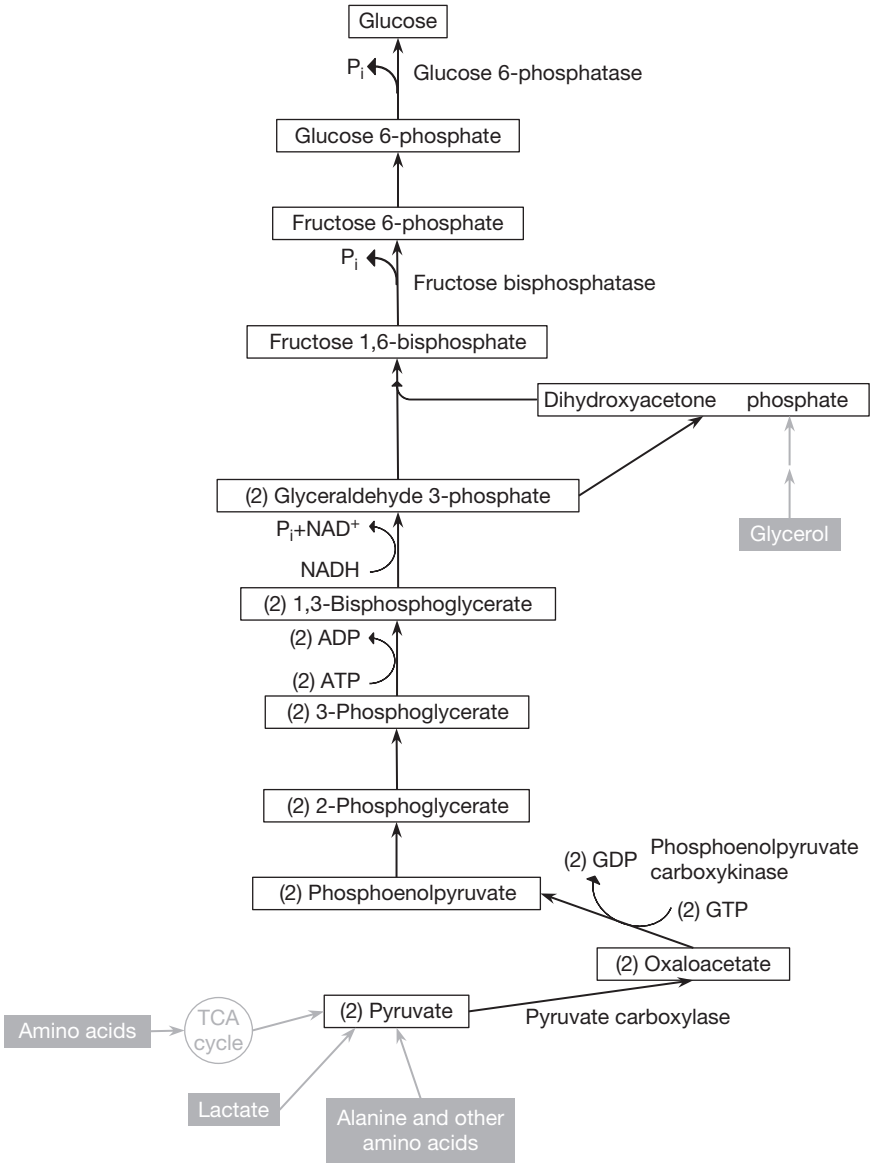

Figure 3 Gluconeogenesis, relationship to glycolysis, and entry points for noncarbohydrate substrates.

point. In the process of removing the branch point, a small amount of free glucose is released. Glucose 1-phosphate is converted back to glucose 6-phosphate. In the skeletal muscle, this will likely immediately proceed into glycolysis to provide the cell with needed energy. However, in the liver, glucose 6-phosphatase removes the phosphate from glucose 6-phosphate to generate free glucose that can then be used to maintain blood glucose levels. These enzymes are regulated by the same hormonal mechanisms as glycogenic enzymes.

Other Metabolic Pathways for Carbohydrates

Glucose metabolism can also be used to generate precursors for biosynthetic pathways, such as amino acid and lipid formation. Pyruvate and intermediates in the TCA cycle can be used for the carbon skeleton of amino acids, such as alanine and glutamate. Acetyl Co-A and glycerol 3-phosphate can contribute to the formation of fatty acids and glycerol backbones, respectively, in lipid formation. The pentose phosphate pathway is an alternative pathway for anaerobic glucose oxidation and can yield NADPH for biosynthetic pathways and as a defense against cellular oxidative damage, as well as ribose 5-phosphate, a precursor for nucleic acid synthesis. UDP-glucose, the precursor for glycogen synthesis, can also be used as a precursor for the formation of lactose in the mammary glands as well as the formation of glycoproteins and glycolipids.

Physiological and Genetic Factors Impacting Carbohydrate Metabolism

As there are a number of pathways involved in carbohydrate metabolism, this also means there are a number of physiological and genetic conditions that can impact carbohydrate metabolism. Fortunately, genetic conditions are fairly rare. However, disorders of carbohydrate metabolism that are

acquired over time, such as type 2 diabetes, are becoming more common. In this section, we will give a brief overview of these conditions that impact carbohydrate metabolism, and for greater depth, see elsewhere in this Encyclopedia.

One of the most common disorders of carbohydrate metabolism is diabetes. There are multiple forms of diabetes (type 1, type 2, and gestational), but all have in common elevated blood glucose levels resulting from the inability of glucose to enter cellular tissues to be oxidized for energy. In type 1 diabetes, this is due to the inability of the pancreas to make insulin, but in type 2 diabetes and gestational diabetes, insulin production may be normal, but the tissues are resistant to the action of insulin. See elsewhere in this Encyclopedia for more information on these conditions.

Inborn errors of carbohydrate metabolism typically result from defects or deficiencies in certain enzymes involved in carbohydrate metabolism. In fructose metabolism, a deficiency in fructokinase can lead to elevated levels of fructose in the urine, which is relatively benign. However, a deficiency in aldolase B (hereditary fructose intolerance), which cleaves fructose 1-phosphate into precursors of glycolysis, can lead to hypoglycemia as an accumulation of fructose 1-phosphate inhibits gluconeogenesis and glycogenolysis. In galactose metabolism, classical galactosemia results from a deficiency in galactosyl uridylyltransferase, which causes a buildup of galactose 1-phosphate, which can lead to systemic problems, such as hepatomegaly, cataracts, and brain damage. While some of these deficiencies can lead to serious physiological issues and potentially death if not treated, most individuals are able to successfully manage their condition by avoiding the offending sugar in their diet.

Deficiencies or defects in enzymes involved in the direct metabolism of glucose have much more serious effects and, because of the reliance on glucose for energy, are difficult to treat with diet. For example, disorders in the metabolism of pyruvate due to deficiencies in pyruvate dehydrogenase or pyruvate carboxylase, while rare, typically lead to neurological issues, lactic acidosis, seizures, developmental delay, and failure to thrive. In the most severe cases, infants with these conditions will not survive. There are a number of enzyme deficiency diseases that have been grouped together in a family of glycogen storage diseases. As many as 11 different diseases have been characterized, each involving a different enzyme in glucose metabolism and varying in their severity and occurrence. For example, glycogen storage disease type V (McArdle's disease) is a deficiency in muscle glycogen phosphorylase with fairly minor effects, such as exercise-induced muscle pain and myoglobinuria. However, glycogen storage disease type IV (Andersen disease), which results from a deficiency in the glycogen branching enzyme, leads to failure to thrive and is usually fatal. While several types of glycogen storage diseases exist, the overall incidence of glycogen storage diseases is 1 in 20 000–25 000. While the frequency of each type is not completely known, it appears that glycogen storage disease types I, II, III, and VI are the most common, while types IV, V, and VII are very rare. While all types must be closely monitored, with treatment, the prognosis is better for those with types I, III, V, and VI. Type IV, type 0, and sometimes type II can result in early death.

Carcinogenic: Carcinogenic Substances in Food

D Anderson, University of Bradford, Bradford, UK
TC Marrs, Edentox Associates, Edenbridge, UK; West Midlands Poisons Unit, Birmingham, UK

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Substances that are known or suspected to be carcinogenic to experimental animals and/or humans are widespread throughout the environment. They occur naturally in the physical environment and are found in a very large number of higher plants, fungi, and microorganisms, many of which are part of the human diet. Some carcinogens have also been introduced into the human diet as a result of traditional cooking and preserving practices. Although carcinogens act through a wide variety of mechanisms, a substantial number have a common mechanism of action in that they react with the genetic material of the body, DNA. These so-called genotoxic carcinogens generally require metabolic activation by the 'host' animal to express their carcinogenicity. Although substantial efforts are being made to develop short-term, nonanimal tests to predict the carcinogenicity of chemicals, animal bioassays remain the only reliable method for establishing the potential of a chemical to be a carcinogen and form the basis of current approaches for the control of potentially carcinogenic chemicals in the human diet.

Naturally Occurring Carcinogens

It has been estimated that the total number of known chemicals exceeds 7 million and that the great majority are naturally occurring. Although only a very small proportion (perhaps less than 0.01%) of these chemicals have been tested for carcinogenic potential in laboratory studies, a high proportion (as high as 50% in some evaluations) have been found to be positive. Therefore, even allowing for the imperfect selection and testing process, it is likely that there are a very large number of naturally occurring carcinogenic chemicals in the universe of chemicals and therefore in the food we eat.

Naturally occurring substances identified as carcinogens in animals and/or humans by the range of approaches available for this purpose include inorganic compounds, organometallic compounds, and both simple and complex organic chemicals (see Table 1). These materials are present in the environment either as naturally occurring minerals or as a result of natural processes acting in the environment such as combustion, radioactive decay, or biodegradation of plant materials to oils. They are also widespread throughout the plant kingdom in both edible and nonedible plants and in many fungi and in unicellular organisms.

Inorganic Chemical Carcinogens

Many metallic elements are present as contaminants in food, being derived from a range of sources including the water used in food processing, soil residues, packaging, and cooking equipment. A number of metals and some of their salts have been shown to be carcinogenic in animals and/or humans, particularly to the lungs. These include arsenic, beryllium, cadmium, chromium, and nickel. Little is known about the mechanism by which metals cause cancer, although evidence is emerging that some metal ions affect the fidelity of an enzyme involved in the biosynthesis of DNA resulting in abnormal DNA being produced. A number of naturally occurring radioactive elements are also carcinogenic, particularly to the lungs. These include uranium and radium (metals) and radon (a gas), and these may act by damaging DNA directly or by increasing oxidative damage as a result of an increase in reactive radical species. In addition, some naturally occurring minerals such as asbestos, silica, and talc are known to be carcinogenic to animals and humans under some circumstances, probably acting by activating macrophages to generate damaging active oxygen species.

Organic Chemicals: Complex Natural Mixtures

The earliest association made between the development of cancer in humans and exposure to an essentially natural rather than man-made chemical was that between scrotal (skin) cancer and soot by Percival Pott in 1775. However, the specific chemical(s) responsible (polycyclic aromatic hydrocarbons (PAHs) such as benzo(a)pyrene and 7,12-dimethylbenzanthracene) were not identified until more than a century later. Since then, a number of other naturally occurring materials have been shown to be carcinogenic. These have included mineral oils, shale oils, and wood dust/shavings, the oils being carcinogenic to the skin, and wood dust to the nasal cavity. Inadvertent ingestion of small amounts of such materials with food may be difficult to avoid.

Organic Chemicals in Higher Plants

Although the acute toxicity of many plant species has been known since written records first appeared, only comparatively recently has the carcinogenicity of plant-derived products been recognized. The list of confirmed animal carcinogens present in plants is still relatively small, and few, if any, are confirmed or suspected human carcinogens. However, developments in analytic chemistry will allow an increasingly detailed inventory to be made of chemicals in plants, which will undoubtedly result in the discovery of many more carcinogens in our foodstuffs. The identification of over 1000 chemicals in coffee beans and the observation that whereas only 3% of the chemicals had been tested for carcinogenicity, nearly 70% of these tested positive are clear pointers to future directions. Although it can be argued that the majority of these compounds are present at very low levels in plants and so the risk to man from any individual compound may be small, reliable methods for assessing both hazard and risk of low-level

exposure are not well developed. In addition, methods for assessing the hazard from complex mixtures of chemicals are also poorly developed, resulting in additional uncertainty in evaluating the risk-posed by natural materials (see the succeeding text). The identified chemical carcinogens in plants tend to be secondary metabolites, often present as part of the plants natural defense mechanism against predation (i.e., natural pesticides), and as such are widespread in fruit, vegetables, herbs, and spices (see Table 2).

One of the first classes of toxic compounds in plants to be identified was the pyrrolizidine alkaloids from the genus *Senecio*. Subsequently, more than 200 related compounds have been isolated from numerous genera and species, many of which are potent liver toxins and liver carcinogens. Other classes of alkaloids found in the plant kingdom include derivatives of the nicotine alkaloids, such as *N*-nitrosonornicotine, which are present in tobacco leaves and are known to be carcinogenic to animals. Tobacco leaves also contain a range of compounds that have been shown to potentiate the carcinogenic effect of the alkaloids present.

Many other classes of carcinogenic plant products have been identified. These include glycosides of azoxy alcohols such as cycasin, an animal carcinogen at various sites including the liver and also a possible human carcinogen. Arecoline, an alkaloid from betel (areca) nuts, is believed to cause mouth cancer in humans, while isoprene glycosides, such as ptaquiloside found in bracken, are liver carcinogens, and phenolic alkylbenzenes such as safrole present in many herbs and vegetables are also principally liver carcinogens. Other phenolic compounds including flavonoids, such as quercetin, rutin, and kaempferol, and tannins, such as trapain and brevifolin, are potent mutagens, but evidence for their carcinogenicity is lacking. In fact, many of these compounds have been shown to exert anticarcinogenic effects.

Table 1 Examples of naturally occurring substances that are believed to be carcinogenic in experimental animals and/or humans

Inorganic chemicals
Arsenic; beryllium; chromium; cobalt; cadmium; lead; manganese; nickel
Polonium; radium; uranium; radon (gas)
Asbestos; silica (glass fiber); talc
Organic chemicals – complex mixtures
Mineral oils; shale oil; soot; wood shaving/dust
Organic chemicals in higher plants
Cycasin (cycads) arecoline (betel nuts); safrole (*Sassafras*); pyrrolizidine alkaloids (Boraginaceae and Compositae); ptaquilosides (bracken [*Pteridium*]); nitrosoalkaloids (tobacco [*Nicotiana*])
Organic chemicals in lower-order plants and microorganisms
Agaratine (mushrooms); aflatoxin, ochratoxin, sterigmatocystin (*Aspergillus* spp. and others); mitomycin, streptozotocin, daunomycin, actinomycin (*Streptomyces* spp.)

Organic Chemical Carcinogens in Other Edible Plants and in Microorganisms

Chemical carcinogens are also found in a wide range of lower plants, such as fungi, and in microorganisms. Simple and complex hydrazines are found in many species of mushroom and have been shown to produce tumors in many tissues in experimental animals. Mycotoxins such as aflatoxin B_1 and the related polynuclear compounds produced by *Aspergillus* species are some of the most potent carcinogens known, being active at dose levels in the nanogram per kilogram range. Human exposure to such compounds occurs when cereal crops or nuts are stored in humid conditions, as they are in many parts of equatorial Africa and China. Aflatoxin B_1 is one of the few established human carcinogens found in the plant kingdom. Other carcinogenic compounds produced as natural products include the antibiotics adriamycin and daunomycin and the antineoplastic agent streptozotocin isolated from microorganisms of the genus *Streptomyces*.

Carcinogens Produced by Food Processing

Despite the widespread occurrence of potentially carcinogenic chemicals in the plant kingdom, most foodstuffs contain only low levels of these chemicals. However, it has now been recognized that a number of processes used in food preparation/processing can introduce significant amounts of carcinogens into the food or the local environment. The most widely studied of these processes is preservation of meats and fish by salting or smoking, grilling or broiling, and cooking in vegetable oils.

Traditional methods for preserving meat and fish involve either salting or smoking. Epidemiological evidence has been found for an association between an increased incidence of

Table 2 Some naturally occurring carcinogenic plant pesticides (a) and their sources (b)

(a)	
Chemical class	*Examples*
Aldehyde	Crotonaldehyde; benzaldehyde; hexanal
Hydrazine/hydrazone	*N*-methyl-*N*-formylhydrazine; methylhydrazine; pentanal methylformylhydrazone
Alcohol	Methylbenzyl alcohol; catechol
Ester	Ethyl acrylate; benzyl acetate
Simple heterocycles	Coumarin; hydroquinone; safrole; sesamol; 8-methoxypsoralen
Polyphenols	Quercetin
(b)	
Generic source	*Examples*
Fruit	Apple; apricot; cherry; grapefruit; lemon; melon; peach; pear; pineapple
Root vegetables	Carrot; onion; parsnip; radish; turnip
Brassica	Broccoli; Brussels sprout; cabbage
Herbs	Coriander; dill; fennel; mint; sage; tarragon
Spices	Allspice; caraway; cardamom; nutmeg; paprika; turmeric

cancer of the mouth and pharynx and intake of salted meat and fish. It seems likely that a reaction between sodium nitrate and/or nitrite used for preserving the meat and alkylamides present in the meat results in the formation of *N*-nitrosamines and nitrosamides. These compounds have been shown to be potent carcinogens in animal experiments to the mouth, pharynx, and other sites. Levels of nitrosamines in cured meats and fish can be as high as 100–200 ppb (parts per billion) for the simple alkylnitrosamines and between 10 and 100 ppb for volatile heterocyclic nitrosamines. Although dose levels required to induce tumor formation in animal studies are substantially higher than those likely to be ingested by man, there is a concern that the presence of nitrosamines in food presents a significant hazard to man.

Preservation of meats and fish by smoking has also been shown to introduce chemicals known to be carcinogenic to animals, particularly PAHs, although direct evidence for an association between an increased incidence of human cancers and consumption of smoked meat and fish is lacking.

The frying or grilling of meats and fish has been found to generate significant quantities of heterocyclic nitrogenous compounds derived from amino acids present in foods. These so-called cooked food mutagens include 2-amino-3-methylimidazo[4,5-f]quinoline (IQ), 2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline (methyl-IQ$_x$), 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP), 3-amino-1,4-dimethyl-5H-pyrido[4,3-b]indole (Trp-P-1), and 2-aminodipyrido[1,2-a:3′,2-d]imidazole (Glu-P-2). They are some of the most potent bacterial mutagens known and have been shown to induce a wide range of tumors in animals. Levels as high as 500 ppb have been found in grilled chicken, and it has been suggested that they may be implicated in the induction of colon and breast cancers in humans. PAHs can also be generated by the grilling of meat and fish and both carcinogenic and noncarcinogenic compounds have been identified. Levels of one particular PAH in foods, the carcinogen benzo(a)pyrene, have been reported to vary from <1 ppb in grain to more than 30 ppb in singed meat.

Heating oils in order to cook foods has also been found to generate a range of carcinogenic chemicals, including PAHs. However, many of the compounds produced are volatile and may therefore represent more of a hazard to the cook than to the food consumer. Thus, cooking with unrefined rapeseed or soya bean oil, which contain significant levels of the polyunsaturated fatty acid linolenic acid, has been shown to result in the release of aldehydes including formaldehyde, acetaldehyde, and acrolein, hydrocarbons including 1,3-butadiene and benzene, and other chemicals. Many of these compounds are mutagenic to bacteria and carcinogenic in animals, and in areas of the world where such cooking practices are common (e.g., China), the incidence of lung cancer in the exposed population is high. The International Agency for Research on Cancer (IARC) considers that emissions from high-temperature frying are 'probably carcinogenic to humans.'

Mechanisms of Carcinogenicity

It is well established that cancer is a multistep process and that chemical carcinogens can induce neoplasia by a wide range of mechanisms involving either interaction with the hereditary material of the organism or interference with one of the many cellular control systems. The former compounds, known as genotoxic carcinogens, interact directly with DNA, resulting in a permanent heritable change to a cell following replication (i.e., an altered genotype). In contrast, nongenotoxic (the so-called epigenetic) carcinogens do not interact directly with DNA but cause cancer by other mechanisms.

Chemicals that react with DNA are invariably electrophiles (i.e., they possess one or more electron-deficient centers in the molecule) that target the nucleophilic (electron-rich) sites in the DNA. The electrophilic center may be present in the molecule itself (activation-independent) as in β-propiolactone, dimethyl sulfate, and α,β-unsaturated aldehydes or be generated following metabolism (activation-dependent) in the target species.

Examples of classes of compounds that are converted to reactive electrophiles by oxidative metabolism include nitrosamines, chlorinated alkanes, hydrazines, and PAHs. Because of the inherent reactivity of these species, they react not only with DNA but also with other cellular macromolecules such as RNA and proteins. These reactions protect the cell against the carcinogenicity of the chemical by reducing the amount of electrophile available to react with DNA, but may lead to other forms of damage and ultimately cell death.

The enzyme system considered to be mainly involved in the activation of chemicals to carcinogenic species is the so-called mixed function oxidase system. This enzyme complex is centered on cytochrome P450 and is present in most, if not all, of the organs of the body. The enzyme system consists of a very large family of related isoenzymes of differing substrate specificity and has a widespread distribution in the animal kingdom. Early work with this enzyme system suggested that only certain isoenzymes were responsible for the activation of carcinogens, although it is now clear that different isoenzymes may activate the same compound in different species.

Most chemical carcinogens appear to be substrates of one particular isoenzyme called CYP1A1. Molecular modeling has shown that only relatively flat (planar) molecules are oxygenated by this cytochrome. Common carcinogens activated by this isoenzyme include PAHs, aflatoxins, and 9-hydroxyellipticine, whereas the related isoenzyme CYP1A2 activates arylamines and amides such as 2-acetylaminofluorene and the cooked food mutagens. Other subfamilies of cytochromes involved in activating carcinogens include CYP2E1, which is known to act on a wide range of small molecules such as dialkylnitrosamines, urethane, vinyl monomers and haloalkanes, and CYP3A, which also activates PAHs, aflatoxins, and cooked food mutagens.

The chemistry of the activation process varies with the type of carcinogen. The oxidation of aflatoxin B_1, for example, results in the formation of the 8,9-epoxide in a single step, whereas the activation of PAHs, such as benzo(a)pyrene, is a multistep process involving an epoxide that is converted to a diol by epoxide hydrolase, which is then converted to the proximate carcinogenic species, a diol epoxide. Activation of arylamines and amides to DNA reactive species, in contrast, frequently involves an initial oxidation step to an *N*-hydroxy derivative, which is then further metabolized to a highly reactive *N*-*O*-ester. This latter reaction is catalyzed by a transferase

enzyme, usually sulfotransferase or acetyltransferase for arylamines and glucuronotransferase for arylamides. Other oxidative reactions result in the formation of unstable compounds that decompose spontaneously to the ultimate carcinogenic species. Thus, simple nitrosamines are oxidized by CYP2E1 to an α-hydroxy intermediate that breaks down to the electrophilic alkyldiazonium ion.

Enzyme systems other than the mixed function oxidase system may also be involved in the metabolic activation of carcinogens. Thus, for aflatoxins, there is evidence that prostaglandin H synthetase can activate this group of compounds, and for arylamines, oxidation may be carried out by prostaglandin peroxidase, by myeloperoxidase, or by flavin-containing monooxygenases.

The direct metabolic activation of compounds to carcinogenic species by phase II metabolism, a process normally associated with detoxification, can also occur. Thus, safrole and related compounds are converted to their sulfate esters, the ultimate carcinogenic species by the phase II enzyme, sulfotransferase.

Metabolic Activation of Epigenetic Carcinogens

Since there is no common mechanism describing the action of epigenetic carcinogens, making predictions as to the likely carcinogenic potential of these chemicals is extremely challenging, and generalizations concerning the effect of metabolism on the activity of chemicals acting by a nongenotoxic mechanism are not possible. The activity of a number of epigenetic carcinogens is reduced as a result of metabolic activation, although in the case of one group of epigenetic carcinogens that produce renal tumors in the rat by binding to and preventing the degradation of a specific kidney protein, alpha-2-microglobulin, metabolic activation is required for carcinogenic activity. Compounds acting by this mechanism include isophorone and isolimonene, which are present naturally in many fruits. Similarly, a wide range of structurally diverse chemicals induce liver tumors in rodents due to their ability to induce the proliferation of hepatic peroxisomes. Food contaminants such as phthalate diesters, which leach out of packaging materials, fall into this category, although no naturally occurring food chemical has yet been found to be a peroxisome proliferator. Some examples of nongenotoxic mechanisms of carcinogenesis are shown in Table 3.

Carcinogenicity Tests

Animal Bioassays

As the mechanism of carcinogenesis in both humans and animals is not well understood, the only acceptable procedure for determining whether a chemical is likely to be a carcinogen is the examination of experimental animals exposed to the suspect material under carefully controlled conditions. This procedure relies on the assumption that animals will behave in essentially the same way as humans to carcinogen exposure; that is, the mechanism of tumor induction will be similar in both experimental animals and humans. Mechanistically based, short-term tests for carcinogenicity prediction not involving experimental animals are still a distant and elusive goal.

The basic approach for carcinogenicity testing involves administering the test material to two suitable animal species for a considerable proportion of their natural life span. Because of their small size and relatively short life expectancy, the rat and mouse are the species of choice, although the hamster is occasionally used. In the United States, inbred strains of animals are widely used (the F344 rat and the $B6C3F_1$ hybrid mouse), although outbred strains are commonly used in Europe. To examine the carcinogenic potential of food components, the test substance is usually given in the diet, although in some circumstances, administration may be in the drinking water or by gavage. The study continues until a certain proportion in one or other of the treatment groups has died or has been killed in a moribund state. As a minimum, 50 animals are allocated at random to each of the experimental groups, allowing a statistically significant carcinogenic effect to be detected if five animals in a test group develop tumors and no animals in the control group do. During the study, the animal's clinical state is regularly monitored, and at the end of the study, a complete necropsy is performed on all surviving animals. Tumors are assessed by a histopathologist, and an attempt is made to determine whether any tumors seen were the cause of the (early) death of the animal (fatal tumors) or were unrelated to the death (incidental tumors). The procedures of these bioassays are conducted under rigorous conditions defined by the Code of Good Laboratory Practice.

Tests are essentially of two types: The first, used widely under the National Toxicology Program in the United States, is designed to examine the ability of the test material to induce cancer in the species used; the second is aimed at determining the cancer incidence in respect of dose – a classical dose–response study. The former requires a few treatment groups, including a relatively high-dose group in order to maximize

Table 3 Some examples of nongenotoxic mechanisms of carcinogenesis

Mechanism	*Examples of chemical classes*
Promotion	Phorbol esters; barbiturates; chlorinated hydrocarbons
Receptor-mediated (e.g., peroxisome proliferation)	Phthalate diesters; hypolipidemic drugs; chlorinated herbicides
Endocrine modulation	Androgens and estrogens (e.g., 17β-estradiol); antithyroid agents
Immunosuppression	Cyclosporine
Tissue specific toxicity	Metals (e.g., arsenic and beryllium)
Cytotoxicity	Metal chelators; branched chain hydrocarbons

the chance of detecting a carcinogenic effect, whereas the latter requires a wide range of dose groups to define accurately the dose–response relationship.

The analysis of a carcinogenicity bioassay is aimed at determining whether the administration of the test chemical has resulted in an increase in the incidence of tumors at one or more sites compared with the normal background level. In order to accomplish this analysis, two major confounding factors may have to be taken into consideration. The first is the effect of differences in mortality rates between the control and treated groups and the second is the effect of differences in food intake and its consequence on body weight. Both factors can substantially alter the tumor pattern observed in different groups. Early deaths may prevent the animals from reaching tumor-bearing age, and reduced food intake, due perhaps to unpalatability of the diet with the test material admixed and the associated reduction in body weight, may result in a considerable reduction in tumor incidence.

The interpretation of the results of a bioassay is complex, but most authorities work to the 'weight of evidence' principle. This evidence is taken in the light of the adequacy of the bioassay, which is dependent on some of the factors previously discussed. Strong evidence for the compound being a genotoxic carcinogen would be increased malignant tumor incidence in two species, with tumors at multiple sites showing a clear dose–response relationship. Rare or unusual tumors at a site would be given added weight. Equivocal evidence may result from a statistically marginal result or only an increase in commonly occurring benign tumors. Tumor development in only one species and in association with species-specific toxicity is characteristic of nongenotoxic (or epigenetic) carcinogens. Sometimes, problems associated with such findings may be clarified by further mechanistic studies or by reference to historical data. When the data from bioassays are considered in human risk assessment, other factors must clearly also be taken into consideration. These may include evidence of genotoxicity in short-term tests and data on metabolism and potential human exposure. Furthermore, a measure of risk at doses substantially below the bioassay dose may be needed. This may require extrapolation using mathematical models. As yet, no general agreement has been reached as to the most appropriate method, and so, the calculated risk given by different methods may vary considerably. Thus, the final assessment may be made on quite pragmatic grounds, in which the experience and expertise of a number of individuals are drawn on to reach a consensus opinion.

Short-Term Predictive Tests

A large number of test systems have been developed to detect damage to the genetic material of cells in an attempt to predict carcinogenic potential and thereby reduce the reliance on animal tests. *In vitro* assays for detecting genotoxicity (i.e., damage to the cells genome that may be directly or indirectly heritable) include tests to detect gene mutation using bacterial or mammalian cells and the so-called indicator tests that detect mechanistic changes associated with the formation of mutations, such as the binding of foreign molecules to the DNA bases. *In vitro* tests are backed up by short-term *in vivo* tests to confirm that the effects seen *in vitro* are realized in the whole animal. These tests are usually undertaken in rats, mice (ordinary and transgenic), and/or hamsters but can also be done in fruit flies (see Table 4). Since many of the cell systems used are unable to activate metabolically the majority of test chemicals, an exogenous mammalian metabolizing system, the so-called S-9 mix, is incorporated into the assay. Chromosome damage seen in such tests includes chromosome and chromatid gaps and breaks, rings, fragments, dicentrics, translocations, and inversions. A short-term *in vivo* assay measuring unscheduled DNA synthesis in rat liver or gut is recommended by most regulatory authorities if there are a positive response in any *in vitro* assay and a negative response in an *in vivo* cytogenetics assay. Other test methods and end points are under consideration by regulatory authorities as indicators of genotoxic potential including the COMET assay for assessing DNA damage and aneuploidy, the change in chromosome number resulting from damage to the cellular architecture (spindle) controlling chromosome replication.

The last two decades has seen extensive efforts to determine whether short-term tests are suitable for predicting carcinogenic potential. The early validation studies suggested good predictability, with correct identification of over 90% of carcinogens (high sensitivity) and over 90% of noncarcinogens (high specificity). In later evaluations, a much lower figure (60%) was obtained. However, when carcinogens known to

Table 4 Short-term test systems for predicting carcinogenic potential

Test system	*Cell used*	*End point*
Bacterial mutation	*Salmonella typhimurium* TA strains *Escherichia coli* WP2	Reversion to histidine independence
Mammalian gene mutation	Chinese hamster lung (V79) Chinese hamster ovary (CHO) Mouse lymphoma (L5178Y) Human transformed lymphoblastoid (TK6)	Loss of HPRT, TK, or Na^+/K^+ ATPase expression
Chromosome aberration *in vitro*	Chinese hamster fibroblast (CHL) Chinese hamster ovary (CHO) Human peripheral blood lymphocytes(PBL)	Chromosome/chromatid aberration (gaps, breaks, and deletions)
Chromosome damage *in vivo*	Bone marrow erythrocytes (mouse)	Micronuclei induction
Heritable damage *in vivo*	Rodent germ cells	Dominant/lethal mutations; heritable translocations, etc.

HPRT, hypoxanthine phosphoribosyl transferase; TK, thymidine kinase.

react by nongenotoxic mechanisms (e.g., hormones or peroxisome proliferators) were excluded, the predictability was improved suggesting that short-term tests are suitable for detecting those carcinogens that act by a genotoxic mechanism.

Although many regulatory authorities have guidelines for carcinogenicity evaluation, which include short-term tests, they all still require animal studies as the ultimate test for carcinogenicity. However, the use made of short-term tests varies. In the United States, the Food and Drugs Administration recommends a battery of short-term tests for all additives for which cumulative dietary intake is expected to exceed 1.5 μg per person per day in order to assist in the interpretation of animal feeding studies. Some bodies, such as the IARC, use short-term tests as an adjunct to animal carcinogenicity studies in their evaluation processes, giving added weighting in their assessment of likely human risk to an animal carcinogen that is also positive in short-term tests.

However, until a consensus can be reached as to what a positive or negative result in an animal feeding study means in terms of whether the compound may or may not be a human carcinogen, the further development of better (faster/cheaper) short-term tests may be a futile exercise.

Monitoring and Control of Hazards and Risks

The complex mixture of chemicals that constitute food, together with the uncertainty of the specific role of the various components in the diet, has made the control of potential carcinogens in food difficult. In particular, the realization that animal carcinogens, as identified by standard animal bioassays, are widely distributed in the general environment, including food, has made control by total elimination impossible. Control of toxic agents in food particularly contaminants and additives has been achieved by examining their hazard in animal studies. Thus, the establishment of a no observable adverse effect level (NOAEL) is followed by the setting of an acceptable daily intake (ADI) through extrapolation based on the relative sensitivity of animals and humans to toxic events. This extrapolation may also take into consideration other properties of the chemical concerned, such as genotoxic potential. For genotoxic carcinogens, however, it is generally considered that there is no NOAEL, and therefore, acceptable intake is based on estimation of likely risk. A maximum risk of between 10^{-5} and 10^{-6} cancers in a lifetime is considered as an acceptable risk by most authorities, particularly those in the United States (in California, 10^{-5} is called the no significant risk level), and acceptable exposure estimates are determined by extrapolation from animal data. In California, the extrapolation (scaling) factor used to estimate human potency from rat potency is 5.5. For nongenotoxic carcinogens (and for some genotoxic carcinogens, particularly those that act as aneugens), it is considered that the NOAEL approach is acceptable, since the carcinogenic response is the result of a prior toxic event for which a no observed effect level (NOEL) can be determined. In most circumstances, an uncertainty (safety) factor of 100 is applied to the NOAEL, to allow for interspecies variation ($\times 10$) and interindividual variability ($\times 10$). In the case of carcinogens where a NOAEL approach is considered acceptable, sometimes, an extra safety factor is required on the NOEL for the tumors (not necessarily the same as the overall NOAEL for the study). If that is the case, the NOEL for the tumors ÷ high safety factor is calculated and the overall NOAEL for the study ÷ the normal safety factor is calculated and the lower resultant quotient is used to set the ADI. More recently, the two factors of 10 have each been subdivided into pharmacokinetic and pharmacodynamic components to reflect increased understanding of the mechanisms underlying the development of toxicity and to allow for factors associated with special groups such as infants and children. It must be said that the scientific basis to support either the acceptable risk or the NOAEL approach is quite limited as even for the best documented cases, the mechanism of the carcinogenic effect is poorly understood, and the relative sensitivity of laboratory rodents and humans is rarely known.

The unequivocal identification of human carcinogens is difficult since direct experimental approaches are precluded. Thus, epidemiological studies involving both prospective and retrospective studies and both cohort and case control studies may have to be employed. These techniques have limited applications to diet-associated carcinogenesis and have proved most useful in identifying specific carcinogens in the workplace or those used as therapeutic agents, where it is easier to quantitate exposure. The specific problem in identifying dietary carcinogens relates to the complexity of diet, the difficulty in identifying specific components, and the sensitivity of the epidemiological methods themselves. It would seem likely that epidemiological data will only be able to link specific chemical carcinogens in food with a carcinogenic effect in a few favorable circumstances, since such chemicals are likely to be present at low levels and induce only a small increase in tumor incidence over background levels. One such example was the identification of a carcinogenic hydrazone in the mushroom *Gyromitra esculenta*, as a result of an epidemiological study in Finland. Such methods have also indicated the relative importance of lifestyle factors in carcinogenesis: in particular, associations have been made between lack of dietary fiber and colon cancer, between a low intake of fresh fruit and vegetables and stomach cancer, and between excess dietary fat and colon and breast cancers, although the specific chemicals responsible have not been identified with any certainty.

Most of the activity aimed at controlling carcinogens in food has been directed at preventing addition of potentially carcinogenic substances to the existing background level of natural carcinogens. This has been tackled through the application of laws governing the adulteration of food, the first of which were enacted in the mid-nineteenth century in the United Kingdom. The relevant UK legislation was the 1990 Food Safety Act, governing the nature and quality of food and its nutritive value. This act, like its forerunner, the 1955 Food and Drug Act, requires that the constituents of food should not be injurious to health and is still in force. There is separate legislation for particular groups of compounds in food, such as pesticides, veterinary medicines, food additives, and food contact materials. Many aspects of food safety including carcinogens in food are now governed under European Union regulations, with risk assessments undertaken by the European Food Safety Authority in Parma, Italy.

The position in the United States up to 1958 was similar to that in the United Kingdom. Food was considered adulterated if injury could arise from its use. Legislation was based on

traditional food, added substances, and unavoidable added substances (contaminants). For added substances, listed in an inventory of over 3000 chemicals and often referred to as 'Everything Added to Food in the United States' (EAFUS), the food was considered adulterated if the added substance could render the food injurious to health; for unavoidably added substances, a balance was applied between the essential nature of the food material and the degree of contamination. These strictures applied to both carcinogenic and noncarcinogenic toxicants. In 1958, a change in emphasis was introduced through the Food Additives Amendment. This established a licensing scheme for substances deliberately added to foods or for substances that could migrate into food, but excluded materials that were generally, through usage, regarded as safe (GRAS). For licensing purposes, the material has to be shown to be 'safe' for its intended use, although in theory at least, the GRAS substance could be a carcinogen.

In 1958, the Delaney Clause was enacted; this required that if there was evidence of carcinogenicity in any test system, the material should be prohibited from food usage. Improved analytic techniques have shown that many foods contain both unintentionally added and natural carcinogens, such as polynuclear aromatic hydrocarbons, nitrosamines, mycotoxins, and arylamines, and no form of regulation could control these materials. Furthermore, bulk components of food may themselves play an important role in the development of carcinogenesis. The recognition that the exclusion of all potentially carcinogenic additives (under the Delaney Clause) is a practical impossibility has given way to the concept of safe tolerance and that safe levels may be set by appropriate, conservative risk assessment in which an insignificant lifetime risk of developing tumors of, for example, 10^{-6} is considered acceptable.

Mixtures of Substances

One criticism of present methods of risk assessment is that assessment is carried out singly; that is, it ignores possible combined action of multiple components in the diet and multiple routes of exposure. The enactment of the Food Quality Protection Act (FQPA) of 1996 in the United States changed this, as the act mandated consideration of all pathways of exposure (aggregate risk assessment) and of exposure to more than one pesticide at a time (cumulative risk assessment). There are a number of methodological problems with the latter, but considerable progress has been made in the United States. However, the most dramatic progress has been with regulated substances particularly pesticides and with end points other than carcinogenicity. The UK Department of Health published a report on risk assessment of mixtures, and the European Union, as a whole, has made further progress.

Carcinogens: Identification of Carcinogens

C Scoccianti, International Agency for Research on Cancer, Lyon, France

© 2016 Elsevier Ltd. All rights reserved.

Introduction

According to Globocan's estimates, 14.1 million new cancer cases and 8.2 million cancer deaths occurred worldwide in 2012, and the burden of cancer is expected to increase over the coming decades because of continuing global demographic and epidemiological transitions, particularly in low- and middle-income countries. More than 20 million new annual cancer cases have been forecast for 2025.

Identifying carcinogens and limiting human exposure are key aspects of cancer prevention. The International Agency for Research on Cancer (IARC) Monographs Programme is an authoritative source for the identification of carcinogenic hazards in the environment. These hazards include chemicals, complex mixtures, occupational exposures, physical agents, biological agents, and lifestyle factors. In order to identify such hazards, the IARC Monographs employ international working groups of independent scientists who evaluate human exposure, epidemiological evidence, evidence from experiments in animals, and from mechanistic studies. Working groups make scientific, qualitative judgments on the evidence for or against carcinogenicity based on the available data.

Each *IARC Monograph* includes information on the production and use, occurrence, sources, and routes of human occupational and environmental exposure. All pertinent epidemiological studies are considered in order to asses the risk of developing cancer in different population groups. Several criteria are used to asses causality and temporality, the precision of estimates of effect, biological plausibility, and the coherence of the overall available literature. From an experimental point of view, an agent is considered to be carcinogenic when its administration to experimental animals induces a statistically significant rise in the incidence of one or more histological types of neoplasia, reduces latency, or increases the severity or multiplicity of cancers, as compared to results in animals not exposed to the substance. The IARC Monographs consider studies that follow the guidelines for conducting long-term carcinogenicity experiments, such as those developed by the Organisation for Economic Cooperation and Development (OECD). Finally, the evaluation of mechanistic data may provide evidence of carcinogenicity and also help in assessing the relevance and importance of findings of cancer in animals and in humans. The nature of these data depends on the biological activity of the agent being considered. Relevant topics may include toxicokinetics, mechanisms of carcinogenesis, susceptible individuals, populations and life-stages, and other adverse effects.

Since 1971, more than 900 agents have been evaluated by the *IARC Monographs* of which more than 400 have been identified as carcinogenic to humans (IARC Group 1), probably carcinogenic to humans (IARC Group 2A), or possibly carcinogenic to humans (IARC Group 2B). These categories only refer to the strength of the evidence that an exposure is carcinogenic, as opposed to the extent of its carcinogenic activity (potency). Classifications may change as new information becomes available. The IARC classifies an agent as *carcinogenic* when sufficient evidence in humans supports a causal relationship between exposure to the agent and an increased risk of cancer in target organs (the identification of a specific target organ or tissue does not preclude the possibility that the agent might also cause cancer at other sites). When the evidence in humans is less than sufficient but evidence in experimental animals and on relevant mechanisms of carcinogenicity in exposed humans are strong, the agent may be classified as carcinogenic as well.

At present, the IARC Monographs have classified the following agents in food and drink as carcinogenic to humans: aflatoxins, ethanol in alcoholic beverages, arsenic in drinking water, and Chinese-style salted fish. This article reviews the listed agents with regard to the source of exposure, patterns of consumption, and evidence of carcinogenicity in humans. The article also discusses several other food components identified as probable or possible carcinogens, as well as food agents recommended by the IARC Monographs for future assessment.

Sources and Production

Aflatoxins

Aflatoxins are natural carcinogens produced primarily by the common fungus *Aspergillus flavus* and the closely related species *Aspergillus parasiticus*. Aflatoxin B1 is the most common and potent of this large group of mycotoxins. It develops when the temperatures are between 24 and 35 °C and the moisture content exceeds 7% (e.g., at latitudes between 40° N and 40° S of the equator). Contamination may occur before harvest, resulting in potentially high levels of aflatoxins in dietary staples, such as maize, peanuts, and rice, and continuing difficulty in eliminating aflatoxins from these products. Various spices sometimes contain aflatoxins, but tree nuts and a wide range of other foods are contaminated less frequently.

With other crops, the prevention of aflatoxin formation mainly relies on the avoidance of contamination after harvest through the use of rapid drying and good storage practices.

Alcoholic Beverages

The predominant commercially produced alcoholic beverages are beer, wine, and spirits. They may be consumed in combination to increase the alcoholic strength of the beverage (e.g., wine may be fortified with spirits). In many developing countries, other types of alcoholic beverage, such as sorghum beer, palm wine, or sugarcane spirits, are produced at home or locally through the fermentation of seeds, grains, fruit, vegetables, or parts of palm trees, using a fairly simple production process.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00118-5

The basic ingredients for beer are malted barley, water, hops, yeast, and sometimes wheat. Beer is available in nearly all countries from transnational producers, their subsidiaries, joint ventures, or local partners. Different beer products may vary widely in ethanol content, from low or no-alcohol beers (pure alcohol, 0.5–2.5%), to stronger stouts, ales, and other malt-based products containing up to 14% pure alcohol.

Nearly all wine is produced from grapes, but wine is also made from other fruits and berries. Wine usually ranges in strength from 10% to 14% pure alcohol. Products with higher alcohol content, such as sherries, ports, cognacs, and brandies, are generally classified as fortified wines, and their alcohol content may be as high as 20–22%.

Spirits are frequently produced from cereals (e.g., corn, wheat), beets, molasses, grapes, cane sugar, potatoes, and other fruits. Distilled spirits vary widely in strength because the distillation process may produce liquids with very high alcoholic content. Approximately 54% of distilled spirits worldwide are so-called traditional or local products. Some previously local products have become global commodities, such as Scotch whisky and tequila, which are now industrially produced and traded internationally. Other spirits continue to be made using low-level traditional technology, which in some cases (e.g., the *kachasu*, or kill-me-quick, of Southern Africa) may involve the use of any available ethanol-strengthening agents, including battery acid. Other regional or national products include the *aguardiente* or cane spirits from parts of Latin America, the Republic of Korea's *shochu*, Mexico's *pulque*, India's *arrack*, and products specifically consumed by local ethnic or tribal groups. Local products are often produced for home use or trade in the informal sectors of developing economies.

Arsenic in Drinking-Water

Arsenic is a naturally occurring metalloid, and it is mainly transported through the environment by water. Arsenic is a component of more than 245 minerals, especially sulfide-bearing mineral deposits, and it has a strong affinity for pyrite, which is one of the more common minerals in the earth's crust. The weathering of rocks converts arsenic sulfides into arsenic trioxide, which enters the arsenic cycle as dust or by dissolution in rain, rivers, or groundwater, thus entering the food chain (e.g., arsenic may be abundant in certain seafoods). The form and concentration of arsenic depend on several factors, including whether the water is oxygenated (e.g., arsenites predominate under reducing conditions, such as those found in deep well-water), the degree of biological activity associated with the conversion of inorganic arsenic to methylated arsenic acids, the type of water source (e.g., water from the open ocean vs. surface freshwater or groundwater), and the proximity of the water source to arsenic-rich geological formations and other anthropogenic sources. The natural and anthropogenic occurrence of arsenic in drinking water has been recognized as a major public health issue in several regions of the world, where high concentrations in fruit, vegetables, grain, and meat have been reported.

Chinese-Style Salted Fish

In southern China, about 20 different fish, such as red snapper, threadfin, Spanish mackerel, croaker, and Japanese mackerel, are prepared in salted form. Salted fish are prepared by salting, brining, dry-salting, pickle curing, or a combination of these treatments. In brining, fish are placed in a solution of crude salt and water until the fish tissue has absorbed the required amount of salt. For dry-salting, fish are mixed with dry salt, and the resultant brine, produced by the dissolution of the salt in the water content of the fish, is allowed to drain away. During pickling or pickle-curing, the fish is mixed with salt and stored under the brine (pickle), which forms when the salt dissolves in the water extracted from the fish. The fish are then dried under the sun for 1–7 days, depending on the size of the fish and the weather. Salted fish prepared in this way are called tough- or hard-meat-salted fish. Softening the fish by decomposition prior to salting produces soft-meat-salted fish that are usually stored for up to 5 months before consumption.

During the drying of salted fish, infestation by insects can be a serious problem, especially in damp weather. In southern China, the high average annual temperature and humidity are favorable to the growth of bacteria such as *Staphylococci*.

Human Exposure

Aflatoxins

Ample evidence suggests that a large proportion of sub-Saharan Africa, south-east Asia, and Latin America experience high-level chronic dietary exposure to foodborne mycotoxins, particularly aflatoxins. The growth of aflatoxin-producing molds is greatly favored by the high temperature and relative humidity, in combination with inadequate processing facilities, storage, or transportation. Aflatoxins have been found in a variety of agricultural commodities, but the most pronounced contamination has been identified in maize, peanuts, cottonseed, and tree nuts. Children are chronically exposed to high levels of aflatoxins in areas where food contamination is endemic and this pattern of exposure continues throughout life. Acute poisoning following exposure to high doses of aflatoxin (aflatoxicosis), is a major public health problem. However, evaluating the extent and severity of aflatoxin's exposure in developing countries can be difficult since diseases in these regions often go unreported, and only major outbreaks are known to investigators. A precise characterization of the exposure might be derived from direct assessments (quantitation of biomarkers such as urinary aflatoxins and aflatoxin-albumin adduct, or the 249*TP53* mutation), in combination with reports of contamination in foods sampled from markets and trade shipments, reports of acute poisoning incidences, and the measurement of organ toxin levels in postmortem reports.

Alcoholic Beverages

Nearly 2 billion adults regularly consume alcoholic beverages, with an average daily consumption of 10–12 g of ethanol (about one drink). Alcoholic beverages have been an integral part of many cultures for thousands of years, and the use of fermented alcoholic beverages persists in all tribal and village societies, except those in Australia, Oceania, and North America. In general, men consume substantially more alcoholic drinks than women, but also age and socioeconomic status are key factors

in determining the levels of alcohol consumption. Within almost all populations, consumption varies widely, usually as a function of availability, price, culture, religion, and dependency. Worldwide, the average consumption is nearly four times higher in high-income countries than it is in low-income countries, and alcohol consumption tends to be highest in Europe, North America, and Oceania. The most recent data from the OECD show that adult individuals (aged ≥ 15 years) drink an average of 9.4 l of pure alcohol each year. Consumption varies within countries, however. Many people do not consume alcoholic drinks, and alcoholic beverages are illegal in Islamic countries. Some people drink occasionally, and others consume at least 15–25% of their dietary energy as alcohol. Consumption also varies with regard to the different types of beverage. Beer is the most widely consumed alcoholic drink worldwide, and it is particularly popular in Europe, North America, and Oceania. Wine is mainly consumed in Europe, Australasia, and the Americas, with highest levels of consumption in western and southern Europe. The data on average consumption of spirits or liquors is scarce. An increasing number of young people report excessive alcohol consumption, especially in high-income countries. Excessive alcohol consumption is also referred to as binge drinking, and it is defined as the consumption of ≥ 60 g of pure alcohol on the same occasion on at least one day in the last month.

Records do not yet track the sales of alcoholic beverages that are not taxed in the country where they are consumed. As a consequence, the average consumption of alcoholic drinks, internationally and nationally, is underestimated. This unrecorded drinking includes the consumption of homemade or informally produced alcohol (legal or illegal), smuggled alcohol, alcohol intended for industrial or medical uses, and alcohol obtained through cross-border shopping.

Arsenic in Drinking Water

Nonoccupational exposure to arsenic occurs mainly through food, except in areas with high levels of arsenic in drinking water. High concentrations of arsenic have been measured in drinking water in large areas of Bangladesh, China, West Bengal (India), and smaller areas of Argentina, Australia, Chile, Mexico, Taiwan (China), the United States, and Vietnam. In some areas of Japan, Mexico, Thailand, Brazil, Australia, and the United States, mining, smelting, and other industrial activities have contributed to elevated concentrations of arsenic in local water sources. Several other regions have reported drinking water that is highly contaminated with arsenic. In most of these regions, the drinking-water source is groundwater, which is naturally contaminated from arsenic-rich geological formations. The epidemiological evidence from drinking-water exposure indicates that carcinogenicity is related to exposure to As^{III} and As^{V}, which are the predominant oxidation states of arsenic under reducing and oxygenated conditions, respectively.

Chinese-Style Salted Fish

Salted fish is popular among coastal populations in southern China and in Southeast Asian countries, where it is often used as an accompaniment to other dishes or rice. Although the amount consumed at any one time is small (not more than 10 g), the dish may appear at every meal. Salted fish mixed with rice has also been used as a traditional weaning food, as well as a food for infants. The consumption of salted fish in Chinese populations has been declining since the second half of the twentieth century, and consumption during weaning and early childhood is now rare. Both cultural changes and other methods of preserving food may be responsible for this decrease.

Evidence of Carcinogenicity

Aflatoxins

The adverse toxicological consequences of aflatoxins in populations are quite varied, owing to a wide range of exposures that lead to a panel of acute effects, including rapid death, impaired growth, immune suppression, and chronic outcomes, such as hepatocellular carcinoma (HCC). The mold-produced aflatoxins were first considered by the IARC Monographs in 1971 and identified as carcinogens in animals before they were shown to be human liver carcinogens (IARC Group 1) in 2009. The relationship between aflatoxin exposure and liver cancer risk is one of the most extensively documented examples of a widely disseminated environmental carcinogen. Several key steps in the development of aflatoxin-induced carcinogenesis are now well accepted by the research community, and provide strong evidence that the mechanism of action involves activation to a genotoxic metabolite, formation of DNA adducts, and induction of a specific mutation in codon 249 of the tumor suppressor *TP53* gene. Geographically distinct cohort studies have independently found that aflatoxin exposure significantly increases the risk of developing HCC. In addition, several case–control studies have confirmed that aflatoxins act synergistically with hepatitis B virus (HBV) to increase the risk of liver cancer 12-fold.

Alcoholic Beverages

As evaluated by the IARC Monographs, the consumption of alcoholic beverages causes cancers of the oral cavity, pharynx, larynx, esophagus, colorectum, liver (HCC), and female breast. An association has also been observed with pancreatic cancer. For the majority of the above-cited cancer sites, risk estimates emphasize a dose-dependent relationship that does not vary by beverage type and does not show a threshold of intake, since the adverse effect is observed even at consumption of less than 1 alcoholic drink per day. For cancers of the upper digestive tract a synergistic effect with tobacco smoking is observed. Drinking patterns play an important role in modulating this relationship. Alcohol consumption results in exposure to acetaldehyde, which is derived from the beverage itself and formed endogenously. Both acetaldehyde and ethanol associated with the consumption of alcoholic beverages are carcinogenic to humans (IARC Group 1). Acetaldehyde is detoxified by aldehyde dehydrogenases (ALDH). The ALDH2*2 variant allele, which encodes an inactive enzyme, is prevalent (up to 30%) in East Asian populations. Heterozygous carriers, who have about 10% enzyme activity, accumulate acetaldehyde and have higher relative risks of

alcohol-related esophageal, head and neck cancers, as compared to individuals with the common alleles.

Among nonsmokers, reported relative risks for esophageal squamous cell carcinoma and laryngeal cancer range from 0.74 (95% CI: 0.47–1.16) for light- ($\leq$1 drink corresponding to 10–12 g of ethanol) to 3.09 (95% CI: 1.75–5.46) for high- ($\geq$4 drinks corresponding to 50 g of ethanol) alcohol daily intakes. Summary effect estimates for colorectal cancer are 1.11 (95% CI: 0.90–1.38) at 1 drink per day and 1.41 (95% CI: 1.16–1.72) at more than 4–5 drinks per day. Associations between alcohol consumption and HCC are generally found at high intakes, with significant increased risk of about 30–40% occurring at consumption levels >40 g day^{-1}. The risk of breast cancer at 10 g day^{-1} ethanol intake appears to be increased by 8% for postmenopausal women and 9% for premenopausal women. Future research should aim to determine if and to what extent these relative risk functions differ by cancer incidence and mortality.

The overall risk of cancer in men who consume more than two alcoholic drinks per day and in women who consume more than one alcoholic drink per day is 6% higher than it is in people with lower alcohol consumptions. Based solely on the discussed evidence on cancer, even small amounts of alcoholic drinks should be avoided. In addition, excessive alcohol drinking is associated with many other acute consequences, such as alcohol poisoning, injury, and violence.

Arsenic in Drinking water

Epidemiological studies indicate that exposure to arsenic through inhalation or drinking water causes cancer of the lung, skin, and urinary bladder. In northern Chile, a case–control study reported significantly increased risk of lung cancer with increased exposure to arsenic from drinking water, with an odds ratio increasing to 7.1 (95% CI: 3.4–14.8). Evidence also points to a dose–response relationship between drinking arsenic-contaminated water and bladder cancer within exposed populations. The highest risks were seen for people who had experienced over 40 years of exposure, with an odds ratio of 4.1 ($P<0.01$). Dose–response relationships are also suggested for skin cancer (squamous cell carcinoma of the skin) within the exposed populations. A retrospective cohort study reported a standardized mortality ratio of 28 (95% CI: 11–59) for skin cancer deaths, based on seven observed deaths.

The available evidence also indicates an association between exposure to arsenic in drinking water and the development of tumors at several other sites, including the kidney, liver, and prostate. However, various factors prevent one from drawing a solid conclusion, and the possibility of chance or bias cannot be ruled out.

The organic arsenicals monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA) are the active ingredients of some herbicides, and they are metabolites of inorganic arsenic. Given the sufficient evidence that DMA caused cancer in experimental animals, and because MMA is extensively metabolized into DMA, both compounds are classified as possibly carcinogenic to humans (IARC Group 2B).

Chinese-Style Salted Fish

The IARC Monographs reviewed uncooked salted fish in different countries and concluded that Chinese-style salted fish causes cancer of the nasopharynx and possibly of the stomach. Two possible mechanisms for the observed cancer risk are (1) the formation of *N*-nitroso compounds, including *N*-nitrosamines, during the preparation of salted fish and (2) the activation of the oncogenic Epstein–Barr virus (EBV).

The effect of salted fish on the risk of nasopharyngeal cancer seems to be most pronounced for consumption in early childhood and during weaning, while the association with adult consumption appears weaker. The association remains after adjustment for EBV status. The effect observed on the risk of stomach cancer is modest, and adjustment for important confounding risk factors (including smoking, alcohol, and *Helicobacter pylori* infection) is missing in several studies. Also, studies lack an investigation of the association between salted fish and EBV-positive gastric carcinomas.

Other Food Carcinogens and Future Perspectives

In addition to the previously discussed factors, the IARC Monographs have assessed the evidence for the carcinogenicity of several other food components. The dried leaves of the *Yerba mate* plant are mainly consumed in Argentina, Brazil, Paraguay, Bolivia, Chile, Ecuador, and Uruguay. Most often, the leaves are prepared in a hot infusion beverage drunk from a gourd or other container through a straw, which places very hot fluid at the oropharynx and esophagus. Hot mate drinking has been classified as probably carcinogenic to humans (IARC Group 2A). Several epidemiological studies support the role of hot mate in increasing the risk of upper gastrointestinal tract cancers. A population-based survey conducted in Brazil showed that the mean temperature just before consumption was 69.5 °C. Thus, temperature could act by directly damaging the mucosa or accelerating metabolic reactions, including those with carcinogenic substances in tobacco and alcohol. At present, it is unclear whether the potential carcinogenic effect of mate is due to the components of the plant, to the temperature at which it is consumed, or both, and the possibility of residual confounding by alcohol drinking and tobacco smoking cannot be excluded. The IARC Monographs will re-evaluate mate drinking, in light of new evidence in support of an association between mate consumption and esophageal squamous cell carcinoma.

Processed meat, such as ham, bacon, sausage, and hot dogs, contains high concentrations of preformed nitroso compounds, some of which are potential carcinogens (IARC Group 2A). Red meat contains heme iron, which promotes carcinogenesis through its catalytic activity on the formation of nitroso compounds and lipid oxidation end-products such as 4-hydroxynonenal. In some processed red meats, heme iron is nitrosylated, because curing salt contains nitrate or nitrite. Also, polycyclic aromatic hydrocarbons, heterocyclic aromatic amines, and aldehydes are formed in meat when amino acids and creatine react at cooking temperatures greater than 180 °C. Numerous studies have shown an association between high intakes of processed meat and colorectal cancer. Consumption of red and processed meat has also been found to be associated with a risk of stomach and pancreatic cancers. In addition to the carcinogenicity of nitroso compounds, the relationship between processed meat and stomach cancer could be due to the high salt content of processed meats. In light of the

cumulating evidence, the IARC Monographs will evaluate the carcinogenic effects of consuming red meat and processed meat.

The consumption of sugar-sweetened beverages may promote carcinogenesis by increasing insulin and glucose levels, and appears to be associated with obesity and diabetes. In turn, overweight and obesity are associated with the onset of cancer at several sites including colon, breast (postmenopausal), endometrium, kidney, oesophagus, and possibly pancreas and ovary. The IARC Monographs will evaluate the potential carcinogenic effects of widely used artificial sweeteners such as aspartame and sucralose.

Several other chemicals in food constituents, contaminants, and flavorings have also been previously evaluated as possibly carcinogenic to humans (IARC Group 2B). These substances include coconut oil, 2,4-hexadienal, methyleugenol, methyl isobutyl ketone, 1,3-dichloro-2-propanol, 3-monochloro-1,2-propanediol, and 4-methylimidazole.

In addition to the agents mentioned above, the IARC Monographs have identified for future evaluation: acrylamide, furan, and 5-(hydroxymethyl) furfura, which are food agents commonly found in cooked foods; coffee; dimethylformamide, which is a widespread contaminant of water; and iron in food and supplements. The evaluation of these substances is considered a high priority for public health, owing to the accumulating evidence on adverse effects.

Carotenoids: Occurrence, Properties and Determination

J Lerfall, Sør-Trøndelag University College, Trondheim, Norway

© 2016 Elsevier Ltd. All rights reserved.

Occurrence

Carotenoids are red, orange, and yellow isoprenoid polyene pigments produced by bacteria, algae, and plants. In nature, more than 700 carotenoids exist, and an annual bioproduction of 100 million tonnes makes carotenoids among the most widespread and largest groups of pigments in nature. Carotenoids are found throughout the plant kingdom and are the major endogenous pigments on flowers, fruits, and vegetables and exogenous pigments in insects, birds, and fish. Carotenoids are also present in green vegetables and leaves, but their colors are masked by chlorophyll. In autumn, however, degradation of chlorophyll means carotenoids are responsible for the typical red, orange, and yellow colors of autumn leaves.

Carotenoids are classified into two main subclasses: carotenes and xanthophylls where the oxygenated xanthophylls are dominant. In addition to the wide variety of carotenoids in nature, carotenoids occur in different stereoisomers (*E*/*Z*) and optical isomers (*R*/*S*) (Figure 1).

The ability to produce carotenoids is mainly reserved to some bacteria, algae, and the higher plants, while higher-order animals are dependent on diet for their carotenoids. However, subsequent transformations of carotenoids obtained from the diet may lead to animal-specific carotenoids that are not normally found in organisms incapable of synthesizing carotenoids *de novo*.

In general, carotenoids in bacteria and algae provide a wider variety of structural types than those found in higher plants. The hydroxyl carotenoids often occur in the form of derivatives, that is, xanthophylls in fruits as fatty acid esters in contrast to the xanthophylls found in leaves. In fungi, some tertiary alcohols and pigments also occur as fatty acid esters. Carotenoid–protein interactions arise where a stoichiometric combination between a protein and astaxanthin-related carotenoids is present. The best-known example is astaxanthin, which was believed to bind weakly to hydrophobic sites of actomyosin in salmon flesh. However, recent research has indicated astaxanthin is associated with other muscle proteins as well as actomyosin, and the major astaxanthin-binding protein in salmon muscle is α-actinin. Other carotenoids, such as β-carotene and lutein, appear in association with proteins without specific interactions. In plants, it is assumed that carotenoids are located in the grana of the chloroplasts in the form of chromoproteins. In addition to these interactions between proteins and carotenoids, a more specific link between proteins and carotenoids also exists; one example is the blue carotenoprotein, crustacyanin, in lobster shell, which typically adopts the color of the carotenoid when cooking denatures the protein–carotenoid complex.

Distribution of Carotenoids in Food

Among the wide variety of carotenoids, only 50–60 of them are present in human diets. Of these, ~35 including nine metabolites are present in human plasma and tissues.

The main sources of natural occurring carotenoids are fruits and vegetables and salmonid fish. In addition, eight natural groups of carotenoids are used as food colorants; these include α-, β-, and γ-carotene (E160a); bixin, norbixin, and annatto (E160b); capsanthin, capsorubin, and paprika (E160c); lycopene (E160d); β-apo-8′carotenal (E160e); ethyl ester of β-apo-8′carotenal (E160f); and lutein. For human health, E160a, E160d, and E161 are probably the most important because they are powerful antioxidants. Those carotenoids presented in fruits and vegetables can, due to their distribution, be categorized as belonging to three different subgroups: (1) green fruits and vegetables, (2) yellow-red fruits and vegetables, and (3) yellow-orange fruits and vegetables.

Green fruits and vegetables: Among green fruits and vegetables, green beans (*Phaseolus vulgaris*), lima or butter beans (*Phaseolus lunatus*), calabrese broccoli, Brussels sprouts, cabbage, kale, kiwi, lettuce, honeydew muskmelon, green peas, spinach, and green-harvested wheat are important sources of carotenoid in human diet. Green fruits and vegetables are rich in chlorophylls and several carotenoids, including epoxycarotenoids, lutein, zeaxanthin, α-carotene, β-carotene, and traces of α- and β-cryptoxanthin. Except for epoxycarotenoids, all these carotenoids are found in human plasma.

Yellow-red fruits and vegetables: Among yellow fruits and vegetables, apricots, cantaloupes, carrots, pumpkin, and sweet potatoes predominate as carotenoid sources in human diets. Common carotenoids are α-carotene, β-carotene, γ-carotene, ξ-carotene, phytofluene, and phytoene. Among red fruits and vegetables, pink grapefruit, tomatoes, and watermelon are typical sources of carotenoids such as lycopene, ξ-carotene, β-carotene, phytofluene, and phytoene. All carotenoids occurring in yellow-red fruits and vegetables give rise to high concentrations of carotenoids in human plasma following dietary intake.

Yellow-orange fruits and vegetables: Among yellow-orange fruits and vegetables, maize, mango, papaya, peaches, prunes, squash (acorn – *Cucurbita pepo* var. *turbinata*), squash (winter – *Cucurbita* spp.), oranges, and citrus fruits dominate as carotenoid sources in human diet. Typical carotenoids include epoxycarotenoids (not observed in human plasma), lutein, zeaxanthin, β-cryptoxanthin, α-carotene, β-carotene, ξ-carotene, phytofluene, and phytoene.

Carotenoid distribution in *Salmonidae* spp. is dependent on the carotenoids in the fish diet. The reddish color typically associated with farmed Atlantic salmon is due mainly to the synthetic but nature-identical carotenoid, astaxanthin, which is commonly used in salmonid fish feed for muscle pigmentation. This carotenoid also dominates in wild salmonid consuming krill and other shellfish. Canthaxanthin is also allowed as an additive in salmonid feed. However, the use is more limited due to the potential for the formation of crystalline deposits in human retina despite the relevant European Food Safety Authority (EFSA) panel concluding that total anticipated combined exposure to canthaxanthin, for adults and children, from food

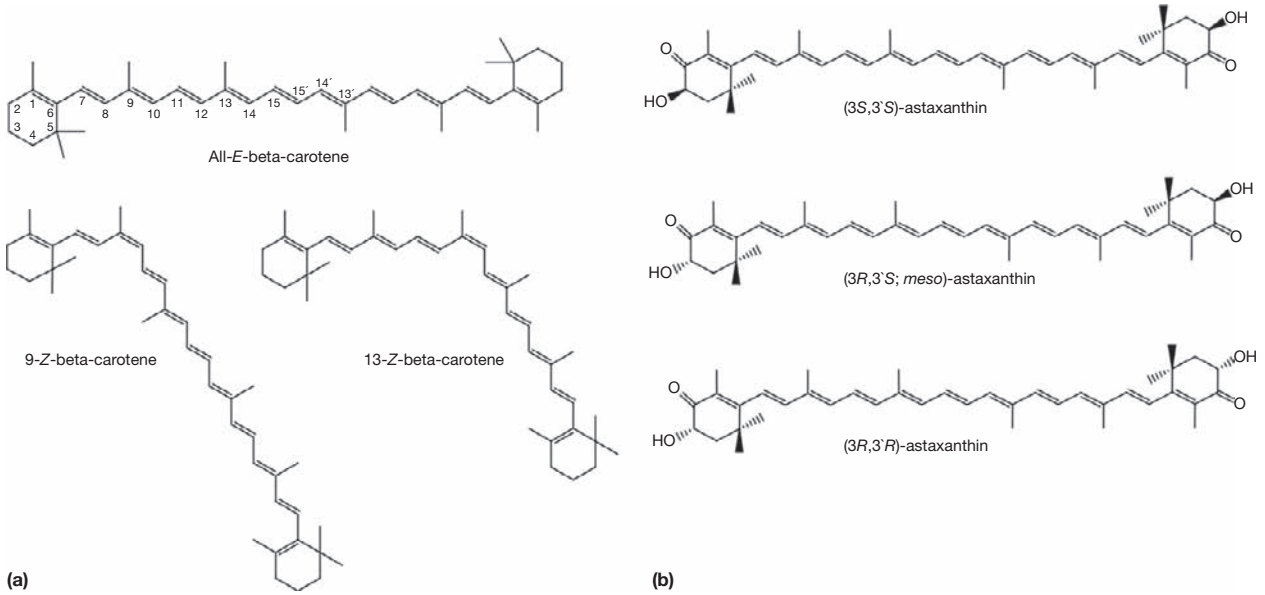

Figure 1 (a) Examples of geometric isomers of β-carotene. (b) Optical isomers of astaxanthin.

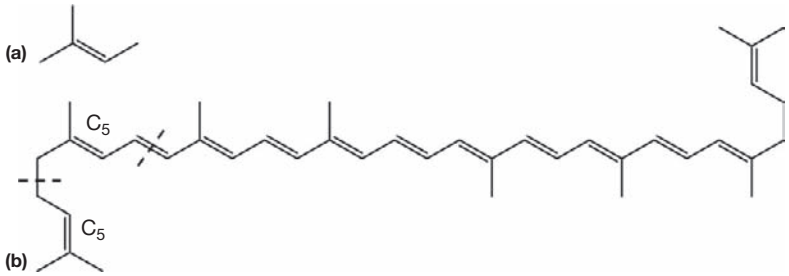

Figure 2 The basic C_5-isoprene units (a) and lycopene (b).

and feed additives is unlikely to exceed acceptable daily intake (0.30 mg kg bw^{-1} day^{-1}). The introduction of vegetable oils and alternative microbiological sources of carotenoids in the feed has, over recent years, introduced traces of other carotenoids such as lutein, zeaxanthin, adonirubin, and β-carotene in the salmon flesh. In production of organic salmon, natural sources of astaxanthin are required, which include the yeast *Xanthophyllomyces dendrorhous* (previously *Phaffia rhodozyma*) and the bacteria *Paracoccus carotinifaciens* (Panaferd-AX).

Properties

The basic carotenoid structure is lycopene, a C_{40} conjugated polyene chain built up of eight C_5-isoprene units, as shown in Figure 2.

This polyene chain represents a chromophore responsible for the characteristic colors, going from colorless (phytoene, three conjugated double bounds), to light yellow (ζ-carotene, seven conjugated double bounds), to yellow (4,4′-diaponeurosporene, nine conjugated double bounds), to red (paprika pigment capsanthin, 10 conjugated double bounds), to orange (β-carotene, 11 conjugated double bounds), to pink (bacterioruberin, 13 conjugated double bounds), to blue with an increasing numbers of conjugated double bounds. When associated with proteins, as carotenoproteins, a dark blue color is obtained such as crustacyanin in lobster shell.

In nature, carotenoids have several functions such as attracting pollinating insects in flowers, indicating maturity in fruits, recognizing and attracting the bird mating process, and signaling molecules in several animal species. Carotenoids are also capable to both transfer and acceptance of photon energy (carotenoid + light energy → ^{1}carotenoid). In photosynthesis, carotenoids absorb visible light where chlorophylls have only weak absorbance. The energy is effectively transferred to the chlorophyll, resulting in singlet-excited chlorophyll (^{1}carotenoid + chlorophyll → carotenoid + ^{1}chlorophyll). Carotenoids are also an important defense against light damage of cells in green plants, algae, and photosynthetic bacteria.

Carotenoids are labile compounds and may decompose when exposed to light, oxygen, high pressure, or potentially other chemical components. In addition, carotenoid stability is affected by esterification and carotenoid–protein interactions. For example, astaxanthin stability in salmon muscle is related to the strength of protein–astaxanthin binding. Several studies have shown decomposition of carotenoids during food processing, where a distinct effect of process parameters can be observed. Some factors affecting carotenoid stability during

processing are increased temperature, prolonged processing time, high concentrations of oxygen and/or sodium chloride, prooxidants, rancidity, and high pressure.

In recent decades, the presence of carotenoids in our food supply, and their role in human health, has been of unprecedented interest. Some carotenoids are vitamin A precursors, and about 35 carotenoids are found in human plasma, depending on dietary composition. Interest in the relationship between carotenoids and human health goes back to the 1930s, but the breakthrough that placed carotenoids among the most important food components occurred in 1981. In a *Nature* publication, the question 'Can dietary β-carotene materially reduce human cancer rate?' was raised. The answer was yes, and 3 years later, a new keystone paper dealing with β-carotene as a newly recognized antioxidant stimulated many carotenoid researchers to search for new functions of carotenoids related to human health. Even after more than 30 years of intensive research, however, it is still not clear if carotenoids have an important role as antioxidants *in vivo*, although their consumption is associated with reduced risk of a range of age-related diseases including cancer.

Antioxidant Properties

Several papers have reviewed antioxidant actions of carotenoids. The role of carotenoids as antioxidants is complex; under some circumstances, carotenoids show a prooxidant effect although this remains controversial and may not distract from their health benefits.

Reactive oxygen species (ROS) are generated constantly in the body by metabolism, and the mitochondria seem to be the subcellular center for ROS production. In addition to ROS generated during respiration and metabolism (e.g., $^1O_2$, $OH^{\bullet}$, $O_2^{\bullet-}$ $ROO^{\bullet}$, and H_2O_2), humans are also exposed to exogenous sources of free radicals (e.g., radiation, tobacco smoke, and pesticides). Free radicals and singlet oxygen can be beneficial, because they kill pathogenic organisms that invade the body, but oxidative stress occurs if there is an overproduction of these extremely reactive components. When oxidative stress arises, ROS/reactive nitrogen species and free radicals react with fatty acids in cell membranes, enzymes, nucleic acids, and endothelial cells causing damage, which may lead to lyses, mutation, and/or inflammation correlated with aging and chronic diseases. Studies show that diets containing carotenoids are related to reduced risk of these pathological conditions.

Carotenoids are known to affect many different cellular pathways. The antioxidant properties of carotenoids are due mainly to excellent physical quenching of singlet oxygen ($^1O_2$) where the energy absorbed to produce triplet oxygen ($^3O_2$) is converted to rotary and vibratory energy by the carotenoid chromophore system. The quenching rate of carotenoids increases with increasing numbers of double bounds and varies with functional groups and chain structure. The role of carotenoids as radical scavengers is more limited. However, several studies have shown that carotenoids also effectively trap free radicals but via a different mechanism compared with more usual chain branching antioxidants (initiation, propagation, and termination). One suggested mechanism is an addition reaction between the carotenoid molecule and peroxyl radicals, which produces a resonance stabilized carbon-centered radical. Several studies (*in vitro*) have verified β-carotene to be highly reactive with peroxyl radicals but only at low oxygen tension (lower than 150 mmHg/20 kPa (atmospheric pressure is 101 kPa)). This correlates well with oxygen pressures found in most tissue under physiological conditions, which supports β-carotene as an antioxidant *in vivo*. At high oxygen pressure, β-carotene behaves as a prooxidant.

Antioxidant actions of carotenoids in living organisms are complex. Several studies have shown that carotenoids interact synergistically with several other antioxidants. The best-known example is probably between β-carotene and α-tocopherol (vitamin E) in protection of lipid peroxidation *in vivo*. Another example, however, is zeaxanthin in combination with ascorbic acid (vitamin C) and vitamin E, which together protect human retinal pigment cells against oxidation induced by photoreactions. To explain the synergism between different antioxidants, it is important to consider the different properties of the molecules involved; some of them are hydrophilic and others hydrophobic. This means they are located in different surroundings throughout membrane systems and subcellular regions. Vitamin C is water-soluble and traps radicals in plasma and cytosol, whereas the carotenoids and vitamin E are fat-soluble and are presented in the lipid phase of membranes. In addition, vitamin C enhances vitamin E activity by reducing the tocopheroxyl radical, while the carotenoid cation radical is repaired by vitamin C.

Provitamin A Carotenoids

Provitamin A activity of carotenoids is well studied, and for humans, the activity is limited to carotenoids that have at least one unsubstituted β-end group (Figure 3). Typical examples of provitamin A carotenoids in humans are α-carotene, β-carotene, and β-cryptoxanthin. On the other hand, species such as the salmonids can convert astaxanthin and other xanthophylls to vitamin A when the dietary supply is insufficient. In humans, the conversion of β-carotene to vitamin A takes place in the intestine and other tissues. Thus, after an oral dose, both intact β-carotene and its metabolite retinol can be found in the circulation. In mammals, the conversion of β-carotene into vitamin A is supposed to happen via two potential pathways: The central cleavage pathway includes the cleavage of the 15,15′ C-double bond producing two molecules of retinal. Alternatively, one molecule of retinal can be produced after stepwise oxidation of β-carotene beginning at any of the double bonds in the conjugated polyene chain.

Vitamin A (retinol), and its chemically related forms retinal and retinoic acid, is essential for development, growth, health, and survival of most living organisms. The role of retinal in

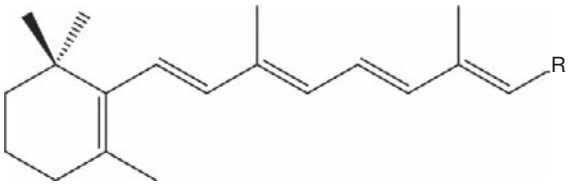

Figure 3 Unsubstituted β-end group.

chromophore pigments, such as rhodopsin, is well understood and vitamin A deficiency is linked directly to reversible night blindness, which may be followed by irreversible loss of sight. Vitamin A deficiency is also linked to impaired immune function, resulting in increased incidence of respiratory and gastrointestinal infections, and measles. In Western societies, where sources of vitamin A are unlimited (e.g., egg, meat, and fish), the conversion of provitamin A carotenoids is limited (<30% of daily intake). In developing countries, where vitamin A deficiency still is a problem, both supplementary programs and food-based interventions are used to increase the vitamin A intake among the population. *Golden Rice* is an example of a fortified food developed for use in areas where their dietary supply of vitamin A is poor. Genetically engineered, this rice produces β-carotene in the edible grain. Details of Golden Rice were published in *Science* in 2000. In 2005, a new variety – Golden Rice 2 – was announced producing 23 times more β-carotene than the original variety.

Carotenoids and the Human Eye

Vision is probably the most important human sensory input, and the largest part of the brain is, therefore, dedicated to processing signals from both eyes. Good vision can be explained as clear imaging and is depending on eye(s) operating across a wide range of light levels. For humans, good vision includes properties like contrast activity, motion perception, and color description. Zeaxanthin and lutein accumulate in the human eye and are known to be important in good vision and reduced risk of age-related macular degeneration. A diet rich in lutein and zeaxanthin, or taken as a food supplement, is known to improve significantly the contrast activity of the eye, which is especially important in dim light. The mechanism is complex and includes both types of photoreceptor cells (rods and cones). Rods are responsible for good night vision, whereas cones function best in daylight. In twilight, signals from both rods and cones are mixed together to mediate vision. Rod cells respond well to bluish light, but blue light is blurred and has many other disadvantages. Both lutein and zeaxanthin filter out blue light and are, therefore, important components in rods to achieve good vision during twilight. The largest concentration of lutein and zeaxanthin is found in a small region of the retina called the yellow spot. This crucial area of the retina gives us the best visual performance, and lutein and zeaxanthin have an important role in extending the usefulness of cone-mediated vision in midrange light levels.

Carotenoids in Skin Photoprotection

Sunlight consists of both UVB (290–320 nm) and UVA (320–400 nm) radiation. UVB is absorbed mainly in the epidermal skin. Activation of proinflammatory cytokines, via photodamage induced by UVB radiation, can lead to sunburn, and through direct interactions with DNA, UVB can cause DNA mutations and skin cancer. UVA may also cause sunburn, but it has a significant role in photoaging. Moreover, UVA can penetrate deeper into dermal skin and induce generation of ROS. ROS-induced mutations of mitochondrial DNA may lead to reduced activity of enzymes involved in oxidative phosphorylation, affecting normal energy metabolism. Carotenoids are involved in the protection of skin against sun-induced damage, be it singlet oxygen ($^1O_2$) quenching, molecules that increase optical density of the skin, or as a source of vitamin A. Provitamin A molecules can be converted into retinoic acid, which is recognized to be a therapeutic agent against photodermatoses. The major carotenoid found in human skin is β-carotene, which is a provitamin A carotenoid. β-carotene is normally found in the epidermal skin, increasing reflection and scattering of light. Several other carotenoids, such as lutein, zeaxanthin, cryptoxanthin, and β-cryptoxanthin, may also accumulate in human skin. The absorption maximum of carotenoids ranging from ~400 to 500 nm is, however, not optical in the absorption of UVA/UVB. Together with carotenoids, eumelanin (a dermal skin pigment that absorbs light across a broad range of the visible spectra) has an important function, as an energy-absorbing pigment, in photoprotection against skin damage.

Carotenoids and Oxidative Stress-Related Diseases

Numerous epidemical, interventional, and clinical studies exploring the role of carotenoids in human health have been performed, and some have found positive effects of different carotenoids on cancer and other diseases associated with oxidative stress. Oxidative stress-related diseases include inflammatory bowel diseases, retinal ischemia, cardiovascular disease and restenosis, AIDS, acute respiratory distress syndrome, and neurodegenerative diseases, such as stroke, Parkinson's disease, and Alzheimer's disease. Treatment with antioxidants including the carotenoids is possible because oxidative injury is present in such diseases. Carotenoids often operate together with other components, including other antioxidants and/or trace elements. For example, selenium is essential for human health, specifically the immune system, but selenium compounds together with carotenoids have also been shown to inhibit carcinogenesis in rodents and humans. Another example is the inhibition of stomach cancer using the combined application of β-carotene, vitamin E, and selenium.

One of the clearest findings in nutritional epidemiology is the relationship between high intakes of fruits and vegetables and reduced rates of cardiovascular diseases including coronary heart disease and stroke. Reductions in coronary disease risk factors and reduced cardiovascular mortality are particularly important. The mechanism for these benefits is not clear, but a lot of attention has been focussed on protection against chronic diseases and the importance of micronutrients with antioxidant properties (e.g., carotenoids). Carotenoids are stored in the liver or in the adipose tissue and are incorporated into plasma lipoproteins during transport. Carotenoids are, therefore, of major importance as a dietary factor against increased risk of chronic diseases, such as heart and vascular diseases, cancer, and diabetes. Most studies dealing with carotenoids, as agents protecting against heart and vascular diseases, have focussed on those carotenoids occurring most commonly in the diet, namely, α- and β-carotene, lycopene, lutein, zeaxanthin, and β-cryptoxanthin. Several other carotenoids may also protect against age-related diseases due to the similarities in their chemical structures. In addition to the established mechanisms, including quenching of $^1O_2$ and scavenging of free radicals, associations between carotenoids and

inflammatory markers, such as C-reactive protein or other biomarkers of vascular disease, are likely.

Carotenoids and the Human Immune System

The human immune system is complex, but carotenoids seem to have an important role in protecting cells against injury induced by ROS. White cells are very active and generate large amounts of ROS during normal activity. For example, the mitochondrial electron transport system generates ATP using oxygen consumed by the cell and ROS, which can damage important functions of the mitochondria. Similarly, phagocytes use ROS to kill host and invading cells. Carotenoids protect subcellular organelles against oxidative injury and are, therefore, important components enhancing cell-mediated immune responses.

In human immunodeficiency virus (HIV)-positive patients, for example, carotenoid deficiencies are more common compared with HIV-negative individuals. HIV infects, specifically, CD4+ cells, which are important components of the immune system. Several studies have shown that supplementation with carotenoids increases CD4+ cells, leukocytes count, and the CD4+/CD8+ ratio in HIV-infected individuals, improving survival rates.

Determination

Isolation, characterization, and determination of carotenoids are performed differently depending on the information available about the sample of interest. Initial steps include extraction with an organic solvent; tetrahydrofuran is used widely because of the excellent solubility of all known carotenoids, but other solvents like hexane (C_6H_{14}), dichloromethane (CH_2Cl_2), chloroform ($CHCl_3$), methanol (CH_3OH), and ethyl acetate (EtOAc) are also used. After extraction, partition into an organic solvent (EtOAc, *tert*-butyl methyl ether (TBME), or CH_2Cl_2) is common. For tissue containing chlorophylls and/or carotenoid esters, saponification to remove chlorophylls or fats from certain foods may be necessary. In some cases, however, saponification has to be performed under a modified atmosphere (e.g., N_2) to avoid oxidation of xanthophylls (e.g., saponification of astaxanthin esters together with oxygen results in the formation of astacene). Separation of the carotenoids in an extract using HPLC–UV/Vis should, thereafter, be optimized on a reversed-phase and/or normal-phase column, either of which may be suitable for specific carotenoids of interest. To identify unknown carotenoids, it is sometimes necessary to purify the extract by column chromatography, and/or preparative HPLC, for isolation and characterization of (*E*/*Z*) and (*R*/*S*) carotenoids. Purified carotenoids can, potentially, be identified using several analytic techniques, such as UV–Vis spectroscopy, mass spectroscopy (MS), nuclear magnetic resonance, and circular dichroism spectroscopy. Some carotenoids can be identified in comparison with HPLC–UV/Vis-MS profiles for synthetic or isolates. Confirmation of structures using MS can be performed for definitive identification.

Due to poor stability of free carotenoids, extraction from biological tissue can be challenging, especially those containing large amounts of unsaturated lipids. Carotenoids can easily decompose or be isomerized when exposed to high temperatures, light, and a range of chemicals or be oxidized when exposed to oxygen and acids. To improve the stability of carotenoids during extraction, it is possible to add antioxidants or solid CO_2 to the sample. Extracted sample stability can also increased with the addition of butylated hydroxytoluene and/or pretreatment using a solid-phase extraction column. In addition, to obtain good results, it is important to protect samples from heat and light during processing.

Chromatographic analyses of carotenoids are similarly difficult, and the choice of column and mobile phases relevant for analysis depends on type of material or tissue being used, the variety of carotenoids, carotenoid concentrations, and analytic equipment available. Since carotenoids are hydrophobic, normal-phase chromatography is used commonly. However, several reversed-phase systems have also been developed with good repeatability.

Detection of carotenoids after HPLC separation is based mainly on UV–Vis detectors due to the excellent UV–Vis properties of these chromophores where maximum absorption (λ_{max}) increases with increasing numbers of conjugated double bonds. Thus, the yellow acyclic ζ-carotene with seven conjugated double bonds (λ_{max} at 378, 400, and 425 nm in acetonitrile/ethyl acetate/methanol (85:10:5)) absorbs light at much shorter wavelengths than the red acyclic carotenoid lycopene (λ_{max} at 444, 470, and 502 nm in petroleum ether). Both the shape of the spectrum (spectral fine structure) and λ_{max} are characteristics of the chromophore (Figure 4). Most carotenoids absorb at one to, at most, three wavelengths, resulting in a three-peak spectrum. The percentage ratio between absorption peaks III and II is often calculated (absorption peaks III/II × 100%) as an indicator of fine structure. However, this information is not sufficient to identify carotenoids. In addition to the main peaks at λ_{max}, *Z* isomers show an extra peak at shorter wavelengths (~320–350 nm).

Several chromatographic systems have been developed to analyze carotenoids from fruits and vegetables as well as leaves. Carotenoids from green fruits and vegetables are often analyzed on a C18 reversed-phase column using a gradient system of mixed mobile phases; mixture A contains acetonitrile (CH_3CN) and CH_3OH (90:10) and mixture B consists of hexane, CH_2Cl_2, and CH_3OH (45:45:10). Another typical HPLC column used is a normal-phase silica-based, nitrile-bonded column also using a gradient system of mixed mobile phases, where mixture A contains hexane, CH_2Cl_2, and CH_3OH (75:25:0.3) and mixture B hexane, CH_2Cl_2, and CH_3OH (75:25:1). This system is well suited to analyze carotenoid epoxides, *E*/*Z* dihydroxycarotenoids, and mono- and diketocarotenoids. For analyses of *E*/*Z* isomers of hydrocarbon carotenoids (carotenes), columns with low carbon loading or large pore sizes are preferable. This can be a C30 reversed-phase column with a gradient system consisting of different mixtures of TBME, CH_3OH, and H_2O. Another excellent system is a C18 reversed-phase column with low carbon loading. In this system, a mixture of CH_3CN, CH_3OH, hexane, and CH_2Cl_2 (85:10:2.5:2.5) is normally used for the mobile phase.

In fish and marine species, astaxanthin is often analyzed on an H_3PO_4-modified silica gel column (e.g., Lichrosorb SI60-5, 125 × 4.0 mm, 5 μm, Hichrom, Reading, the United Kingdom)

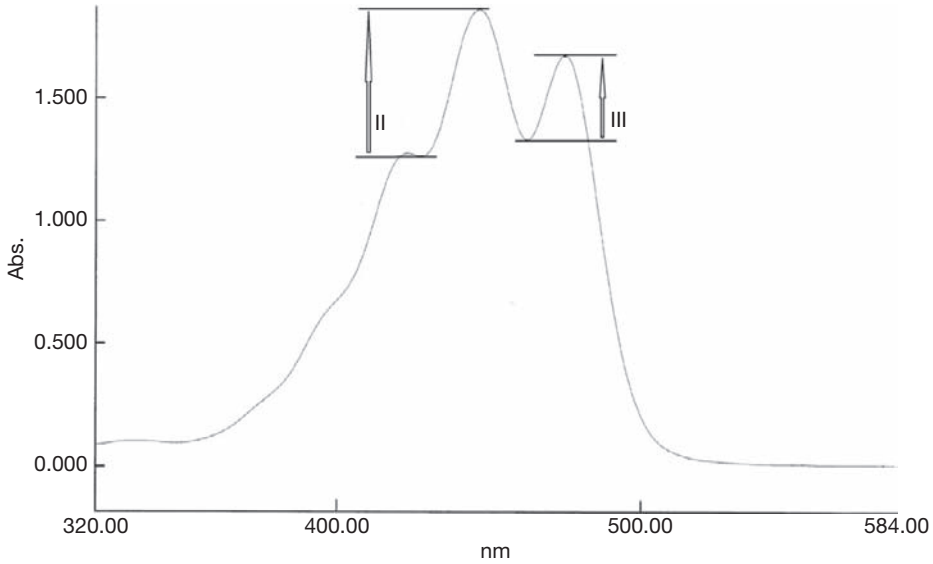

Figure 4 UV–Vis spectrum of lutein showing a typical three-peak spectrum. Calculation of % ratio between absorption peaks III and II (absorption peaks III/II $\times$ 100%) is often used as an indicator of specific fine structures of carotenoids.

Table 1 Relevant HPLC columns for the separation of carotenoids in extracts from natural products and biological samples

HPLC column	*Type of carotenoids*
C18 reversed-phase[a]	Monohydroxycarotenoids and carotenes
C18 reversed-phase (low carbon bonding)[b]	*E*/*Z* isomers of carotenes
C30 reversed-phase[c]	*E*/*Z* isomers of carotenes
Silica-based, nitrile-bonded column[d]	Carotenoid epoxide, *E*/*Z* dihydroxy-, mono-, and diketocarotenoids
Tris-(3,5-dimethylphenylcarbamate) chiral column[e]	*R*/*S* isomers of hydroxycarotenoids
$H_3PO_4^-$-modified silica gel (SI60-5) column[f]	Astaxanthin

[a]Khachik et al. (1986). *Journal of Agricultural and Food Chemistry* **34**, 603.

[f]Vecchi et al. (1987). *Journal of High Resolution Chromatography & Chromatography Communications* **10**, 348.

and absorption detected at 470 nm with hexane and acetone (86:14) as the mobile phase (isocratic, flow 1.0 ml min^{-1}). This system separates *E*/*Z* isomers of astaxanthin and other actual carotenoids, such as canthaxanthin, zeaxanthin, and lutein. A new method for homogenizing, extracting, and quantifying astaxanthin, canthaxanthin, lutein, and zeaxanthin from fish flesh was developed in 2010 by a group at the Norwegian Seafood Federation, FHL. This method was developed to standardize pigment analyses in salmon tissue to avoid conflicting information arising from variable results obtained using different analytic methods.

Normally, a standard HPLC column is not capable of separating carotenoids' optical isomers (*R*/*S*). To do that, specific chiral columns are used where an amylose *tris*-(3,5-dimethylphenylcarbamate) chiral column together with a mobile phase containing hexane and propan-2-ol is an option. This system is well suited to separate *R*/*S* stereoisomers of hydroxycarotenoids.

To summarize, HPLC separation of carotenoids in extract from foods and human plasma and tissues is best accomplished by employing a combination of reversed- and normal-phase chromatography and chiral chromatography. A summary of relevant HPLC methods is presented in **Table 1**.

Introduction

Carotenoid Discovery

Carotenoids are a group of red, orange, and yellow pigmented molecules that are synthesized by photosynthetic plants, algae, bacteria, and fungi but not animals. The discovery of carotenoids can be attributed to Heinrich Wilhelm Ferdinand Wackenroder who, in his 1831 publication, described a method where he pressed carrots, diluted the juice with water, and extracted the liquid with ether. After the liquid evaporated, he was left with 'a yellow fatty oil and carotin.' Since the discovery of 'carotin,' over 600 naturally occurring carotenoids have been identified. Although hundreds of carotenoids have been documented, alpha- and beta-carotene, beta-cryptoxanthin, lutein, lycopene, and zeaxanthin account for 90% of carotenoids found in the human diet and body.

Physical Properties of Carotenoids

Carotenoids typically have a 40-carbon chain backbone composed of eight isoprene molecules. Carotenoids are differentiated and produce different pigments, via modifications to the isoprenoid backbone through cyclization of end groups and oxidation. The amount of pigmentation depends not only on the accumulation of carotenoids but also on the regulation of genes involved in carotenoid synthesis, degradation, and storage. There are two major subgroups of carotenoids found in nature: carotenes, which are made up of carbon and hydrogen molecules, and xanthophylls, which are oxygenated carotenes. The composition of alternating double bonds, which is common to all carotenoids, allows them to absorb light in the visual range of the spectrum.

Figure 1 contains chemical structures of the six most prevalent carotenoids in the human diet.

Overview of Carotenoid Function

Plants, specifically fruits and vegetables, produce the majority of carotenoids in the human diet. Research conducted across many species has shown that the core carotenoid biosynthetic pathway is conserved in most plants. More information regarding the carotenoid biosynthetic pathway can be found in the 'Further Reading' section of this article. In plants, carotenoids have a critical role in photoprotection, light capture, abscisic acid (ABA) and strigolactone production, and attracting pollinators. Carotenoids are utilized by humans as an important source of vitamin A and have been shown to have a significant role in maintaining eye health, immune function, and disease prevention.

Carotenoid Physiology in Plants

Photoprotection and light capture

Carotenoids have a fundamental role in harnessing energy during photosynthesis as the key components of light-harvesting complexes in photosynthetic organisms. Additionally, carotenoids protect photosynthetic machinery in the presence of excess light. During the assembly of photosystems, which carry out the primary photochemistry of photosynthesis, carotenoids bind to light-harvesting complexes where they best absorb sunlight in the blue-green visible range ($\lambda = 450–550$ nm). This complements the nearby chlorophyll molecules that absorb light in the red range ($\lambda = 800–850$ nm). Carotenoids then transfer this excitation energy to adjacent chlorophylls to contribute significantly to photosynthesis. Moreover, carotenoids quench triplet chlorophyll, scavenge reactive oxygen species, which can damage cell membranes and proteins, and dissipate excess energy via xanthophyll-mediated nonphotochemical quenching. The utility of carotenoids in photoprotection can be demonstrated with carotenoid-deficient mutants that display bleaching, delayed greening, or even lethal phenotypes.

Abscisic acid and strigolactone production

Carotenoids are also the precursors of key signaling molecules and hormones, such as ABA and strigolactones. The β-xanthophylls, violaxanthin, and neoxanthin are cleaved via members of the 9-*cis*-epoxycarotenoid dioxygenase gene family to produce the hormone abscisic acid. Abscisic acid mediates response to environmental stresses, usually through the control of stomatal aperture and transpiration during high salinity, temperature, or light exposure as well as drought, and may induce many stress-related gene products. Additionally, abscisic acid promotes several developmental processes, including seed dormancy, germination, and maturation and the transition between vegetative growth and reproductive growth.

Strigolactones are carotenoid-derived terpenoid lactones that inhibit shoot branching. Strigolactones were initially characterized for their ability to trigger germination of parasitic plant seeds, such as *Striga*, when present in the root exudates of their host. More recently, however, strigolactones have been identified to play a crucial role in the mutualistic symbiotic interaction with arbuscular mycorrhizal fungi, which improves nutrient uptake of more than 80% of land plants. Strigolactone production is dependent upon the action of carotenoid cleavage dioxygenases, which are responsible for cleaving numerous carotenoids.

Utility as attractants

Carotenoids result in brightly pigmented plant organs that attract birds and insects, assisting in the dispersal of pollen and seeds and, thereby, aiding in plant pollination and reproduction. In addition to providing visual cues, carotenoid

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00120-3

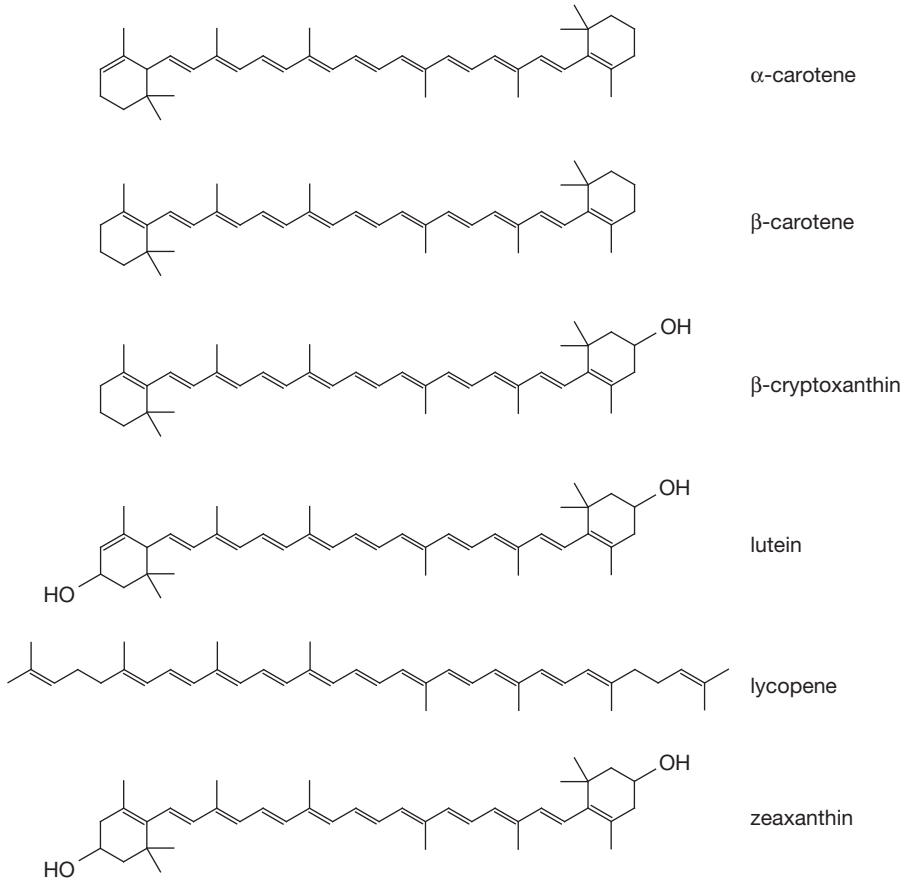

Figure 1 Chemical structures of the carotenoids found most often in the human diet.

derivatives serve as substrates in the biosynthesis of plant volatile compounds that further attract insects and animals for pollination and seed dispersal. Furthermore, carotenoid pigments may serve as visual cues that signal undesirable plant flavors or even antinutritional or lethal compounds. Consumers deciding to purchase carotenoid-based products also use pigmentation intensity and uniformity as an acceptability criterion.

Carotenoid Physiology in Animals

Utility in reproduction, predation, and consumer appeal

Dietary carotenoids can accumulate in animals, particularly birds and fish, where they are important for sexual behavior, reproduction, or avoidance from predation. Accumulation of dietary carotenoids can boost immunity and advertise health, leading to preferential selection by sexual partners.

The pea aphid (*Acyrthosiphon pisum*) was the first animal known to have acquired the carotenoid biosynthetic machinery necessary to produce carotenoids, which provides the reddish pigmentation distinguishing them from green forms. Phylogenetic analysis indicates the acquisition of carotenoid genes was likely the result of a horizontal gene transfer from the fungi to the aphid genome. The red-green color polymorphism appears to be maintained by frequency-dependent selection imposed by natural predators, which search for prey using different visual cues, resulting in differential susceptibility of the red and green individuals.

Animal-based food products consumed by poultry, fish, and mammals are frequently supplemented with carotenoids to provide a dietary vitamin A source as well as to color meat and animal products, making them more appealing to consumers. For the same reason, medicines and cosmetic products are often colored with carotenoids. The nutraceutical industry synthetically manufactures several carotenoids on an industrial scale, including beta-carotene, lycopene, and zeaxanthin, for a wide range of food products and cosmetics, such as vitamin supplements and other health products as well as animal feed additives.

Prevalence, uptake, detection, and recommended dose

Prevalence

Carotenoids have a critical role in human nutrition because they are an essential source of provitamin A – particularly in developing countries – and carotenoid-rich foods provide many other phytonutrients, plant-based compounds that have a potentially beneficial role in the prevention and treatment of human disease. Provitamin A is metabolized in the body into retinal and retinoic acid, the active forms of vitamin A, which support a plethora of physiological processes

including vision, reproduction, embryonic growth and development, immunity, and cellular maintenance. As humans are unable to synthesize carotenoids, they must ingest plant products or animal products that have been enriched with carotenoids to meet daily health recommendations.

The six most commonly ingested carotenoids in the human diet (see Figure 1) can be separated into two groups: (1) provitamin A carotenoids (alpha-carotene, beta-carotene, and beta-cryptoxanthin) and (2) non-provitamin A carotenoids (lutein, lycopene, and zeaxanthin). Most provitamin A comes from orange and yellow fruits and vegetables as well as some leafy green vegetables (see Table 1). Preformed vitamin A, retinol and retinyl ester, is found in animal products, such as liver and fish oil, meat, poultry, dairy, eggs, and fortified cereals. Carotenoid and vitamin A supplements are also available to improve low dietary intake.

High concentrations of the non-provitamin A carotenoids (e.g., lycopene) can be found in red and pink fruits and vegetables (see Table 2). Tomatoes and tomato-based foods account for over 85% of the dietary intake of lycopene. The remaining non-provitamin A carotenoids (lutein and zeaxanthin) are often difficult to separate so are typically reported together. Rich sources of lutein and zeaxanthin include dark leafy greens, egg yolks, and corn products (see Table 3). Non-provitamin A carotenoids have high levels of antioxidant activity and have been implicated in the prevention of vision impairment, cancer, and cardiovascular disease.

Uptake

The bioavailability of carotenoids is dependent on the degree of food processing, the nature of the food matrix, amounts of dietary fat and fiber coingested, and factors related to the individual. Generally, food processing (e.g., chopping, pureeing, and cooking) will break down plant tissue releasing carotenoids and increasing absorption. The presence of dietary fat in the meal will aid solubilization of free carotenoids, as they are lipophilic compounds. For example, egg yolks may be a better source of lutein and zeaxanthin, compared with some fruits and vegetables, because of their high fat content. In contrast, the presence of dietary fiber will have a negative effect on carotenoid absorption. Finally, human-based factors, including current vitamin A status, malnutrition, intestinal inflammation, and genetic profile, will determine the overall bioefficiency after ingestion and processing.

Table 2 Fruit and vegetable products containing high concentrations of lycopene

Description	*Lycopene (g/100 g)*
Grapefruit, raw, pink, and red	1419
Guava sauce, cooked	3909
Guavas, common, raw	5204
Papayas, raw	1828
Tomato juice, canned	9037
Tomato products, canned, paste	28 764
Tomato sauce, canned	13 895
Tomatoes, crushed, canned	5106
Tomatoes, red, ripe, canned	2537
Tomatoes, red, ripe, raw	2573
Tomatoes, sun-dried	45 902
Watermelon, raw	4532

Nutrient data were sourced from the USDA National Nutrient Database SR27, 2014.

Table 1 Fruit and vegetable products containing high concentrations of provitamin A carotenoids

Description	*β-Carotene (g/100 g)*	*α-Carotene (g/100 g)*	*β-Cryptoxanthin (g/100 g)*
Carrots, canned	5331	2743	0
Carrots, frozen, cooked, boiled	8199	3716	199
Carrots, raw	8285	3477	0
Collards, frozen, chopped, cooked, boiled	6818	127	28
Kale, frozen, cooked, boiled	8823	0	–
Kale, raw	5925	56	81
Melons, cantaloupe, raw	2020	16	1
Orange juice, frozen concentrate	53	19	191

Peppers, sweet, red, cooked, boiled	1525	18	460
Peppers, sweet, red, raw	1624	20	490
Persimmons, Japanese, raw	253	–	1447
Pumpkin, canned	6940	4795	0
Pumpkin, raw	3100	4016	0
Spinach, canned	5881	0	–
Spinach, cooked, boiled	6288	0	–
Spinach, frozen, chopped, or leaf	7035	0	–
Squash, winter, butternut, cooked, baked	2793	1130	3116
Squash, winter, butternut, raw	4226	834	3471
Sweet potato, canned, mashed	5219	0	–
Sweet potato, raw	8509	0	7
Tangerines (mandarin oranges), canned	193	133	503
Tangerines (mandarin oranges), raw	155	101	407
Turnip greens, frozen, cooked, boiled	6459	0	–

Nutrient data were sourced from the USDA National Nutrient Database SR27, 2014.

Table 3 Food products containing high concentrations of lutein and zeaxanthin

Description	Lutein + zeaxanthin (g/100 g)
Chard, Swiss, cooked, boiled	11 015
Collards, cooked, boiled	6197
Collards, frozen, chopped, cooked, boiled	10 898
Corn grain, yellow	1355
Cress, garden, cooked, boiled	8402
Egg, whole, cooked, hard-boiled	353
Kale, cooked, boiled	18 246
Mustard greens, frozen, cooked, boiled	6672
Noodles, egg, spinach, cooked, enriched	2232
Spinach, canned	10 575
Spinach, cooked, boiled	11 308
Spinach, frozen, chopped or leaf, cooked, boiled	15 691
Spinach, frozen, chopped or leaf	12 651
Turnip greens and turnips, frozen, cooked, boiled	9532
Turnip greens, frozen, cooked, boiled	11 915

Nutrient data were sourced from the USDA National Nutrient Database SR27, 2014.

Once ingested, a fraction of carotenoids are solubilized into micelles, which are molecular aggregates transporting fat-soluble materials. Solubility depends on homogenization, heat treatment, and the presence of dietary fat and fiber. Carotenoids are absorbed via passive diffusion into the gastrointestinal mucosal cells, which act as a selective barrier. Subsequently, they are packaged into chylomicrons and released into the lymphatic system where they are taken up by the liver and stored or reexcreted into the bloodstream. Vitamin A liver stores are in the form of retinyl esters. Carotenoids are differentially absorbed by the tissues and are typically targeted to the eye macula, liver, lungs, adipose tissue, brain, prostate, and skin. Typically, about 10% of ingested carotenoids are assimilated.

Vitamin A bioefficiency can be reduced in the presence of certain medications. Cholesterol-lowering drugs cholestyramine (Questran) and colestipol (Colestid), antiobesity drug orlistat (Xenical), or the coingestion of mineral oil may reduce the absorption of fat-soluble compounds including carotenoids. Manufacturers of these medications recommend patients take dietary supplements to increase their vitamin A and carotenoid intake.

Detection

Carotenoid levels are usually assessed using blood plasma, in particular plasma retinol levels. These levels are useful for accessing vitamin A inadequacy, but not effective for detecting marginal levels. Relative dose–response tests analyze plasma retinol levels before and after administration of small quantities of food or supplements. Supplementation studies analyze plasma retinol levels over a longer period of time, usually days or weeks. While these studies are very useful, they lack detailed analysis of food matrix composition and other absorption factors. Several digestion and assimilation assays *in vitro* have been used to analyze these factors instead.

Recommended intake

Provitamin A carotenoids are the only carotenoids recognized as essential for humans. The recommended dietary allowance (RDA) for vitamin A is given in terms of micrograms (μg) of retinol. A provitamin A RDA of 900 μg day^{-1} for males and 700 μg day^{-1} for females (14 years and older) is sufficient to support normal gene expression, immune function, and vision. The RDA for women who are pregnant or breastfeeding can be as high as 1300 μg day^{-1}, although supplements containing vitamin A are not recommended for pregnant women; no risks are associated with beta-carotene intake during pregnancy. Twelve micrograms of dietary beta-carotene provide the human body with 1 μg of retinol, which gives beta-carotene a retinol activity equivalent (RAE) ratio of 12:1. Alpha-carotene and beta-cryptoxanthin each have an RAE ratio of 24:1 while beta-carotene in oil, as a supplement, has a ratio of 2:1. Finally, preformed vitamin A, consumed as an animal product, has an RAE ratio of 1. Although non-provitamin A carotenoids are not recognized as essential nutrients, they are often linked with combating oxidative stress, eye health, and prevention of chronic disease. With this in mind, recommendations of 5000–7000 μg day^{-1} for lycopene and lutein plus zeaxanthin have been suggested, with higher intake possibly increasing prevention of certain diseases.

Carotenoid deficiencies and toxicities

Deficiencies

Plasma retinol levels lower than 0.7 μmol l^{-1} or 200 μg l^{-1} indicate vitamin A deficiency. While not common in industrialized countries, vitamin A deficiencies are more common in developing countries where individuals have limited access to preformed vitamin A and/or supplements as well as diets consisting almost exclusively of staple starch-based crops, which are typically low in provitamin A. The World Health Organization estimates that over 190 million preschool-age children and over 19 million pregnant women around the world have serum retinol concentrations below 0.7 μmol l^{-1}. Further, it is estimated that 650 000 children under the age of 5 die from vitamin A deficiencies each year.

Groups most at risk for vitamin A inadequacy are premature infants, young children, pregnant or breastfeeding women, and individuals with cystic fibrosis. Premature infants do not have adequate liver stores of vitamin A at birth and their serum retinol concentrations remain low for the first year of life. Infants and young children who are breastfed exclusively will have insufficient levels of vitamin A if the mother's breast milk volume and vitamin A content are suboptimal. Pregnant and breastfeeding women require additional vitamin A stores for fetal growth and development as well as their needs. Finally, those with cystic fibrosis typically have pancreatic insufficiency, making it difficult to break down and absorb nutrients from their diet. An estimated 15–40% of cystic fibrosis patients have a vitamin A deficiency.

To date, no known deficiency symptoms have been identified in individuals consuming low-carotenoid diets as long as they still consume adequate provitamin A, preformed vitamin A, or vitamin A supplements. However, the National Cancer Institute, American Cancer Society, and the American Heart Association suggest consuming a variety of fruits and vegetables daily, partly to increase intake of carotenoids from the human diet.

Toxicity

Excess consumption of beta-carotene- and lycopene-rich food sources results in the benign conditions carotenodermia and lycopenemia, respectively, which cause a deep yellow and an orange discoloration of the skin, respectively. These conditions can be reversed by reduced consumption of carotene- and lycopene-rich foods.

Vitamin A toxicity (hypervitaminosis A) is caused by overconsumption of preformed vitamin A. Large doses of beta-carotene have never been associated with vitamin A toxicity. However, severe cases of hypervitaminosis A may result in liver damage, hemorrhage, and coma. Toxicity is associated with prolonged intake of preformed vitamin A in excess of ten times the RDA. Most multivitamin A supplements contain RDA information to prevent cases of toxicity.

Disease prevention

Vision

The first sign of vitamin A deficiency is often night blindness or the inability to see in low light and darkness. More advance deficiencies lead to xerophthalmia, where the conjunctiva becomes dry, thick, and wrinkled and, ultimately, if untreated, can cause blindness as a result of corneal damage.

Lutein and zeaxanthin are present at high concentrations in the macula lutea, the central part of the retina, which is yellow in color, and are known to provide eye photoprotection. The chemical structures of lutein and zeaxanthin allow them to absorb efficiently relatively high-energy short-wavelength light, reducing the amount of blue or UV light that reaches critical eye structures. Filtering protects the underlying cell layers from light-induced oxidative damage and improves visual perception.

Higher concentrations of lutein and zeaxanthin in the body have been associated with lower risk of developing age-related macular degeneration (AMD) and cataracts. The World Health Organization reports that cataracts and AMD comprise 51% and 5% of the major causes of blindness, respectively. While cataracts are the principal causes of blindness in aging adults from developing countries, AMD is the leading cause of blindness in those over 65 years of age in industrial countries. As the world's population continues to age, the prevalence of AMD and cataracts is estimated to increase sharply in the next 10–15 years. Aging appears to be the most likely factor contributing to the onset of AMD and cataracts. AMD contribution factors include increased exposure to UV and blue light, excess oxidative stress, environmental factors, and diets high in polyunsaturated fatty acids. External factors influencing the development of cataracts include poverty, poor nutrition, and strict vegetarian diets that lack important antioxidants and phytonutrients. A multicenter eye disease study found that higher dietary intakes of carotenoids, specifically lutein and zeaxanthin, are associated with reduced AMD risk. Other studies have found that those consuming diets rich in lutein and zeaxanthin are significantly less likely to require cataract extraction or develop cataracts. Further, experts have recommended that the consumption of at least 6000 μg day^{-1} of dietary lutein and zeaxanthin from fruits and vegetables may decrease the risk of AMD.

Immune function

Vitamin A is an immune-stimulant, which is essential for the human immune system to function normally. Retinol and its related metabolites maintain the integrity and function of the skin and mucosal cells and support the development and differentiation of white blood cells. Vitamin A deficiencies increase the risk of infections, particularly diarrhea and measles, and reduce resistance to infectious diseases. In regions of the world where vitamin A deficiency is common, over 1% of those with measles die and the World Health Organization recommends giving vitamin A supplements to children with measles.

Cancer

Several studies have suggested that the non-provitamin A carotenoid, lycopene, and lycopene-rich diets and increased serum levels of lycopene significantly reduce the risk of prostate cancer, particularly aggressive types. Exploratory studies have also found that men with enriched lycopene intakes from cooked tomatoes and tomato products are less likely to develop prostate cancer than men with lower intakes. There is also growing evidence that lycopene may play a protective role in other cancers including breast, lung, gastrointestinal, cervical, ovarian, and pancreatic.

Carotenoids have also been implicated in the prevention of skin cancer by contributing lifelong photoprotection against exposure to the harmful effects of the sun. Additional research has documented the significant role that natural and synthetic retinoids may have in the reduction of carcinogenesis in the skin, breast, liver, colon, and prostate. While diets high in carotenoid-rich foods are associated with reduced risk of some cancers, high-dose beta-carotene supplements have been linked with increased risk of lung cancer in smokers and former asbestos workers. Most experts feel the risks of taking high-dose beta-carotene supplements outweigh any potential cancer prevention benefits, particularly in smokers or other high-risk groups.

Antioxidant activity

Carotenoids provide antioxidant properties by absorbing high-energy short-wavelength light and scavenging reactive oxygen species. While studies invariably show that non-provitamin A carotenoids provide protection from DNA damage, provitamin A carotenoids show mixed effects. Studies that were carried out using low (dietary) concentrations of provitamin A carotenoids found protective effects, while those using higher concentrations (in excess of high-dietary intakes) were associated with an increase in DNA damage. These findings may be caused by provitamin A carotenoids acting as a prooxidants rather than antioxidants in high concentrations.

Osteoporosis

The most prevalent metabolic bone disease, osteoporosis, may be caused by oxidative stress to the skeletal system. Natural and synthetic antioxidants, such as non-provitamin A carotenoids, may counteract the damaging effects of oxidative stress that are produced during intensive exercise and among smokers.

Cellular communication and differentiation

Independent of the antioxidant activities, carotenoids have been shown to stimulate intercellular communication by increasing or inhibiting the expression of specific genes. Through the regulation of gene expression, vitamin A metabolites have a major role in cellular differentiation and specialization. Vitamin A metabolites, such retinoic acid, are essential for fetal development, especially the limbs, heart, eyes, and ears.

Summary

A large body of research has contributed significantly to our understanding of carotenoids since their discovery almost 200 years ago. It is quite clear that carotenoids orchestrate several essential roles in both plant and animal physiologies. In plants, carotenoids help harness additional energy by capturing light at wavelengths outside the range of chlorophyll activity and also provide photoprotection from reactive oxygen species. Furthermore, the accumulation of carotenoid pigmentation, in both plants and animals, helps with reproductive success and advertises health. In animals, especially humans, provitamin A carotenoids are converted to vitamin A, which is critical for maintaining healthy vision, immune response, and cellular communication and differentiation. The RDA for vitamin A in healthy male and female adults (age 14 +) is 900 and 700 μg day^{-1}, respectively. Diets rich in vibrant orange fruits and vegetables, such carrots, squash, sweet potatoes, and cantaloupe, provide high concentrations of provitamin A. While there is no current RDA for non-provitamin A carotenoids, these compounds have been shown to have antioxidant activity and may help prevent AMD, cataracts, and some cancers. High concentrations of the non-provitamin A carotenoid, lycopene, can be found in red and pink fruits and vegetable products, such as tomatoes, tomato products, and watermelon. The non-provitamin A carotenoids lutein and zeaxanthin are most prevalent in dark leafy greens, egg yolks, and corn products. Bioaccessibility of carotenoids from the diet is increased when foods are cooked and the carotenoids coingested with fat. While the importance of carotenoids in plant and animal physiology is clear, there are still many facets to be explored. This article focussed on the six most common carotenoids in the human diet, but there are still over 600 other carotenoids that need further investigation.

Introduction

Casein is the most important protein component in milk, both quantitatively and nutritionally, accounting for about 80% of milk's total nitrogen. It was used in industries producing paper, textiles, paint, leather, fiber, and other materials. Edible casein and caseinates are also long established dairy byproducts with uses in many foods. Casein is a very rich source of essential amino acids, with the only possible exception of cysteine. It is a phosphorylated and glycosilated complex synthesized by mammary glands. It is constituted of three different polypeptide chains (αs_1, αs_2, and ß) held together by noncovalent interactions. Casein fractions are organized in micellar aggregates that also contain bivalent cations (calcium and smaller amounts of magnesium), ranging 20–300 nm in diameter. This structure allows highly stable dispersion of hydrophobic fractions in a colloidal state by the action of hydrophilic bonds.

The amount of casein in whole milk varies according to the animal breed and stage of lactation. It is generally in the range 24–29 $g\,l^{-1}$. Casein contains 0.7–0.9% phosphorus, covalently bound to the protein by a serine ester linkage. Consequently, casein is known as a phosphoprotein. All the amino acids that are essential for humans are present in casein in high proportions, with the possible exception of cysteine. Thus, casein is considered to be a highly nutritious protein. It exists in milk in complex groups of molecules called as micelles. The micelles consist of casein molecules, calcium, inorganic phosphate, and citrate ions, and they have a typical molecular weight of several hundred million daltons.

In terms of physical chemistry, the casein micelles exist in milk as a very stable colloidal dispersion. As a protein, casein is made up of hundreds of individual amino acids, each of which may have a positive or a negative charge, depending on the pH of the milk system. At some pH value, all the positive charges and all the negative charges on the casein remain in balance (i.e., the net charge on the protein is zero); this pH value is known as the isoelectric point (IEP), which is 4.6 for casein. The IEP is the pH at which the protein is least soluble. Milk has a pH value of about 6.6, at which the casein micelles have a net negative charge and are quite stable. Casein consists of several individual casein components (αs1-, αs2-, β-, and κ-casein), each having slightly different properties.

Casein is precipitated from skim milk by acidifying it to produce acid casein, or the milk is treated with rennet to produce rennet casein. The precipitated casein curd is separated from the whey, washed, and dried. The water-soluble derivatives of acid caseins, produced by reaction with alkalis, are called caseinates. Edible casein is a long-established dairy byproduct used as an ingredient in many food products, including dairy products. The general development of food technologies and their applications has increased the production of and demand for casein. Its manufacture differs from that of nonedible casein (also called industrial casein) in that casein for food is produced under sanitary conditions. Further, during its manufacture, food-grade chemicals are used and sufficiently heat-treated to make the casein safe for human consumption. The intensive investigation into manufacturing technologies over the years and the introduction of efficient plant designs have immensely improved the technology for edible casein production.

Production of Caseins: A Scenario

The world production of caseins and caseinates is hard to define due to lack of a significant data. However, it could be 430 000–460 000 tons. The largest producers of caseins are New Zealand (~150 000 tons), Netherlands (~85 000–10 000 tons), and Germany (25 000–40 000 tons). The world market for casein or caseinates used in the food industry fluctuates between 200 000 and 2 500 000 tons. The United States is the biggest importer of caseins. The demand for food-grade casein in the US is about 25 000 tons per annum, and the corresponding demand for caseinates is around 30 000 tons. About 20% of this demand is for nutraceutical applications. Casein is also utilized for the manufacture of imitation cheeses. Japan is the second largest importer of casein.

The production of edible casein is only economically feasible when the whey is efficiently and economically utilized. This has been one of the main reasons why edible casein is not produced on a large scale. Most of the requirements of this byproduct, even for industrial uses, were met through import. During 1999–2014, a few new large, automatic, and continuous manufacturing plants have begun to produce edible casein, lactose, and whey protein concentrates. The production of caseinates has not picked up in many dairying countries, including India, however, because of its high drying cost, low bulk density, and high packaging, storage, and transportation costs.

Casein Manufacturing Processes

Processes for the manufacture of edible casein from milk are well known all over the world (Figure 1). The efficient separation of fat from milk is essential. For this, filtered and warmed milk (40–45 °C) should be separated in a hermetic cream

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00122-7

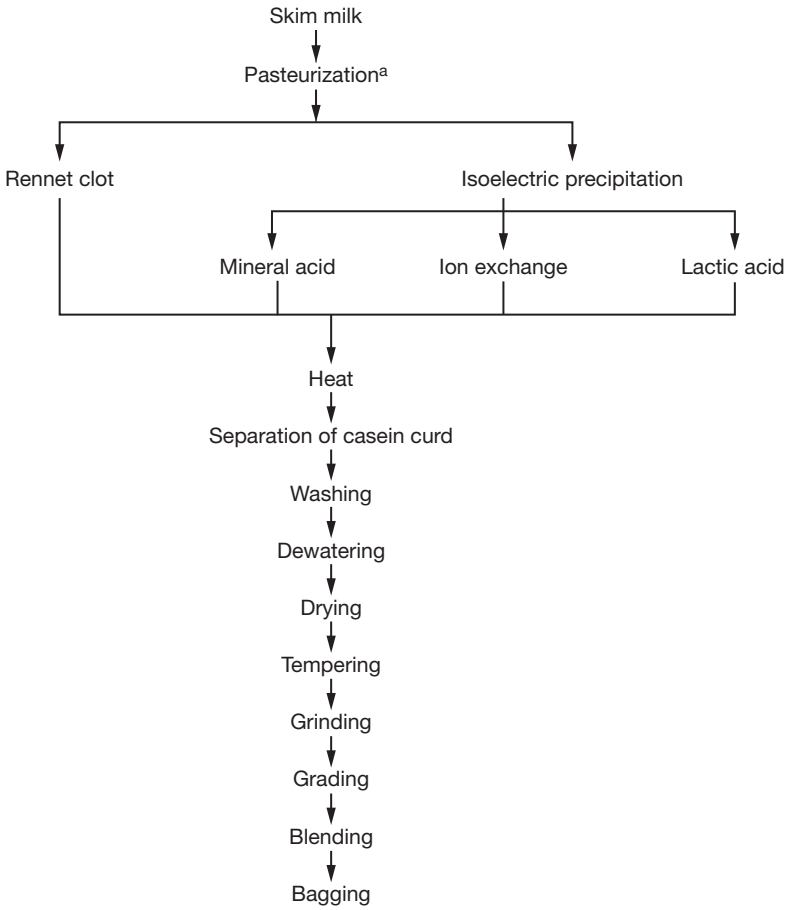

Figure 1 Manufacture of the various types of caseins. [a]Milk for the manufacture of rennet casein for nonfood use is not pasteurized.

separator so that the fat in the skim milk is reduced to less than 0.05%. Achieving the microbiological standards for edible casein also requires the pasteurization of either or both the milk and the curd. Heat treatment tends to produce a higher yield of casein. Some researchers hold that the heat treatment of milk for casein manufacture causes slight insolubility and other defects.

Separation

To extract the casein from milk, it is first separated by means of centrifuges to produce cream and skim milk. Skim milk can thus be considered to be the raw material from which casein products are made.

Precipitation

An important use of surplus skim milk is in the production of casein. Casein exists in milk as a calcium caseinate–calcium-phosphate complex. When an acid is added to the milk, this complex is dissociated. As the pH of the milk is lowered, the calcium is displaced from the casein molecules by hydronium ions, H_30^+, and the calcium phosphate associated with the complex is converted into soluble Ca^{2+} ions and $H_2PO_4^-$ ions. At about 5.3 pH, the casein begins to precipitate out of solution, and at the IEP of casein (about pH 4.6), maximum precipitation occurs. At this pH all the calcium is solubilized. Not only is the calcium from the caseinate molecule removed, but the calcium phosphate is also liberated in its soluble form. This allows the plant to wash the soluble salts from the curd in order to achieve low ash content in the final product.

Ideally, all the casein in a sample of milk would be precipitated simply by adding enough acid to bring the pH value to ~4.6. However, the reaction between the acid and the caseinate complex is not instantaneous, and the pH tends to rise slowly with time. Therefore, ample time should be allowed for achieving equilibrium conditions. When casein is precipitated from skim milk by the direct addition of acid, the temperature and pH of precipitation and the mechanical handling of the curd during its formation are very important in determining the subsequent properties of the curd.

Enzymatic coagulation

In the case of the enzymatic coagulation of casein, the pH of the milk does not change. Instead, the coagulation depends on the addition of a specific enzyme, chymosin/rennin, which cleaves a highly charged portion from the κ-casein, called glycomacropeptide. This action causes the remainder of the κ-casein (now called para-κ-casein) to lose its considerable

power in stabilizing the micelles in milk, and the result is the formation of a three-dimensional gel network or coagulum of casein in the presence of calcium ions. This reaction is essential for the manufacture of virtually all cheeses and in the production of rennet casein.

Acid coagulation

Casein precipitated by acid usually includes the name of the acid in its description, as with hydrochloric acid casein and lactic acid casein. Any of the acid precipitation processes can be used to produce edible casein. The choice of the method for reducing the pH of skim milk to precipitate casein is governed by the cost of acid. The lactic fermentation process is attractive in terms of its cost effectiveness. For lactic acid casein, the pasteurized skim milk is cooled to 22–26 °C and inoculated with a 0.5% starter of mixed lactic starters and incubated for 14–16 h, during which time the pH reduces to 4.6, producing a coagulum. The coagulum is cooked to 50–55 °C to create a curd firm enough for subsequent processing. The acid and heat help in the syneresis of whey.

The use of mineral acids has the advantage of completely continuous operation with no holding time for coagulation. Hydrochloric acid is a superior coagulating agent. When sulfuric acid or hydrochloric acid is used to precipitate curd, it should be diluted before being added to the skim milk; otherwise, the local action of the acid may injure the curd, even though the agitation is rapid. Within reasonable limits, the more dilute the acid the better the quality of the casein produced.

Temperature of precipitation

The kind of curd formed is sensitive to heat. Curd precipitated at temperatures below 35 °C is very soft and fine, and consequently, it is slow to settle and difficult to wash without loss. Precipitated at temperatures between 35 and 38 °C, the curd is coarse, provided stirring is not too fast. Stirring is necessary to distribute the acid uniformly, but rapid stirring at temperatures below 38 °C produces a curd so fine that it settles very slowly during drainage and washing, and it may be lost to some extent in the whey and washings. The curd can be made firm either by heating to a temperature above 38 °C or lowering the pH to 4.1. Curd precipitated at about 43 °C has a texture resembling chewing gum, being stringy, lumpy, and coarse, containing practically no fine particles, and separating cleanly from the whey.

High-grade casein, which is low in ash and readily soluble, is made by the grain-curd process in which the pH and temperature are closely controlled. The best product is made by the use of hydrochloric acid, but lactic and sulfuric acids may be used successfully. The temperature of the skim milk should be held close to 35 °C for hydrochloric acid curd. The pH 4.1 is adjusted by adding dilute acid slowly with continuous stirring. It produces a granular curd that is easy to drain and wash.

Draining of Whey

After precipitation, curd gets settled. Whey should be removed from contact with the curd as soon as possible. The longer the curd remains in contact with the whey, the more difficult it is to wash out acids, salts, whey protein, and lactose, as the freshly broken curd tends to anneal itself, thereby enclosing these constituents within a protein film.

Washing of Casein Curd

The washing of casein curd is one of the most important steps in casein manufacture as most quality improvement in casein is achieved through efficient washing. Large portions of lactose, minerals, and acids are trapped within the curd, which prevents their ready removal during washing of the curd. It is necessary to allow sufficient holding time during each washing stage in order to permit the diffusion of these whey components. The diffusion rate depends on the size and permeability of the curd particles and the purity, amount, and rate of movement of the wash water. Smaller size and better permeability of the curd particles are important for efficient washing. Three separate washes of casein curd are required with contact times of 15–20 min each. As soon as the whey is removed the wash water should be added in equal quantity to the whey that has drained off. The curd should be well stirred in the wash water, either by rakes or by mechanical agitators, but care should be taken not to break the curd into fine particles. Firm and friable curd particles are required to avoid creation of excessive fines. Rubbery and plastic curds cannot be washed effectively. Efficient washing can be achieved through the removal of as much whey as possible at the whey off stage. The temperature and pH of wash water are important factors affecting quality of casein.

Temperature of wash water

Casein curd acts like a sponge in the water, contracting to expel water when heat is applied (termed as syneresis) and relaxing when the water temperature is lowered. Heating leads to hard and rubbery curd, while cold water softens it and causes the curd to be fragile and readily broken. The temperature of the first wash should be the same as the precipitation temperature in order to produce good curd shrinkage. With lactic casein, higher temperatures (70 °C or above) are necessary at some stage of washing to reduce the bacteria, which multiply during the incubation of milk with starter. The temperature of the final wash water should be adjusted to 32–40 °C for better expulsion of water during subsequent pressing.

pH of wash water

The pH of the water should be around 4.6 for the first two washings to avoid the formation of a gelatinous layer over the curd particles in excessively acid water, as well as the softening and dispersion of the curd in alkaline waters. The gelatinous layer, if formed over the curd particles, inhibits the drainage of salts and lactose from the curd. Making the pH of the wash water the same as that of casein helps maintain the equilibrium. Dilute sulfuric acid is preferred for this purpose because casein is much less soluble in this acid than it is in hydrochloric acid. The third wash should be given with neutral water.

Pressing of Casein Curd

The efficient pressing of washed casein curd is important for minimizing the energy required for the removal of the remaining water by drying. Inadequate pressing leads to the formation of lumps of curd on subsequent grinding. It also produces a hard, impervious surface that resists the escape of moisture from the inside, a condition known as case hardening. The mechanical removal of water is cheaper than thermal vaporization.

The batch pressing operation is usually an overnight operation (not less than 12–15 h) with 34 kg cm^{-2} pressure. The proportion of water in washed curd and its ease of removal depend on the type of curd made. The appropriate pH and a temperature of 41 °C produce a firm, friable curd that drains and presses well. The final moisture content is usually 55–60%.

Milling and Drying of Casein

Pressed curd is prone to microbial attack and, therefore, should be shredded and dried as promptly as practicable. Pressing produces particles of uniform size and surface for drying. Uneven drying leads to large particles or lumps that dry on the outside, forming a hard, impervious outer surface that prevents the diffusion of the remaining moisture from the interior of the particles.

The ground curd is spread on trays. It should be spread evenly, and no more than 0.9–1.1 kg of curd should be placed on a tray of 75 × 75 cm. The bottom tray on each truck should have a finer mesh than the others, or it should be covered with a cloth to catch fine particles that may sift through the other trays. The proper control of the temperature and humidity of the air coming in contact with the curd are essential for the efficient drying of casein. The inlet air temperature of 52–57 °C is suitable for any type of curd. Once started, drying should not be interrupted until the moisture content is about 8%. Properly dried casein has the same fine, granular characteristics as the properly ground curd from which it is made.

Tempering, Grinding, Sieving, and Bagging of Casein

Tempering: It is the holding of casein for a period of 24 h to allow efficient cooling, hardening, and even distribution of moisture throughout the batch. Casein shows variation in moisture content during a day's run, as it comes from the drier. The most efficient tempering consists of recirculating the dried casein by pneumatic conveyers. It has the advantage that the air used for the transport of the casein assists in cooling the curd.

Grinding: The casein must be cooled before grinding because warm casein is plastic and causes 'burn on' of the rollers. Grinding and sieving are necessary to produce the highest proportion of the product in the size range desired by the buyer. The grinding is completed by roller mills, pin mills, or hammer mills. For the production of 60- and 80-mesh casein, pin mills are much more efficient than hammer mills.

Sieving: The grinding operation is followed by sieving into various mesh sizes, and then bagging. Common mesh sizes are 30–40 mesh casein, 60-mesh casein, and 90-mesh casein.

Bagging: The casein is packed in sacks or bags of 100 or 200 lb capacity, as prescribed by the grade classification of the casein. Burlap sacks lined with closely woven cloth or heavy papers, or three-ply paper bags may be used for bagging of caseins.

Continuous Casein Manufacture

Due to the advancement of technology and automation, continuous casein-manufacturing plants have replaced batch processes for large-scale production. These plants reduced the manufacturing costs for improving the value of milk proteins, related to that of dried milk, and also elevated the status of casein for both industrial and food uses. These plants are also highly labor-saving, because a large casein plant, with continuous hydrochloric acid precipitation and a capacity of 14 000 l h^{-1}, requires only one person to operate it. The systems are designed to accurately measure pumping rates in order to ensure a constant flow of milk and acid, mixing acid with skim milk at controlled temperatures of 25 °C or lower. This ensures equilibrium conditions before coagulation begins, automatic regulation of steam injection to achieve the coagulation temperature, and a holding tube capable of obtaining complete coagulation and a well-settled curd, all of which lead to less than 1% losses of casein in whey.

After precipitation, casein curd is concentrated by passage over stationary, inclined and fine mesh screens, which remove between 70% and 90% of the whey. Several dairy companies have installed and are successfully operating roller presses and lately decanters for removing the whey. Hydrocyclones may be employed to recover fine particles from whey and wash water. For continuous washing of casein curd, the most common procedure now adopted is a counter flow which reduces both the volume of water needed and the loss of casein fines; the technique involves as many as five washing stages. These storage tanks are of sufficient capacity to permit an average holding time of 20–30 min. Continuous curd pressing is done in mechanically driven roller presses, by belt, or by passing the material through decanters, where water is sufficiently expelled for subsequent economical drying.

There are a number of types of equipment for the drying of casein. The most widely used in recent years is a vibratory type of drier. The curd passes through a mill to reduce it to even-sized particles, which then travel by means of a vibratory action over trays of perforated stainless steel, transferring to successively lower trays. The heated air flows through the beds of curd from the bottom to the top, thus encountering layers of curd of increasing water content and providing improved efficiency of heat utilization.

Method of Manufacture of Caseinates

The caseinate is prepared from freshly precipitated acid casein curd or from dry acid casein by reaction with dilute alkali solutions (Figure 2). Sodium caseinate is the most commonly used form of casein, and it is used in wide range of processed food products as a source of protein, and for their physicochemical, nutritional, and functional properties. Next to sodium caseinate, calcium caseinate is common and finds its use in both pharmaceutical preparations and as a food ingredient. It functions as supplier of both calcium and protein. The specifications for this product vary with its end use, but they frequently include a limitation of calcium content to within the range of 1.0–1.5%.

Manufacturing Process

The fresh acid casein curd is preferred over dried casein as a raw material because the former yields caseinates with blander

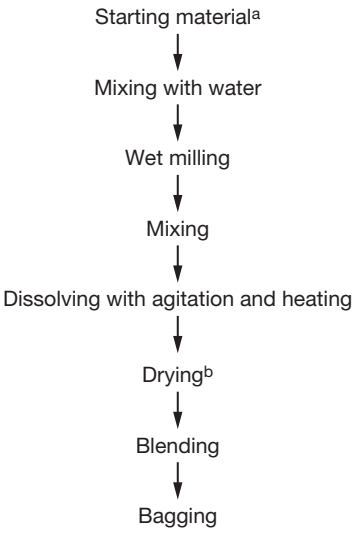

Figure 2 Conventional method for the manufacture of caseinates. [a]Either fresh, acid casein curd, or dried casein; [b]usually spray- or roller-dried.

flavor than does the latter. Caseinates prepared from dry casein will also incur the additional manufacturing costs associated with the drying, dry processing, bagging, and storage of the casein prior to its conversion to sodium caseinate. However, in countries that import casein, buyers may still prefer to purchase casein and produce their own sodium caseinate. Casein should have a low calcium content (0.15% dry basis) in order to produce a caseinate solution with a low viscosity, and a low lactose content (0.2% dry basis), with the goal being sodium caseinate with the best color, flavor, and nutritional value. Control of the curd characteristics is also important to ensure rapid dissolution.

Sodium Caseinate

The manufacture of sodium caseinate consists of the formation of a casein suspension, solubilization of casein using sodium hydroxide, and drying the sodium caseinate produced.

Casein Suspension and Solubilization

The main difficulties experienced in the conversion of acid casein to sodium caseinate are as follows:

(a) The very high viscosity of sodium caseinate solution of moderate concentration limit the solids content for spray drying to 20%.
(b) The formation of a relatively impervious, jelly-like, viscous coating on the surface of casein micelles impedes their dissolution on the addition of alkali. To overcome the former difficulty, it is essential that the pH and temperature are controlled during conversion, because these influence viscosity. The latter challenge can be overcome by reducing the particle size by passing the casein and water mixture through a colloid mill prior to the addition of alkali.

After the final casein wash, the curd is dewatered to about 45% solids and then mixed with water (to 25–30% solids) prior to entering the colloid mill. The temperature of the emerging slurry, which has a pasty consistency, should be below 45 °C, because it has been observed that milled curd can reagglomerate at higher temperatures.

Addition of Alkali and pH Control

The common alkali used in the production of sodium caseinate is sodium hydroxide in the form of 2.5 M solution. The quantity of alkali required is generally 1.7–2.2% by weight of the casein solids. Other alkalis such as sodium bicarbonate or sodium phosphates may be used, but the amounts required and their costs are both greater than those of sodium hydroxide. Hence, they are used only for specific purposes, such as the manufacture of citrated caseinate. The addition of the dilute alkali, preferably by dosing into the recirculating line just prior to the pump, must be carefully controlled with the aim of reaching a final caseinate pH of 6.6–7.0.

Dissolving

The viscosity of sodium caseinate solutions can be expressed as a logarithmic function of the total solid concentration. Each dissolving vat, therefore, must be equipped with a powerful agitator and a high speed recirculating pump. In addition to concentration, temperature, and pH, the calcium content of the curd, the type of alkali used, and seasonal and genetic factors also affect the viscosity of the product. Once the alkali has been added to the casein, it is important to raise the temperature as quickly as possible to 60–70 °C, in order to reduce the viscosity. During the dissolving operation, the incorporation of air should be kept to a minimum, because caseinate solutions form very stable foams.

Drying

The homogeneous sodium caseinate solution is usually spray-dried in a stream of hot air. In order to ensure efficient atomization of the sodium caseinate solution, the solution must have a constant viscosity as it is fed to the drier. It is common practice to minimize the viscosity by preheating the solution to a temperature of 90–95 °C just prior to spray drying. Care should be taken to minimize the time for which the caseinate solution is at high temperature.

Other Caseinates

The manufacture of potassium and ammonium caseinates is very similar to that of sodium caseinate, although, in the case of ammonium caseinate, a lot of the ammonia is evaporated from the solution during the drying process. A solution of sodium caseinate, like those of potassium and ammonium caseinates, has a straw-like color, and it is completely different in appearance from milk. Solutions of calcium caseinate, on the other hand, are very white and opaque (even whiter than milk), and they are less viscous than solutions of the other caseinates. Calcium caseinate solutions are produced by

adding a slurry of lime (calcium hydroxide) in water to a casein curd–water mixture, and the combined slurries react at a relatively low temperature (<45 °C) until the neutralization is completed. Use of higher temperatures before neutralization is likely to result in the precipitation or coagulation of the partly reacted calcium caseinate, with the probable dumping of the contents of the reaction vessel. All caseinate powders have a white appearance.

Composition of Casein and Caseinates

The typical composition of casein and caseinates is shown in Table 1. The caseins produced from lactic, sulfuric, or hydrochloric acid precipitation are almost indistinguishable from one another. The rennet casein differs from acid casein particularly in ash content and pH. During the acidification process, the calcium and inorganic phosphate, which are associated with the casein micelles in milk, are dissolved and leached from the curd leaving only the organic phosphorus and a small residue of calcium. Rennet casein contains about 3% calcium and approximately 1.4% phosphorus. Sodium and calcium caseinates are spray-dried products, their moisture content is much lower than that of the caseins, and their protein content is higher. With a pH in the range 6.5–7.0, sodium caseinate usually contains 1.2–1.4% sodium, whereas the calcium content of calcium caseinate is in the range 1.3–1.6% (Table 2).

Properties of Casein and Caseinates

Solubility

Acid and rennet casein are insoluble in water. Virtually all applications of casein products require them to be dissolved first. Consequently, before use, acid casein must be dissolved using an alkali to produce a solution with a pH of 6.5 or higher. For nonfood, technical applications, acid casein may be dissolved in other alkalis, such as borax or ammonia, usually to a somewhat higher pH (7.5–9.5, or higher) than that used for edible applications.

Table 1 Composition of casein products

Parameters	*Acid casein*	*Rennet casein*	*Sodium caseinate*	*Calcium caseinate*
Moisture (%)	12.0	12.0	3.8	3.8
Protein (%) (Nx6.38)	90.0	84.0	91.4	91.2
Ash (%)	2.5	7.5	3.8	3.6
Lactose (%)	1.0	1.0	0.1	0.1
Fat (%)	2.0	2.0	1.1	1.1
pH	–	–	6.5–6.9	6.8–7.0

Table 2 Mineral content of caseinates

Minerals	*Sodium caseinate*	*Calcium caseinate*
Sodium (%)	1.2–1.4	0.1
Calcium (%)	0.1	1.3–1.6
Iron (mg kg^{-1})	3–20	10–40
Copper (mg kg^{-1})	1–2	1–2
Lead (mg kg^{-1})	<1	<1

Water Absorption and Viscosity

Casein products can absorb substantial amounts of water, and, as a result, they can modify the texture of dough or baked products, serve as the matrix former in cheese-type products, produce specialized plastic materials, or increase the consistency of solutions such as soups. They are good film-formers and find use in whipping and foaming applications, and in emulsions of fats or oils in water.

Melting Properties

Casein exhibits melting properties that are unique among proteins. Following limited proteolysis, casein becomes thermoplastic and flows when heated. A similar affect can be achieved by chelating of some of the calcium ions present. These phenomena are the basis for the melting of natural cheeses and the production of process or imitation processed cheeses. A structure must exist before a substance can be said to melt. With caseins, this structure may be obtained by precipitation with calcium, acid, or the addition of rennin. Casein does not form thermal gels and has little functionality in applications that require temperature set.

High heat stability and the ability to melt are the two properties of caseinates that make them difficult to replace in many food applications. The demand for casein for use in products such as cheese analogs (processed cheese, mozzarella cheese) depends on the formation of a protein matrix from calcium caseinate, which undergoes thermomelting similar to its processed cheese counterpart.

Whipping/Foaming Ability

Caseinates generally produce higher foam overruns, but they also produce less stable foams than egg white or whey protein concentrates. The excellent surfactant property of the amphiphilic casein is also responsible for its use in whipped toppings, cake mixes, and ice cream.

Nutritional Properties

The nutritional quality of a protein is primarily determined by its essential amino acid content. For adult man, eight amino acids are essential. These are isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine; the infant requires histidine as well. In comparison with an ideal reference protein composition that was developed by the FAO in 1973, casein contains an adequate amount of all the essential amino acids, with the possible exception of the sulfur-containing amino acids methionine and cysteine.

Cashew Nuts

AM Kluczkovski and M Martins, Federal University of Amazonas, R. Comendador Alexandre Amorim, Manaus, Brazil

© 2016 Elsevier Ltd. All rights reserved.

Sources and Production

Cashew nut is made up of a fruit in which the kernel is embedded. The real fruit of the cashew is commonly a nut. It is a kidney- or heart-shaped achene, in any normal variety. Its color varies from bottle green to grayish brown (dried fruit). It is attached to the end of a fleshy footstalk or peduncle, which is in fact the receptacle of the flower, that is, broadened and swollen, and forms the false fruit. The nut is composed of kernel and pericarp or shell. The kernel is slightly curved back on itself and forms two cotyledons, representing about 20–25% of the nuts weight. It is wrapped in a thin, difficult to remove peel (testa), reddish-brown membrane, which in turn approximates to 5% of the whole nut. Figure 1 shows the different cashew nut parts. Cashew is of considerable economic importance because its components have numerous uses. The annual production of cashew nuts (with shells) is the highest of all tree nuts, with a value of more than 3.5 million tons. Cashew nut, native to Brazil, was introduced about two centuries ago to the Goa region of India, which became one of the major producers of cashew nuts, accounting for almost 50% of the total world export. Operations involved in the processing of cashew kernels are basically cooking; drying; cutting; decortication; peeling; classification; frying, in the case of roasted almonds; and packaging. The cashew kernel is of high food value with about 40–57% oil and 21% protein contents. It is an important delicacy, which is mainly used in confectionery and as a desert nut. Cashew is globally one of the most popular tree nuts and is eaten as a snack or incorporated as an ingredient in a variety of foods. Cashew ranks third in the international tree nut trade with over 20% of the market. The kernel can be roasted and consumed; it can also be used as an adjunct in chocolate and chicken feeds. Powdered milk used in the standard milk chocolate recipe could be replaced with 25% roasted cashew kernel. In view of the increasing production of cashew globally, there is a need for an increased utilization of the cashew nut, especially the nutritious cashew kernel.

Patterns of Consumption

Lipids and proteins in edible nut seeds account for the major portion, typically 50–90%, of seed weight and are well known to significantly influence seed properties. In recent years, nut seed lipids have received significant attention due to not only their importance in sensory properties but also their possible role in human health and weight management. In a study, the cashew nut diet was more efficient than the other experimental diets in promoting weight gain in rats, but all these diets were less efficient than the casein diets. The protein quality of edible seeds and nuts studied varied significantly, with protein digestibility-corrected amino acid score values ranging from 57% for *baru* almond to 90% for cashew nut. Thus, the cashew nut has the best-quality protein among these foods, mainly because of its essential amino acid profile (AAS = 103%). The inclusion of these seeds and nuts grown in Brazil in healthy diets has been recommended, especially in vegetable-based diets, since a portion (20 g) of cashew nuts provides around 10% of the protein Dietary Reference Intake for adults. It has also been reported that the amino acid score (AAS) values of the seeds and nuts studied (Table 1) were higher than those reported in the literature for the cashew nut (AAS = 103% vs. 95%).

Several studies showed the inclusion of cashew nut bran at levels of 7.5 and 15% in animal broiler diets, decreasing the levels of cholesterol, palmitic (C16:0) acid, and linoleic (C18:2) acid and increasing oleic acid (C18:1) content of abdominal fat. It was demonstrated that 13% cashew nut bran in the diet did not contribute to increase oleic acid (C18:1) in goat meat.

Availability, Absorption, and Metabolism

Nutritionally, cashew nut provides a lot of energy, providing a reasonable balance of carbohydrates and lipids and proteins; its high energy and protein content makes cashew nut an ideal supplement for feeding children, pregnant women, nursing mothers, and convalescents. The almond flavor appreciated by much of the population allows its incorporation in various types of dishes and culinary delights, increasing the nutritional value of the diet. Table 2 shows the approximate composition of almond cashew, according to various authors.

The most abundant of the minerals present in the cashew nut was potassium (38.5 ± 0.0) followed by magnesium and calcium with values of 36.4 ± 0.2 and 21.4 ± 0.1, respectively. The least abundant were copper, iron, and zinc. Anacardein, the predominant soluble globulin in cashew, also known as CMP, is a multimeric globulin (13S) and constitutes about 40–45% of the total cashew soluble seed proteins. Tree nut allergies affect about 1% of the population and are one of the leading causes of fatal and near-fatal food-induced allergic reactions. Patients with a severe allergy to tree nuts rarely become tolerant of these foods, and these allergies can persist throughout life. Cashew proteins seem to be very potent allergens. Six of 30 (20%) patients with type I hypersensitivity to cashew nut were reported to experience an anaphylactic reaction in one study. Ingestion of chocolate candy containing cashew nut has also been reported to cause an anaphylactic reaction. In the United Kingdom, recent wide availability of cashew nut butter-type spread has increased the potential for a higher rate of exposure. It has been reported that 0.08% of British 4-year-olds are allergic to cashew, whereas 40% of 142 French patients allergic to peanuts were found to be sensitized to cashew. On the other hand, only Brazil nuts (24.5%), cashews (20.9%), macadamia nuts (17.1%), and pistachios

(13.3%) were higher in saturated fatty acids. This is one reason that Brazil nuts, cashews, and macadamia nuts were excluded from the USDA qualified health claim for tree nuts. In the same study, it was observed that cashew was the only nut type possessing all of the minor sterols elucidated with the exception of Δ7-stigmastenol. Table 3 shows the composition of fatty acids in cashews.

Cashew nut skins are a natural source of phenolic compounds; the levels of (+) catechin (5.7 g kg^{-1} DM) and (−) epicatechin (4.46 g kg^{-1} DM) in the testa of cashew nuts are higher than those reported for green tea and chocolate. The testa-containing cashew nuts possess significantly higher amounts of carotenoids and tocopherols, but a lower level of thiamine when compared to testa-free kernels.

Health Effects

Nuts constitute a good source of certain vital bioactive compounds that could elicit many health benefits in human beings. Cashew nut contains the best-quality protein for humans. Results of several epidemiological studies suggested that there may be a connection between frequent nut consumption and reduced incidence of several chronic diseases. Long-term consumption of nuts has been associated with a lower risk of body weight gain and obesity. The consumption of nuts as a part of the healthy diet has a positive influence on the fatty acid profile of persons with type 2 diabetes. Analysis of the effects of the inclusion of cashew nut in the diet on the antioxidant status of human subjects with metabolic syndrome resulted in an increased antioxidant capacity. Nut consumption seems to apply a cholesterol-lowering effect and reduce the risk of lipoprotein-mediated cardiovascular disease, and recent emerging scientific findings have demonstrated that the bioactive constituents of whole nuts have cardioprotective, antiobesity, anticancer, and antioxidant effects by a number of different mechanisms. Cashew nut represents one of the cheapest major sources of nonisoprenoid phenolic lipids, which have a variety of biological properties and medicinal applications and have demonstrated a potential antioxidant activity. Quantitative determination of the major phenolic lipids in cashew apple, kernels, and shells of cashew nut at various stages of development suggested the possibility of fatty acid-type biogenesis of these phenolic lipids. The presence of unsaturated fatty acids, tocopherols, squalenes, and phytosterols and the antioxidant activities of various bioactive compounds such as phenolic, flavonoids, phospholipids, sphingolipids, sterols, and tocopherols were reported in cashew nut samples. Furthermore, the ethanolic extract of cashew nut testa has exhibited significant antioxidant activity, and the polyphenolic compounds present in the testa appear to contribute to the antioxidant activity. Concerning the functional properties of cashew nuts, recently, the isolation of protein from defatted cashew nut shell (CNS), with the crude protein product containing 91.07% protein, was reported. Under its natural conditions, the solubility of this protein isolate is comparable (74.02%) to that of mustard green meal protein. The solubility of the protein isolate decreases with decreasing pH, with the minimum solubility observed at its isoelectric point (pH 3). The water-holding capacity, oil-holding capacity, foaming capacity, foam stability, emulsifying capacity, and emulsion stability were found to be 2.56 cm^3 H_2O/g protein, 4.28 cm^3 oil/g protein, 76.88%, 70.98%, 62.0%, and 79.0%, respectively. The profiles of these functional properties were determined with varying pH values and NaCl concentrations, and improved properties were observed in the alkaline pH range and in the presence of NaCl. Electrophoretic analysis showed that the high-molecular-weight protein globulin was the major protein in the protein isolate. The cashew nuts have been associated with two distinct hypersensitivity reactions. The first, contact or systemic dermatitis, has been linked to cardol and anacardic acid found in the CNS oil, both of which are related to poison ivy urushiol. The second type of hypersensitivity reported from North America and Europe is IgE-mediated food allergy; reactions can range from atopic dermatitis to fatal systemic allergic reactions. Recent studies on cashew nut

allergy suggest that the prevalence of cashew nut allergy is increasing. Cashew nut consumption by allergic patients can cause severe reactions, including anaphylaxis. The major cashew allergens are Ana o 1, Ana o 2, and Ana o 3. Ana o 1 is a 50 kDa vicilin-like protein resistant to heat and proteolysis. The other two known allergens are Ana o 2,a 33 kDa legume-like protein, and Ana o 3, a 13 kDa 2S albumin. All three allergens were classified as seed storage proteins. Patients allergic to cashew nut (50% (10of 20 sera) are sensitized to recombinant Ana o 1, 62% (13 of 21 sera) to recombinant Ana o 2, and 81% (21 of 26 sera) to recombinant Ana o 3 determined by Western immunoblotting allergens from these families of seed storage proteins) are known to be allergic to other tree nuts and legumes and seeds.

Cassava: The Nature and Uses

T Shigaki, National Agricultural Research Institute, Lae, Papua New Guinea

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Cassava (*Manihot esculenta* Crantz) is a woody shrub that belongs to the spurge family (Euphorbiaceae). Cassava, an annual crop native to South America, is also called manioc or yucca. It is now extensively cultivated throughout tropical and subtropical regions, mainly for its edible tubers as a source of carbohydrates. In some communities, its green leaves are also consumed as a vegetable, although leaves are rich in cyanogenic glycosides and require careful processing. Starch is made from cassava root and used in many culinary and industrial applications (Figures 1 and 2).

The domestication of cassava took place over 10 000 years ago in west central Brazil, and it became a staple food among pre-Columbian Americans. It was introduced to Africa by Portuguese in the sixteenth century, where it replaced native African crops. Along with maize, another introduction from South America, it is now one of the most important staple crops in Africa. Currently, Africa accounts for over half of the world's cassava production. The popularity of cassava in Africa originates from the fact that African slaves who migrated to South America brought back with them the knowledge and technology of cassava cultivation, processing, and cooking to Africa when they returned home.

Cassava originated in tropical rainfed areas, and therefore, the yield is not optimal under dry climatic conditions. Nonetheless, cassava is still considered one of the most drought-tolerant crops, and its importance for food security in drought-prone areas is widely recognized. However, it contains cyanogenic antinutrients that can cause serious health effects when improperly processed cassava is consumed. During drought, cassava is often the only crop that is able to survive the low moisture, and the cyanide content in cassava is elevated during such times as a normal stress response of the plant. Another constraint is that cassava is low in protein, and an exclusive dependence on cassava-based diet can cause serious health consequences.

Cassava has been a crop consumed mainly where it is produced and has not been considered for intra- or international trade due to factors that prevent long-term storage and lengthy transportation. However, with modern technology, this picture is now changing, and cassava products are becoming an important export in some countries, notably Thailand.

With these in mind, this article discusses the production, patterns of consumption, nutritional profile, and health effects of cassava. This article also describes projects aiming at improving the agronomic and nutritional qualities of cassava.

Sources and Production

Leading Countries in Cassava Production

A phylogenetic study by Olsen and colleagues indicates that the origin of cultivated varieties of cassava, *Manihot esculenta* subsp. *flabellifolia*, occurred in regions around west central Brazil, and its cultivation started at least 10 000 years ago.

Cassava was introduced to other parts of the world, mainly by Portuguese colonists, and it is now cultivated in most tropical and subtropical countries. Over half of the cassava production takes place in Africa, followed by Asia and South America. According to an FAO report published in 2008, top five countries in terms of cassava production were Nigeria, Brazil, Thailand, Indonesia, and the Republic of Congo (in order of the amount produced). These five countries account for 57.0% of the world production. Of note, since 1980s, Nigeria has dramatically increased its output and became the top country in cassava production.

Advantages and Disadvantages of Cassava

Several traits of cassava make it an ideal crop in dry areas and during drought. First, cassava plants can survive drought conditions and resume growth when water becomes available, either from rain or irrigation. It can grow in marginal soils without fertilizers, where other crops cannot grow; however, the yield can be compromised. Second, it can be harvested in varied times after planting, ranging approximately from 6 months to 3 years, unlike grain crops such as rice and millet, which must be harvested during a narrow window of time. Third, per area yield is higher than most other crops. Studies show that cassava can produce 250×10^3 cal ha^{-1} day^{-1} under excellent growing conditions and when supplied with organic and chemical fertilizers. This compares favorably with 200×10^3 for maize, 176×10^3 for rice, 114×10^3 for sorghum, and 110×10^3 for wheat. Last, but probably as important as other factors, cassava cultivation is generally easy requiring little care such as weeding. Besides, cassava root is less prone to insect and rodent damages, as it grows underground.

Despite these excellent traits that made cassava popular throughout the tropics, it is nonetheless slow-growing and may take 10–12 months to harvest roots. This is significantly longer than grain crops such as rice and millet. A number of pests and diseases are known for cassava, and they are often devastating, causing famines.

Cassava Cultivation

Cassava is propagated vegetatively using stem cuttings, although it flowers and produces seeds. The stem cuttings for planting, 10–15 cm long, are obtained from disease-free stakes of 8–15-month-old cassava plants. Planting should take place when there is sufficient rainfall to promote good sprouting. Seeds are not used as planting materials for cassava production. However, they are used for breeding purposes.

Three different ways are known to plant cassava cuttings, and the best way is chosen depending on the soil moisture, pest occurrence, and how the tubers are harvested. Vertical planting, with two-thirds of the cutting in the soil, produces tubers deep in the soil, and therefore, they are relatively difficult to pull out, but it is suited in the area with low rainfall. This

Figure 1 Cassava plants in a smallholder farm in Honiara, Solomon Islands.

Figure 2 Cassava roots sold at a market in Honiara, Solomon Islands.

method produces roots with good soil anchorage. Angled planting, with two-thirds in the soil, produces tubers that are easy to harvest and suitable in loam soil. In horizontal planting, cuttings are placed horizontally, approximately 10 cm deep in the soil. This method produces multiple stems but the tuber size may be small. Horizontal planting is used in mechanized planting.

The first and the best harvest takes place 9–12 months after planting. Tubers can grow in the soil up to 3 years. However, under extensive rainy and waterlogged conditions, starch in the tuber can get hydrolyzed into sugars, and the tubers become difficult to cook as the starch content decreases. As well, older tubers tend to become fibrous and woody, thus often unsuitable for consumption. Thus, harvesting of the tubers should be planned based on weather conditions.

Cassava is mainly grown to harvest its roots, but cassava leaves are also edible after extensive cooking, as the raw leaves are rich in cyanogenic glycosides. Cassava leaves are an excellent source of nutrients that lack in its roots, such as protein, vitamins, and minerals. Older leaves tend to have undesirable levels of cyanogens, and therefore, young leaves are preferred. In some African countries, especially Cameroon, Congo, Malawi, and Tanzania, cassava leaves are popular and used in local recipes.

Pests and Diseases

As most other vegetatively propagated crops, it tends to accumulate viruses over the period of cultivation. Among a number of viruses infecting cassava, cassava mosaic virus is one of the most important viruses that cause diseases. It is vectored by whiteflies. A new mutated strain of this virus was found in Uganda in 1980s, and it is spreading throughout Central Africa. Another important virus infecting cassava is cassava brown streak virus that can cause total crop failure. The use of virus-free planting material is the key to prevent the diseases. Quarantine procedures must be in place when cassava germplasm is exchanged internationally. New virus-tolerant/virus-resistant cassava strains are available that are produced by breeding.

Insect pests include cassava mealybug (*Phenacoccus manihoti*) and cassava green mite (*Mononychellus tanajoa*). These pests can be biologically controlled using natural enemies introduced from South America, the cassava's center of origin. Nematode damages may not be evident from casual observation of the field because the pathogen's main entry is through the roots. However, it is a major concern, and control measures can potentially increase the yield significantly.

Currently, climate change appears to affect many parts of the world in various ways. For example, Pacific countries are experiencing droughts more often in recent years than before, causing food shortages. Most popular energy sources in the Pacific are root crops, including taro and sweet potato. Compared with grain crops, root crops are susceptible to postharvest degradation and pest damages. Therefore, cassava is gaining popularity as a food security crop because it can survive in the soil even in dry times and the harvesting time is flexible. Climate change also alters the occurrence and epidemiology of pests and diseases. Timely monitoring is essential to minimize the damages.

Cyanogenic Glycosides

Despite many of cassava's desirable traits, it requires careful processing, as it contains cyanogenic antinutrients, making it potentially poisonous and occasionally fatal. Depending on the amount of cyanogenic glycosides, cassava varieties are classified into two types, 'bitter' and 'sweet.' Bitter varieties contain toxic levels of cyanogenic glycosides and therefore not usually suitable for human consumption without extensive processing. Sweet varieties contain relatively low levels of cyanides and are edible. However, they tend to be less tolerant to pests and diseases. Historically, the two types of cassava were classified into two separate species, *Manihot esculenta* (the bitter cassava) and *Manihot palmata* (the sweet cassava). However, molecular phylogenetics indicated that the two types should be classified as a single species. In fact, the bitterness (cyanogenic glycoside content) depends on factors such as soil, climate, and physiological status and not on a genotypic character.

Postharvest and Transport

Cassava is difficult to store once it is harvested because of a process termed postharvest physiological deterioration. In this process, a natural healing response to physical damages that

involves coumaric acids fails to switch off in harvested cassava tubers. The tubers become completely oxidized in 2–3 days after harvest, making them worthless.

Another hindrance comes from the fact that ~70% of fresh weight of cassava is water. Therefore, it is heavy and difficult to transport a large amount of fresh cassava, especially in Africa where road conditions are not ideal and transportation options are limited. For this reason, unprocessed cassava is generally consumed locally. Cassava can be dipped in wax after harvest, and this enables long-range shipping and storage. Cassava is also stored frozen when it can be stored for many months or dried in sunlight after chopping into pieces.

Patterns of Consumption

Preparation of Cassava

Cassava is grown mainly for its starchy roots. It is a major staple crop in many tropical and subtropical countries. However, in some areas, especially in Central Africa, cassava leaves are also consumed as a vegetable. Cassava is an important source of nutrients in these areas, and unique local recipes were developed to prepare cassava cooked with accompanying ingredients that provide proteins, vitamins, and minerals that are not abundantly present in roots.

Most tissues of cassava contain cyanogenic glycosides, in both sweet and bitter varieties. Cyanogenic glycosides found in cassava are linamarin and lotaustralin. However, linamarin is more abundant than lotaustralin and accounts for over 90% of the total cyanogenic glycosides.

Bitter varieties of cassava contain a larger amount of cyanogenic glycosides than sweet varieties, and these are the varieties that are preferentially cultivated in many countries because they can resist pests and diseases and deter thieves. Therefore, it must be processed before it is consumed safely. Five ways to minimize the toxic effects are practiced to safely consume cassava. First, cassava varieties with low toxicity can be selected. However, by doing so, other favorable traits may be compromised. Second, cyanogenic glycosides can be removed by soaking in water. Third, maceration of cassava tissues will release endogenous enzymes to decompose cyanogenic glycosides. Fourth, enzymes of microbial origin can be utilized for the decomposition. Lastly, cyanogenic glycosides can be reduced by heating.

Cassava roots can be simply eaten boiled or fried to accompany greens, meat, or fish dishes. Cassava is also a versatile crop that can be used in numerous different recipes all over the world. Some examples are described here to illustrate its versatility.

Cassava Recipes

Cassava meals

Fufu: Cassava root is boiled and then pounded into a dough to make this popular staple food in African and Caribbean countries. It is often mixed with yam and plantain banana. Fufu can be made with a flour of cassava and other plants. Similar food made with maize flour is consumed in East Africa and called ugari. Fufu is usually eaten with a soup, which is often scooped with fufu made into a spoonlike shape.

Gari: Gari is a granular flour made from fermented cassava roots. Its color is off-white, and it is popular in Nigeria and other Western African countries. To make gari, freshly harvested cassava root is peeled and grated, and then, it is fermented for 3–7 days. The fermentation process removes the toxic cyanide and also contributes to make the desirable flavor. Then, it is sieved and heated for preservation. Heating serves three purposes: to destroy the enzymes and microorganisms, to remove cyanide, and to dry the gari. It has a shelf life of up to 6 months if stored properly. To serve, gari is soaked in water with roasted peanuts, dry fish, sugar, etc.

Farinha de mandioca (Brazil): Farinha de mandioca is grated and dried cassava roots used as condiments or a side dish. It is commercially available in varying degrees of coarseness. To make farinha de mandioca, cassava roots are first detoxified by soaking in water. Then, the detoxified roots are ground and squeezed to remove most of the liquid content. The dried pulp is subsequently dried on a saucepan. Western Amazon is the major area for the production of farinha de mandioca.

Breads, cakes, fries, and noodles

Cassava bread: Cassava flour is mixed with wheat flour to make bread in some African countries such as Ghana, Cameroun, Congo, Malawi, and Nigeria. The cassava flour used for this purpose must be of high quality.

Cassava cake (the Philippines): Grated cassava root is mixed with coconut milk, eggs, and butter. It is one of the most popular sweets in the Philippines.

Cassava cake (Pacific): Similar to the cassava cake in the Philippines, grated cassava root is mixed with coconut milk in many Pacific countries such as Papua New Guinea, Solomon Islands, and Vanuatu. Meat and other ingredients are often sandwiched between the layers of cassava cake. It is typically sold wrapped in banana leaves (**Figure 3**).

Cassava pone (Caribbean countries): Cassava pone is a dessert originated from Trinidad and Tobago, but it became popular also in other Caribbean countries such as Guyana. To make cassava pone, cassava is grated and mixed with grated coconut, coconut milk, sugar, and spices and then baked.

Brazilian tapioca: A crepe made with cassava powder, 'Brazilian tapioca' is topped with shredded coconut, chocolate, or fruit jam and eaten for breakfast or dessert.

Figure 3 Cassava cake wrapped in banana leaf sold at Arawa Market, Bougainville, Papua New Guinea.

Cassava fries: Cassava can be a substitute for French fries. Cassava fries are popular in Central and South American countries and Malaysia.

Cassava derivatives

Cassareep (Guyana): Cassareep is a juice from bitter cassava, boiled to form a thick, black syrup, with added spices and condiments (e.g., cayenne pepper, cinnamon, cloves, salt, and sugar). It is a base for a variety of sauces prepared in South America. Cassareep gives food distinctive bittersweet flavor and is also used as a preservative. Cassareep is produced and exported from Guyana.

Cassava leaves

Mixed vegetables: Cassava leaves can substitute any green leafy vegetable. Leaves are not widely consumed, compared with the roots, but in many communities, they are part of local diet. For example, in coastal regions of Kenya, cassava leaves are washed, pounded, and boiled in salt water for an hour and added to other vegetables such as onions and tomatoes that are prefried. Curry powder and coconut cream are used to season such mixed vegetables. The dish accompanies starchy staples.

Cassava leaves: Boiled cassava leaves are eaten with sambal (shrimp paste) or tempoyak (fermented durian) in Sarawak.

Saka saka (Congo): 'Saka saka' is made by crushing the greens in a mortar and pestle and then boiling in water with other ingredients (palm oil, onion, garlic, capsicum, eggplant, okra, etc.), until it is cooked to a pulp. It is commonly served with fish, meat, or chicken.

Tapioca recipes

Tapioca pearls: Tapioca is shaped into small balls, typically with a diameter of 2–8 mm, depending on their use. In Asian countries, they are used in desserts. Tapioca pearls are often referred to as 'sago' pearls, because they are similar to those made from starch derived from sago, a palm species. Due to its lower price, tapioca pearls can be used as a substitute for sago pearls.

Sagu: 'Sagu' is a cold dessert popular in Brazil made with tapioca pearls, cinnamon, and cloves cooked in red wine.

Tapioca tea (Taiwan and other Asian countries): Also known as bubble tea, this is a cold milk tea served with tapioca pearls. It is served in a cup and drunk with a large straw. Originally developed in Taiwan in the 1980s, it is now enjoyed throughout Asia (Figure 4).

Udon (Japan): Tapioca is mixed with wheat flour to improve the texture of frozen udon noodles in Japan. The frozen cassava-wheat udon is considered to be of superior culinary quality.

As a food additive: Tapioca is used in food industry to improve the taste and texture and to give consistency or stickiness to many products, including confectionary, yogurt, and noodles.

Alcoholic beverages

Kasiri (cassava beer): Alcoholic beverages are produced from cassava in many countries. Amerindians in Suriname and Guyana produce a cassava beer called kasiri from grated cassava roots by pressing to extract its juice and then fermentation of the juice.

Figure 4 Tapioca tea served at a tea stall in Taipei. Take note of the black tapioca pearls at the bottom of the tea.

Cassava beer (South Africa): An industrial scale production of cassava beer has started by SABMiller. The beer, named Impala, uses traditional home brew recipe from villages.

Cassava starch in food industry

Besides the aforementioned recipes, cassava and its derivatives such as tapioca are widely used for food additives and as an ingredient of processed foods, often to enhance the texture and other qualities of the products. Some applications include the use as thickeners for soups, sauces, and baby foods; as binders for sausages and other processed meats; and as stabilizers in ice cream.

Nutrition, Availability, Absorption, and Metabolism

Nutrition Profile of Cassava

Cassava roots are essentially a source of carbohydrates and very poor in protein and fats, although it is a good source of calcium and vitamin C. The main amino acids in the protein are arginine, histidine, isoleucine, leucine, and lysine. In the tropics, cassava is the third most important carbohydrate source, only after rice and maize, and in arid areas and in times of drought, it is often the only source of nutrition (Table 1).

Cassava is the third largest source of food carbohydrates in the tropics, after rice and maize.

Protein content in cassava can be increased by biofortification through genetic engineering and breeding. An alternative approach is the use of solid-state fermentation. Solid-state fermentation is a century-old technology that utilizes fungal

species and has been used for manufacturing soy sauce and other products in Asia and particularly in Japan. Smith and colleagues reported an increase in the protein content of cassava roots using solid-state fermentation with the fungus *Sporotrichum pulverulentum*.

Cassava is generally considered a poor source of carotenoids. However, carotenoid content in cassava roots can range widely from 1.02 to 10.40 μg g^{-1}, and its retention depends on how the cassava roots are processed. Therefore, it may be possible to improve cassava for the carotenoid content by conventional means using breeding and improved processing technologies. Cassava is also a moderate source of folate, thiamine, pyridoxine, riboflavin, and pantothenic acid.

Cassava root contains minerals such as zinc, iron, magnesium, copper, and manganese and is an important source of these minerals for poor communities. Besides, it is a decent source of potassium.

Young cassava leaves are a good source of vitamins and protein. Of note, it is rich in vitamin K. Vitamin K plays a role in the treatment of Alzheimer's disease and also is involved in bone mass building by osteotropic activity in the bones.

The low protein status of cassava can be an advantage for kidney patients who require diet with low protein content.

As mentioned earlier, cassava is a poor source of certain essential nutrients. Nonetheless, many sub-Saharan African communities depend on cassava for their dietary needs. The result is, according to the World Health Organization, the malnutrition that often leads to blindness, disability, or death. Estimated 250 000–500 000 children die each year in these countries. Enhancing nutritional properties of cassava could, in theory, correct this and save many lives. Donald Danforth Plant Science Center in St. Louis, Missouri, the United States, is working with African scientists to develop two cassava varieties, one for West Africa and one for East Africa. For West Africa, a popular cassava variety is improved in beta-carotene and iron in the roots. For East Africa, a variety resistant to cassava mosaic virus is fortified with beta-carotene, and resistance to cassava brown streak virus is added. This initiative is funded by Bill & Melinda Gates Foundation.

Cyanogen as an Antinutrient

Antinutrients are compounds typically found in crop plants that interfere with nutrient absorption by the human body. Cyanogenic glycosides are the most important antinutrient in cassava. They have an important role for plants to deter herbivory and resist pests and diseases. In modern cultivars, high antinutrient traits have been selected out. However, in the case of cassava, cyanogenic property is still retained in all varieties, perhaps, due to their benefits and also difficulty to breed cyanogen-free varieties.

Cyanogenic glycosides are found in a number of food crops. They are, in their original forms, relatively nontoxic. However, when plant material is macerated upon chewing, hydrogen cyanide (HCN) is released by the action of endogenous enzymes (Table 2).

According to a report by Santana and colleagues, cyanide is produced in cassava as the result of the hydrolysis of linamarin by linamarase, forming an acetone cyanohydrin, which is subsequently transformed to release HCN, either spontaneously or enzymatically.

Recently, an Ohio State University team, led by Richard Sayre, developed a cassava line that is nearly free of cyanide by blocking the expression of the genes that are responsible for linamarin synthesis. The plant contains reduced amount of cyanogens in leaves (by 60–94%) and in roots (by 99%), compared with unmodified cassava. Whether this approach is

Table 2 Food sources of cyanogenic glycosides and amount of hydrogen cyanide (HCN) produced[a]

Plant	*HCN (mg/100 g)*	*Glucoside*
Bitter almonds	250	Amygdalin
Cassava root	53	Linamarin
Whole sorghum	250	Dhurrin
Lima bean	10–312	Linamarin

[a]According to Shibamoto, T. and Bjeldanes, L. F. (1993). *Introduction to food toxicology*. California: Academic Press, San Diego.

practical requires careful greenhouse and field testing as linamarin may play important physiological roles.

Health Effects

Effects of Cyanogens

Despite its high yield and low water requirement for growth, cassava consumption has major health problems. As stated earlier, cassava contains cyanogenic glucosides that liberate HCN by endogenous enzyme termed linamarase. Therefore, proper processing is necessary to reduce the toxic compounds to a safe level for consumption. However, long-term effects of the low levels of cyanide are also a concern.

The symptoms of cyanide poisoning appear several hours after the ingestion of improperly processed cassava or cassava derivatives. They include vomiting, vertigo, collapse, and sometimes death. Sulfur can convert cyanide to thiocyanate in human body. Therefore, the poisoning is treatable with an injection of thiosulfate.

The conversion of cyanide to thiocyanate requires a reserve of sulfur-containing amino acids that are also building blocks for other proteins essential for normal physiological functions. Therefore, detoxification depletes the sulfur reserve of the body that leads to various protein deficiency symptoms.

However, this thiocyanate is a compound known to affect the function of thyroid gland to store and process iodine and cause goiter.

In many tropical and subtropical communities, cassava is the only crop that survives during famines. At such times, the normal and often lengthy process of cyanide detoxification is cut short, resulting in incomplete removal of the toxins. Besides, during the drought, cyanogenic glycoside content increases in cassava as a physiological response to the stress, elevating the chance of cyanide poisoning epidemics. Such epidemics often occur in poverty-stricken communities in Africa.

The processing of cassava, by soaking, by heating, or by fermentation, can remove most of the cyanogens, but the processed flour and other products can still contain toxic levels of cyanide. To improve the safety, Howard Bradbury of Australian National University recently developed a simple method to remove the cyanide in cassava flour. The flour is mixed with water to make a thick paste and spread into a thin layer over a basket and kept in the shade for 5 h. During this process, an endogenous enzyme breaks down the cyanide, which escapes into the air. The flour is then safe for consumption.

Besides ingestion of cyanide, poisoning can occur during the detoxification process from the vapors.

Disorders Due to Chronic Toxicity of Cyanogen

Konzo

Konzo is a neurological disorder typically characterized by a sudden onset of an irreversible (but nonprogressive) and symmetrical spastic paralysis/tetraparesis. Konzo is associated with the consumption of cyanogenic glucoside from improperly processed bitter cassava, combined with low-protein diet deficient in sulfur-containing amino acids. Epidemics of this disorder are reported from many cassava-consuming areas in Africa.

This disorder affects women and children under the age of three. In the communities affected by konzo, the position of women in the hierarchy may be lower than that of men, who have better access to nutritious foods that are low in cyanogens and high in protein. Women may be responsible for the processing cassava and exposed to toxic vapor from the preparation. Breast-fed children, typically under the age of three, are not likely to suffer from konzo, as the toxin is not passed from mother to breast milk.

As described earlier, the production of cassava is on the increase, and the likelihood of drought is rising globally in the face of global warming. Therefore, it follows that the cases of konzo will also increase and healthcare workers should monitor any outbreak of this disease.

Tropical ataxic neuropathy

This is a disease in cassava-eating countries in the tropics. Its symptoms include paresthesia (tingling) of the sole of the feet, weakened arms, blurring or loss of vision, ataxic/or spastic gait, deafness, and weakness and thinning of legs. It is considered to be a result of chronic ingestion of subtoxic levels of cyanide. It is suspected to be linked to thiamine deficiency. Most tropical ataxic neuropathy patients are adults, while konzo affects primarily children and women of childbearing age.

Goiter

A goiter is a disease with symptoms of swollen neck or larynx due to the enlargement of the thyroid gland. Iodine deficiency accounts for more than 90% of the goiter cases worldwide. When the body breaks down cyanide in cassava, it generates thiocyanate, which limits the ability of thyroid gland to store iodine, causing iodine deficiency. The function of thyroid is severely compromised without iodine. Iodine deficiency can be corrected by using iodized table salt.

Other Disorders from Cassava Consumption

Malnutrition

As cassava is naturally low in protein and other essential nutrients, diet based solely on cassava can lead to malnutrition.

Kwashiorkor

Extreme dependence on cassava for dietary requirements can lead to a condition known as kwashiorkor, caused by protein deficiency. Lack of protein causes an osmotic imbalance in the digestive system that results in the swollen gut due to the

retention of water (edema). Edema is often mistaken by uninformed parents as a sign of good nourishment, while in fact, it is a form of malnutrition. Getting more protein and calories is the best treatment for this condition.

Allergy to cassava

People who are sensitive to latex can be allergic to cassava. A few cases have been reported that patients with latex allergy suffered from anaphylaxis after eating cassava. It is attributable to a chitinase that cross-reacts with prohevein in latex, because the N-terminal domain of the class I chitinases shows homology to prohevein. These chitinases are also found in avocado, banana, and chestnut.

Medicinal and Other Uses

Cassava has been claimed to be effective for treating prostate cancer. However, the American Cancer Society discounts this claim, as there is no convincing evidence from controlled studies.

A derivative of cassava juice, cassareep, exhibits antiseptic property and is used as an ointment and for the treatment of eye diseases.

Cassava is free of gluten that is present in wheat flour. Therefore, it is a good substitute for the people who are sensitive to gluten.

Conclusion

Cassava is a crop of primary importance in many parts of the world, especially in poverty-stricken, arid areas, as it is often the only crop that can survive the drought and poor soils. Recent research found many food and industrial uses of this traditionally subsistence crop, and the production is on the increase. Many cassava projects to improve the nutritional status of the people who depend on this crop are being implemented and must be continued. Research on the diseases associated with cassava diet should be continued to improve the welfare of the cassava-dependent communities.

Cellulose Origin

Cellulose is an almost inexhaustible polymeric raw material with fascinating structure and properties. Cellulose and its derivatives are used in countless commercial products ranging from paper and textiles to pharmaceuticals and foods. In nature, cellulose is the main structural component of the plant cell wall (e.g., cottons and woods) and also exists in some lower plants, such as algae and mosses. In addition, cellulose can also be produced by certain bacteria and fungi. Regardless of the different sources, the chemical structure of cellulose remains the same.

Cellulose Chemical Structure

Cellulose is a linear polymer composed of repeating units of glucose rings. Figure 1 shows the molecular structure of cellulose, which is composed of repeating β-D-glucopyranosyl building blocks that are covalently linked by β-1,4-glycosidic bonds between the hydroxyl groups of C4 and the C1 carbons. The beta linkage between these building blocks makes an extended and rigid conformation with each glucose ring 180° from its neighbor. Although the cellulose molecule is a simple polymer composed of thousands of identical glucose units, lots of cellulose chains are aggregated together in parallel by hydrogen bonds to form a highly compact, fully extended cellulose sheet structure. These sheets assemble by van der Waals interactions. Each cellulose chain is composed of one reducing end terminated with C1–OH group, which is in equilibrium with the aldehyde structure. The other end is a nonreducing end with a C4–OH group. This highly packed, linear-chain homopolymer is responsible for the stable property of cellulose and its aqueous insolubility.

Such molecular structure imparts cellulose with its characteristic properties of hydrophilicity, crystallinity, and chemical modifying variability due to the abundant presence of hydroxyl groups. These hydroxyl groups are basis for extensive hydrogen bond network, which gives rise to a highly rigid and ordered cellulose molecular structure. These hydroxyl groups also provide sites for etherification to make cellulose ethers.

Cellulose Biosynthesis

The majority of cellulose is produced from higher plants, such as cotton, trees, and ramie. In very few cases, cellulose is present in an almost pure state, for example, in cotton seeds. In most cases, however, cellulose exists in wood embedded in the matrix of hemicellulose, lignin, and other cell wall components. These matrices play roles in hindering the degradation and utilization of cellulose biomass. Cellulose can also be generated from certain bacteria (e.g., *Gluconacetobacter xylinus*, previously called *Acetobacter xylinum*), fungi, algae, and animals (tunicates). Bacterial cellulose is typically pure cellulose with high crystallinity and long fiber structure. In contrast to plant cellulose, the absence of lignin and hemicellulose allows easier extraction and purification of cellulose for various applications.

Cellulose Microfibril Organization

The biosynthesis of cellulose has been investigated in details over the past decades. In nature, cellulose exists as a composite of many glucan chains, called microfibrils. It is proposed that cellulose is initially synthesized as individual linear glucan chains, and a number of glucan chains are packed together by hydrogen bonds to form cellulose crystalline sheets, and these sheets are further aggregated together by van der Waals' interaction to form elementary fibrils. Elementary fibrils are then assembled into larger units, forming microfibrils, bundles, which are in turn packed into fibers.

Cellulose microfibrils have varied sizes depending on their origins (Figure 2). Small microfibrils from higher plants (also called elementary fibrils) usually contain approximately 36 glucan chains or less, while large microfibrils from algae contain more than 1000 chains. Microfibrils adopt different shapes and aspect ratios depending on their origin.

Cellulose Crystal Structure

Cellulose has varied crystal forms: cellulose I, II, III, and IV. Cellulose I, also called native cellulose, is the most abundant form occurring mainly in plant cell walls. Cellulose I exists in two distinct allomorphs (Iα and Iß). It has been revealed that cellulose Iα has a triclinic unit cell, while Iß has a monoclinic unit cell. Cellulose produced by bacteria and algae is enriched in Iα, while the cellulose synthesized from higher plants is predominantly Iß, and cellulose from tunicate is considered to be almost pure Iß. Cellulose I can be irreversibly transitioned to a more stable crystalline form, cellulose II. Cellulose II is always found in mercerized (alkali-treated) cotton and in regenerated cellulose. Cellulose III is prepared by the treatment of native cellulose with anhydrous ethylamine or liquid ammonia. Cellulose IV is produced with certain treatments at high temperature.

The crystal structure of cellulose has been extensively studied by several structure-analysis methods, such as x-ray diffraction (XRD), 13C solid-state nuclear magnetic resonance spectroscopy, Fourier transform infrared spectroscopy, and neutron diffraction analysis. The crystallinity index of cellulose crystal allomorphs is shown in Figure 3, in which different XRD patterns are observed for different allomorphs. The crystal structure and crystallinity contribute to the high insoluble property of

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00127-6

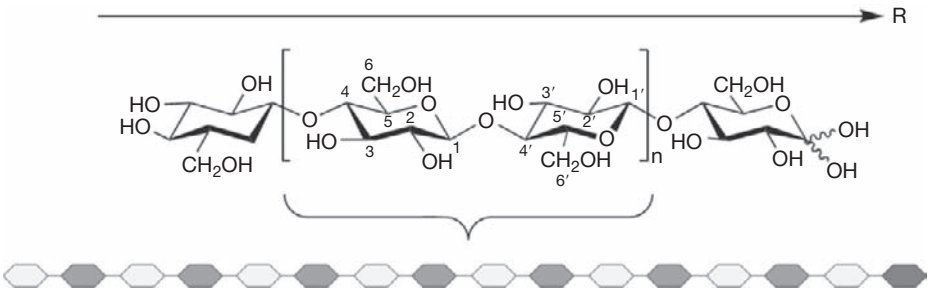

Figure 1 Molecular structure of a typical cellulose chain. The repeating units of cellobiose are denoted in gray. The reducing end (R) of cellulose chain is indicated in dark gray. Taken from Perez et al. (2010).

cellulose. This highly ordered crystalline structure needs to be destroyed in order to make cellulose material soluble or more accessible to solvents.

Cellulose Molecular Weight and Degree of Polymerization

The chain length of cellulose is described as the degree of polymerization (DP), which varies with the source and treatment of the raw material. Cotton and higher plant fibers usually have DP in the range of 800–10 000; bacterial cellulose has similar DP. In the case of wood fibers, the DP values are 300–1700. Regenerated cellulose contains 250–500 repeating units. As cellulose is an unbranched polymer, high DP is associated with high molecular weight (M_W). In soluble cellulose derivatives, M_w and DP are critical in determining the rheological properties, for example, viscosity and flow behavior. Generally, M_w and DP are positively correlated with solution viscosity.

Production of Cellulose Derivatives

The presence of many hydroxyl groups (three hydroxyls per cellulose building block, anhydroglucose unit (AGU)) makes it possible for etherification of those hydroxyl groups to produce various cellulose ethers. This occurs via the following reaction:

$$\mathrm{ROH} + \mathrm{R'Cl} \rightarrow \mathrm{ROR'} + \mathrm{HCl}$$

R′ can be methyl, ethyl, etc. ROH represents one of the three hydroxyl groups in an AGU.

Cellulose ethers are widely used for coatings, films, membranes, drilling, pharmaceuticals, and foods. Some modified celluloses are generally approved as food additives, such as methylcellulose (MC) E461, hydroxypropyl cellulose (HPC) E463, hydroxypropyl methylcellulose (HPMC) E464, methyl ethyl cellulose (MEC) E465, sodium carboxymethylcellulose (CMC) E466 (also called cellulose gum), and ethyl cellulose (EC) E462 (Figure 4). Those modified celluloses (hydrocolloids) are derived from cellulose raw materials by various chemical reactions.

Generally, modified celluloses are made through a solubilization step in alkali solution to first form alkali cellulose (eqn [1]) and then with an etherification reaction to incorporate side groups onto the main polymer chain. MC is made by treating alkali cellulose with methyl chloride (eqn [2]). HPMC is made by treating alkali cellulose with propylene oxide under methyl chloride (eqn [3]). EC is made by treating alkali cellulose with ethyl chloride (eqn [4]).

$$\text{R--ONa} + \text{CH}_3\text{Cl} \longrightarrow \text{R--OCH}_3 + \text{NaCl} \quad [2]$$

$$\text{R--ONa} + \text{CH}_3\text{Cl} + \text{H}_3\text{C}\text{—}\underset{\text{O}}{\overset{\text{H}}{\text{C}}}\text{—}\text{CH}_2 \longrightarrow \text{R--OCH}_2\text{CHOCH}_3 + \text{NaCl} \quad [3]$$

(CH_3 substituent on the CHOCH$_3$ group)

$$\text{R--ONa} + \text{CH}_3\text{CH}_2\text{Cl} \longrightarrow \text{R--OCH}_2\text{CH}_3 + \text{NaCl} \quad [4]$$

Figure 5 shows a simplified block flow diagram of the process to produce MC and HPMC. This process typically includes the production of alkali cellulose and reaction of alkali cellulose with other reagents, followed by purification, drying, and packaging. These two products are manufactured in a similar process except propylene oxide that is used in the reactor step for HPMC. Due to the high reactivity of epoxy, alkali cellulose first reacts with propylene oxide to form sodium alcoholate, which subsequently reacts with methyl chloride to produce HPMC.

Cellulose Derivatives in Food Applications

MC and HPMC

MC and HPMC show similar properties and are used to achieve similar functionalities in food applications. They hydrate in cold water and gel upon heating. Schematic description of dispersion, hydration, and gelation of MC and HPMC as a function of temperature is shown in Figure 6. As seen, the polymer powder is dispersed into water above its solubility temperature, hydrates when the temperature drops below the solubility temperature, and gels when the temperature increases above the gelation temperature. Since the gelation process is reversible, the gel reverts back to liquid state upon cooling. The solubility and gelation temperatures of different chemistries of HPMC and MC are provided in Table 1.

The other properties of MC and HPMC are water binding, surface activity, and adhesion. Based on these properties, MC and HPMC grades have been used to provide boil-out control, binding, moisture retention, volume improvement, and texture enhancement in various food applications including bakery fillings; bakery; frozen desserts; meat analogs; and processed meat applications.

While incorporating MC and HPMC into the food formulations, two main considerations must be kept in mind: First is to avoid agglomeration of MC/HPMC when incorporating into water-based system and second is to solubilize MC/HPMC to benefit fully from its functionality. There are three main methods that can be used to incorporate MC/HPMC into food formulations:

- *Preparation of MC and HPMC solution*: Desired amount of MC/HPMC is dispersed into one-third of required water that is above the solubility temperature of the particular MC/HPMC material. The remaining two-third of the water is added cold while stirring. The mixture then is cooled to hydration temperature of the MC/HPMC and stirred for at least 2 h.
- *Blending with dry ingredients*: Desired amount of HPMC/MC grades is blended with other dry ingredients to avoid agglomeration or lumps. Water is added at correct temperature to hydrate while stirring.
- *Dispersion in oil*: Desired amount of HPMC/MC grades is dispersed in organic solvents/oil. The dispersion is then added to the water at correct temperature to hydrate.

Example of Food Applications for MC and HPMC

Meat analogs

Meat analogs are food products that are designed to mimic the appearance, flavor, and texture of meat products. Their consumption has recently been increasing for various reasons including personal beliefs, health concerns, and social causes. Soybean proteins, wheat gluten, cottonseed proteins, and other plant proteins are used to formulate meat analogs. MC is used in the formulation as a binder to help the product maintain its shape and have a firm texture. Thermal gelation holds the ingredients together and reduces moisture loss during heat treatment while providing a structure to help achieve desired meat-like textural properties at the consumption temperature. Addition of MC also emulsifies the fat and helps prevent oil separation.

The ingredient list to formulate soy patties is provided in Table 2. Cold water is placed in a mixer with an attached wire whip. Gluten and MC are dry-mixed together and added into the water while mixing at medium speed until slurry is formed. Beef flavoring, dextrose, and salt are blended into the slurry while mixing for 1 min at high speed. Texturized soy protein

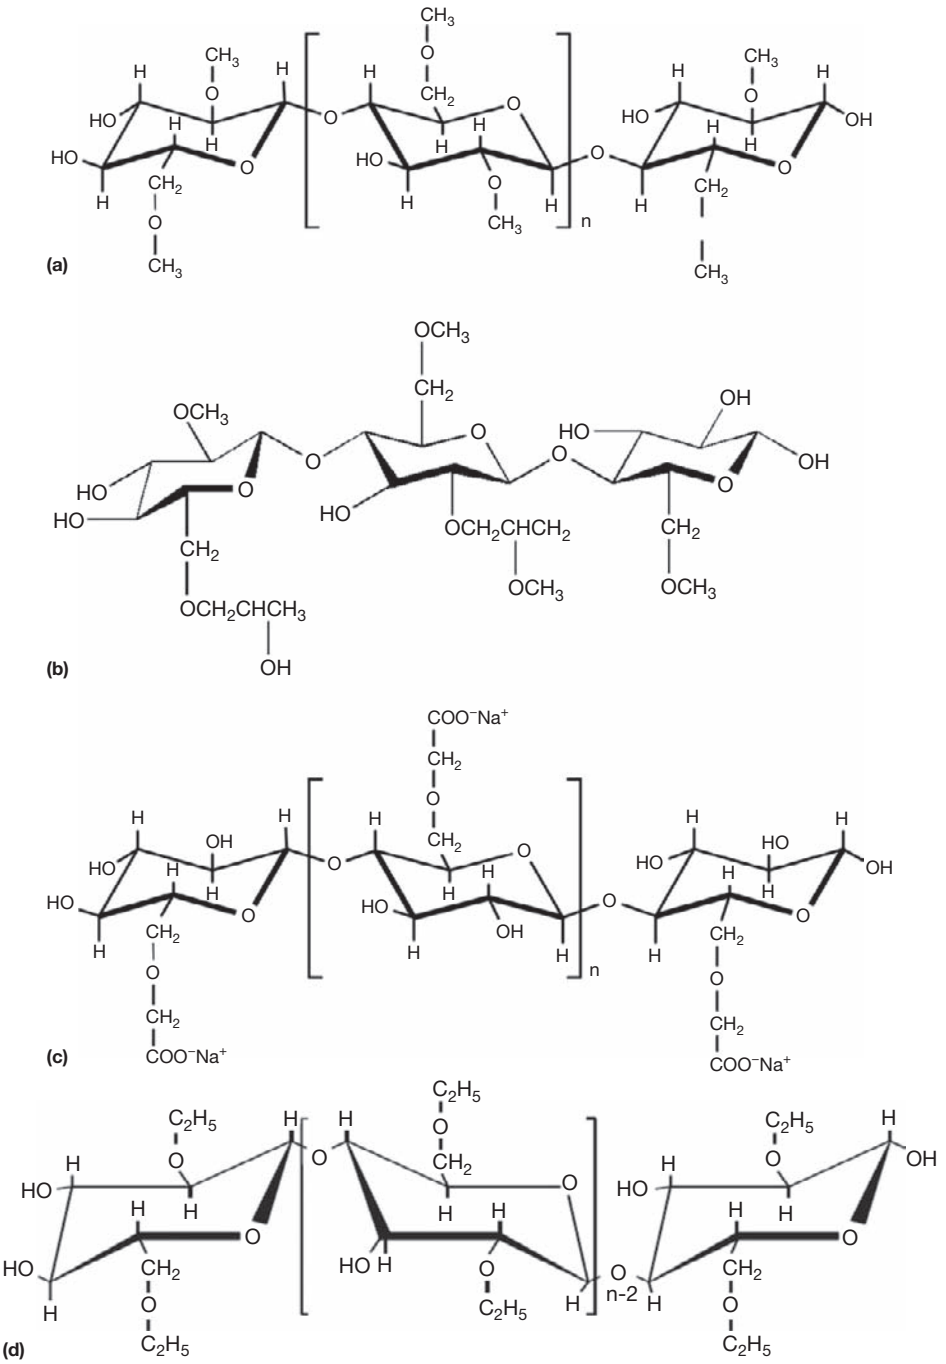

Figure 4 Structure of chemically modified cellulose: (a) methylcellulose (MC); (b) hydroxypropyl methylcellulose (HPMC); (c) carboxymethylcellulose (CMC); (e) ethyl cellulose (EC).

is added next and mixing continues for 5 min. Then the soy protein concentrate is added to the bowl and mixed for five more minutes. The resulting mixture is refrigerated or frozen prior to forming soy patties to promote hydration and binding of MC.

Bake-stable fillings

MC and HPMC are commonly used in both salty and sweet bakery filling formulations to provide stability during baking. During the baking or microwaving process, the viscosity of the filling decreases, causing the filling to boil and run out of the dough product. This phenomenon is known as boil-out. With the addition of MC/HPMC, the filling gels during baking and prevents boil-out.

A formulation for bake-stable chocolate filling for pastry applications is provided in Table 3. Cold water is placed in a mixer with an attached paddle. The dry ingredients are blended together and added into the cold water at low speed and mixed for about 3 min until the mixture is homogeneous. Then, the oil is added into the mixture while blending at high speed.

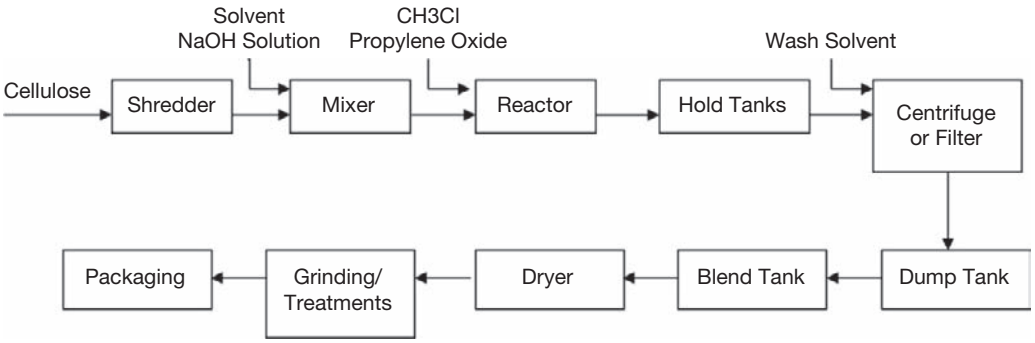

Figure 5 Manufacturing process of MC and HPMC.

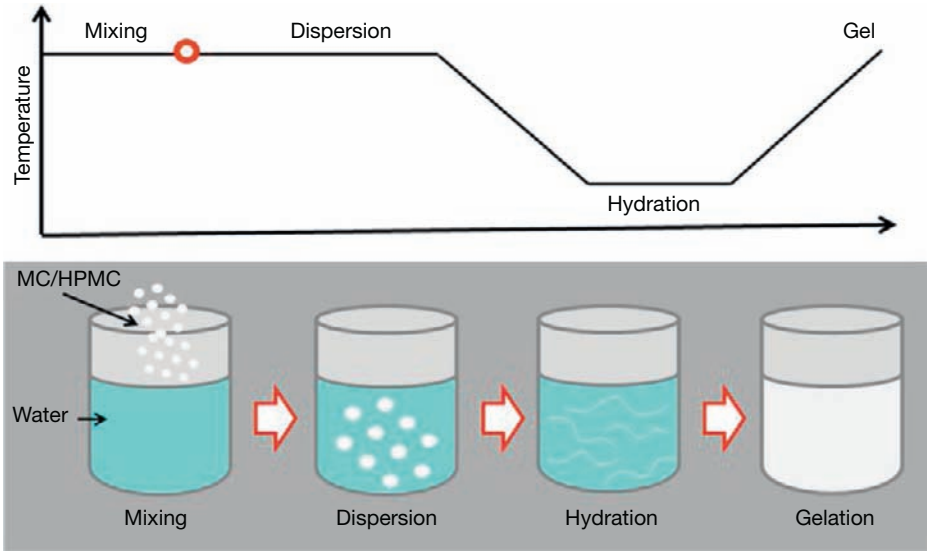

Figure 6 Schematic description of dispersion, hydration, and gelation of methylcellulose and hydroxypropyl methylcellulose as a function of temperature.

Table 1 Hydration and gelation temperatures of methylcellulose and hydroxypropyl methylcellulose as a function of their chemistries

		Hydration temperature		*Gel temperature*	
Type	*Chemistry*	*F*	*°C*	*F*	*°C*
MC	SG A	54	12	110–114	38–44
MC	A	68	20	122–131	50–55
HPMC	E	90	32	136–147	58–64
HPMC	F	90	32	143–154	62–68
HPMC	K	120	50	158–194	70–90

SG A, E, F, and K chemistries are differentiated by the degree of substitution by methyl and hydroxypropyl groups.

Table 2 The ingredient list for soy patties

Ingredients	*%Weight*
Cold water	63.50
Texturized soy protein	19.50
Flaked soy protein concentrate	3.20

Mixing continues for two more minutes at high speed, and the resulting chocolate filling is refrigerated or frozen prior to usage to ensure complete hydration of MC. While baking, MC containing filling will gel and prevent boil-out. As a result, the filling will remain within the pastry, and visual and sensory attributes of the end product will be preserved.

Carboxymethylcellulose

Carboxymethylcellulose (CMC) is an anionic, water-soluble cellulose derivative. Solubility of CMC depends on the DP as well as the degree of substitution and the uniformity of the substitution distribution. Water solubility of CMC would increase with decreased DP and increased carboxymethyl

substitution and substitution uniformity. The viscosity of the solution increases with increasing DP and increasing concentration.

CMC is soluble in water at any temperature. Because of its highly hygroscopic nature, CMC hydrates rapidly. Rapid hydration may cause agglomeration and lump formation when the CMC powder is introduced into water. Lump creation can be eliminated by applying high agitation while the powder is added into the water or preblending the CMC powder with other dry ingredients such as sugar before adding into water.

Due to its high solubility and clarity of its solutions, CMC is commonly used in beverages and beverage dry mixes to provide rich mouthfeel. It is also used in acidified protein drinks to stabilize protein and prevent it from precipitating. CMC is also added to syrup and sauce formulations to increase viscosity. Bakery is another application where CMC is commonly used to improve the quality and the consistency of the end product. In tortilla breads, for example, it is used to improve the process ability of the dough and the textural properties of the end product, including foldability and rollability.

Example Food Applications for CMC

Cocoa drinks

CMC is used in cocoa drink formulations to control viscosity, improve body and mouthfeel, stabilize solid particles, and prevent syneresis and sedimentation at hot and cold temperatures. The ingredient list to formulate cocoa drinks is provided in Table 4.

Ice cream

Blends of hydrocolloids and emulsifiers are used in ice cream formulation to contribute body, provide creamy mouthfeel, increase overrun and the amount of air incorporated into ice cream mix, and prevent ice crystal growth during freeze–thaw cycle. CMC is included in the blends to improve freeze–thaw stability of ice cream. Medium-viscosity CMC at a level of 0.02–0.5% (weight) is used in ice cream formulations to eliminate crystal growth and prevent undesired sandy mouthfeel.

Availability, Absorption, and Metabolism

Fermentability and Fiber

Dietary fibers impact all aspects of gut physiology and are a vital part of a healthy diet. There is a need for the development of novel fiber-rich foods that both are acceptable to the consumer and have proved health benefits. However, many fibers (particularly those that are rapidly fermented) can result in gas production, bloating, and diarrhea.

Several cellulose ethers are recognized as fibers. For example, HPMC is a nonfermentable soluble dietary fiber, which has been used in the manufacturing of many foods for several decades. It has a long safety record and is generally recognized as safe (GRAS) by the US Food and Drug Administration (FDA) with intake concentration of up to 20 g day^{-1}. Cellulose ethers have unique physical properties apart from most dietary fibers. Because of this, the Association of Official Analytical Chemists (AOAC) published a special test method (AOAC 2006.08) to analyze the soluble fiber content provided by HPMC, MC, and CMC.

Health Effects

Cellulose ethers have been used in foods for several decades as functional additives. During this time, most of the uses focused on the ability of these polymers to modify the rheology of the food. However, within the last decade, a new focus has emerged due to their ability to provide broad health benefits when included in the diet. Cellulose ethers can be used as fibers, to substitute allergenic food ingredients, to shift fat content to healthier oils, to influence satiety, and to blunt postprandial insulin levels.

Replacement of Gluten in Bakery Products

Celiac disease (CD), an immune-mediated enteropathy, is one of the most common lifelong disorders on a worldwide basis. At present, the only available treatment for CD is strict adherence to a gluten-free diet, which means a permanent withdrawal of gluten from daily food. The majority of leavened cereal-based products are made of wheat flour or other cereal flours containing gluten. Gluten is an essential structure-building component in bread and other bakery products. Its removal impairs the dough's capacity to properly develop during kneading, leavening, and baking. This results in baked goods with very low volume and a dense pore structure. Hydrocolloids and mixtures of hydrocolloids can mimic the structuring role of gluten due to their physical properties. The usage of HPMC or the combination of HPMC and CMC (WELLENCE™) as a gluten replacement in baked goods has been in practice since at least 1985. The pictures in Figure 7

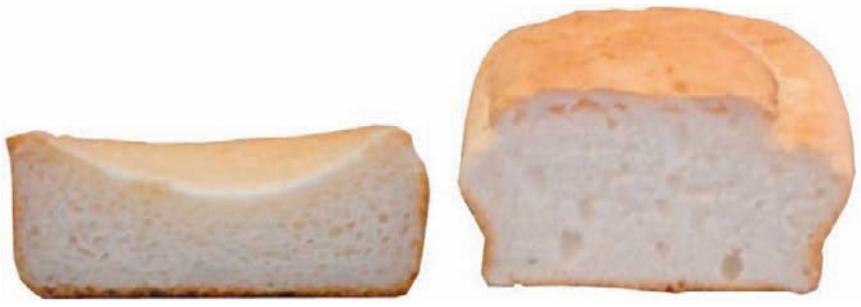

Figure 7 Visual images of gluten-free bread with and without METHOCEL™ addition.

demonstrate the ability of HPMC to build a structural network inside the product ensuring that cakes and breads retain the desired shape and volume.

Reduction of Fat Update in Foods

Deep-fried food is globally popular due to its distinct texture (crispy crust and tender and moist inside) and taste. However, with the increasing global obesity rate, according to the World Health Organization (WHO), an increasing number of health-conscious shoppers look for convenient, healthy, and satisfying fried food for themselves and their families. Technologies have been developed in recent years to make healthier fried foods with reduced/low-fat products. An interesting approach to reduce the health risks of consumer foods is to reduce the overall fat content of fried food by a coating with cellulose derivatives. Cellulose derivatives such as CMC, MC, and HPMC are used in the batter or breadcrumbs to reduce oil absorption during frying, for example, in doughnuts, fried dough products, and structured, extruded, and coated products. MC and HPMC in batters as viscosifying agent make a uniform and consistent batter for continuous batter coating manufacturing. MC and HPMC also improve the adhesion property of coating onto the food matrix and help to control batter pickup and the adhesion of seasoning and flavoring agents onto food surface. Most importantly for fat reduction, the thermal gelation and film-forming properties help to form a protective film barrier, which hinders the heat and mass transfer during deep frying, thus reducing the amount of oil absorption/ penetration into foods.

'Healthier' Fats

Although *trans* and saturated fats have beneficial attributes from the standpoint of food formulation, including firmness, reduction of oil migration, and leakage, they have also been linked to detrimental health effects. As a result, the WHO recommends that fat consumption should be shifted towards unsaturated fatty acids as opposed to saturated and *trans* fats. However, fat sources composed of mostly unsaturated fatty acids are in liquid form and lack structure at room temperature. As a consequence, they create significant challenges during food processing and adversely affect the product quality when used as a direct substitute for solid fats. An emerging strategy is to structure oil without the presence of *trans* or saturated fats. Cellulose ether, EC, is known to solubilize in liquid oil at elevated temperature and gel upon cooling. The resulting EC-oil gel has the desired structure that has potential to replace *trans* and saturated fats. The incorporation of edible EC-oil gels into food systems is now an active area of research, and applications currently under investigation include finely comminuted meat products, cream fillings, and bakery applications including puff pastry.

Figure 8 An image of layer formation in a puff pastry product that has 91% saturated reduced fat compared to puff pastry formulated with butter.

Puff pastry is a light and flaky type of pastry that contains several layers of thin rolled dough, which are formed by repeatedly rolling and folding the pastry dough. The roll-in is part of the puff pastry formulation that is composed of more than 90% fat and it is placed between the dough to assure separate layer formation during the rolling and folding. The fat used in the formulation of the roll-in needs to be highly saturated so that it is in the semisolid state at room temperature, to be spreadable onto the dough, and to help create the layers. However, due to its high saturated fat content, laminated pastry is undesirable for a healthy diet. Therefore, reducing saturated fat content of puff pastry without compromising the sensory properties is desirable. Figure 8 shows an image of a puff pastry that was prepared with a roll-in containing EC-oil gels. The pastry has 91% less saturated fat compared to a puff pastry formulated with butter.

As the figure shows, the resulting pastry had desired layer structure and a light and flaky texture.

Reduction of Blood Cholesterol

Elevated levels of total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) are associated with an increased risk for coronary heart diseases. In several human clinical trials, HPMC was found to reduce TC and LDL-C while having only a minor effect on high-density lipoprotein cholesterol (HDL-C), thus improving the HDL/LDL ratio. For example, it was found that HPMC with varying dose and viscosity combinations showed LDL-C reductions ranging from 6.1% to 13.3% compared to a nonsignificant reduction (1.9%) in the control group. Changes in total and non-HDL-C paralleled those for LDL-C. Concentrations of HDL-C were not altered significantly. A recent study demonstrates that HPMC is an effective adjunct to statin therapy for further lowering atherogenic lipids and lipoproteins in humans with primary hypercholesterolemia. In the European Union (EU), the Commission Regulation No. 432/2012 allows the following health claim: "HPMC contributes to the maintenance of normal blood cholesterol levels."

In a diet-induced obesity mouse model, a significant decrease in the concentrations of plasma cholesterol was seen when the mice were fed with cationic hydroxyethyl cellulose (cHEC). Plasma TC was 16.7%, 19.7%, and 25.3% lower in mice that were fed with the 2% or 4% cHEC-supplemented diet.

Glycemic Response

Diabetes is associated with numerous adverse health outcomes, including cardiovascular diseases. Dietary fibers produce viscous solutions in the digestive system, blunt postprandial glucose, and insulin excursions. The degree of viscosity appears to be inversely related to glycemic response, with the more viscous dietary fibers producing greater effects. The fibers form viscous solutions when mixed with the gastrointestinal (GI) tract contents, slowing gastric emptying and thickening small intestine contents. This may reduce contact between food and digestive enzymes and interfere with diffusion of nutrients to absorptive surfaces, thus slowing the rate at which glucose molecules become available for absorption at the small intestine brush border. It has been suggested that lowering dietary glycemic load may be advantageous for individuals at risk for type 2 diabetes, coronary heart disease, and obesity.

Several studies have suggested that consumption of HPMC has potential therapeutic values in the management of risk factors for type 2 diabetes and cardiovascular disease. Consumption of high-viscosity (HV; 1% 5 Pa·s) and ultrahigh-viscosity (UHV 1% 7.5 Pa·s) HPMC with a meal significantly blunted postprandial insulin excursions and was well tolerated in overweight and obese men and women. However, only UHV HPMC blunted the peak glucose level. Further studies in subjects with and without type 2 diabetes mellitus have demonstrated that inclusion of HV-HPMC in a meal significantly blunts the postprandial glucose response. In a hamster model, it was demonstrated that after 8 weeks of feeding, 8% HPMC supplementation had better efficacy in glucose reduction compared to natural fibers such as pectin.

In the EU, the Commission Regulation No. 432/2012 allows the following health claim: "Consumption of HPMC with a meal contributes to a reduction in the blood glucose rise after that meal (4 g of HPMC per portion)."

Effects on Lipid Metabolism

HPMC modulates plasma lipoprotein profiles and hepatic lipid levels. HPMC is not absorbed by the body, but its presence in the intestinal lumen increases fecal fat, sterol, and bile acid excretion and as a result changes hepatic lipid metabolism. It has been suggested that HPMC may be facilitating fat excretion in a biased manner with preferential fecal excretion of both *trans* and saturated fats in hamsters fed with fast-food diets.

In preliminary studies, maturing hamsters on a high-fat diet put on significantly less body weight when they were supplemented with HPMC than the control animals, due primarily to the reduced deposition of abdominal fat tissue and fat accumulations in their livers and skeletal muscles. In obese mice, 4% and 8% HPMC supplementation in a high-fat diet led to significant weight loss. Also reductions in plasma cholesterol, glucose, and insulin levels were seen, which are strongly correlated with reduced leptin concentrations. Moreover, an increase in the fecal secretion of total bile acids, sterols, and fats indicated altered fat absorption when HPMC is incorporated in the diet. The data indicate that HPMC not only reduces body weight but also normalizes the metabolic abnormalities associated with obesity. The data suggest as well that the effect of HPMC on glucose and lipid homeostasis in mice is mediated through improvement in leptin sensitivity resulting from reduced fat absorption. HEMC was shown to be similarly effective in improving the lipid metabolism under high-fat diet condition.

Satiety

Overweight and obesity, as well as consequent cardiovascular disease, are primarily driven by overavailability of food and an increasingly sedentary lifestyle. One approach to treatment is to manipulate appetite and reduce food intake through control of satiety (inhibition of hunger as a result of having eaten). Dietary fibers are thought to impact satiety, by a viscosity effect. Viscous soluble fibers may be useful because they prolong the intestinal phase of nutrient digestion and absorption. Materials incorporated into the diet that form a gel mass in the stomach, such as alginate and pectin, have been shown to enhance satiety by distending the stomach wall. Novel food-grade MC (SATISFIT^{TM}-LTG cellulose) was developed to gel at temperatures below the body temperature and is not influenced by pH. It was shown *in vivo* by magnetic resonance imaging trials that SATISFIT^{TM}-LTG forms a gel mass that persists for at least 2 h. In contrast, the conventional MC that does not gel at body temperature clears the stomach rapidly. An initial clinical trial with healthy human volunteers demonstrated clear perception of greater satiety. Analysis of results from the visual analog scale indicates that appetite recovery is slower with novel

gelling MC than with control products. A significant reduction in the energy intake observed in the human trial might be explained by the gelation of the MC in the stomach. The satiety effect has been shown to last for at least 2 h after ingestion of the product. Further, human trials have to be performed to validate impact on satiety and on compensation effects.

Introduction

Cereal-based foods are by far the major source of food, energy, protein, B vitamins, and minerals for the current world population estimated in more than 7.3 billion people (Figure 1). Basically, the population growth experienced during the past two centuries has been closely associated with the production of cereal grains. In most countries, diets have a single cereal as the primary staple. The most widely used are rice, wheat, and maize, which provide 93% of the total cereal calories (Figure 1). These grains constitute the main staple for Asians, Europeans, and Americans, respectively. In Africa and India, sorghum and millets are widely grown and consumed.

According to the Food and Agriculture Organization, the amount and proportion of food energy and protein provided by cereals in human diets in 2011 were 1296 kcal, nearly 50% of the average per capita caloric intake. Likewise, cereals provided 31.9 g protein of the total estimated daily intake of 73.9 g protein (Figure 1). Cereal grains are considered primarily as caloric or starchy foods and, more recently, as an important source of dietary fiber. However, their protein quality, especially for infants, is marginal. In developing countries, cereals are usually consumed with legumes and pulses, thus significantly increasing protein intake and, more importantly, enhancing protein quality by the improvement of the essential amino acid profile. Protein and/or calorie malnutrition (*kwashiorkor and marasmus*) is prevalent among groups of people who have inadequate food intake or rely solely upon cereals and/or starchy roots or tubers as their source of protein.

Plant breeders have developed maize, sorghum, and barley genotypes with high lysine, which results in an improved protein quality and nutritional value. A high-lysine and high-tryptophan maize, called quality protein maize, with satisfactory grain yield and structure is being commercially grown in different places around the world (Brazil, China, Ghana, and other African countries).

Carbohydrates

Starch is the most abundant carbohydrate in cereals and the main contributor of calories (Table 1). It is composed of molecules of branched amylopectin and linear amylose. Most cereals contain 70–75% amylopectin. Waxy maize, rice, and sorghum contain more than 95% amylopectin. Most food processes partially or totally gelatinize the starch granules, making the molecules more prone to amylases.

Starch is highly digestible by the human digestive system. Practically, all starch disappears in the gastrointestinal tract. A small portion of the starch (1–5%) resists enzymatic hydrolysis when cereal foods are thermally abused. This residual or resistant starch can be quantified in the soluble dietary fiber residue and is highly susceptible to fermentation in the hindgut.

Other factors that can decrease starch digestibility are excessive amounts of fiber and enzyme inhibitors. The digestible energy of cereals is negatively related to the grain fiber content and positively related to the grain lipid content. Refined grains contain more digestible energy than whole counterparts (Table 1).

Cereals contain small quantities of soluble carbohydrates such as glucose, fructose, maltose, and sucrose and therefore are suitable for diabetics. Highly refined cereals have a higher glycemic index compared with whole grain products.

Whole cereal grains are considered a rich source of dietary fiber (Table 1). However, foods from grains have marked differences in the amount and type of fiber. Fibrous components are concentrated in the pericarp or bran. The dietary fiber content in cereal-based foods varies greatly depending on the extent of milling. Refined flours lose most of the fiber during milling. All cereals are considered a rich source of insoluble dietary fiber constituted by cellulose, insoluble hemicellulose, and lignin, which speeds up intestinal transit and binds carcinogens. Epidemiological evidence has related a high-fiber diet to a lower incidence of diabetes, obesity, and diverticular disease. A high dietary fiber consumption benefits diabetics because of the reduced diffusion of glucose in the intestinal mucosa and the diminished insulin secretion rate. Oats, barley, and rye are considered good sources of soluble dietary fiber constituted by arabinoxylans, β-glucans, and soluble hemicelluloses, which increase the excretion of bile salts and dietary cholesterol, thus lowering blood cholesterol levels.

Protein

Cereal grains provide 43% of our total protein intake in 2011 (Figure 1). Genotype, environment, and growing conditions affect the amount of protein in the kernel. In general, brown rice and oats contain the lowest and highest protein content, respectively (Table 1). Protein quality is mostly dictated by the amino acid profile and digestibility (Table 2). The apparent protein digestibilities in cereals range from 80% to 90%. Sorghum (especially kernels with condensed tannins), whole barley, rye, and oats are consistently lower in digestibility than other cereals. Milling, decortication, fermentation, and germination all increase protein digestibilities because of the removal of fiber components.

The storage protein in cereals (prolamins) contains small amounts of essential amino acids, especially lysine. The albumins and globulins, mainly located in the germ, contain the best essential amino acid profile. High-lysine cultivars of maize, sorghum, and barley contain lower amounts of prolamins and higher amounts of the other protein fractions. Thus, they have a more balanced protein.

For all cereals, the most limiting amino acid is lysine. Oats, rice, rye, barley, and the high-lysine cultivars contain a more

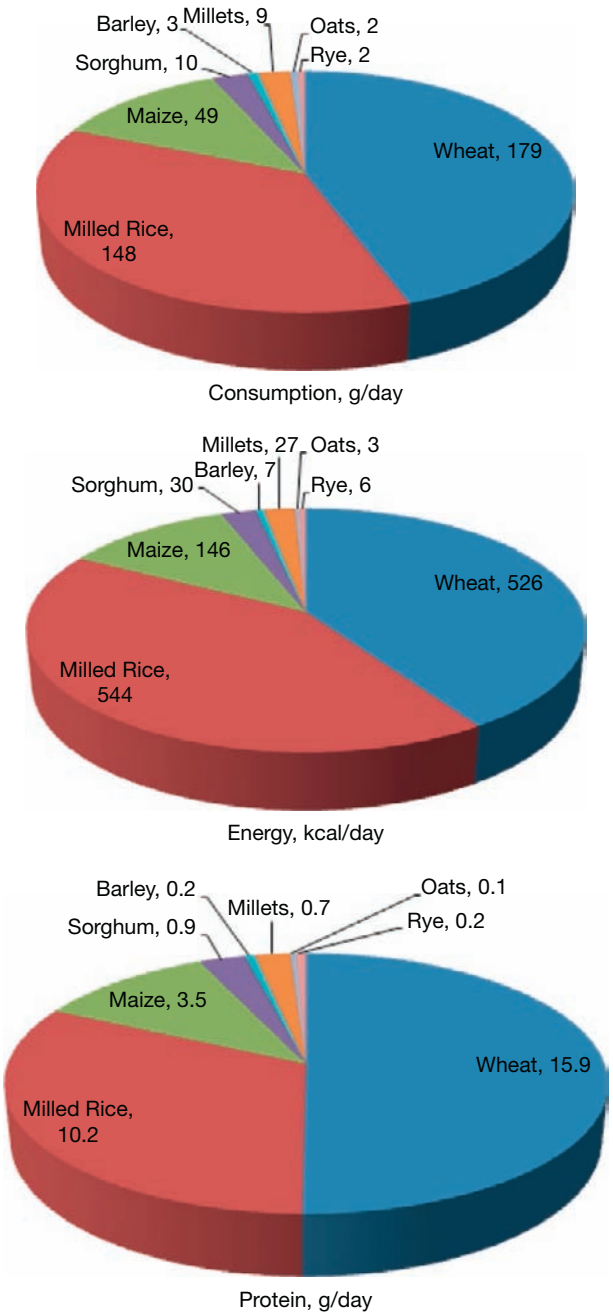

Figure 1 Consumption, energy, and protein daily intake of different cereals in the year 2011. Data taken from FAO (2014). Electronic page: http://apps.fao.org/. Rome: Food and Agriculture Organization.

favorable essential amino acid composition than the rest of the cereals (Table 2). Lysine deficiency is observed particularly in postweaned infants who suffer *kwashiorkor* and rely on cereals and/or starchy tubers as the only food source. The supplementation of cereal-based foods with small quantities of legumes or animal foods improves protein intake and protein quality. The next most limiting amino acids for maize and the rest of the cereals are tryptophan and threonine, respectively.

Decortication or milling partially or totally removes the pericarp and germ tissues, therefore improving the digestibility and reducing the lysine level. Malting improves protein quality due to enzymatic degradation of proteins. Fermentation improves protein quality via improved digestibility and *de novo* synthesis of lysine by the fermenting biomass.

Lipids

Lipids are relatively minor constituents in cereal grains (Table 1). However, cereal lipids are rich in the essential fatty acid, linoleic acid (18:2 Δ 9,12; 30–60% of total fatty acids) and practically devoid of saturated fatty acids. Cereals contain trace quantities of phytosterols; they do not have any cholesterol. Cereals with yellow endosperm (i.e., yellow corn, yellow sorghum, and durum wheat) contain some provitamin A activity imparted by β-carotenes. Various types of tocopherols are responsible for the vitamin E activity of cereal grains. Degermination of cereal grains greatly reduces the content of lipids and tocopherols.

Minerals and Vitamins

The pericarp, germ, and aleurone layer are rich in vitamins and minerals. Refined cereal products therefore lose part of these important nutrients. The enrichment of cereal-based foods is aimed toward the replacement of minerals (Fe and recently Zn) and vitamins (thiamine, riboflavin, niacin, and folic acid) lost during milling. In many countries, the fortification of cereal-based foods is required by law.

Phosphorus is the mineral found in greatest amounts (Table 3). Unfortunately, its availability is low because most is associated with phytic acid. The phytic acid has the property of binding strongly with other cations, thus decreasing their bioavailability. Phytic acid decreases significantly during sprouting and fermentation due to activation of phytases. These processes considerably improve the bioavailability of minerals (Table 4).

In general, cereals are poor source of calcium, except for finger millet and teff (Table 3). Some food processes, such as nixtamalization of maize for tortilla production, greatly increase calcium. The bioavailability of this mineral in lime-cooked tortillas is high.

Cereals are considered a good source of potassium and are practically devoid of sodium. Whole grains provide a significant source of magnesium, iron, zinc, and copper, which are reduced by degermination, decortication, and milling.

Cereals are also considered an important source of B vitamins (except B_{12} or cobalamin), but dried matured grains do not contain vitamin C. B vitamins are concentrated in the aleurone layer. Beriberi (a thiamine deficiency disease), endemic in Eastern and Southern Asia, is prevalent among people who consume milled rice. Milled rice contains about 10% of the thiamine of brown rice (Table 3).

Niacin is found in a free and bound form and can be synthesized from tryptophan. The alkali treatment of maize for tortilla production considerably improves niacin bioavailability because the glycosidic bond that renders it unavailable is alkali-labile. Niacin deficiency produces pellagra, which causes dermatitis, diarrhea, and dementia, and has been prevalent in regions of Southern Africa where people rely on maize as the main food source.

Table 4 Effects of cereal processing on the nutritional value

Processing method	*Effects on nutritional value*
Dry milling, decortication, degermination	The removal of the pericarp and germ tissues considerably modifies the chemical composition. Refined products are practically fiber-free and contain lower amounts of oil, minerals, vitamins, and even essential amino acids. In addition to physical losses, thermal treatments usually lower the bioavailability of important vitamins. The protein quality of refined products is inferior compared with whole grains because the proteins of the germ contain a more balanced essential amino acid composition
Germination or sprouting	Germination or sprouting has been an effective way to improve the nutritional value of cereal-based products. The high enzymatic activity of malted cereals improves nutrient digestibility, mineral bioavailability, and the bioactivity of some nutraceuticals
Fermentation	Fermentation causes similar benefits as germination. Fermentation is known to improve protein quality due to higher nitrogen digestibility and *de novo* production of some amino acids such as lysine and tryptophan. In addition, these processes lower the presence of antinutritional factors. Fermented breads usually contain more protein and better protein quality due to yeast
Cooking	Water, alkali, or acid cooking slightly reduces protein digestibility due to the insolubilization of prolamins and formation of disulfide bonds. Maize and sorghum are frequently alkali-cooked to produce traditional foods such as tortillas and Tô. Cooking in the presence of alkali leachates (i.e., wood ashes, lime, or potassium hydroxide) slightly lowers protein quality and lysine bioavailability. Lime cooking of maize solubilizes albumins, globulins, and prolamins with the consequent increase in residual or nonextractable proteins. These changes slightly reduce protein digestibilities. Lime cooking of maize increases calcium content, which is highly bioavailable. It is also known that lime cooking enhances niacin bioavailability. This is very relevant or important in countries where pellagra is still endemic among some groups
Parboiling	Parboiling of rice and other cereals such as sorghum and millets produces important changes in the nutritional value. The thermal treatment gelatinizes starch and hardens the endosperm, reducing the kernel susceptibility to break during milling. Parboiled rice has higher quantities of vitamins and minerals because the nutrients located in the aleurone diffuse into the inner endosperm during hydration and parboiling

Effect of Processing on Nutrient Composition

Humans usually consume processed cereal products instead of whole grains. Most processed foods are manufactured from refined milled products such as decorticated grains, flours, meals, semolina, and grits. Commonly, cereals are milled and then cooked in order to produce an array of foods. Milling and cooking have a profound effect on the nutritional value of prepared foods. Table 4 summarizes the main effects of processing on the nutritional value of cereal-based foods.

Phytochemicals and Nutraceutical Properties of Cereal Grains

Besides the dietary fiber, cereals are considered as a good source of important antioxidants and nutraceuticals, which exert proved positive effects in human health because they combat oxidative stress, chronic diseases, and cancer. Table 5 summarizes the main phytochemicals associated with cereals with their main effects on human health.

Among the cereals, sorghum and maize have higher antioxidant activity compared with wheat, oats, and rice.

Phenolic compounds are divided into three major categories: simple phenolics, flavonoids/anthocyanins, and tannins. All cereals contain simple phenolics and only brown sorghum condensed tannins. The most relevant simple phenolic is ferulic acid in its free, conjugated, and bound forms. It is considered as a potent antioxidant and a nutraceutical that prevents inflammation, cancer, LDL oxidation, and neuron degeneration (Table 5). Cereals may contain significant amounts of flavonoids such as flavanols, flavanones, flavones, and anthocyanins. Red-, blue-, and purple-pigmented corn kernels are rich in anthocyanins, and several reports indicate that these are similar to the ones found in red wine. The main anthocyanins are cyanidin and peonidin glycosides, which diminish the incidence of various chronic and degenerative diseases. Their health benefits have been related to their high-antioxidant and antiradical activities. Sorghum is the most promising cereal in terms of flavonoids and nutraceutical potential. For instance, sorghum may contain flavan-3-ols, flavan-4-ols, and anthocyanins such as apigeninidin and luteolinidin. Among flavanols, the flavan-4-ols have particular therapeutic interest because of their antitumor activity and enhancement of immune response (Table 5).

Cereal lipids can be subdivided into nonpolar, polar, and nonsaponifiable. By much, the most abundant type is the nonpolar fraction consisting of triglycerides. In all cereal grains, except brown rice and oats, the major fatty acid component is linoleic acid followed by palmitic acid (16:0). In brown rice and groats, oleic acid (18:1 $\triangle 9$) is the major unsaturated fatty acid.

The lipid fraction of cereals contains significant amounts of phospholipids such as phosphatidylcholine, phosphatidylinositol, phosphatidylethanolamine, and phosphatidylserine. These polar lipids are considered nutraceuticals because they form part of cell membranes and keep their integrity. Phosphatidylcholine helps to keep the proper functioning of the liver and to transport lipids, and its deficiency is related to increased susceptibility to hepatic cancer. Lecithin and choline lower the risk of

Table 5 Major nutraceuticals associated with cereal grains and their health benefits

Nutraceutical compound			
Family	*Class*	*Anatomical part/main cereals*	*Preventive or therapeutic effect*
Phenolics	Simple phenolics such as ferulic acid	Mainly associated with the pericarp. Present in all cereal grains	Prevent oxidative stress, cancer, cholesterolemia, atherosclerosis, and aging
	Avenanthramide	Associated with the outer layers of oats (pericarp, aleurone)	There are 35–40 phenolic alkaloids that occur as amides of substituted anthranilic acids. They are anti-inflammatory and anti-irritant and prevent chronic inflammatory disease, cardiovascular disease, cancer, diabetes, Alzheimer's disease, and schizophrenia
Flavonoids	Anthocyanidins Flavonols Flavan-3-ols Flavanones	Mainly associated with the aleurone of blue- and red-colored maize. Flavanones (eriodictyol and naringenin) are found in lemon-yellow sorghums	Prevent oxidative stress, cancer, cholesterolemia, atherosclerosis, and aging
	Condensed tannins	Mainly associated with *testa* of high-tannin or brown sorghums	Prevent oxidative stress, cancer, cholesterolemia, atherosclerosis, stomach ulcers, and aging
Carotenoids	Carotenes	Mainly associated with starchy endosperm in yellow endosperm cereals	β-Carotenes are converted to vitamin A or retinol. Prevent cancer and cardiovascular disease and strengthen the immune system
	Xanthophylls *Lutein* *Zeaxanthin* *Cryptoxanthin*	Mainly associated with yellow endosperm maize, wheat, and sorghum	Prevent age-related macular degeneration and cataracts (opacity of the crystalline lens of the eye). Slow down symptoms of retinitis pigmentosa. Prevent cardiovascular disease and cancer
Phytosterols	Sitosterol Stigmasterol Campesterol Avenasterol	Mainly associated with the germ, pericarp, and aleurone of most cereals	Compete with cholesterol for absorption and therefore is hypocholesterolemic. Prevent cardiovascular diseases
Fibers	Soluble	Mainly associated with oats and rice bran	Improve the function of the gastrointestinal tract, increase viscosity, and lower glycemic index. Reduce risk of diabetes and hypercholesterolemia. Most soluble fibers are probiotic because they readily ferment in the hindgut yielding short-chain fatty acids that inhibit hepatic HMG-CoA reductase
	Insoluble	Mainly found in the pericarp associated with cell walls of all cereal grains	Improve gastrointestinal functionality. Increase bile acid binding and fecal bulk and reduce constipation, hemorrhoids, diverticulitis, and cancer of the large bowel
Phytic acid Inositol	Inositol hexakisphosphate	Mainly associated with the aleurone and pericarp of all cereal grains	Antioxidant, antineoplastic properties in breast, colon, liver, prostate, and skin cancers, leukemia, and sarcomas
Polyunsaturated fatty acids	Linoleic acid (18:2 ω6) Linolenic acid (18:3 ω3)	Mainly associated with the germ or *scutellum* of all cereals	Help to reduce cholesterol and hyperlipidemia. Linoleic and linolenic acids are transformed into prostaglandins and nutraceutical fatty acids EPA and DHA
Lecithin and choline	Phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine	Mainly associated with the germ	Phosphatidylcholine (lecithin), phosphatidylethanolamine, phosphatidylinositol, and phosphatidylserine are essential for proper function of the cell membranes and brain. Slow down the process of cell aging and prevent high cholesterol. Choline is used for the synthesis of acetylcholine, which is the main neurotransmitter

(*Continued*)

Table 5 (Continued)

Nutraceutical compound			
Family	*Class*	*Anatomical part/main cereals*	*Preventive or therapeutic effect*
Vitamins	Tocopherols	Mainly associated with the germ of all cereals	Tocopherols are important antioxidants. α-Tocopherol or vitamin E is considered as the second line of defense against oxidative stress. Prevent cardiovascular disease and high cholesterol and improve mental health and brain functionality and are considered antimutagenic and anticancer
	Folic acid	Mainly associated with the aleurone of all cereal grains	Prevents neural tube defects in newborn babies and miscarriages and helps for proper brain development. Lowers homocysteine and therefore helps to prevent cardiovascular diseases
Policosanols	Long-chained alcohols (waxes): Octacosanol Triacontanol Hexacosanol Dotriacontanol	Mainly associated with the outer part of the pericarp and germ Maize and sorghum contain significant quantities	Have beneficial physiological activities such as reducing blood lipid levels and platelet aggregation

Source: Serna-Saldivar, S. O. (2010). *Cereal grains: properties, processing and nutritional attributes*. Boca Raton, FL: CRC Press (Taylor & Francis Group).

cardiovascular disease and positively affect brain and mental development of both the fetus and infants, and their chronic inadequacy may be related to Alzheimer's disease. Phosphatidylinositol and phosphatidylserine are lipotropic, reduce blood triglycerides and fatty liver, and prevent bipolar disorders and Alzheimer's disease.

Phytosterols such as β-sitosterol, campesterol, avenasterol, and stigmasterol inhibit the absorption of cholesterol from the small intestine, thus effectively lowering both serum total cholesterol and LDL.

Other important groups of antioxidants are the carotenoids and xanthophylls, which are minor constituents of cereal grains. They are most abundant in yellow maize, yellow sorghum, and durum wheat. The consumption of yellow endosperm cereal grains can potentially benefit at least 1 million children that die every year due to weakness and deficiency of vitamin A and 350 000 more that become completely blind. The main nutraceutical role of carotenoids to humans is the molecular protection against free radicals. From the nutritional viewpoint, the most important carotenoid is β-carotene because one molecule is converted into two of the active forms of vitamin A or retinol in a normal human system. In addition, β-carotene can regenerate the activity of vitamin E and possibly other oxidized antioxidants. β-Carotene also acts as an antioxidant that scavenges free radicals deep in human LDL and HDL and in cell membranes. Lutein, zeaxanthin, and cryptoxanthin are xanthophylls that have received special attention because they prevent macular degeneration highly associated with blindness in geriatric patients.

Tocopherols and tocotrienols are responsible for the vitamin E activity of plant tissues. Various combinations of all eight tocols are found among cereals. The most predominant forms are α-tocopherol, γ-tocopherol, and α-tocotrienol. Among the structural parts of cereal grains, tocol derivatives are most abundant in the germ. These compounds are potent antioxidants that block the formation of free radicals in cell membranes. Thus, they prevent cardiovascular diseases and LDL oxidation and strengthen the immune system.

Cereals: Storage

SO Serna Saldivar and S García-Lara, Centro de Biotecnología-FEMSA, Tecnológico de Monterrey, Monterrey, México

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Storage of cereal grains is critical in terms of food security for the more than 7.3 billion people inhabiting the world. The main purpose of grain storage is to equilibrate supply and demand, and this postharvest operation is a key step in the complex logistics of moving grain from producers to processors and grain products from processors to consumers.

Most cereal grains have to be stored on farms or commercial grain elevators because they are harvested in specific seasons of the year and are gradually utilized by the various industry segments. Generally, imported grains are also stored for significant periods of time because they are usually acquired in large quantities in order to keep low costs and large inventories. The main objective of storage is to provide wholesome cereals, free of insects, insect fragments and rodent filth, mold damage, mycotoxins, and pesticides.

The final target is to manage stored grain wisely with insignificant losses while maintaining its nutritional and functional qualities.

The FAO has estimated that grain storage losses in most developing countries, mainly located in tropical and subtropical areas of the globe, are up to 35% higher compared with developed counterparts due to lower investments in proper infrastructures. Therefore, there is a great opportunity to upgrade storage systems in order to diminish losses and assure food quality especially for people with scarce economic resources. If new and better storage facilities are built, the world can save at least 15% of the total cereal production estimated in 2013 in more than 2.78 billion tons. Worldwide storage facilities have been calculated in less than 65% of all production, which indicates a lack of infrastructure especially in developing countries. An ever-growing population and the food crisis demand for new storage facilities at collection points close to the harvest areas, especially in regions where industrialization is not completed yet. Up to 70% of world's food reserve crops are still stored outdoors in bags piled on raised earthen platforms or stored bagged in godowns. Only about 20% is stored in modern silos.

Cereal grains deteriorate due to intrinsic and/or extrinsic reasons. The intrinsic deterioration is due to respiration, whereas the extrinsic deterioration is caused by biotic agents such as insects, molds, and rodents. Regardless of the sort of losses, grains lose dry matter, quality, and nutritional and economic values as raw materials and feedstocks. From the health viewpoint, the consumption of mold-infested grains could lead to animal or human mycotoxicosis. The toxins of greatest concern are aflatoxins because of their known carcinogenesis and fumonisins, ochratoxins, T-2, and zearalenone.

Grain Deterioration

The key to maintain cereal grains under optimum conditions is the control of their moisture. When grain moisture exceeds the permissible level, increase of the grain respiration rate is activated. Stored cereals have latency, that is, limited respiration, when maintained under their critical moisture content (considered 14%). Below this critical moisture, pests have more problems to reproduce and survive. The temperature and air relative humidity are the most important environmental factors affecting grain deterioration, insect infestation, and mold growth. High grain moisture, environmental temperature, and air relative humidity increase the grain metabolic activity and enhance the growth and development of insects and molds.

Intrinsic Deterioration

This grain deterioration is caused by the metabolic activity resulting from respiration. The grain generates energy or heat, carbon dioxide, and water. The activation of the grain releases important enzymes that break down lipids, proteins, and starch generating carbon dioxide as the end-respiration metabolite and hydrolyzed compounds, which are detrimental for functionality and quality of processed or finished products.

In general terms, the intrinsic grain deterioration favors the extrinsic because most pests require water as one of the most relevant substrates. The air relative humidity plays an important role in the susceptibility of the grain to deterioration. The grain can surpass its critical moisture content when it is exposed at a high air relative humidity (more than 70%). When the cereal grain surpasses its critical moisture content (14%), it activates and generates heat that catalyzes the respiration process. This is the most common way how adequate stored grains lose latency and progressively deteriorate. More importantly, the respiration process that generates heat and water attracts insects and molds, which damage kernels that contain more than 1.5 and 3.5% moisture above the critical.

Grains tend to equilibrate with the environmental moisture and are hygroscopic when exposed at high relative humidities. Commonly, storage facilities situated in tropical areas are the most difficult to manage because of the high temperatures and air relative humidities.

Extrinsic Deterioration

The extrinsic deterioration is the most important in terms of grain losses. It is mainly caused by insects, followed by molds. Insects can proliferate at relatively lower grain moisture or water activities than molds. Rodents and birds also play an important role in extrinsic grain deterioration especially in open storage facilities. All these biotic agents cause direct and indirect losses. The indirect damage is due to insect fragments and feces, rodent hair and feces, and bird droppings that can contaminate a given lot of grain with pathogenic bacteria. The presence of these contaminants is highly penalized by regulatory agencies.

Management of Stored Grains

Grains are preferably stored in weather- and pest-proof storage structures so that their viability, food energy, nutritional quality, and marketability can be assured. Grain elevators are centers where the grain is concentrated with the aim of preserving and improving the grain grade. Incoming lots of grains are in most cases sampled; analyzed in order to assign class, grade, and other quality attributes; weighed; unloaded; cleaned; and stored. The most critical operation is the one related to testing grain quality because it is related to the economic value of the grain and will determine other important management decisions such as the need for drying, cleaning, commingling, and end use.

Grain Analysis

After sampling, most grain lots are inspected and graded by licensed inspectors or by experienced employees. The main grain quality factors are moisture, test weight, dockage, heat damage, insect damage, and mycotoxins. Moisture is generally determined with the electronic moisture meter or a near-infrared apparatus. The first determines moisture via electric conductivity, whereas the second, by scanning whole or ground kernels in the infrared spectrum.

Test weight is a measure of the apparent grain density and is the most widely used parameter, related to grain condition and therefore to its commercial value. It is negatively affected by insect and mold damage. The most common way to perform a measurement of it is using the universal dockage test meter equipped with different sets of sieves for each specific type of cereal. Heat-damaged, insect-damaged, moldy, and/or sprouted kernels are visually identified and manually removed and quantified.

One of the main concerns in grain elevators is the acquisition and merchandising of mycotoxin-contaminated kernels. This is because domestic and export markets have strong federal regulations regarding the maximum allowable amounts of these metabolites. In most countries, the maximum aflatoxin permitted level for direct human and animal use is 20 and 200–300 ppb, respectively. Needless to say, when grains exceed 20 ppb and contain less than 250 ppb, they have to be sold as animal feed with a discount price. Grain elevators routinely test for mycotoxins, especially aflatoxins. Suspected grains are usually first observed under ultraviolet light to see their fluorescence. This practical test does not determine the type of mold nor the mycotoxin level; however, it is used as a screen test to decide if the sample must be further tested with a quantitative assay. The most common assay to determine mycotoxins is based on a quick solvent extraction (methanol–water, ethanol, chloroform, etc.) of the mycotoxin, followed by filtration and quantification via ELISA (enzyme-linked immunosorbent assay) columns.

Weighing and Grain Unloading

Grain shipments are usually weighed on platform scales and then dumped into underground bins via gravity. Most grain elevators are equipped with a hydraulic platform that positions the locked truck in an angle so to speed up the unloading process and to assure the complete removal of the grain. A similar system is used to unload trainloads. The train wagon is positioned into the unloading zone, and then, the gate or bottom door is opened to discharge the grain directly into an underground bin. Depending on the grain characteristics, the discharged lot is dehydrated, precleaned, or simply conducted to storage facilities. Grains are elevated or conveyed using screw conveyors or buckets.

Grain Dehydration

Some cereal grains such as paddy rice are usually harvested at high moisture contents and therefore need artificial drying before storage. The aim of this operation is to lower the grain moisture content to levels adequate for storage to maintain grain viability and to keep to minimum grain physical damages such as stress cracks. This is especially relevant for paddy rice, which is commonly harvested at moistures above 22%. Drying temperatures of up to 45 °C are generally safe although higher temperatures may be used in cereals used for feed.

Artificial drying is the most common practice to lower the moisture content of cereal grains. There are batch or continuous dryers differencing in the air flow: cross, concurrent, or counterflow. Regardless of the dehydration technique, the principal factors to regulate are air temperature and relative humidity, airflow, depth of the grain, and the desired rate of dehydration. The heated air is injected at a flow rate of approximately 1 m^3 per ton.

Grain Cleaning

Grain cleaning is a common operation before storage especially when the grain is going to be directly channeled to the food industry. Cleaning improves grade, increases uniformity of grain lots, and decreases amounts of damaged grains. The grain with lower foreign material will be more stable during storage because the extraneous matter contains high amounts of insect eggs and mold spores and serves as physical protection to biotic agents. The cleaning system typically consists of air aspirators and sifters equipped with magnets to trap metals. Air aspiration removes most of the light contaminants such as plant material, glumes, and empty kernels, whereas milling separators are designed to remove larger and smaller contaminants than the grain. Milling separators generally consist of two or more sieves positioned one on top of the other on an oscillating or vibrating frame. Other cleaning apparatuses seldom used by grain elevators but frequently used by milling industries include gravity and disk separators and color sorters.

Grain Rotation

Turning is the process of moving bulk stored grains with conveyors within the storage facilities. The operation is practiced in order to break hot spots in storage, facilitate insect control, and make more efficient the aeration or ventilation operation. Insecticides can be effectively applied during rotation, and if fumigation is necessary, tablets of aluminum phosphide can be distributed throughout the grain mass. The main disadvantage of grain rotation is that it increases kernel damage and the incidence of broken kernels.

Grain Aeration

Aeration is considered as the cheapest preventive measure for the preservation of grains. It is defined as the movement of air through a bed of stored grain. Its main advantages are that the quality of grain is maintained without moving the grain, the significant reduction of the wear and tear on both the grain and handling machinery, and the suitability and effectiveness in applying fumigants. The aim of this operation is first to equalize stored grain temperature to prevent moisture migration, remove sour and off-odors caused by molding, and cool the grain to prevent or minimize hot spots and insect and mold growth. Most aeration systems consist of perforated air ducts positioned in X or Y configurations on the floor before the facility is filled. The ducts are fed with outside air by fans placed on the external walls of the bins.

Types of Storage Facilities

There are many designs of grain storage facilities. The facilities should be designed to protect cereals from weather, insects, molds, rats, and birds. Facilities range from a simple pile of unprotected grain on the ground to expensive storage bins or elevators that contain equipments for sorting, cleaning, drying, fumigating, and transferring grain lots to trucks, railcars, barges, and ships.

Storage on the Ground

This is the simplest method and the one that requires the lowest economic inputs. It is widely used as a short-term or transitional storage especially after harvesting. However, since the grain is exposed to the air, it is susceptible to weather conditions and biotic infestations. The grain is simply unloaded and conveyed into the prepared ground getting the typical hill configuration. The slope and form of the grain hill is critically important to minimize losses due to rain. The slope of the grain hill should minimize the penetration of the rainwater, and the ground floor of the pile should also help to absorb water. When the grain pile is exposed to rainfall, a 5 cm deep external grain layer forms, protecting the rest of the grain. The ground systems can be improved when a circular contention wall of approximately 1 m tall is built with grain bags, by placing aeration ducts on the ground and by covering the surface or external part of the stored grain with plastic covers.

Underground Storage

Underground storage is considered as one of the oldest practices to store grains. The method protects kernels from adverse environmental conditions and inhibits pests due to the low oxygen and high carbon dioxide concentrations. The underground facility should be hermetically sealed in order to preserve the grain. The grain will gradually utilize the oxygen in the headspace producing carbon dioxide that will decrease the respiration rate and create an adverse environment for insects and molds.

Grain Elevators

Grain elevators are the most widespread facilities to store cereal grains. They are called elevators because the unloaded grain is conveyed with augers or bucket elevators into the top of the storage bins and discharged by gravity. There are many different types of grain elevators. The most widely distributed throughout the globe are the flat bins and silos built from concrete or steel. Flat or horizontal facilities are usually built wider and lower than silos to reduce cost and side pressures. There are round steel or concrete bins designed to resist the maximum volume of grain to store. They are usually built with concrete floors; the roof tends to follow the slope of the pile of grain, and they are equipped with fixed loading and unloading mechanical systems.

Upright silos are round, hexagonal, or even square-shaped concrete or steel bins usually constructed in rows, so one straight conveyor can service a whole series of bins. The most common form is round because it is the most resistant and is built in such design to take advantage of the interstitial spaces to increase storage capacity. Silos are often built on two or more rows of cylindrical bins with diameters ranging from 2 to 10 m. The grain is usually elevated by a leg consisting of an endless vertical belt equipped with attached buckets. The inferior part of the silo is usually conical to aid in the grain unloading.

Controlled Atmosphere Storage

The objective of controlled atmosphere storage is increasing the concentration of carbon dioxide in airtight facilities to reduce grain respiration and growth of insects and molds. Most insect species of stored grains will perish when the oxygen concentration is less than 2%. Fungi can still grow at lower oxygen concentrations (0.2%), but infestations will occur only if the lot is stored at moisture contents above 16%. Low-oxygen conditions can be created by the use of carbon dioxide or nitrogen gases. Carbon dioxide is more effective than nitrogen for killing insects. The gases are injected from cylinders or by addition of dry ice (solid carbon dioxide) to a silo before sealing. The major advantage of using controlled atmosphere storage is the reduction of pesticides for controlling insects.

Insects

There are between 20 and 30 insect species that attack cereal grains during storage. The warm temperatures of tropical and subtropical areas are the preferred habitat for these insects, whereas the cold weather inhibits insect activity. Insects are the main agents responsible for grain losses in the world. Besides the direct losses, insects contaminate grains and processed products with fecal material, uric acid, weblike material, and body fragments. Insects are classified as primary or secondary according to their habits and characteristics (Table 1). Primary insects are more harmful because they have the ability to damage sound kernels. They usually perforate the grain for feeding and reproductive purposes. These insects mainly consume the endosperm and germ tissues and use the grain as site for oviposition and larvae development. Secondary insects are

Table 1 Biology and habits of the most common insects that infest cereal grains and their products

Common (scientific name)	*Biology, habits, and type of damage*
Lepidoptera	
Angoumois grain moth (*Sitotroga cerealella*)	Adults measure 7.6 mm long and 12.7 mm wide (extended wings). The front and back wings are yellow and gray. The hind wings have a characteristic pointed tip with posterior hairs. The female lays 40–300 eggs over the grain surface. The larvae tunnel into the kernels where they complete their life cycle of 5 weeks. The 5 mm long larvae are white caterpillars with three pairs of legs. Before pupating, the larvae prepare a thin escape hole through which the moths emerge. During development, the larvae consume up to 50% of the grain. Larvae develop in a brown pupa after to 2–3 weeks. The infestation is characterized by the extensive webbing over the lot of grain
Indian mealmoth (*Plodia interpunctella*)	Cosmopolitan insect that in the adult stage measures 5–10 mm long. The basal and distal halves of the front and hind wings are light coppery- and dark coppery-colored. The 13 mm long larvae differ in color from white to green. Adult moths lay clusters of 12–30 eggs on the grain surface totalizing 60–300 eggs during the life cycle. Eggs hatch into larvae, which is the destructive stage. The larvae usually come to the outside of the kernels to spin cocoons and pupate. The adult emerges from the pupa and under optimum conditions has a 4–8-week cycle. The infested grain usually has the typical webbing
Mediterranean flour moth (*Anagasta kuehniella*)	The moth is light gray-colored measuring 6–12.5 mm long. The wings are distinctively marked with two black lines in zigzag. The female lays on flours and crevices eggs that hatch 3–6 days later into measure worms. The larvae pupate in silk cocoons for 8–12 days. The adult emerges from the pupa and have a life cycle of 9–10 weeks during warm weather
Coleoptera	
Maize weevil (*Sitophilus zeamais*) Rice weevil (*Sitophilus oryzae*) Granary weevil (*Sitophilus granarius*)	These primary insects are the most destructive. The head has a pair of antennae and a prolonged snout. The granary weevil is brown or black and does not have functional hind wings. The maize and rice weevils are reddish brown to black and have two light spots on each front wing. The hind wings function as flight wings. The 5 mm long adults perforate the grain to lay one egg. Each female may lay from 300 to 400 eggs that hatch 5–15 days later. The larva develops inside the grain and gradually consumes the grain during 15–40 days. The life cycle under optimum conditions lasts 4–5 weeks
Lesser grain borer (*Rhyzopertha dominica*)	Primary insect that in the adult stage measures 2.5 mm long. The brown or black beetle has a cylindrical shape and is capable of flying. Both the larvae and adults are destructive. Females lay 2–30 eggs outside the grain. The cream-colored larva with a dark head and three pairs of legs perforates the grain and develops inside in approximately 60 days
Larger grain borer (*Prostephanus truncatus*)	The larger grain borer is a small, dark-brown, elongated, cylindrical beetle about 4.2 mm long. It is similar in appearance to the lesser grain borer. It is considered one of the most harmful tropical pests especially in maize granaries
Confused flour beetle (*Tribolium confusum*) Red flour weevil (*Tribolium castaneum*)	These secondary insects are 3.6 mm long and brown/reddish and are considered the most destructive in flours and processed grain products. The antennal segments of the confused flour beetle gradually increase in size toward the tip, whereas the antennae of the red beetle end with three abruptly enlarged segments. The female lays 400 or more sticky eggs (6–12 per day) on sacks, cracks, or grain products. The eggs hatch into a white-colored 1.5 mm long worm. These insects leave feces and dead bodies, cast skins and exoskeletons, and excrete quinones that produce off-odors and undesirable color changes in flour
Sawtoothed grain beetle (*Oryzaephilus surinamensis*) Merchant grain beetle (*Oryzaephilus mercator*)	The reddish-brown saw-toothed and merchant beetles are relatively small insects (2.5 mm long) with six toothlike projections on each side of the thorax. Generally, these beetles feed on damaged grains, flour, and processed foods
Yellow mealworm (*Tenebrio molitor*) Dark mealworm (*Tenebrio obscurus*)	These cosmopolitan mealworms are one of the largest secondary pests that infest stored products

Source: Serna-Saldivar, S. O. (2010). *Cereal grains: properties, processing and nutritional attributes*. Boca Raton, FL: CRC Press (Taylor & Francis Group).

opportunistic because they attack grains that have already been damaged by primary counterparts or processed products such as flours or processed foods.

Table 1 summarizes the habits, characteristics, and biology of the principal insects that attack cereal grains during storage. Five primary pests cause most of the insect damage. These are the granary, rice, and maize weevils; the larger and lesser grain borers; and the Angoumois grain moth. The large grain borer is of economic importance in tropical areas around the globe. Temperature is the most important environmental factor affecting insect development and reproduction. Most insects do not reproduce at temperatures lower than 12 or higher than 34 °C. The optimum temperature for reproduction is about 26 °C.

Molds

After insects, grain molds are the most important biotic agents negatively affecting grain viability and quality. Molds have potent lipolytic, amylolytic, and proteolytic enzymes that degrade stored nutrients; moreover, they can produce mycotoxins that have the potential to cause serious diseases and deaths in humans and domestic animals. The most relevant genus of storage molds are *Fusarium*, *Aspergillus*, and *Penicillium* (Table 2). These molds usually infest cereal grains when they contain moisture in the range of 16–20% and the air relative humidity and temperatures are 85% and 25–30 °C, respectively. The main harmful effects of storage fungi are lower

seed viability, grain discoloration, nutrient degradation, mycotoxin production, grain heating, and generation of musty off-odors.

Diseases related to the consumption of mycotoxins have been known for hundreds of years. Cases of ergotism in the seventeenth century and ochratoxicosis during the Middle Ages are well documented. Aflatoxins are now recognized among the most potent naturally occurring carcinogens in nature. During the past decade, fumonisins have received special attention because of their potent harmful health effects on equines and humans. Table 2 summarizes the main types of mycotoxins found in stored cereal grains and their harmful effects in humans, domestic animals, and poultry. Undoubtedly, maize is the most susceptible cereal to mold infestation and mycotoxins. This is because the cob is covered with husks creating an ideal and protective environment for molds.

Rodents

Rodents are considered the most destructive vertebrates in the planet. The main reasons why these mammals cause huge economic losses are their wide range of adaptation, high reproduction rate, and the complexity for their control.

The most common rodents present in grain storage facilities are the Norway and roof rats and the house mice. Table 3 summarizes the features of these species that destruct grains in the field and throughout storage.

Table 2 Characteristics and toxicological effects of the main mycotoxins that occur in cereal grains and their products

Mold	*Mycotoxin*	*Toxic effects on humans and domestic animals*
Aspergillus flavus, *Aspergillus parasiticus*	Aflatoxins	There are several types of aflatoxins; the most relevant and toxic in cereals is B_1. Other important metabolites are B_2, G_1, G_2, M_1, and M_2. These are of great importance because they cause toxicity at very low concentrations (10 ppb). Aflatoxins produce acute hepatitis, widespread hemorrhages, and poor immunologic response and are potent carcinogens and mutagenic agents
Aspergillus ochraceus, *Penicillium verrucosum*	Ochratoxin	Ochratoxins are isocoumarin derivatives bound to phenylalanine. The toxicosis known for several centuries involves progressive renal failure and atrophia, anemia, polyuria, anorexia, headaches, and uremia. In most instances, the disease is fatal
Fusarium moniliforme, *Fusarium verticillioides*, *Fusarium proliferatum*	Fumonisin	They are the group of toxins that have received more recently attention. They are highly toxic to livestock, mainly horses. In humans, fumonisins have been related to esophageal cancer and interference with folic acid metabolism. Therefore, they can exacerbate fetal malformation such as neural tube defects
Fusarium graminearum	Zearalenone	Chemically is an acid lactone with a phenol–resorcinol configuration. Swine are the most affected animals because it causes the 'estrogenic syndrome' or animal feminization, characterized by vulvovaginitis, vaginal prolapse, and infertility in sows and testicular atrophy, infertility, and swelling of the mammary glands in boars
Fusarium	Trichothecenes (T-2 toxin)	About 180 trichothecenes are known. High-moisture cereals are frequently contaminated with these toxins considered as potent protein synthesis inhibitors and immune suppressors. Trichothecenes can produce the fatal syndrome named 'alimentary toxemia'
Fusarium graminearum	Deoxynivalenol (DON) Vomitoxin	Vomitoxin is a deoxynivalenol derivative. The toxin causes feed refusal, vomiting, and lower feed efficiency. The beer industry is especially concerned about these toxins because they may contaminate beer when infested barley or malt is used

Table 3 Biology and features of rodents commonly present in grain storage facilities

Type of rodent	*Biology and features*
Norway rat (*Rattus norvegicus*)	They grow in temperate and urban areas. The robust adults weigh 300 g and have small eyes and ears and short and blunt noses and their hair coats are usually dark. The most distinctive feature is that the tail is shorter than the body. The adults are aggressive and dominant and daily consume an average of 28 g food. The dam has the capacity of producing up to 7 litters per year of 8–12 pups each. This rat excretes large (1.9 cm long) fecal pellets with blunt ends
Roof rat (*Rattus rattus*)	This rat is comparatively smaller compared with the Norway counterpart, but it adapts better to tropical regions and its color varies from black to grayish white. Two distinctive characteristics are that the ventral or abdominal part is lighter than the rest of the body and that the tail is longer than the body length. In addition, the rat has larger eyes and ears and a pointed nose. These rats can climb and live in overhead areas especially when they coexist with Nordic rats. The roof rat excretes fecal pellets of 1.2 cm long with pointed ends
House mouse (*Mus musculus*)	House mice are small cosmopolitan rodents common to human dwellings that only weigh 15 g. They have a longer tail compared with the body, a light-brown or gray hair color, a pointed nose, small eyes, and long ears. Females give birth up to 8 litters per year of 9–12 pups each. They specialize in consuming cereal grains, and the control program should consider that these animals are excellent climbers. The house mouse droppings average 0.6 cm long with pointed edges

Cereals: Types and Composition

SO Serna Saldivar, Centro de Biotecnología-FEMSA, Tecnológico de Monterrey, Monterrey, México

© 2016 Elsevier Ltd. All rights reserved.

Introduction

Cereals belong to the *Gramineae* family commonly known as grasses. Most of these plants are perennial; however, all commercial cereal grains are annual. It is believed that prehistoric men selected plants that yielded large kernels in a relatively short period of time. Since then, mankind has manipulated cereals in order to increase their yield through a better adaptation to different ecosystems, climates, and soils. This continuous plant breeding effort has sustained the dramatic increase of the world population experienced since 1900 (from approximately 1.7 billion in 1900 to more than 7.3 billion in year 2014).

Cereals have a wide array of assets and advantages. They yield high amounts of food per surface area and mature grains that are not perishable when properly stored. Furthermore, these grains concentrate calories and other nutrients in a relatively small package that has sustained mankind since they became sedentary. Among the major food groups, cereals are undoubtedly the largest supplier of calories and proteins for the average human being.

According to the Food Agriculture Organization, cereals are by far the most important foods with an annual production exceeding 2.78 billion tons in year 2013. Cereals are the staple for the world inhabitants and the major source of feed for animals that supply meats, eggs, and dairy products.

Among cereals, three contrasting grains, rice, wheat, and maize, yield approximately 89% of the total production. Rice and wheat are almost exclusively channeled to human foods, whereas maize is widely used as feedstock for animals and fuel ethanol. Maize is the cereal with the highest production and yield followed closely by rough rice and wheat. The United States harvests 35% of the world production due to the use of high-yielding hybrids including an increasing number of genetically modified organisms (GMOs). Wheat is still considered the icon of cereals because of its versatility to produce a wide array of leavened foods, which is possible due to its unique gluten properties. Wheat is the cereal that contributes the most in terms of human caloric intake. About 45.5% of the wheat is produced in China, India, the United States, and Russia.

In 2014, more than 75% of the paddy rice was harvested in China, India, Indonesia, Bangladesh, Vietnam, and Myanmar. The per capita consumption of rice in developing Asian countries averages 80 kg $year^{-1}$, with the people from Myanmar, Vietnam, Bangladesh, Cambodia, and Indonesia being the most dependent on this cereal grain with yearly consumptions of 195,167, 160, 147, and 140 kg per capita, respectively.

Barley is currently the fourth cereal grain in terms of production with a global production of 144.7 million tons in year 2013. Rye, barley, and oats are mainly planted in Europe, Russia, and the United States. These winter small grains are also planted for forage or as dual-purpose crops. About 65% of the rye is harvested in Eastern Europe due to its adaptation to harsh winters and poor soils. In these regions, rye flour is usually mixed with wheat flour for the production of many traditional breads and other bakery goods. Likewise, most of the barley and oats are planted in United States, Canada, and Europe for food and feed. Barley is used for malting, brewing, and distilled alcohol spirits, whereas milled oats or groats are used for the production of composite breads and other bakery items.

Sorghum is currently the fifth cereal grain in terms of production with a global production of 61.4 million tons in year 2013. It is directly used to produce a wide array of traditional foods in Africa and India and almost exclusively used for animal feed in the United States, Mexico, and other Latin American countries. Sorghum as feed competes strongly with maize although is considered to have a slightly lower nutritional value.

The millets are grown as subsistence crops because of their hardiness and droughts resistance. These cereals are mainly produced in developing countries of Africa and Asia. The main producers are India, Nigeria, Niger, and China. The African countries located south and west of the Saharan desert (Mali, Burkina Faso, Niger, and Nigeria) have traditionally depended on millets and sorghum as the main source of nutrients.

The most relevant features of cereal plants are stems with nodes where buds and leaves originate, alternate spear-shaped leaves, and an inflorescence that could be a spike or panicle. These bear multiple flowers enclosed in glumes that upon fertilization and maturation yield monocotyledon starchy fruits composed of pericarp, germ, and endosperm. The cotyledon is located in the germ's *scutellum* and is considered as the first reserve tissue, whereas the endosperm is the largest part where protein and starch are stored as secondary reserve tissues. Cereals are divided according to the photosynthesis pathway into two groups: C_3 plants that form three-carbon compounds via the Calvin-Benson metabolic cycle where rice wheat, barley, rye, triticale, and oats are included and C_4 plants such as maize, sorghum, and millets that form four-carbon compounds via the acidic Crassulacean metabolic pathway. C4 cereals generally grow in hot climates with a high light intensity and are more efficient in terms of CO_2 utilization and water and nutrient uptake.

The inflorescences of wheat, barley, rye, and triticale are spikes, whereas rice, sorghum, oats, and all millets produce panicles. In the specific case of maize, the cob is classified as a fused panicle or central axis. Maize, rye, sorghum, and pearl millet cross-pollinate, whereas wheat, oats, barley, and rice self-pollinate.

The cereal fruit is botanically named caryopsis and consists of three major anatomical parts: pericarp, endosperm, and germ. There are some species that loose the glumes or husks during harvesting and others that tightly retain these protective coats. Maize, sorghum, wheat, rye, triticale, and pearl millet are examples of naked caryopses, whereas rice, oats, and barley are covered caryopses.

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00128-8

The pericarp or bran is the outer layer that covers the kernel and contains most of the fiber, whereas the endosperm is the main anatomical part in terms of quantity and food utilization. It could constitute up to 75% of the total grain weight and is mainly composed of starch and protein and is practically devoid of fiber. The starch is stored in granules that are classified as simple or compound. Among cereals, only rice and oats synthesize compound starch granules. The germ, which encloses the *scutellum* and embryo, contains most of the oil and is also rich in protein and vitamins. The *scutellum* or cotyledon and endosperm are considered as the first and second reserve tissues, respectively. These anatomical parts store nutrients necessary for germination.

Adaptation and Cytogenetic Origin

The various cereal genus and species are adapted to produce in most of the ecosystems around the globe.

Maize (*Zea mays* L.)

Maize is the most produced cereal crop in the world and the most adapted to different ecosystems. Ancient Mesoamerican farmers started to select and manipulate teosinte (*Zea mexicana*) and in a couple of centuries transformed this native grass into several pre-Columbian maize races. Today, plant breeders recognize more than 300 races that evolved from these prehistoric ethnic groups. The Mesoamericans created maize by transforming a tiny two-rowed ear of teosinte of about 3 cm long into the first small maize ears with four ranks of paired female spikelets. This transformation took perhaps only 100–200 years. The maize crop produces under irrigation and in dryland conditions; however, the plant is highly susceptible to frosts. Among commercial cereals, maize is the only one that has the male and female flowers separated. The staminate or male inflorescence is borne in the tassel and the pistillate or female inflorescence on the ears. These are located in the top and middle parts of the plant, respectively. Maize is classified according to color into white or yellow and kernel configuration into dent or corneous or flinty. The main specialty types are popcorn, waxy, high-amylose or amylomaize, sweet, blue, Cuzco, and quality protein.

Rice (*Oryza sativa*)

Rice is considered as a sacred plant in Asia and is still the most important food for more than 50% of the world population. Archaeological evidence has proved that rice was planted and used at least 4000 years BC. In developing Asian countries, the yearly per capita intake of rice is higher than 80 kg. Production data indicate that about 90% of the world rice production is harvested in Asia. Rice is planted in tropical and subtropical regions of the world close or neighboring the equatorial line where there is high relative humidity and rainfalls. Rice is also traditionally grown in some European countries such as Italy, Spain, and France. The agronomics of rice is different from other cereals because this plant is generally planted on flooded soils and by transplanting seedlings previously grown in nurseries. Three major groups of rice are widely recognized: Japonica, Indica, and Javanica. The first two are the most relevant. Japonicas are usually high yielding and produce short caryopses that upon cooking yield sticky or glutinous rice. On the other hand, Indicas usually yield less compared to Japonica counterparts and produce long caryopses that upon cooking yield drier and firmer rice. Commercially, rice is classified as long, medium, and short. The main specialty rices are glutinous, black or purple, red, Basmati, and Risotto.

Wheat (*Triticum* sp.)

Wheat was one of the first cultivated plants and is considered as the most important cereal in terms of energy supply for humans. It is planted in temperate regions and considered as a winter crop. In the early part of the 1900s, taxonomists recognized three species that possessed different chromosome numbers: diploid, tetraploid, and hexaploids, which contain 14, 28, and 42 chromosomes, respectively. Commercially, the wheats planted nowadays are hexaploids and tetraploids. The hexaploids are the most widely grown throughout the planet and provide the hard and soft kernels suited for the production of yeast-leavened breads and cookies/cakes and other related chemically leavened bakery items, respectively. The tetraploid durum (*Triticum durum*) is one of the most cultivated today to fulfill the pasta market. Wheat is the only cereal that possesses functional gluten. The flour upon hydration and the mechanical work of mixing forms a cohesive and elastic dough suited for the production of leavened bakery items and pasta products. Wheat is classified according to kernel hardness into hard, soft, or durum, color into red or white, and growth habit into winter and spring. The main specialty types are waxy and the ancient types known as spelt, einkorn, and emmer.

Barley (*Hordeum vulgare*)

Barley was one of the first crops cultivated by men since the origins of farming. Historically, barley preceded wheat as a food grain in ancient Egypt and since then it has been consumed in many cultures. Barley ranks fourth among cereals and significantly contributes to the world's food supply as human food, malt products, and livestock feed. Approximately 64% of the world barley is channeled to the feed industry. Cultivated barley is one of the 31 *Hordeum* species. Most are diploids ($2n = 14$ chromosomes) with about the other half being tetraploids or hexaploids. Barley is a cool season crop cultivated in the spring and summer at temperate latitudes. It is cold-tolerant and considered the most drought-resistant, alkali, and salt-tolerant among the small grains. Barley is classified into malting or feed and into two- or six-rowed types. The main specialty types are hull-less or naked, waxy, high-amylose and hyproly, or high lysine.

Sorghum (*Sorghum bicolor*)

Sorghum originated in equatorial Africa where it has been grown for more than 2000 years. It is one of the cereals with the highest genetic variability because more than 30 000 selections are preserved in the world collection bank located in India. Sorghum

continues to be a traditional crop in Africa and India and constitute a major source of calories and protein for millions of people. About half of the world production is processed into a wide array of traditional foods. In developed countries, sorghum has gained popularity because of its drought resistance and high productivity especially when planted under good agronomic practices and inputs. Sorghum is the preferred cereal in semidesert areas of the world or in areas where maize strives due to high temperatures, poor soils, or lack of rainfall. Sorghum is classified as high- and low-tannin types. Brown, bird-resistant or high-tannin sorghums have a reduced nutritional value and are grown because of their agronomic advantages including bird resistance, decreased weathering, mold infestation, and sprouting. Most cultivated sorghums do not contain condensed tannins and have similar food and feed nutritional value when thermal treated compared to maize. White sorghums are currently viewed as an excellent source of gluten-free flours or meals suited for the production of snacks, cookies, breads, and beer. Good-quality sorghums can substitute maize in most of industrial applications including bioethanol. The main specialty types of sorghum are waxy, popping, black or Shawaya, high-lysine, and lemon.

Rye (*Secale cereale*)

Rye has a better resistance to harsh winters, cold weather, and lack of water compared to wheat and is generally planted in less fertile soils under dryland conditions. It is primarily a winter crop that is sown in the fall, becomes dormant during the winter, and is harvested early in the spring. Occasionally, rye is sown in the spring and harvested during the summer. Most rye is harvested in Europe and Russia and is dry-milled and processed similarly to wheat. The grain has been traditionally used for the production of flat breads and yeast-leavened breads, which varies in crumb color from practically white to dark-brown and in taste from a mildly sour to a strong distinctive acidic. Rye flour is preferred for the production of sour breads and is also used for the manufacture of crackers, cookies, and breakfast cereals. Compared with wheat flours, rye flours deteriorate faster but contain higher levels of protein, pentosans, and minerals.

Oats (*Avena sativa*)

The origin of oats can be traced back to approximately 2000 BC in the Middle East or surrounding Mediterranean areas. *Avena sativa* and *Avena byzantine* are the two most widely grown. Oats are a cool season crop and ranks sixth in world cereal production. The demand for oats for human consumption has steadily increased due to its nutritional health implications, the best protein quality among cereals, and especially due to the unique properties of its dietary fiber. In the processing of oats for human foods, the hulls or glumes are removed and the naked caryopsis, named groats, is generally consumed as whole grain. The main drawback of whole oats and their milled fractions is the high fat content prone to oxidation. That is the main reason the dry milling of oats is aimed toward the deactivation of lipolytic enzymes via thermal treatments. Flaked and milled oats are mainly used for the production of breakfast cereals, nutrition bars, cookies, and composite breads.

Triticale (*Triticum secale*)

Triticale is the only plant species created by man who crossed wheat and rye. It was first deliberately produced in 1876 although the first varieties emerged in the 1930s in Russia, but it was until the 1960s when it was commercially planted. Triticale is a hybrid resulting of the cross of wheat (mother) and rye (father) with the aim of obtaining kernels with the best features of these cereals (gluten functional and better agronomic performance or hardiness and resistance to pests). Triticale has regained popularity during the past 20 years. World production in 2013 (14.6 million tons) was approximately three times greater than in 1993. However, most of the triticale currently grown does not meet gluten expectations and therefore is mainly used as forage or feed. In 2013, the triticale planted area was approximately 3.85 million hectare.

Millets

The grasses known collectively as millets are a set of highly variable small-seeded cereal species indigenous to different areas of the world. In some African countries such as Niger, Mali, Burkina Faso, and Gambia, the yearly consumption of millets amounts to 160, 71, 55, and 52 kg, respectively. In 2012, about 29.9 million tons were directly used for the production of many African and Asian traditional foods. Similar to sorghum, millets are mainly adapted to semidesert, tropical, and subtropical areas of the world, but they are usually planted on barren and low-moisture soils and under hot environmental conditions. These cereals are of special value in semiarid regions because of their short growing cycle. Most millets are viewed as either subsistence or cash crops in developing and developed countries, respectively. Average yields of millets seldom exceeds 1 ton Ha^{-1}.

The most relevant millet is pearl (*Pennisetum americanum*), which originated in the corridor from Western Sudan to Senegal. It is believed to be one of the earliest domesticated millets because kernels have been found in West African sites inhabited 2000 BC. Pearl is the most productive millet and is used instead of sorghum with the advantage that it possesses a better nutritional value. Pearl millet produces a very unique cylindrical panicle containing hundreds of oblong–round-shaped kernels.

After pearl millet, the most relevant are foxtail (*Setaria italica*), proso (*Panicum miliaceum*), and finger (*Eleusine coracana*). Foxtail millet is especially important in China, Japan, and India. Proso or common millet (*Panicum miliaceum*) originated in Manchuria and first appeared as a crop in Transcaucasia and China 5000 BC. It is considered as one of the most drought-resistant millets. The kernels are small (2–3 mm) and can be cream, yellow, orange-red, or brown in color. Kernels are usually traditionally milled into flours for preparation of a wide array of traditional foods or used for birdseed. Finger or ragi millet originated in Ethiopia and reached India between 3000 and 4000 years ago. Its name is due to the digitally arranged panicle. Finger is among one of the most productive millets with average yields of about 1.8 tons Ha^{-1}. The two main races are the African highland, widely grown in the cooler higher altitudes regions of East Africa and Asia, and the Afro-Asiatic lowland. Finger millet is generally dry-milled into flour for the production of flatbreads, dosa and rotis.

Kodo (*Paspalum scrobiculatum*) and barnyard (*Echinochloa frumentacea*) millets are indigenous to the Indian subcontinent. Kodo kernels are enclosed in hard horny persistent husks that are difficult to remove. Barnyard is considered as one of the fastest growing among all millets.

Teff (*Eragrostis tef*) originated 4000 BC in northern Ethiopia. Maximum production is achieved at high altitudes (1800–2000 m), with rainfall of 450–500 mm and a temperature range of 10–27 °C. Today, teff accounts for about one quarter of the total cereal production in Ethiopia where it is mainly processed into the traditional fermented pancake known as injera. Among millets, teff produces the smallest kernels (< 1 mm in diameter), which are rich in dietary fiber and iron and contain a better protein quality and calcium compared to other cereals.

Fonio (*Digitaria exilis*) is an important subsistence crop in the savannas of West Africa where it has been planted because of its short growing cycle (2 months) and resistance to arid conditions, scarce rainfalls, and poor soils. Fonio also yields very small kernels that are milled into flours, which are mainly used for preparation of porridges, couscous, traditional breads, and opaque beers.

Physical and Chemical Properties

The grain physical properties of cereal grains are depicted in Table 1 and the chemical composition in Table 2. Cereal grains are composed of carbohydrates, protein, lipids, vitamins, and minerals.

All cereals are classified as starchy grains because they contain at least 60% of this carbohydrate. The starch is a polymer of glucose units joined by α 1–4 and 1–6 glycosidic bonds that after digestion provide most of the energy consumed by humans. The starch is an excellent source of energy because in practical terms it is completely digested and utilized by a normal human being. The starch has contrasting properties if it is in its native, gelatinized, or retrograded stages. Most foods processed are aimed toward the partial or total starch gelatinization because the thermal-treated starch turns into molecules with high affinity for water that yield viscous doughs, gels, or slurries. The starch molecules are stored in granules, which are packed with amylose and amylopectin molecules. The amylose contains about 1500 glucose molecules in a linear chain joined by α 1–4 glycosidic bonds. The amylopectin or branched starch is composed of glucose molecules not only linked by α 1–4 glycosidic bonds but also containing branches that occur when α 1–6 bonds form. Only about 4–5% of the total glycosidic bonds are α 1-6. These glucose polymers have a molecular weight of 108×10^6 g mol^{-1} (600 000 glucose units/amylopectin molecule) and structurally are divided in type A, B, and C chains. The starch of most cereals contains 75% amylopectin and 25% amylose. However, some cereals such as maize, wheat, rice, barley, and sorghum can contain from 95% up to 100% amylopectin and therefore are almost amylose-free. These cereals are named waxy because their endosperm

Table 1 Physical properties of cereal grains

Cereal	Test weight (kg hl^{-1})	1000 kernel weight (g)	Dimensions				Density (g cm^{-3})
			Length (mm)	Width (mm)	Thickness (mm)	Length: width ratio	
Maize							
Dent	68.5–78.0	240–370	8.0–17.0	5.0–9.8	–	1.1	1.20–1.36

[a]Nitrogen-free extract (NFE) that gives an indication of nonfibrous carbohydrates (starch and sugars).

Source: Serna Saldivar, S.O. (2010). *Cereal grains: properties, processing and nutritional attributes*. Boca Raton, FL: CRC Press (Taylor & Francis Group).

acquires this appearance when viewed with the naked eye. These waxy cereals and their starches have special industrial uses.

The second most abundant chemical component is the various types of protein fractions distributed in the different anatomical parts of the cereal kernel. Those associated with the endosperm are commonly denominated gluten proteins, whereas those associated with the germ are the albumins and globulins. The range of protein of cereals is from 8% to 16% (Table 2). Proteins from cereals have good rate of digestibility but lack of an adequate essential amino acid balance or composition especially for preschool infants and children. The most limiting amino acid is lysine followed by tryptophan in maize and threonine in most other cereals.

Cereals are considered as a good source of dietary fiber. From the health viewpoint, the importance of dietary fiber

and consumption of whole grains has greatly increased during the past years. The dietary fiber is viewed as therapeutic for people with diabetes, high cholesterol, and gastrointestinal problems. Both insoluble and soluble dietary fibers have positive health benefits. The insoluble fiber increases the peristaltic movement, increases the fecal bulk, and prevents constipation, hemorrhoids, diverticulosis, and colon cancer. On the other hand, the soluble fiber reduces blood cholesterol and lowers the sudden increase in blood glucose levels. Both types of fibers have the ability to bind bile acids decreasing cholesterol. The insoluble fiber is mainly composed of cellulose and lignin, whereas the soluble counterpart is composed of hemicellulose, arabinoxylans, and β-glucans.

Lipids are relatively minor constituents of cereal grains. Cereal lipids are divided into polar and nonpolar and are mainly located in the germ. In most cereals, the nonpolar triglycerides constitute more than 95% of the total fraction. Maize, sorghum, and pearl millet are the cereals that contain the highest amount of these compounds, whereas oat is considered the only cereal that contains significant quantities of lipids in the starchy endosperm. The ash or mineral fraction material is mostly associated with the glumes, pericarp, and aleurone layer. The most abundant mineral is phosphorus that is generally bound to phytates. Unfortunately, cereals are low in essential minerals iron and zinc.

Nutritional Value

Cereals grains and their products provide most of the total food intake and nutrients that sustain mankind. According to the FAO in 2011, an average human being daily consumed more than 403 g of total cereals and obtained approximately 1296 kcal and 31.9 g protein.

Most of the calories are derived from the starch, which is almost completely digested and utilized in a normal human system. Another advantage of starch is that it releases the glucose at a slower rate to the blood stream and therefore is suited for diabetics. The consumption of whole cereals rich in dietary fiber is even better because of their lower glycemic index. The consumption of whole grain foods lowers energy density, blood cholesterol, and glucose and reduces the incidence of several cancers, mainly colon. Oat-based products exert positive health effects because they contain significant quantities of both insoluble and soluble dietary fibers. The rest of the cereals have a higher ratio of insoluble to soluble fiber and therefore do not exert the same positive effects as the oat's dietary fiber.

The major drawback of cereals is their low protein quality. Protein quality is affected by the digestibility rate and mainly by the essential amino acid balance. Cereals usually contain from 8% to 12% protein (**Table 2**), have a good rate of protein digestibility (80–90%), but unfortunately lack lysine, the most important essential amino acid in practical human nutrition. The malnutrition problems still widely distributed throughout the world are almost always observed in infants living in places where cereals provide most of the daily food intake. The problem worsens when diets lack of legumes and/or animal-based products.

Cereals are considered a good source of all B vitamins except B_{12}, but they are low in fat-soluble vitamins and devoid of vitamin C. It is common to observe vitamin A deficiencies in populations that depend on cereals. Scientists are trying to develop high β-carotene varieties using molecular biology with the aim of reducing vitamin A deficiency and night and permanent blindness endemic to some regions of Asia and other parts of the world.

Introduction

Chapati is the oldest in wheat-based food category that is consumed by a majority of the population in the Indian subcontinent and also widely consumed in the United Kingdom, Middle East, and other countries with an Asian ethnic community. Also known as Roti, it is used as a staple diet by a major segment of the population of the Indian subcontinent. It is a flat and unleavened baked product made from whole wheat flour. Chapati constitutes an important source of dietary proteins, calories, some vitamins, and minerals for the poorer section of the Indian population. In India, about 75% of the wheat grown within the national boundaries is used for the preparation of chapati.

There are some other similar flat bread products like chapati (leavened or unleavened) that are prepared from wheat flour and are popular worldwide, that is, tandoori roti, naan, parotha, phulka, kulcha, poori, litti, missi roti, tortilla, matzo, pita, yufka, sangak, balady, barbari, taftoon, lavash, ciabatta, baati, bafla, and gyro bread. Whole wheat flour is the main ingredient for chapatis and related other products, but sometimes yeast and fat are also included in the formulation to improve the dough handling, mixing, and textural properties. Good-quality chapatti should be pliable, soft in texture, light creamish brown in color, and slightly chewy and should have a baked wheat aroma.

In this article various types of chapati and related flat bread products, their traditional preparation methods and the advancement made in this direction are discussed.

History of Chapati

Flat breads have been known to humans for over the last 6000 years. Babylon is the oldest to have a baker's oven in the world in 4000 BC. In the old kingdom of Egypt, as long ago as 2500 BC, hot ashes or heated stone slabs were used to bake flat bread. These were the Egyptians who passed their bread-making skills, including fermentation, to the Greeks and Romans. Bread occupied an important place in Roman culture and religion; therefore, large commercial bakeries were developed in the second century BC to meet the demands of increasing bread consumption. The possibility of mashing edible grains into a paste and then baking into a flat bread was discovered by the Sumerians in ancient Mesopotamia (modern-day Iraq).

Flat breads in Scandinavian tradition were stored for lean months and tough weather. Flat breads, made in large batches and sometimes in the form of flat rounds with holes in the center, were strung together and stored hanging. Tandoor originated in Persia (Iran) and was brought to India via Afghanistan by Arabs way back in 3000 BC. Small mud-plastered ovens have been found in Harappa and Mohenjo-Daro. Abu'l-Fazl ibn Mubarak, vizier of Mughal Emperor Akbar, has also mentioned chapati in his book 'Ain-i-Akbari,' in the sixteenth century.

Classification of Flat Breads

Flat breads can be classified in two different categories: single layered and double layered. Single-layered bread is again classified in two subgroups as leavened/fermented (risen by a process of yeast fermentation) and unleavened. According to this classification barbari, gomme, lavash, tandýr, and pide are classified as leavened single-layered flat bread, whereas yufka and parotha are classified as unleavened single-layered flat bread, and pita (Arabic flat bread) and baladi are double-layered flat bread.

Double-layered flat bread is widely used in Middle Eastern and North African countries and is gaining popularity in Western countries. High extraction flour (flour having a good amount of fiber) is generally used for double-layered flat bread, making it acceptable as a high dietary fiber food.

Some Popular Flat Breads Worldwide and Their Preparation

The flat breads are usually produced from a simple recipe consisting of flour, salt, and water in varying proportions; however, sometimes the manufacturer also uses optional ingredients like yeast fat, skim milk powder, and certain additives for quality improvement and shelf life enhancement. In addition to the numbers of emulsifiers, hydrocolloids and enzyme preparations have been added to the recipe to modify the process conditions to offer the consumer fresh bread at any time.

In different regions of world different flat breads are produced and consumed.

China

Green Onion Pancakes

Green onion pancakes are made with all-purpose flour, oil, and minced scallions (green onions).

Sanchuisanda

Sanchuisanda are baked in ashes.

Europe

Blintz/Blini (Russia)

Blintz is a yeast fermented thin pancake, somewhat similar to a crepe, although yeast is not used in crepe preparation.

Ciabatta (Italy)

Ciabatta is an Italian white bread made from wheat flour and yeast. The loaf is somewhat elongated, broad, and flat like a slipper and somewhat collapsed in the middle. It has become

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00131-8

popular across Europe and the United States and has been widely used as sandwich bread since the late 1990s.

Crepes (France)

Crepes are a very thin pancake made of wheat flour. The word *crepes* is derived from the Latin word crispa, meaning 'curled.' Crepes are considered a national dish. They are now also popular in North America and South America.

Flat Bread (Norway)

Flat bread of Norway is made with barley flour, salt, and water.

Focaccia (Italy)

Focaccia is a traditional Italian bread somewhat similar to pizza. It has various flavors and shapes such as the 'focaccia al rosmarino,' 'schiacciata' in Tuscany. Each region of Italy has its own local recipe for making focaccia.

Lefse (Norway)

Lefse is a traditional soft, Norwegian flat bread made by using potato, milk or cream (sometimes lard), and flour and cooked on a griddle.

Pizza (Italy)

Pizza is a traditional Italian thin flat bread baked on a very hot stone-oven at temperature about 900 °F/450 °C. Traditional topping is done with tomato sauce, mozzarella cheese, and basil.

Rye Flat Bread

Rye flat bread is produced in the Scandinavian countries. For preparation, mixing of barley, oat, and rye flours with water is done; the dough is rolled to a thin layer; and it is baked on a hot plate. Cohesive dough is produced and allowed to ferment for 45 min. Dough pieces weighing 400 g are rounded and sheeted to 0.7–1.0 cm thickness. A round central portion of the sheeted dough (5.0 cm diameter) is cut and removed. It is then again fermented for 30–45 min and baked at 230 °C for 30 min.

Indian Peninsula

Wheat-Based Products

Bhatura

Bhatura, a deep-fried Indian bread, is soft and fluffy and is often enjoyed with chole (chickpea curry), making the dish 'chole bhature.' The ingredients required are maida, yogurt, ghee or oil, and yeast. The lactic acid in the yogurt reacts with baking soda to make dough light and rise (6 h). The dough, once kneaded well, is left to increase in volume. Small balls of this dough are then sheeted either by hand or using a rolling pin. Then they are deep fried (175 °C) for about 40 s until they turn into puffed, light brown, elastic, chewy, and soft fluffy bread.

Chapati

Chapati is a single-layered, unleavened Indian traditional flat bread. Usually whole wheat flour is used for chapati preparation, but sometimes yeast and fat are also included in the formulation to improve the dough handling, mixing, and textural properties. It is usually consumed immediately after preparation. Wheat flour, salt, oil, and an appropriate amount of water are the basic requirements in the formulation thereof. Chapati is prepared by mixing flour with water and other ingredients for development of dough, sheeted, and baked for a short time on a hot pan. Chapatis are prepared generally in a circular shape of about 15 cm diameter and 0.2 cm thickness.

Khakhra

Khakhras, generally served as breakfast, are thin crackers made from mat bean, wheat flour, and oil. Khakhras are hand-made and roasted snacks. They are delicious, crunchy, and healthy and can be enjoyed with pickles and chutneys.

Kulcha

Kulcha is a typical North Indian leavened bread prepared with refined wheat flour. Various ingredients such as wheat flour dough, mashed potatoes, onion, and lots of spices are rolled into a flat round bread and then baked in a tandoor until it turns golden brown. After baking, it is smeared with butter and then enjoyed with spicy chole. Dough is prepared by adding salt, sugar, oil, curds, and yeast to a flour and mixed using hot water. Kneaded dough is covered by a damp cloth and incubated in a warm place for 2 h. Then the dough ball is rolled into flat circular kulchas and baked on a pan with small quantity of butter/oil on its surface.

Litti/baati

Litti/baati is a traditional staple food of the Bihar state of India. Litti is a variation of baati and is stuffed with sattu, flour made of roasted Bengal gram dal. Being high in nutrients and fiber, sattu litti is an ideal power brunch food for field workers and is served with chokha made of boiled potatoes, roasted brinjal, and ghee.

Sattu flour is known for its cooling effects, is considered a must-have food during summers, and is relished in form of littis, parantha, laddoos, and drink. Another peculiar feature of this platter is the extensive use of mustard oil. The aroma and the slightly pungent taste provided by mustard oil gives an interesting flavor to the dish. Litti is traditionally baked over cow dung cakes in villages, but can be baked in gas tandoor or electric ovens as well.

Naan

Naan is a traditional Indian leavened flat bread, made from maida, enriched with yogurt, and baked in a tandoor. A variety of naan is available in the market, for example, Peshwari naan (filled with nuts and raisins), Kema naan (stuffed with minced meat), or Kashmiri naan. It is relatively more nutritious than chapati and roti, due to milk, curd (yogurt), and egg in its formulation.

Parotha

Parotha is a typical Indian flat bread. The main ingredients are wheat flour, water, oil, and salt, whereas sugar and egg are optional ingredients. Two types of Parotha are generally prepared in India: South Indian Parotha and North Indian Parotha, differing in extraction rate of flour. South Indian parotha is multilayered, circular-shaped, creamish white-colored flat bread made from refined wheat flour (maida). In south India, parotha is one of the staple food items. It is also called Kerala parotha, Ceylon parotha, or simply parotha. It possesses light brown spots on the surface. Soft pliable handfeel, soft and slightly chewy texture with distinct layers, optimum oiliness, easy breakdown in the mouth, and pleasant taste and aroma are the characteristics of a good-quality parotha. In north India various types of parotha are prepared by stuffing with potato, cauliflower, and so on. A special type of parotha, that is, Lachcha Parotha is very famous in north India.

Poori

Poori is close to chapati in terms of consumption. It is an unleavened flat bread prepared in many of the countries in South Asia including India, Pakistan, and Bangladesh. It is consumed for breakfast or as a snack or light meal. It is an unleavened traditional deep-fried product (oil content 28–30%) of India, prepared from whole wheat flour dough. Wheat flour dough is sheeted to a circular shape of about 10–12 cm diameter and 0.1–0.3 cm thickness and then deep-fried in vegetable oil to a soft pliable texture with typical aroma. Due to its high oil content it has limited use for calorie conscious people.

As poori cannot be made from any cereal/pulse flours other than wheat, in many regions of the world it is prepared from blends of imported wheat flour and locally grown maize (*Zea mays* L.), jowar (*Sorghum vulgare* Pers.), and Bengal gram (*Cicerarietinum* L.). The possibilities of using composite flours for poori making have been studied. Incorporation of maize, Bengal gram, and jowar flours to whole wheat flour (atta) at 10%, 15%, and 20% levels, respectively, yielded fully puffed pooris with a very good rating. Texture of pooris containing up to 20% of Bengal gram flour had better texture than those containing maize or jowar flour. Pooris of good overall acceptability could be obtained from composite flours based on atta incorporated with maize/jowar flours at the 15% level and Bengal gram flour at the 20% level.

Tandoori roti

Tandoori roti is also an unleavened single-layered flat bread similar to chapati. Its preparation is also similar to chapati. The flour is mixed with water, shortening, salt, sourdough, or yeast and then sheeted and baked in a tandoor. It is creamish brown to brown in color. The tandoor is an oval in-ground oven, the walls of which are plastered with clay. Wood or natural gas is burned to heat the tandoor. With the help of a cloth pad, the sheeted dough is placed on the heated walls of the tandoor. The roti takes 60–90 s for baking depending upon the heat in the tandoor.

Non-Wheat-Based Products

Bhakri

Bhakri is made primarily with sorghum flour, water, and oil. It is sometimes made with suitable blend of wheat flour. This is also a flat and unleavened bread.

Dosa or dosai

Dosa is a crispy fermented crepe or savory pancake originated from South India. It is made from rice, black gram, and salt. A mixture of rice and black gram that has been soaked in water is ground finely to form a batter. The proportion of rice to black gram is basically 4:1 or 5:1. The batter is allowed to ferment overnight. A thin layer of the batter is then spread evenly onto a hot greased tava (griddle). A crisp pancake is formed. A dosai is served hot, either folded in half or rolled like a wrap, usually with aloo curry, chutney, or sambar.

Pappad

Pappad is a thin and crispy Indian cuisine sometimes described as a cracker or flat bread. It is served as an accompaniment to a meal in India. Pappad is also used as an appetizer or a snack and can be enjoyed with various toppings, such as chopped onions, chutney, or other dips and condiments.

Mediterranean/Middle East

Aish Mehahra

Aish Mehahra is a product of Egypt. It is made with ground fenugreek seeds (5–10%) and maize.

Baladi

Baladi is also a product of Egyptian origin. It is a pocket bread and is used as kebab wrap, sandwich bread, or as a spoon. Wheat flour and whole wheat flour are used to prepare traditional Egyptian pita bread Aash Makamar and Aash Baladi, respectively.

Barbari Bread

Barbari is an Iranian/Persian flat bread. Hazara migrants, referred to by Iranians as 'Barbars' brought it to Iran in the nineteenth century. This is most commonly baked in Afghanistan.

Bazlama

Bazlama is a product of Turkey and Middle East countries. It is a single-layered leavened flat bread having a creamy yellow color and circular shape with an average thickness of 3 cm and diameters ranging from 10 to 20 cm.

Lavash

Lavash is a fermented single-layered flat bread of Armenia. It is formed in an elliptical shape, 20–30 cm long, 10–20 cm wide, and 0.3–0.5 cm thick. The ingredients required are flour, salt, water, and baker's yeast. All the ingredients are mixed and kneaded into a fully developed dough and allowed to ferment for 30–60 min at 30 °C. The dough is then weighed, divided, rounded, and final proofed for 15–20 min at 30 °C and then sheeted. Baking is done at a temperature of 320 °C for 15–40 min in an oven.

Matzo

Matzo is a very thin bread of Israel having a cracker-like texture.

Pide

Pide, mostly consumed in the holy month of Ramadan, is a circular flat bread made of leavened dough of slight viscosity. It has a thickness of 1.5–2 cm and a diameter of 20–25 cm. The ingredients required for Pide production are flour, salt, water, shortening, sugar, baker's yeast, and some additives. Pide resembles Iranian barbari and Indian tandoori naan bread. The ingredients are mixed and kneaded for 15–20 min to obtain homogenous dough. The dough is fermented for 40–50 min at 30 °C, then divided in an appropriate weight and rounded. The dough is sheeted, and final proofing is done for 30–40 min at 30 °C. Baking is done at a temperature of 320 °C for 18 min in the oven.

Pita

Pita, also Pitta, breads, also called Arabic bread, balady, shamy, Syrian bread, and pocket bread, are circular, leavened double-layered flat breads that originated in the Middle East. It is prepared with flour, water, baker's yeast, and salt. All the ingredients are mixed into a fully developed dough with a temperature of 24.5–25.5 °C and fermented for about 1 h. The dough is then rounded and intermediately proofed for 15–20 min. Sheeting is done, and then final proofing is given for 30 min at 30 °C and 95% RH. Then baking is done in a hot hearth oven at 370–500 °C. Top and bottom crusts are formed instantaneously as the loaves are exposed to such a high temperature. Subsequently heat penetrates the interior of the loaf and transforms the interior moisture into steam within some 30–45 s. Steam expands the loaf into a puffed-up form. Thus the baking creates the voids in the interior upon cooling.

Sangak

Sangak is single-layered leavened flat bread of Iranian origin. Sangak is usually prepared as 70–80 cm long, 40–50 cm wide, and 0.3–0.5 cm thick. There are indented blisters on the bottom crust. The top crust contains small blisters and is sprinkled with sesame or poppy seeds. The ingredients required for preparation are flour, water, sourdough, and salt that are mixed and fermented for 2 h. A portion of the dough (500 g) is sheeted, docked, and transferred onto the hot pebbles of the oven. The temperature of pebbles is kept between 350 and 500 °C, and the baking time required is 2–4 min.

Taftoon

Taftoon, also known as Tanoor bread, is a leavened single-layered and docked flat bread. Docking avoids pocket formation during baking. It is popular in the southwestern part of Iran. The ingredients required are flour, active dry yeast, salt, and water. Taftoon preparation involves mixing, dividing, proofing, sheeting, docking, baking, and packaging. Crust color becomes reddish brown. High-quality tanoor is of uniform thickness with an even distribution of small blisters on the top crust.

Yufka

Yufka is a Turkish unleavened single-layered flat bread. It is circular, cream-colored, 1–2 mm in thickness, 4–5 cm in diameter. The flour is mixed with water, salt, a little vinegar or lemon juice, and very little olive oil and then kneaded. The dough is divided, rounded, and then baked on both sides on a hot plate for a shorter time about 15–30 s.

North America

Pancake

A pancake is a thin, flat cake often round prepared from a batter and cooked on a hot griddle or frying pan. Some use a yeast-raised or fermented batter to make pancakes. Most pancakes are cooked one side on a pan and flipped to cook the other side.

Southeast Asia

Khanombuang

Khanombuang is a product of Thailand made with rice flour. Khanombuang are usually first topped or filled with coconut cream, followed by sweet or savory toppings such as shredded coconut, or egg yolks, or chopped scallions. They are thin and crispy with a juicy interior.

Roti Canai

Roti canai is circular flat bread prepared in Malaysia. It is known as roti prata in Southern Malaysia and Singapore and is similar to the Indian Kerala porotta.

Various chapati products are depicted from Figures 1–3.

Ingredients Required for Preparation of Flat Breads

Quality of used raw materials as well as bread making methods affect the quality of bread. The desired quality of bread is a good digestibility, a delicious and fine aroma, and no easily crumbling or staling characteristics. The basic ingredients are flour, water, salt (sodium chloride), and naturally fermented starter dough with either baking powder or baker's yeast. In addition, sugar, butter, vegetable shortening, or nonfat dry milk may be added to enhance taste and aroma.

Flour

Flour is the basic ingredient in a flat bread recipe as it affects the texture and sensory properties. The quality characteristics of chapati depend on the quality of wheat used and the processing conditions given to convert it into whole-flour. Flours of different extraction rates give different bread types with colors varying from creamy white to pale brown. Total protein content is the most important character of wheat flour that affects the bread quality. Flat breads such as lavash, taftoon, barbari, and sangak are generally produced from soft white wheat flours. It has been observed that the quality of flat bread is

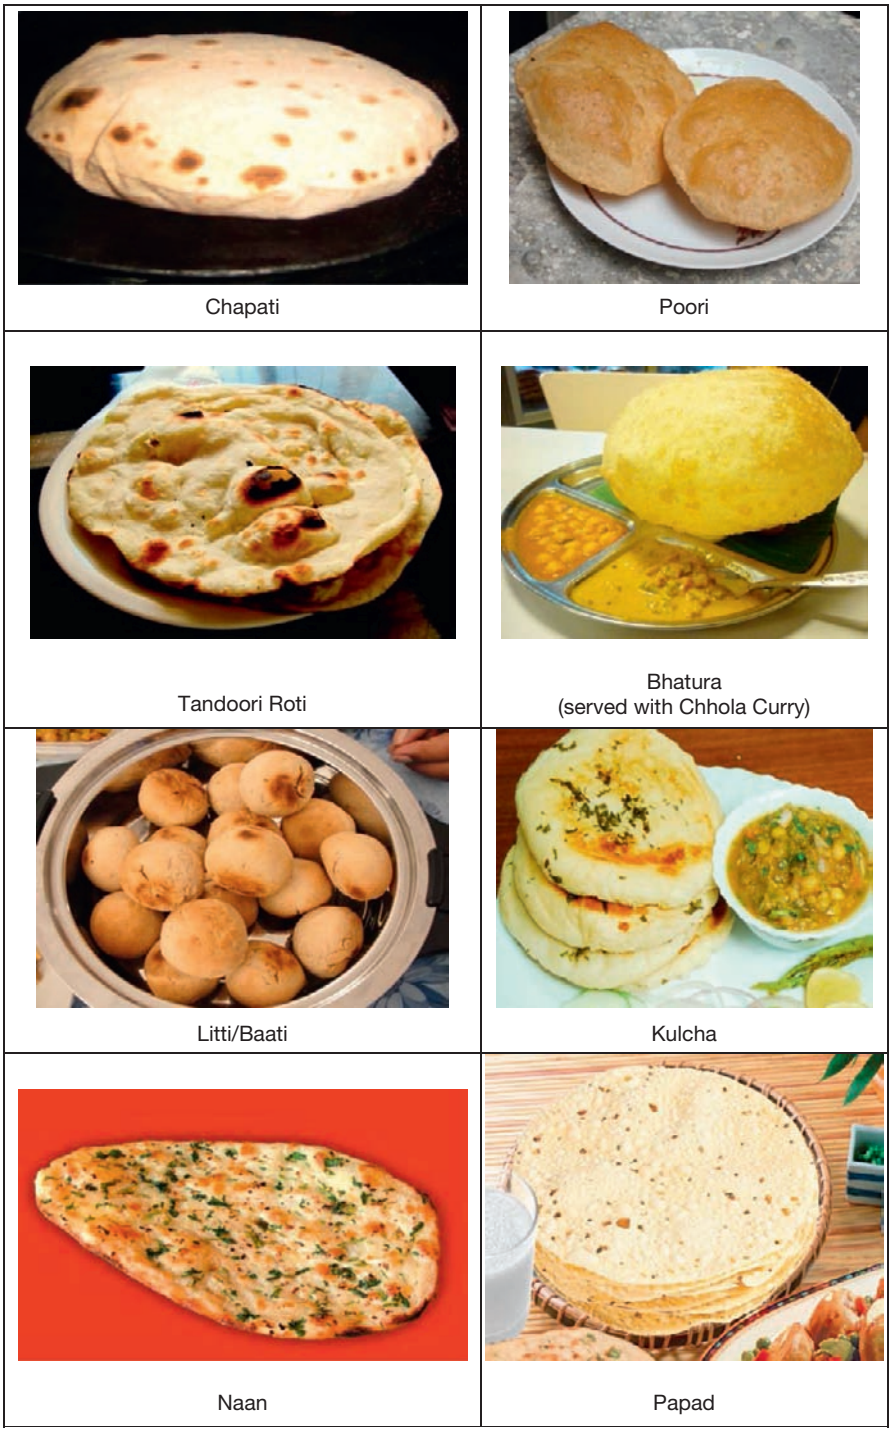

Figure 1 Various flat breads of Indian subcontinent.

(Continued)

superior when made with hard wheat flour associated with medium gluten strength, high starch damage, higher water absorption capacity, and good mixing and sheeting properties. The addition of durum wheat flour and Indian wheat flour raises the quality in chapati production. Wheat varieties with higher levels of lipids give chapatis with a softer texture.

Water

Water is a basic component that helps to get a homogeneous mixture of other ingredients and provides a desired viscoelastic structure to dough. Water helps dissolving hydrophilic components such as salt, sugar, and insoluble proteins and forms

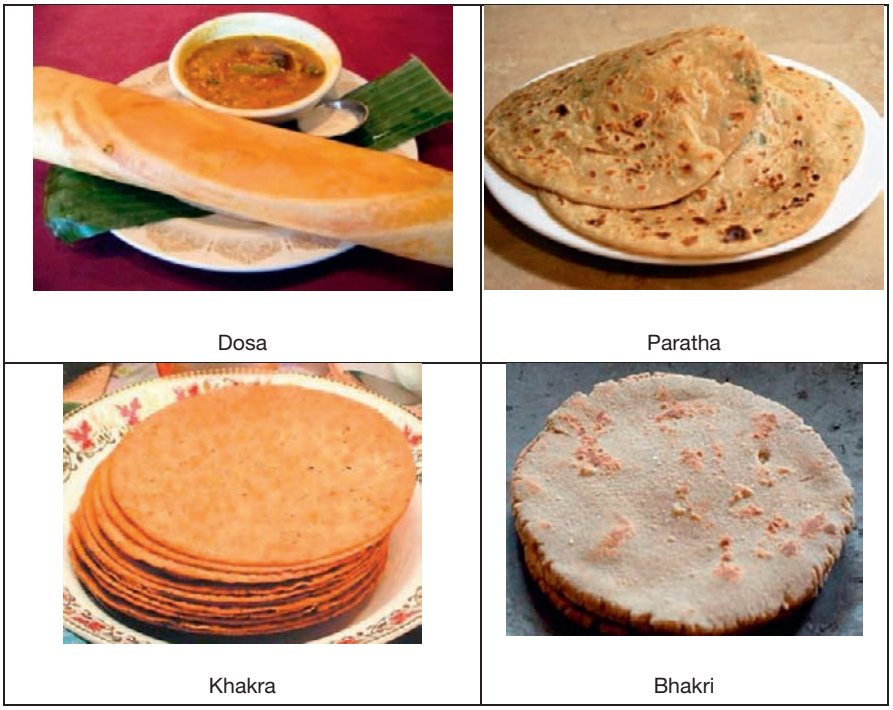

Figure 1 (Continued)

gluten by hydrating insoluble proteins in water. The amount of water used during flat bread production depends on the type of flour and bread. Approximately 50% water results in finely textured, light flat bread. Some artisan bread formulas contain from 60% to 75%. In yeast-leavened flat breads, the higher water absorption results in more carbon dioxide bubbles and a coarse bread structure. The addition of bran to the flour influences its water-absorbing capacity as it contains pentosans that have a high ability to absorb water.

Salt

Salt is an important ingredient in bread making. Use of salt in appropriate quantity is required to get a high bread quality. It should have a high solubility level in water and should be physically clean, bright, and white. Salt is mainly used for flavor and taste enhancement in flat bread production. The normal range of salt addition is about 0.5–3% of flour weight. Without salt, the weak flours make wet doughs, therefore the addition of salt improves the strength of proteins and gives good texture and better loaf volume and controls the action of yeast for optimum leavening of dough.

Baker's Yeast or Sourdough

Flat breads may be leavened or unleavened. The fermentation or rising of dough is due to leavening agents like yeast, sourdough, and baking soda. The leavening agent generates gas (CO_2) within the liquid phase that leavens the dough. Baker's yeast helps forming aroma, maturing dough by fermentation of some fermentable carbohydrates available in dough, and rising dough by formation of carbon dioxide.

Sourdough is also used for flat bread fermentation. Sourdough is a piece of dough saved from the previous batch that is then mixed with flour, salt, and water to produce bread. Sourdough is a complex biological system having a dynamic interaction among endogenous lactic acid bacteria and yeasts. Sourdough fermentation improves texture and palatability of whole grain, fiber-rich or gluten-free products, stabilizes or increases levels of various bioactive compounds, retard starch bioavalibility, and improves mineral bioavailability.

Baking powder is the most widely used leavening agent in flat bread production due to its low cost. Utilization of baking soda acts as a leaving agent and can change the color and flavor of bread.

Utilization of Composite Flours in Chapati/Flat Bread Making

Cereal flours other than wheat or starchy materials can also be used for chapati making if wheat flour is not available in sufficient amount or is an expensive imported material. Sweet potato has been used in Kenya for chapati making partially replacing wheat flour Protein content and nutritive value of wheat flour products can be improved by using flours from other cereals or legumes. For example, soy flour has been incorporated in chapatis to improve nutritional quality. Barley flour and germinated wheat flour have been incorporated in wheat flour to yield acceptable chapatis. Researchers have studied organoleptic acceptability of chapatis made from a combination of durum and aestivum wheat supplemented at different levels with Bengal gram flour and soy protein concentrate. The nutritional quality of chapati has been improved by the addition of soy flour or rice bean flour to wheat flour. Triticale could be blended with wheat at a level of 50% to make chapatis. Various oilseed flours (cotton seed, mustard, and

sunflower seed flours) can be/are also added with whole wheat flour for chapati making. Oilseed flours, because of their high contents of protein and essential amino acids, especially lysine, significantly improve the quality of wheat flour. Flaxseed and linseed flours have been incorporated in wheat flour to prepare omega-3 rich chapatis. Rice bran addition in wheat flour up to 20% is acceptable for increasing the dietary fiber content of chapati.

Addition of Green Leafy Vegetables in Chapati to Fortify Micronutrients

Wheat flour is a staple food for half of the world's population, it nevertheless does not guarantee a balanced diet, as it lacks micronutrients. Balanced diets are not available to a large population of the world, particularly those in developing countries, where multiple micronutrient deficiencies are more common than single deficiencies due to poor consumption and poor bioavailability of micronutrients. To tackle this issue, traditional flat breads like chapati/parotha are prepared by incorporating green leafy vegetables to enhance the nutritive value. Green leafy vegetables have been used as valuable additives for different products as they are inexpensive, easily available, and quickly cookable products. Hence, they can be used to overcome the deficiencies prevalent in vulnerable groups of socioeconomic classes. Some studies report that when chapatis are added with spinach, their shelf-life is extended up to 12 months by using an antimycotic agent like sorbic acid, in pack-sterilization, and storing them in PFP packaging materials. Curry leaves can also be incorporated in chapatis and up to a 10% addition of curry leaf powder is found acceptable. Moreover, when chapatis is fortified with curry leaf powder, calcium and carotene content increases. Less-utilized leaves of beet root (*Beta vulgaris* L.), carrot (*Daucuscarota* L.), cauliflower (*Brassica oleracea* L.), and turnip (*Brassica rapa* L.) can also be used in flat breads. Leaf mixture addition is accepted up to 10% in missi roti and dosa, and it significantly increases calcium and iron content in the products. Dried leaves of bathua (*Chenopodium album* L.) are added in paratha, and the results show that the carotene and iron content increases in the product.

Changes in Chapati During Storage and Their Prevention

The desired sensory quality characteristics of chapati are greater pliability, soft texture, light creamish brown color, slight chewiness, and baked wheat aroma. Freshly baked flat breads are soft and elastic. When kept at room temperature, chapati becomes stale within a few hours, and the texture becomes hard and tough. The shelf-life of freshly baked chapaties is 24–36 h, and due to mold growth, ropiness, and texture deterioration depending upon storage conditions, it becomes unsuitable for consumption. Various attempts have been made to preserve chapatis for more than 6 months with the use of antimycotic agents like propionic acid, sorbic acid, and other ingredients. However, during storage the chapatis develop a slight bitter taste due to preservatives. Recently, long shelf-life chapatis were developed by lowering the concentration of sorbic acid in combination with the biopreservative nisin. Highly acceptable no-preservative chapatis can be prepared through a thermal process at a F_0 value of 3.0. The product remained stable and highly acceptable even after a storage period of 12 months under ambient temperature (14–35 °C) conditions. Development of a retort pouch has enabled the preservation of traditional products like chapattis for long-term storage and increased their commercial scope and viability.

Automation in Chapati Making

Chapati making is not only a household practice. It is being done at a large scale in hotels, hostels, *Gurudwaras*, and so on. Hence there is a need of an automated chapati making plant. A chapati making machine developed at the Central Food Technological Research Institute, Mysore, for defense canteens and hotels is a fine example. It comprises two units: (a) chapati sheeting and (b) chapati baking. This machine is useful to prepare chapati on a large scale (at a commercial level). A traditional chapati maker, made up of iron and marble (Figure 4), is also available in the market. Automated baking and sheeting machines are also available in the market, and they reduce the chapati making time (Figures 5 and 6).

Scientific Interventions in Chapati Making

Various researchers have given their contribution in the field of flat bread making. Some important findings are as follows:

1. Partially baked chapati shows better retention of quality as compared to fully baked ones during storage at ambient and frozen conditions.
2. Flour extraction rates, fermentation times, and baking conditions directly affect the bioavailability of magnesium in flat breads.
3. Shortening and sodium stearoyl-2-lactylate (SSL) are of great help in retarding the staling of flat breads.
4. A molder was designed to produce flat breads with a variation of 0.01 mm to get consistent thickness flat bread, being thickness a major bread quality.
5. High alpha amylase flours are better in continuous production of flat breads by direct extrusion cooking.
6. Flour with 11–13% protein and 85% extraction was best suited for the production of tandoor bread.
7. Storage quality of flat breads made with different types of wheat can be improved by adding SSL (0.5%) and calcium propionate (0.5%). Shelf life can be extended up to 8 days at room temperature.
8. Durum is not a suitable variety for making good-quality flat breads or chapatis.
9. Guar gum increases the softness, extensibility, and other sensory attributes in fresh bread. Though extensibility and softness reduce significantly during storage at room temperature, refrigerated chapati containing guar gum shows less loss in extensibility up to a period of 2 days.
10. Proteinase and xylanase improve the quality of parotha by modifying rheological properties of the dough, glucose oxidase reduces the spread ratio, fungal alpha amylase produces a fragile bread lacking typical chewiness.
11. High-protein flours with wet gluten, high sedimentation value, and increased particle size give better-quality Iranian breads.
12. Gluten and oxidizing chemicals like ascorbic acid or potassium bromated increase extensibility and viscosity, compressive hardness and cohesiveness while reducing agents decrease them, and increase dough adhesiveness.
13. Moisture content, *in vitro* enzyme digestibility, and water-soluble starch decrease steadily during the storage at room temperature and at refrigerated temperature. Refrigerated temperature slows the rate of staling, but the texture of the chapatis becomes progressively harder at both room and refrigerated temperatures.

Figure 4 Roti maker.

Figure 5 Continuous baking machine.

Conclusion

Chapati and other related flat breads are used as staple diet of a major segment of population globally. It is a source of macro- as well as micronutrients. The preparation and formulation of flat bread varies with country and community. Various other cereals as well as oil seed and legume flours can be added to the main ingredient of chapati, that is, wheat flour to enhance its

Figure 6 Continuous sheeting machine.

nutritional value. Automation has also being done in chapati and related flat bread product preparation.

Introduction

Milk has an average composition that varies depending on the species (human, cow, goat, and buffalo; see Table 1), the breed, the animal's feed, and the stage of lactation. In cheesemaking, the curds obtained after coagulation of milk will usually undergo significant modifications (Figure 1), depending on the type of cheese. Said modifications are caused by the specific technological procedures, which influence the activity of the microbial flora present throughout the cheese processing, and the enzymes native or added to milk. All together, these factors lead to the final product – cheese – that has a chemical composition quite different from milk (Table 2).

However, for simplification, those transformations may be considered essentially caused by three chemical reactions – proteolysis, lipolysis, and glycolysis – acting on milk major components: proteins, fats (lipids), and sugar (lactose).

Protein and Proteolysis in Cheese

Proteins are chains of amino acid molecules connected by peptide bonds (Figure 2). There are many types of proteins, and each has its own amino acid sequence (typically containing hundreds of amino acids). There are 22 different amino acids of which nine are essential (they cannot be made by the human body), and they can combine to form protein chains.

The amino acids within protein chains can bond across the chain and fold to form three-dimensional structures. Proteins can be relatively straight or form tightly compacted globules or be somewhere in between. The term 'denatured' is used when proteins unfold from their native chain or globular shape, due to a physical (heat), chemical (acids), or enzymatic (rennet) action.

On average, cow's milk contains 3.3% total protein. Milk proteins contain all nine essential amino acids required by humans. The milk proteins can be divided into two main groups: the casein family that contains phosphorus and will coagulate or precipitate at pH 4.6 and the serum (whey) proteins that do not contain phosphorus and remain in solution in milk at pH 4.6. The principle of coagulation, or curd formation, at reduced pH is the basis for cheese curd formation. In cow's milk, approximately 82% of milk protein is casein and the remaining 18% is serum or whey protein.

The casein family of protein consists of several types of caseins (α, β, κ), and each has its own amino acid composition, genetic variations, and functional properties. The caseins are suspended in milk in a complex called a micelle (see Figure 3). The high phosphate content of the casein family allows it to associate with calcium and form calcium phosphate salts. In cheese manufacture, casein is cleaved between certain amino acids, and this results in a fragmented protein, which will precipitate.

The behavior of the different types of caseins (α, β, κ) in milk when treated with heat, different pH (acidity), and different salt concentrations provides the characteristics of cheeses. The serum (whey) protein family consists of approximately 50% ß-lactoglobulin, 20% α-lactalbumin, blood serum albumin, immunoglobulins, lactoferrin, transferrin, and many minor proteins and enzymes. Like the other major milk components, each whey protein has its own characteristic composition and variations.

Degradation of proteins in cheesemaking occurs essentially by means of enzymes (proteases) coming from several sources: the native milk, airborne bacterial contamination, enzymes or bacteria that are added intentionally, and somatic cells present in milk. Casein proteolysis in cheesemaking starts when rennet (mainly chymosin) is added to milk and the enzyme acts on casein causing the aggregation of casein micelle, which will precipitate (coagulate). Because this enzyme is acidic (its activity is optimized in acidic environment), a starter culture is previously added to milk so to cause a slight, but important, pH lowering. Afterward and during cheese ripening, proteolysis occurs by the action of enzymes native to milk (plasmin) or released by lactic acid bacteria from the starter culture, leading to the formation of smaller fractions such as peptides or even amino acids (Figure 4).

The degree of breakdown of proteins in a cheese can be followed via the analytic method called electrophoresis as shown in Figure 5. The bands in each column represent proteins, polypeptides, or peptides, whose size is more or less inversely proportional to their distance of migration, from top to the bottom of the column. Peptides released during cheese proteolysis have a key role in the development of cheese taste, and a few may also exert specific bioactive or physiological effects such as opioid, antihypertensive, immunomodulatory, and antimicrobial.

Lipids and Lipolysis in Cheese

Fats are made from individual fatty acid molecules attached to glycerol, a three-carbon backbone. The most common type of fat is called a triglyceride, which contains three fatty acids attached to the backbone. Because there are many different fatty acids that can be attached to the backbone (see Figure 6), there are many different types of triglycerides or fats. Fatty acids may be saturated, which means that each carbon has a single bond to another carbon and two hydrogen atoms, or fatty acids may be unsaturated, which means that a carbon has two bonds to the adjacent carbon, called a double bond, and a single bond to another carbon and a hydrogen atom.

Other fatty compounds include phospholipids, which make up approximately 1% of the fat in milk.

Milk contains approximately 3.4% total fat, and cheeses will have an average ten times more fat than milk. Milk fat contains approximately 65% saturated, 30% monounsaturated, and 5% polyunsaturated fatty acids; thus, cheese is a high-caloric food also containing high levels of saturated fatty acids (butyric, myristic, palmitic, and stearic acids), which,

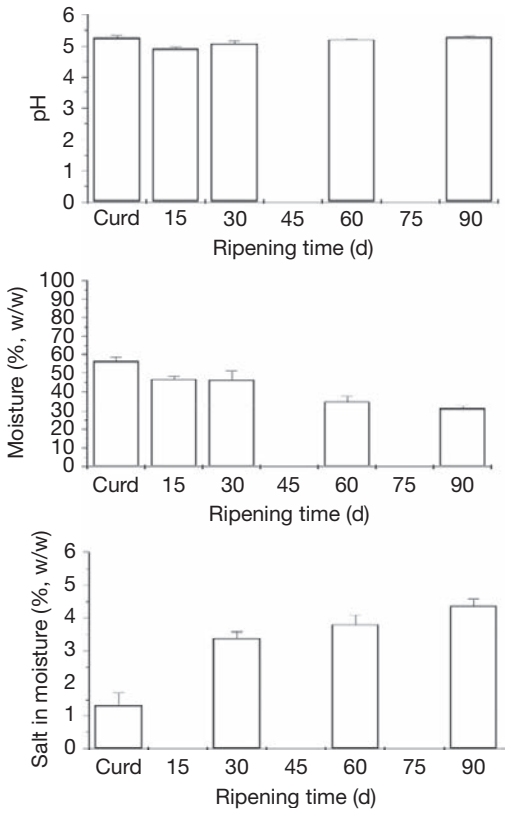

Figure 1 Evolution of physicochemical parameters of an experimental cheese (average ± standard deviation) throughout ripening.

Table 2 Composition (average ± standard deviation, $n = 4$) of São Jorge cheese by 90, 120, and 210 days of ripening

Ripening time (days)	*Parameters*		
	Moisture (%)	*Fat content (%)*	*pH*
90	36.19 ± 0.93^a	34.5 ± 0.4^a	5.27 ± 0.09^a
120	36.78 ± 0.66^a	32.5 ± 0.3^b	5.43 ± 0.04^b
210	36.63 ± 1.29^a	32.0 ± 0.6^b	5.36 ± 0.03^b

Different letters represent means with statistical differences for $p < 0.05$.

when consumed in excess may contribute to onset of high blood cholesterol and associated diseases. The conjugated linoleic acid (CLA) is a *trans*-fatty acid present in milk and cheese that is beneficial to humans in many ways. The biological properties of dietary CLA are attracting considerable interest because studies suggest that it may have a powerful anticarcinogenic, immunomodulating, growth-promoting, lean body mass-enhancing, and antidiabetic properties.

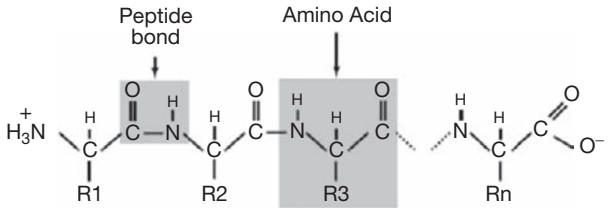

Figure 2 Structure of proteins (R1, R2, etc. are radicals specific to each amino acid. The number of amino acids in the caseins of milk varies from 199 to 209).

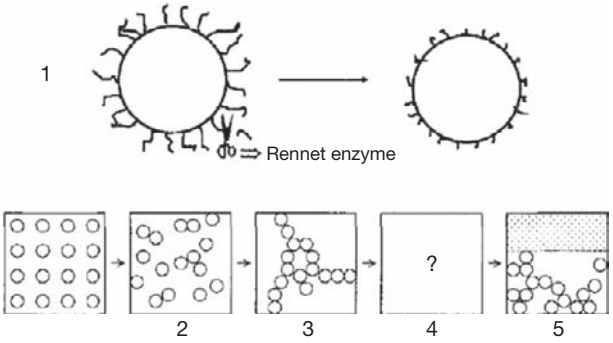

Figure 3 Model sequence of casein micelles changes during gelation by action of rennet leading to precipitation (coagulation) of casein.

The contents of CLA in cow's raw milk may vary from 0.2% to 3.7% of total milk fat, and it is established that dairy products derived from ruminants fed predominately on pasture are richer in CLA. Cheeses are thus considered important sources of CLA, with typical content values varying between 8 and 18 mg g^{-1} of fat.

Lipolysis (degradation of fats by enzymes called lipases) is crucial in the development of cheese aroma and taste. Throughout ripening, lipases transform the milk fat into short-chain fatty acids that may be volatile. The type of the starter culture, the length of the ripening period, and the conditions prevailing are important in defining the rate and type of lipolysis.

Sugar and Fermentation (Glycolysis)

The principal carbohydrate in milk is lactose (Figure 7). The concentration of lactose in cow's milk is relatively constant and averages about 5%.

Glycolysis or fermentation is the chemical reaction by which milk sugar (lactose) is transformed by the microflora into lactic acid and energy and other components.

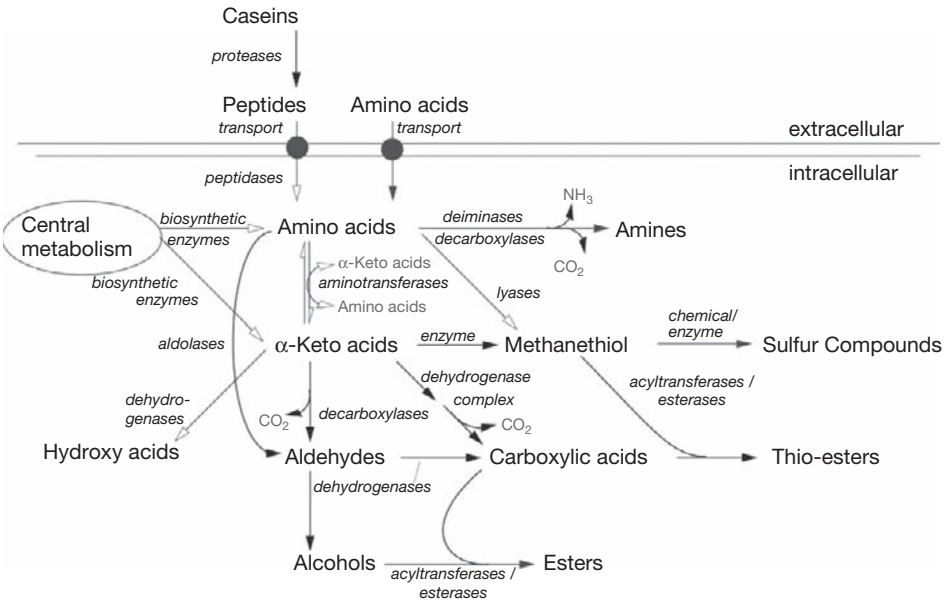

Figure 4 General pathways leading to intracellular metabolites and their degradation routes to potential flavor compounds. More specifically, pathways from methionine to flavor compounds (methanethiol, thioesters, and sulfur compounds) are shown. Adapted from Kranenburg, R., Kleerebezem, M., Vlieg, J. H., et al. (2002). Figure 6 Chemical structure of a saturated (left) fatty acid and unsaturated (right) fatty acid.

The accumulation of lactic acid leads to the lowering of the pH of the curd, thus making it inhospitable for many unwanted bacteria and helping in syneresis (whey release). The amount of lactic acid released depends on the starter culture type and on the technological specificities used in the cheesemaking. Long-ripened cheeses may be depleted of lactose making them suitable for consumption by lactose-intolerant consumers.

Cheese Microbiology

Cheesemaking is based on the application of LAB in the form of defined or undefined starter cultures that are expected to cause a rapid acidification of milk through the production of lactic acid, with the consequent decrease in pH, thus affecting a

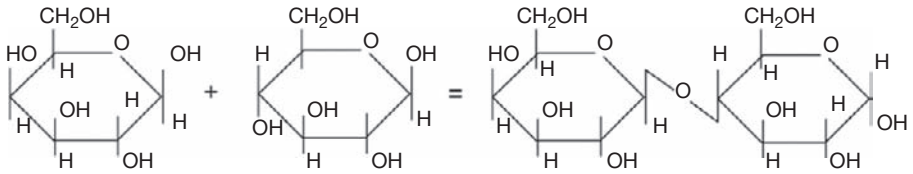

Figure 7 Lactose structure made of one molecule of glucose and one molecule of galactose.

number of aspects of the cheese manufacturing process and ultimately cheese composition and quality.

The LAB or non-LAB microflora of cheese may originate from three main sources: strains present in milk, those of the starter culture added, and those from adventitious 'in-house' contamination. While in industrial cheeses, bacteria from the starter culture will dominate from early manufacture to late ripening, traditional cheeses usually owe their typical flavors to the presence of microorganisms from (raw) milk and from 'in-house' contamination; in this case, cheeses obtained from distinct milk batches and farms will likely exhibit different viable numbers of several species. Although several species have been identified in various research works, the groups described in the succeeding text are those most frequently found in traditional cheesemaking.

Lactic Acid Bacteria

LAB are the most important group of microorganisms in milk and most dairy products. Species identified in cheese may be homofermentative, such as lactococci, or heterofermentative, such as lactobacilli. Distinct groups of LAB show different degrees of proteolytic activity in cheese, but their main role apparently is the formation of aminic and ammoniacal nitrogen, by degrading peptides and metabolizing amino acids – hence playing a complementary role to rennet in milk protein degradation throughout the whole manufacture process of cheese. The main bacteria associated to cheese and other dairy products are shown in Table 3.

The earliest productions of cheeses were based on the spontaneous fermentation, resulting from the development of the microflora naturally present in the raw milk and its environment. The quality of the end product was a reflex of the microbial load and spectrum of the raw material. Spontaneous fermentation was later optimized through backslopping, that is, inoculation of the raw material with a small quantity of whey from a previously performed successful fermentation, and the resulting product characteristics depended on the best-adapted strain dominance. Today, backslopping is still used to produce many artisanal raw milk cheeses, that is, those bearing the PDO (Protected Designation of Origin) status. The starter culture applied in this so-called natural fermentation is usually a poorly known microflora mix that, although having a predominance of LAB, may also contain non-LAB microorganisms, and its microbial diversity and load are usually variable over time.

Nonstarter Lactic Acid Bacteria, Yeasts, and Molds

As previously stated, the microbiology of a cheese, namely, those made from raw milk, is complex. Most cheeses will often be contaminate by LAB bacteria from the dairy environment (nonstarter lactic acid bacteria), which may also play a role in the development of the final cheese aroma, and by other groups such as enterococci, Enterobacteriaceae, micrococci, and molds and yeasts, the so-called in-house contaminants.

The wide variation in the dynamics of the species in association with the prevalent physical and chemical peculiarities of each cheese creates the diversity of aroma and taste among

Table 3 Main bacteria associated with cheeses or other fermented products

Species/subspecies	*Main uses/other comments*
Lactococcus

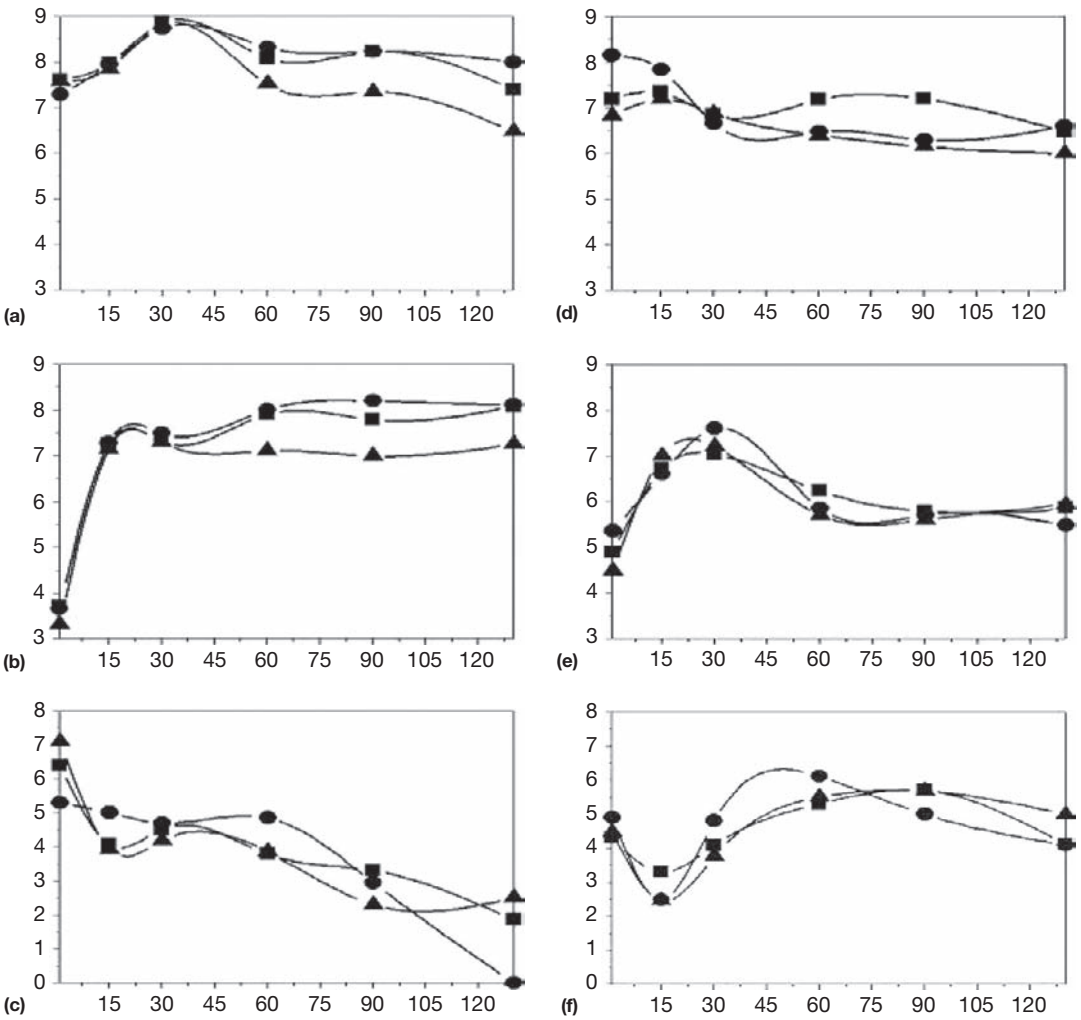

Figure 8 Evolution of viable numbers of the microflora in São Jorge cheeses from dairies A (■), B (●), and C (▲) by 1, 15, 30, 60, 90, and 130 days of ripening: (a) total mesophiles, (b) lactobacilli, (c) Enterobacteriaceae, (d) lactococci, (e) enterococci, and (f) yeasts and molds.

cheeses. Many strains isolated from raw milk cheeses were associated with the formation of more complex volatile profiles and higher scores for some sensory attributes. This, associated with a greater typical microflora biodiversity, makes raw milk cheeses more prone to developing more intense flavor than cheeses made from pasteurized milk.

Molds and yeasts are usually present in raw milk, and they do not survive pasteurization. Thus, unless the cheese is made from raw milk, its contamination with yeasts and molds is essentially caused by reinfection during manufacturing by yeasts and molds present in the environment of cheese factories, like walls and shelves of ripening rooms, air, equipment, water, milk, and brine. Yeasts can metabolize lactic acid in the cheese, causing the rise in pH and leading to the formation of the characteristic undesirable yeasty or fruity flavor and gas in cheeses. However, due the production of metabolites, for example, short-chain fatty acids and other compounds, some specific strains contribute to maturation and aroma formation.

The characteristic feature of some mold-ripened cheese types is extensive proteolysis and lipolysis, releasing peptides and fatty acids that contribute to the development of distinctive flavor and aroma, as in the case of Camembert cheese. Wild types of molds such as *Aspergillus flavus* may influence the organoleptic characteristics of cheeses or even produce mycotoxins that represent a potential health risk to the consumer. The most common molds found in raw milk cheeses belong to the genera *Geotrichum*, *Aspergillus*, *Mucor*, *Fusarium*, and *Penicillium*.

Finally, recall also that poor hygienic practices, inadequate pasteurization, or poor handling during processing may allow for accidental presence of pathogens such as *Bacillus cereus*, *Listeria monocytogenes*, *Salmonella* spp., *Escherichia coli* O157:H7, *Campylobacter jejuni*, and *Staphylococcus aureus* in cheeses.

Figure 8 shows the microflora dynamics throughout ripening of São Jorge raw milk cheese.

Introduction

Cheese is a dairy product strongly appreciated by consumers at large, not only due to the unusual complexity and variety of its sensory attributes but also owing to its outstanding nutritional value. Cheese constitutes an important dietary source of essential nutrients and health-promoting compounds, such as proteins, amino acids, bioactive peptides, lipids (e.g., polyunsaturated fatty acids (PUFAs), and conjugated linoleic acid (CLA) isomers), minerals, vitamins, and polyphenolic compounds. However, cheeses are also characterized by high contents of fat, saturated fatty acids (SFAs), *trans*-fatty acids (TFAs), cholesterol, and salt, features that have contributed to its negative health image, arising from the association between intake of these components and an increased risk of cardiovascular diseases. Due to this association, nutritional recommendations promote the reduction of cheese consumption, ignoring that such product may also be a good dietary source of beneficial nutrients. In fact, several studies suggest no or inverse relationship between cheese intake and the risk of cardiovascular disease. Moreover, dairy products including cheese potentially may have many other beneficial physiological properties, such as anticariogenic, antihypertensive, and anticarcinogenic effects, as well as beneficial effect on bone health.

Cheese nutritional composition is determined by several factors, such as characteristics of milk used (which depend on numerous factors linked to the animal source, including species, breed, stage of lactation, physiological status, and diet) and the cheesemaking and the ripening conditions, resulting in a wide diversity of cheese types worldwide – each one with distinct and unique sensory and nutritional properties. Although the chemical composition of cheeses varies considerably, overall, they are composed mainly of fat, protein, vitamins, and minerals, which are retained in the curd during manufacture, and of relatively small amounts of water-soluble constituents (whey proteins, lactose, and water-soluble vitamins and minerals), once these milk components are lost in the whey. The proximate composition of some cheeses is shown in Table 1.

Fat and Cholesterol

Consumers are more aware of the relationship between diet and health, and the great consumer concern regarding to cheese intake is not only due to high levels of fat in some cheese types but also due to its fatty acid composition. The fat content of cheese is very variable, with some cheeses with very low levels of fat (e.g., the cottage cheese has <4 g per 100 g of fat), but most cheeses have between 20 and 40 g per 100 g of fat, which may even represent about 50% of the cheese weight (e.g., cream cheese) (Table 1). Fat constitutes an important source of energy and essential fatty acids in human diet, but on the other hand, its consumption has been claimed to increase the risk of cardiovascular diseases – particularly in the case of cheese fats rich in SFAs and TFAs.

Milk and dairy products are characterized by high contents of SFAs and TFAs and low levels of PUFAs, as the result of the extensive microbial metabolization of dietary lipid in the rumen, where the lipids are hydrolyzed and the released unsaturated fatty acids are biohydrogenated with the production of high level of SFAs, as well as TFAs. Cheese fat contains about 60–70% of SFAs, palmitic acid (16:0) being the most abundant SFA, followed by myristic (14:0) and stearic acids (18:0) (Table 2). Monounsaturated fatty acids (MUFAs) represent 20–30% of total fatty acids in cheese, while only 4–6% of total fatty acids are PUFAs (Table 2). TFAs may represent about 5% of total fatty acids in cheeses (Table 2), being composed mainly of 18:1 *trans*-isomers. Vaccenic acid (18:1 *trans*-11) is the major 18:1 *trans*-isomer in ruminant-derived food products; however, under feeding systems based on the utilization of high levels of the concentrates, 18:1 *trans*-10 may become the major 18:1 *trans*-isomer.

Cheese constitutes an important source of fat in human diet, contributing significantly to SFA and TFA intake. Results on TFAs in foods in Europe – TRANSFAIR study – showed that in western Europe countries, cheese contributes between 3.0% and 14.0% of total fat intake, providing between 5.9% and 24% of total SFA intake and between 5.4% and 33.8% of total TFA intake. Consumption of SFAs and TFAs has been associated with deleterious effects on human health, such as increase of the cardiovascular disease risk. So, the present nutritional guidelines from WHO/FAO recommended that intake of SFAs and TFAs should not exceed 10% and 1% of total energy intake, respectively. However, individual SFAs and TFAs seem to have different biological effects that are not considered in nutritional recommendations. Overall, SFAs are known to increase the total and low-density lipoprotein (LDL) cholesterol; however, only lauric (12:0), myristic (14:0), and palmitic (16:0) acids seem to have a cholesterol-raising effect, whereas stearic acid (18:0) appears to have neutral cholesterolemic effect. Moreover, hypercholesterolemic SFAs seem to have distinct cholesterolemic effects, but the comparative effect among such SFAs is still inconsistent.

Trans-fatty acids are provided in human food by several sources but mainly by ruminant-derived foods and partially hydrogenated vegetable oils. The content and profile of the TFAs from each source are distinct, depending on the mechanism of their production. Contrary to what happens in ruminant fat that has as the main TFA vaccenic acid (18:1 *trans*-11), in partially hydrogenated vegetable oils, the TFA profile is characterized by higher diversity of the main TFAs. The results

on biological effects of TFAs from ruminant and industrial sources are still not completely clear. However, some studies suggest that the current levels of TFAs from ruminant origin consumed in diets do not contribute significantly to cardiovascular disease risk. Moreover, 18:1 *trans*-11 is considered as a beneficial TFA, once it is the precursor of endogenous synthesis of CLA in animals and humans.

The putative deleterious effect of milk and dairy products on health, particularly on cardiovascular diseases, has been the target of extensive researches, and recent epidemiological studies have shown that higher intake of milk and dairy products may not be detrimental to cardiovascular health and even contribute to cardiovascular disease risk reduction. Most of these evidences are related to milk, and only few studies evaluated the association between cheese consumption and cardiovascular disease risk. However, overall, these few studies suggest no association or inverse relationship between cheese intake and the risk of cardiovascular disease. The potential beneficial effects of cheese consumption on cardiovascular diseases may be due to several healthy nutrients present in cheeses, such as vitamins, minerals, bioactive peptides, and lipids, such as PUFAs and CLAs.

In recent years, CLAs have received much attention due to their potential beneficial properties to human health. CLA refers to a mixture of positional and geometric isomers of linoleic acid with a conjugated double-bond system. Several studies realized in animal models and cell cultures have shown that CLAs exhibit numerous beneficial physiological activities, including anticarcinogenic, antiobesitic, antiatherogenic, antidiabetogenic, immunomodulatory, and osteosynthetic effects. Ruminant fat is naturally rich in CLA, particularly in rumenic acid. However, the cheese content in CLA varies considerably, reflecting the CLA levels in the original milk, with CLA levels between 0.5 and 1.71 g per 100 g of total fatty acids (**Table 2**). Cheese constitutes an important dietary source of CLA in human diets, and in some countries, it is the major source of CLA, such as Portugal where it is estimated that cheese contributes to 40% of total CLA intake.

To meet the consumers' demand for healthy foods has led to the development of reduced- and low-fat and even fat-free cheeses. Nevertheless, fat is essential for the development and perception of the correct sensory characteristics of cheeses; it has been reported that fat removal leads to defective cheeses in terms of flavor, texture, and appearance. So, the uncharacteristic sensory properties of low-fat cheeses when compared with full-fat cheeses may compromise the popularity of such cheese type, since the consumers cannot be willing to sacrifice the

typical sensory perceptions associated with a particular cheese variety for a plain reduction of fat intake.

Changes of the cheese fatty acid profile, in order to reduce its saturation and increase the levels of beneficial unsaturated fatty acids, particularly $n-3$ PUFAs and CLAs, also have been extensively explored. The final content of fatty acids in cheese is mainly dependent on the fatty acid levels of the unprocessed milk, and the utilization of milk with improved fatty acid profile appears to be a good approach to manufacture cheeses with enhanced nutritional value. Milk fatty acid composition is determined by several animal intrinsic factors, like species, breed, genotype, lactation and pregnancy stages. In addition, the milk fat composition is largely dependent on the diet supplied to animals. Several studies show that there is opportunity to improve naturally the nutritional value of milk fat through changes of animal diet and nutritional strategies to increase the concentration of specific beneficial fatty acids in milk fat, which have been a major target in ruminant milk research. Utilization of diets based on fresh pasture and supplementation of diets with lipid sources rich in PUFAs has shown to be effective to improve the fatty acid profile of milk and dairy products, decreasing its content in SFAs and increasing beneficial fatty acids, including CLAs and $n-3$ PUFAs. Although the strategies for improving the milk fatty acid composition have been the goal of numerous studies, the effect of dairy products with modified fatty acid composition through manipulation of the animal diet on cardiovascular disease is little known. The current evidence is still insufficient, but a few studies show that intake of milk and dairy products with improved fatty acids composition via modulation of animal diets may have beneficial effect on cardiovascular risk in both healthy and hypercholesterolemic individuals.

Enrichment in $n-3$ PUFAs also has been experimentally attained by incorporation of lipid sources rich in $n-3$ PUFAs, such as fish and flaxseed oils, at different stages of cheesemaking. Moreover, *in vitro* studies have shown that several strains of food-grade microorganisms are able to convert linoleic acid (18:2 $n-6$) into CLA, and the enrichment of cheese with CLA by utilization of microbial cultures has been explored. Nevertheless, the utilization of CLA-producing microorganisms only has allowed a marginal CLA enrichment in cheese. Unlike fat removal, the enrichment of cheese with CLAs and $n-3$ PUFAs by animals' diet manipulation or by cheese fortification with low levels of lipids has minor effect on sensory characteristics of cheeses, resulting in cheeses with good acceptability by

consumers, demonstrating the feasibility of producing these cheeses with high nutritional value.

The cheese cholesterol content is consumers' concern regarding the consumption of cheese, due to generic association of dietary cholesterol to increase the total cholesterol and LDL cholesterol. However, epidemiological and clinical studies indicate that for the general population, the dietary cholesterol constitutes a minor risk for the development of cardiovascular diseases, once the dietary cholesterol has little effect on the plasma LDL/high-density lipoprotein cholesterol ratio. The cholesterol content of cheese varies among cheese types, with values of cholesterol < 100 mg per 100 g of cheese (Table 1), not constituting the cheese intake, due to the supply of cholesterol a significant risk for development of cardiovascular disease.

Protein

Cheese has high biological value proteins. The protein content of cheese varies considerably among cheese types, ranging between about 3 g per 100 g of protein (e.g., cream cheese) and 40 g per 100 g of protein (e.g., parmesan cheese) (Table 1). The protein of cheese is composed mainly of caseins (α_{s1}-CN, α_{s2}-CN, -CN, and κ-caseins). Caseins constitute a rich source of essential amino acids, calcium, and inorganic phosphate. Throughout cheese ripening, the casein molecules are hydrolyzed, producing a great diversity of peptides and eventually free amino acids. Several studies have shown that many of the peptides formed during cheese ripening have physiological activities, such as angiotensin-converting enzyme (ACE)-inhibiting peptides, phosphopeptides, immunopeptides, and casomorphins and antimicrobial and antioxidant peptides. In Table 3 are several cheeses types where bioactive peptides were identified.

The ACE-inhibiting peptides constitute the majority of the bioactive peptides detected and investigated in cheese. ACE plays an important role in blood pressure regulation – converting the angiotensin I into a potent vasoconstrictor, the angiotensin II, and inactivating a vasodilator, the bradykinin, resulting in an increase in blood pressure. Several studies showed that many cheeses have a potential to lower blood pressure. For example, *in vitro* studies have reported high ACE-inhibitory activity ($> 70\%$ of inhibition) in water-soluble extract obtained from Italian cheeses, as Gorgonzola and Italico, and Spanish cheeses, as Idiazabal, Manchego, Roncal, Mahon, goat cheese, and Cabrales. It is known that the ACE-inhibitory peptides derived from dairy products are less potent than the drug commonly used to control high blood pressure in hypertensive individuals. However, the cheese bioactive peptides may constitute a natural dietary approach with the potential to control hypertension.

In some cheeses also, phosphopeptides have been identified (Table 3). Such peptides may interfere with mineral absorption, due to their ability to bind and solubilize the minerals, aiding the mineral absorption in the intestine. Moreover, it is well documented that phosphopeptides exert anticariogenic effect, inhibiting the caries lesion by promoting the recalcification of the dental enamel and by inhibiting the adhesion of plaque forming bacteria. Moreover, due to their ability to bind and solubilize the minerals, phosphopeptides have been associated with other beneficial effects, as prevention of osteoporosis, hypertension, and anemia.

The proteolytic phenomena throughout cheesemaking depend on numerous factors like the chemical and microbiological characteristics of feedstock milk, the specific steps along cheesemaking, and the environmental patterns prevailing during ripening. The pattern and extent of casein degradation during ripening influence strongly on the sensory properties of the final cheese, as well as its nutritional value; therefore, the great diversity in cheese manufacture with regard to the milk characteristics and cheesemaking conditions contributes to a great variety of cheeses, each one showing distinct and unique sensory and nutritional properties. Moreover, the profile of bioactive peptides in ripened cheeses is dependent on the equilibrium between their formation and degradation. So, the cheese bioactivity seems to depend not only on the manufacturing conditions but also on the ripening stage.

Carbohydrates

Most cheeses show residual levels of carbohydrates (Table 1). Lactose constitutes the main carbohydrate in milk, but during cheese manufacture, it is lost in whey. Moreover, the residual lactose that is retained in cheese curd is fermented to lactic acid during ripening process. A considerable percentage of the world population is lactose-intolerant. Due to the lack of enzyme lactase needed for hydrolysis of lactose into monosaccharides, the lactose absorption is compromised in lactose-intolerant individuals. In this population, the lactose consumption leads to the development of several symptoms, such as diarrhea, abdominal discomfort, and flatulence. However, the ripened cheeses are free of lactose, thus constituting a dairy product adequate to lactose-intolerant people.

Minerals

Cheese is a good dietary source of several minerals, such as calcium, phosphorus, and magnesium. The beneficial effect linked to cheese consumption has also been related to its mineral composition, mainly with its high levels of calcium, which show positive effects on various disorders, namely, controlling hypertension, osteoporosis, obesity, and dental caries.

High levels of sodium also are found in cheeses, as result of the cheese salting step. Salting constitutes the major source of sodium in cheese and, depending the cheese variety, may occur in different ways – salt can be added directly to the cheese curd (e.g., cheddar and cottage cheeses) and rubbed into the surface of the molded cheese (e.g., some blue-type cheeses), or the molded cheese is immersed in brine solution (e.g., Edam, Feta, and Gouda cheeses). Salting is an important step in the manufacture of the majority of cheeses, playing a relevant role in cheese preservation and development of its adequate sensory properties. Moreover, salt addition to cheese provides a source of sodium and chloride ions, which play an essential role in a number of life processes, such as in nutrient absorption and transport, in the regulation of blood pressure, and in the

transmission of nerve cell impulse. However, the high levels of salt in cheese have favored the negative health image of cheese, due to association of high salt intake with an increased risk of development of several chronic diseases, as hypertension, stroke, osteoporosis, kidney stones, or cardiovascular diseases.

The amount of salt is variable among cheese types, with values between 0.7 g per 100 g in Emmental cheese and 6 g per 100 g of NaCl in Domiati cheese (Table 4). Overall, cheese contributes relatively small amounts to sodium daily intake; for example, in France, where the cheese consumption is high, cheese contributes only to 9.2% of total sodium intake. Nevertheless, to satisfy the consumer concerns over high levels of sodium intake, various types of cheese have been developed with reduced sodium content. Different approaches for reduction of the sodium content in cheese have been explored, such as decrease of the NaCl amounts added; partial or total replacement of NaCl by other salts like KCl, $MgCl_2$, and $CaCl_2$; and addition of flavor enhancers. Overall, these approaches have led to positive results, producing cheeses with reduced sodium content well accepted by consumers. However, great reductions of salt addition lead to the development of cheeses with undesirable sensory properties. Moreover, it is reported that

sometimes, the substitution of NaCl by other salts results in cheeses with unsuitable flavor.

On the other hand, cheese has a low content of iron and zinc. In order to enhance cheese nutritional value and its contribution to iron and zinc intake, cheese fortification with these minerals has been explored. Several cheese types have been successfully fortified with these minerals without relevant effects on their sensory properties; however, higher fortification levels lead to changes in sensory properties of cheese, which may limit the consumer acceptability by the product.

Vitamins

Vitamins are widely recognized for its importance in human health, contributing to multiple and different vital functions in the organism. Cheeses constitute an excellent source of liposoluble vitamins, as retinol, carotene, vitamin D, and tocopherols. Although the majority of water-soluble vitamins of milk are lost in the whey during cheesemaking, some water-soluble vitamins, such as vitamin B_{12}, riboflavin, niacin, and folate, are present in sufficient levels in cheese. Therefore, cheese consumption could play a significant role in vitamin supply, contributing to adequate vitamin intake.

Some vitamins are widely distributed in food and human deficiency in such vitamins is improbable. However, for other vitamins, very few natural sources are available, as the case of vitamin D, which may result in insufficient consumption. Fortification of foods already normally consumed is a good strategy to achieve an adequate intake of these nutrients. The fortification of cheeses with vitamins, like vitamins A and C and particularly vitamin D, has been explored. Overall, the results have shown that fortification of cheeses with vitamins can be successful by enhancing vitamin content in these cheeses without compromising their sensory properties.

Polyphenolic Compounds

In recent years, the polyphenolic compounds have received much attention due to their potential beneficial properties to human health. Dietary polyphenolic compounds exhibit a variety of biological activities, including protection against oxidative stress and several degenerative diseases. So, owing to the beneficial health effects associated with the consumption of polyphenols, foods enriched in these compounds, including cheeses, are demanded. The polyphenols in cheeses may result of several circumstances, including: transference from feed and from animal metabolism to the milk, arising of the amino acid catabolism or the enzymatic activity in product, as well as from direct incorporation of polyphenolic compounds to milk or during cheesemaking processing, and finally through contamination from the environment.

The polyphenols are secondary metabolites produced by plants and therefore widespread throughout the plant kingdom. Several studies showed that utilization of dietary sources rich in polyphenols in ruminant nutrition – such as forage, shrubs, and industrial by-products – besides being able to change the chemical composition of milk, including its fatty acid profile, can also lead to transference of various polyphenolic compounds of the feed to milk and dairy products. On the other hand, the addition of single phenolic compounds or extracts rich in polyphenolic compounds in unprocessed milk or during cheesemaking in order to manufacture cheese with increased levels of polyphenolic compounds also has been explored. Both approaches seem to be feasible to improve the nutritional value of cheeses. However, independent of their origin, the polyphenolic compounds have a strong impact on sensory characteristics of cheese and at high levels may lead to undesirable changes in flavor and color of cheeses.

Introduction

Cheesemaking implies the elimination of whey (the watery portion of milk) after coagulation of milk, thus resulting in the concentration and preservation of the most important milk nutrients – protein, fat, and minerals. For many cheeses, namely, those undergoing the process of ripening, the optimization of coagulation and whey elimination (syneresis) are obtained by first adding a lactic acid bacteria (LAB) starter culture to milk. At this initial phase, the starter culture is expected to cause a slight and rapid acidification of milk through the production of lactic acid, with the consequent decrease in milk pH. Next, rennet (an acidic enzyme) is added to coagulate the milk, and this, with the contribution of the subsequent cheesemaking steps, leads to formation of the initial texture and the almost insipid flavor of the cheese. Ripening, a slow process that may last from 1 to 24 months depending on the cheese variety, is the final step that imparts the final and most significant changes of cheese flavor. Thus, the final sensorial features of a cheese are more or less a consequence of the combined actions of all steps involved in its processing. Consequently, understanding and controlling the effect of each of the processing steps during cheesemaking is crucial toward directing the process to deliver the final product in mind. Also, due to the key role the sensorial factors play in the cheese consumer's choice, attempts to understand and control the dynamics of the development of texture and flavor have been an important part of the activity in the field of food science.

Cheese Processing and Starter Cultures

The basic principles involved in cheese manufacture have remained the same for over 1000 years. Basically, milk must be first heat treated to kill the harmful bacteria that it may harbor. Starter cultures, usually LAB, are then added to the milk and their growth 'ripens' the milk and later helps to develop the desired flavors and aromas in the cheese. For raw milk cheeses, in case a starter culture is added, it can be of a pure or mixed undefined (whey from previous day) type. The starter culture produces lactic acid, a natural preservative that, besides acting on cheese taste, will cause the pH of milk to drop, thus creating optimal conditions for the activity of rennet that is usually added afterward. This will cause the coagulation of the main protein present in milk - casein - by lowering its solubility, leading to its precipitation and formation of a gel that will separate into curds and whey. LAB may later have a different number of metabolic activities, namely metabolizing citric acid, acting on the breakdown of the protein (in conjunction with the rennet and enzymes from milk), as well as on the breakdown of the diglycerides formed from the milk triglycerides, and in some cheeses, on the breakdown of hippuric acid to benzoic acid. The formed curds are then heated according to the type of cheese, and salt is added as a preservative, flavor enhancer, and syneresis promoter, reducing also the *aw* of the curd. Finally, the pressed curds are put to the ripening process so that the required biochemical reactions that lead to specific flavors will occur.

Fresh, soft, or hard cheeses are made essentially by the same process with slight differences in one or more of the steps described (see Figure 1). Thus, while fresh cheeses are ready for use as soon as the manufacturing process is complete, hard cheeses are allowed to mature in temperature- and humidity-controlled rooms from 1 to 24 or more months depending on the type of cheese.

From coagulation, cutting, and pressing, the pH of the curds will usually change markedly (see Figure 2). Later, during ripening, the pH will usually keep dropping in most cheese varieties as shown in Table 1, and the pH of the final cheese will usually vary between 4.8 and 5.4 as a result of the continuous acidification by the starter culture, which also contributes to the release of volatile components in the ripening curd.

Cheese Texture

Texture can be defined as the sensory manifestation of structure of the food and the manner in which this structure reacts to applied forces. Texture affects the immediate perception of a consumer to the quality of a product, through vision, kinesthesia, and hearing, making it a key flavor indicator. The final

texture of a cheese is developed throughout ripening, a slow process involving the concerted series of biochemical, microbiological, and chemical reactions, which are predetermined by the manufacturing processes. Generally, a cheese may be classified as having a typical soft, semisoft (medium), or hard texture, and the said classification is related to the cheese water and fat contents, to which many factors will contribute.

As previously stated, processing conditions – temperature of coagulation, cutting and cooking the curds, pressing, salting, and ripening – will affect directly the cheese texture or hardness. The pH at drain determines the retention of rennet (which participates in hydrolysis of α_{s1}-casein) and the amount of plasmin (a native milk proteinase that is responsible for much of casein breakdown in the curd), while the salt-to-moisture ratio affects the amount of intact casein. Finally, the changes in body and texture that transform the rubbery, elastic mass of curd to a cheese with a firm close texture are essentially the results of the three primary biochemical processes – glycolysis, lipolysis, and proteolysis – occurring mainly during ripening. With aging, the cheese texture will also change as a result of the evaporation of available water on the surface, leading to a 'drier,' harder, and less deformable cheese. Finally, the storage temperature (or ripening temperature) impacts the rate of proteolysis, namely, proteolysis of α_{s1}-casein hydrolysis.

In general, cheese texture will change markedly in the first 1–2 weeks of ripening as the hydrolysis of a small fraction of α_{s1}-casein by the rennet to the peptide α_{s1}-I results in a general weakening of the casein network. The following and usually relatively slow (occurs over a period of months) change in texture is often associated with the rate of proteolysis, which in turn is controlled largely by the proportion of residual rennet, plasmin, microflora peptidases, salt-to-moisture ratio, and storage temperature.

Cheese composition also affects the final texture, as both dissolved calcium in the cheese serum and calcium bound to the protein network have been shown to affect the rate of proteolysis, and cheeses having a higher fat content are less firm and more elastic.

Sodium chloride affects both the matrix and the serum phases of the cheese, which, in turn, affects the overall texture. It is known that brine-immersed cheeses show dramatic changes in texture during the early stages of aging. Many soft cheeses are obtained by a combination of a low degree of syneresis and the use of specific types of vegetable curds (such as cardosin) or starter cultures (viz., specific fungi of the group *Penicillium*), which are highly proteolytic and thus will contribute to loosening the matrix formed by casein to peptides and amino acids, involving high fat content and water.

Table 2 Definitions of textural properties attributed to cheeses and other dairy products

Textural properties	*Definition*
Adhesiveness	Work necessary to overcome the forces between dissimilar materials
Chewiness	Energy required for masticating a solid food material until it is ready for swallowing
Cohesiveness	The strength of the internal bonds making up the body of the product or degree to which the sample deforms before rupture
Gumminess	Energy required to disintegrate a semisolid food material to a state ready for swallowing
Hardness	Force necessary to attain a given deformation
Resilience	How well a product fights to regain its original position
Springiness	Degree or rate at which the sample returns to its original shape/size after partial compression between tongue and palate

In conclusion, the texture of a cheese is a reflection of its microstructure, formed essentially by the casein matrix entrapping fat globules and bounded to water, forming a structure that is affected by the biochemical activities occurring during ripening, which change the amount, type, and physicochemical relation of the said components.

A cheese may have several important textural properties as listed in Table 2.

Flavor in Cheese

While the perception of a cheese texture also contributes to its general flavor, texture may be seen as a simpler contact by means of the sense of touch, while flavor usually requires a more profound use of our senses of vision, taste, and smell with the food product.

As previously stated, the initial fresh curds from any cheese type taste more or less the same. It is only during ripening that the biochemical processes occurring by the action of LAB and

milk native enzymes present in the curd will cause the main contribution to cheese flavor development. Those primary changes are followed and overlapped by a host of secondary catabolic changes, including deamination, decarboxylation, and desulfurylation of amino acids and β-oxidation and esterification of fatty acids. While the primary reactions are mainly responsible for the basic textural changes of the curd and for the basic flavor of cheese, the secondary transformations are responsible for the finer aspects of cheese flavor and also modify the texture. A number of metabolites, important contributors to a cheese's flavor, are formed from the three main milk components during ripening, as shown in Tables 3 and 4.

It can thus be stated that a cheese flavor is composed of a complex large number of dissolved volatiles of low-molecular-weight compounds and ions, which act synergistically in the perception of flavor, and their sensory contribution may not be directly dependent on their comparative concentration. If in excess, any of these metabolic products may also result in an off-flavor appearance in cheeses.

Many of the enzymes involved in the said processes may be dependent on cooperation between strains, making the metabolic processes by LAB important in flavor formation.

Biochemical Reactions and Cheese Flavor Development

Cheese flavor is a direct result of three biochemical reactions generally known as glycolysis, lipolysis, and proteolysis.

Table 3 Flavor compounds formed from main milk components during ripening

Casein	*Milk fat*	*Lactose and citrate*
Peptides	Fatty acids	Lactate
Amino acids	Keto acids	Pyruvate
Acetic acid	Methyl ketones	CO_2
Ammonia	Lactones	Diacetyl
Pyruvate		Acetoin
Aldehydes		2,3-Butanediol
Alcohols		Acetaldehyde
Carboxylic acid		Acetic acid
Sulfur compounds		Ethanol

Glycolysis

The fermentation of lactose is one the first LAB activities that contribute to flavor in cheese. The general simplified pathway of lactose metabolism (glycolysis) by LAB (starter and nonstarter LAB (NSLAB)) in cheese is shown in Figure 3.

Lactose can be metabolized to lactate and then to acetate and diacetyl by strains of *Lactococcus lactis diacetylactis* and *Leuconostoc* spp. and CO_2, which is responsible for the characteristic eyes of many cheeses, and to citrate that contribute to flavor.

In the case of many traditional cheeses, a mixed culture of unknown composition is used in the so-called *back slop* method.

Lipolysis

Lipolysis in cheese is important as a process leading to the formation of many flavor metabolites due to the activity of

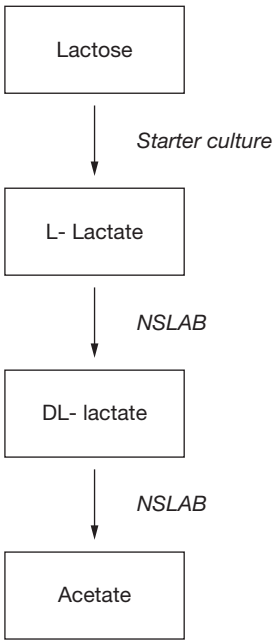

Figure 3 Simplified pathway of lactose metabolism in LAB.

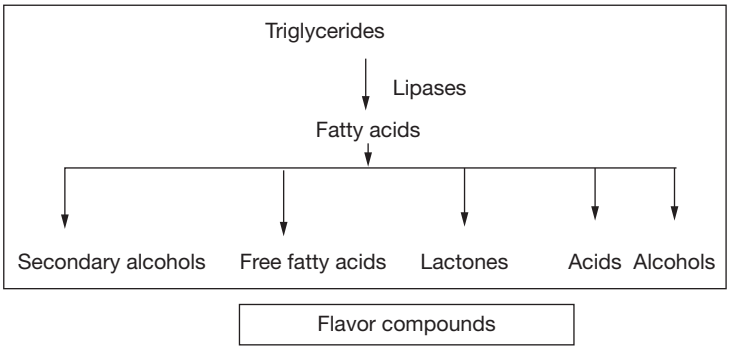

Figure 4 A simplified pathway of milk triglyceride and fatty acid flavor compound formation during cheese ripening.

such enzymes as lipases and esterases. The hydrolysis of triglycerides, which constitutes more than 98% of cheese fat, is the main biochemical transformation of fat occurring during ripening and causes the production of short-chain free fatty acids (FFAs) that contribute to the aroma of cheese, depending on the amount of the aqueous phase and the pH of a cheese. LAB play an important role in this process that leads to the formation of flavor. The presence of specific FFA can give the perception of flavor such as rancid, sharp, goaty, soapy, and coconut-like. FFA can be further hydrolyzed to methyl ketones, which are responsible for the characteristic aroma of blue cheeses. Lactones have also been identified as possessing strong aroma that may be important in overall cheese flavor. A simplified pathway of milk fat metabolism is shown in Figure 4.

Proteolysis

Proteolysis is probably the most important biochemical event in cheese ripening accounting for the development of a number of organoleptic features, encompassing both flavor and texture.

Thus, early-stage hydrolysis (primary proteolysis), that leads to the formation of large specific peptides, and the later-stage proteolysis (secondary proteolysis) will occur when the said peptides are digested into smaller ones and even free amino acids by enzymes from starter or nonstarter microorganisms, leading to changes in texture and taste of the cheese. Generally, the rate of breakdown of α_{s1}-casein is greater at lower storage pH than the rate of breakdown of β-casein, thus, changes in pH during storage affect the rate of proteolysis and consequently texture.

Proteolysis in cheese is defined as changes in β-, γ-, and s-casein peptides and other minor proteins that lead to the formation of large water-insoluble peptides and smaller water-soluble peptides from the action of rennet (chymosin), milk native proteases, and peptidase enzymes from starter and NSLAB. The hydrolysis of casein to high-molecular-weight peptides is thought to be primarily the result of chymosin and plasmin, while the subsequent hydrolysis of high-molecular-weight peptides is primarily the result of proteolytic enzymes from LAB. In general, many proteolytic compounds contribute to the typical aroma of a cheese. They are a result of different reactions including deamination, transamination, decarboxylation, and cleavage of the amino acid side chain by the microflora. Products such as keto acids, aldehydes or carboxylic acids, ketones, lactones, esters, alcohols, aldehydes, pyrazines, sulfurous compounds, carbonyl compounds, FFAs, free amino acids, and salts have been detected and reported to contribute to cheese aroma. In general, different nitrogen catabolisms will result from different starter cultures, and such products as 3-methylbutanal, an important volatile compound formed during the ripening of Parmesan cheese, or methyl alcohols and methyl aldehydes derived from the branched-chain amino acids, leucine, isoleucine, and valine, may be formed. A general overview of proteolysis and the pathway of formation of methylbutanal are shown in Figures 5 and 6.

As consequence of the dynamic of activity of LAB throughout ripening, cheese taste and texture will obviously change with aging, as more biochemical reactions occur and because moisture and salt content and pH also change throughout ripening.

Cheese Microflora and Flavor Development

Fermentation with LAB is a cheap and effective food preservation method that can be applied even in more rural/remote places and leads to improvement in texture, flavor, and nutritional value of many food products. LAB have a long and safe history of application and consumption, namely, in cheese processing, thus, being generally recognized as safe.

Cheesemaking is based on the application of LAB in the form of defined or undefined starter cultures that are expected to cause a rapid acidification of milk through the production of lactic acid, with the consequent decrease in pH, thus, affecting a number of aspects of the cheese manufacturing process and ultimately cheese composition and quality.

Traditionally, mixed or undefined strain starter cultures composed of a number of strains of *Lactococcus* spp., *Lactobacillus*, and even *Enterococcus* spp. were used.

The earliest productions of cheeses were based on spontaneous fermentation, resulting from the development of the microflora naturally present in the raw milk and its environment. The quality of the end product was a reflex of the microbial load and spectrum of the raw material. Spontaneous fermentation was later optimized through backslopping, that is, inoculation of the raw material with a small quantity of whey from a previously performed successful

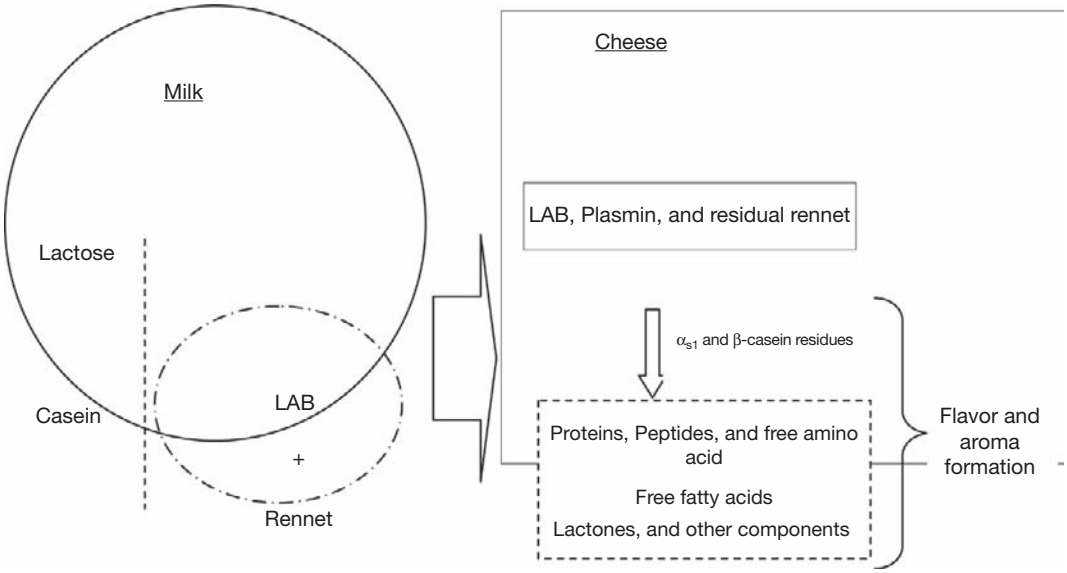

Figure 5 General view of proteolysis during cheese processing.

Figure 6 3-Methylbutanal formation by LAB during ripening of cheese.

fermentation, and the resulting product characteristics depended on the best-adapted strains dominance. Today, backslopping is still used to produce many artisanal raw milk cheeses, namely, those bearing the PDO (Protected Designation of Origin) status, which are considered to be an important source of LAB genetic diversity. The starter culture applied in this, so-called natural fermentation, is usually a poorly known microflora mix that, although having a predominance of LAB, may also contain non-LAB microorganisms, and its microbial diversity and load are usually variable over time.

Moreover, traditional cheeses also obtain their flavor intensity from the NSLAB, which are not part of the normal starter flora but develop in the product, particularly during maturation, as a secondary flora.

In the high-output cheese industry, defined cultures are rather used, optimizing the process, namely, the lactic acid formation. Bacteria existing in the processing environment – the so-called nonstarter lactic acid bacteria – often contaminate the cheeses, thus, having also a role in flavor development. For specific varieties of cheese, such as 'blue cheeses,' a starter culture made up of specific molds such as the *Penicillium* spp. is also used. Due to a lower diversity of the microflora in industrial cheeses, they are commonly recognized as developing weaker flavors.

The starter culture in cheesemaking is thus very important for two obvious reasons of producing lactic acid via metabolism of lactose: lowering the pH of the curd (recall that at lower pH values, undesirable bacteria have more difficulties to grow and therefore the pH history during processing of the cheese is a good indicator of the actual product safety) and producing the distinctive flavors and textures via metabolism of fat, lactose, and protein.

Undesirable flavors, namely, bitterness, may develop in cheeses, often as consequence of combined excessive activity of rennet and mesophilic starter cultures. Bitterness is considered a result of excessive accumulation of bitter peptides (usually of 2–23-amino-acid residues), predominantly containing hydrophobic amino acids. Excessive use of certain types of rennet and starter cultures with high proteolytic activity can lead to formation of bitterness and it has been shown that this defect often occurs in cheeses made without NaCl and in low-fat cheeses. Also, it seems that fast acid producers, heat-tolerant strains grown under uncontrolled pH conditions, are more prone to producing high levels of bitter components. Off-flavors such as rancidity may develop due to excessive or unbalanced lipolysis caused by lipases/esterases from starter or NSLAB, from enzymes produced by psychrotrophic bacteria, or from indigenous milk lipoprotein lipase. Finally, late gas blowing and other off-flavors in certain hard cheeses result from the metabolism of lactate (or glucose) by *Clostridium* sp. to butyric acid and H_2.

Texture and Flavor Analysis

While texture (mouthfeel) of a food product may be subjective, it plays a key role in consumer acceptance and market value of a food product, namely, cheeses. The sensory measurements of a cheese may be taken by consumers (say, in shopping malls, supermarkets, or any other area having a large number of consumers) or by a trained panel. The purpose of a consumer taste test is usually for a general evaluation (acceptance/rejection) of a dairy product, while the trained panels are

trained to detect a specific food characteristic (bitterness, sandiness, and crumbliness) with a high degree of reproducibility.

However, attempts have been made to standardize measurements of texture and flavor. In fact, food texture characterization is rooted on human sensory evaluation; however, many instrumental methods have been developed to analyze some physical and chemical properties in finished products, allowing for corrections and control of the manufacturing and storage processes in order to consistently deliver the expected final product.

The evolution of a cheese microstructure can be followed by microscopy techniques, generally known by such acronyms as TEM, SEM, and CLSM, imaging techniques, and infrared spectroscopy, while mechanical properties such as firmness and hardness (texture profile analysis (TPA)) may be evaluated by mechanical methods using a testing machine such as the Instron model (Figure 7), a penetrometer, or a rheometer. Figures 8 and 9 are results of a study of texture characterization of samples of São Jorge cheeses at different ripening periods.

Due to good separation efficiency and versatility, gas chromatography methods have found increasing acceptance and application in food science and in technology for separation and identification of a large variety of compounds. These techniques are thus helping to elucidate and understand the mechanisms and chemistry of flavor formation in cheeses.

A cheese map developed for cheddar cheeses is shown in Figure 10. Different cheddar cheeses from around the world can be placed in the map due to their specific flavors.

In conclusion, cheese flavor and texture are complex and slow processes resulting from the extent of the biochemical pathways of glycolysis, lipolysis, and proteolysis, which are

affected by the cheesemaking specificities and the microflora (starter and NSLAB) present in the curd and by the native enzymes of milk and rennet. Studies and attempts to control cheese flavor are important activities in food science due to the key role flavor and texture play in the consumer's choice of a cheese.

Introduction

Semihard cheeses are probably the largest group of known cheeses. Production is usually by rennet coagulation, after slight acidification of milk with lactic acid from added or adventitious starter culture. The amount of moisture removed from the curd depends on the water temperature/time used in the cooking and wash of the curd. Higher temperatures during cooking or washing cause the curd to contract and expel more moisture. Typically, these cheeses mature for 15 days to 3 months. Roquefort, mozzarella, Stilton, manchego, Gorgonzola, provolone, Gouda, Edam, and São Jorge cheese are part of the long list of medium cheeses. The texture and aroma of medium cheeses change during ripening due to solubilization of calcium phosphate, proteolysis, lipolysis, and loss of moisture, which are all dependent on the manufacturing technology such as the starter used, temperatures used for cooking the curds, degree of syneresis, and salting, as these will determine the pH, moisture content, degree of proteolysis, and calcium and fat content of the cheese.

PDO Cheeses

Many traditional PDO (protected designation of origin) cheeses are medium cheese types, and in Europe, they are perceived as being an important part of the cultural heritage in places where they are made.

Consumers in Europe have defined traditional food product as 'a product frequently consumed or associated with specific celebrations and/or seasons, normally transmitted from one generation to another, made accurately in a specific way according to the gastronomic heritage, with little or no processing/manipulation, distinguished and known because of its sensorial properties and associated with a certain local area, region or country.' The PDO status (Figure 1) or 'appéllation d'origine contrôlée' is a designation applied to foodstuffs (cheeses) that are produced, processed, and prepared in a given geographic area using a recognized and unique technology, determined by human and natural factors dependent on the area where it is produced, such as the raw milk used in the cheesemaking. This is usually seen as a way of protecting and increasing the market for foodstuffs with typical characteristics. About 8% of the cheese produced in the EU (i.e., 3–4% of the world's production) is protected by a PDO registration, and these includes names such as Grana Padano, Comté, queso manchego, Serra da Estrela, São Jorge, Feta, and many more.

Because these cheeses are in general produced in small factories and represent an important source of income for local population, their protection may fulfill an important socioeconomic role in creating local jobs and in maintaining the agricultural population in areas, which could otherwise be abandoned. In fact, the World Intellectual Property Organization indicates that the PDO system was developed because of the perceived necessity of providing solutions against fraudulent commercial practices, related to the origin of agricultural products.

PDO cheeses are often made from raw milk; thus, as a way of establishing the required improvements toward increasing their safety, many scientific projects have been set in Europe toward characterization and improvement in processing of traditional cheeses.

Semi-hard cheeses also encompass the so-called "industrial" cheeses, which, in contrast to PDO cheeses, are produced in high output factory plants. The increasing scientific knowledge, started with discoveries by Pasteur and the technological development in the dairy field, allowed cheeses (even if initially they were of the artisanal type) to be manufactured in a more controlled and directed processing in large plants. These cheeses may often be considered as having a weaker taste, as compared to PDO ones, however, they are the most available, and thus, most consumed especially for large urban areas around the world. In fact the high-output dairy industry is one of the largest food industries in the world.

For medium cheeses in general, the starter culture – LAB species intentionally added to milk – plays a crucial and complex role in the development of final aroma and taste. Their central function is the fermentation of the milk sugar (lactose) to lactic acid and the degradation of milk protein and fat. During processing, after the protein (casein) has been coagulated, the resulting decrease in pH due to the lactic acid released by LAB will result in moisture expulsion (syneresis) and curd shrinkage, influencing also the final cheese texture. The starter culture is an active contributor to the shelf life and safety of cheese, gives a sharp, fresh flavor to the curd, and is essential in typical taste and aroma development throughout ripening.

The changes in body and texture that transform the rubbery, elastic mass of curd to a cheese with a firm close texture are the results of protein and fat degradation. The release of volatile components from the curd gives the aroma to cheese and associated flavors, and the pH of the final cheese will usually vary between 4.8 and 5.4 (Figure 2) as a result of the continuous acidification by the starter culture.

Mozzarella

Mozzarella (Figure 3) is one the most famous cheeses due to its association to pizza food. Mozzarella is a low-moisture medium cheese with an unusually broad compositional range in terms of moisture (45–52%) and fat (about 30–50% fat in dry matter), and it is a rindless cheese that can be eaten fresh. The essential quality attributes of mozzarella (pizza cheeses) are its functional properties such as flowability, stretchability, browning, free oil formation, and shredability. Mozzarella is a rennet-coagulated

cheese, and thermophilic starter cultures are commonly used in its processing allowing for a fast rate of acidification that, in combination with a short time processing, results in a less syneresis and thus higher moisture in the final cheese. In the final stage of processing, the curds are stretched while heating with hot water. Its processing requires a unique step, at the later phase of its processing, at which the curds are stretched at a high temperature. While traditionally it was made from buffalo milk coagulated with a starter derived from the whey of a previously successful batch (backslopping), the world's high demand requires that most of the mozzarella cheeses available now are made from cow's milk.

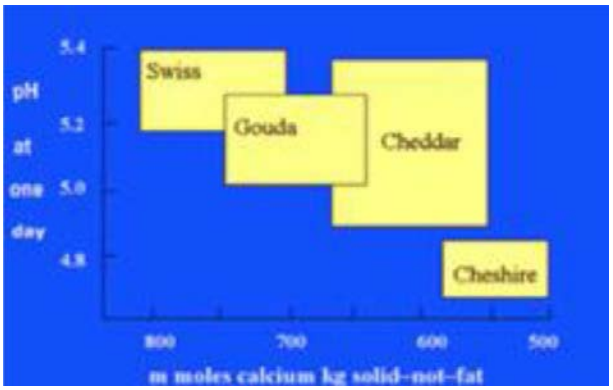

Figure 2 Average pH variation in different types of cheeses. Reproduced from Lawrence, R. C., Gilles, J. and Creamer, L. K. (1983). The relationship between cheese texture and flavour. *New Zealand Journal of Dairy Science and Technology 18*, 175.

Roquefort

Roquefort (Figure 4) is a popular French cheese, reported to be called in France the 'cheese of kings and popes.' This cheese is protected by AOC (PDO) guidelines. Roquefort cheese is moist and breaks into little pieces easily. Genuine Roquefort is made from sheep's milk, and after aging for 3–5 months, the cheese is creamy with a sharp, tangy, salty flavor. Roquefort belongs to the group of the so-called blue cheeses due to the blue-colored veins it develops from the growth of *Penicillium roqueforti*, which is added to the curd or introduced through holes poked in the rind.

Gouda

Gouda (Figure 5) is a Dutch cheese named after the city of Gouda in the Netherlands and one of the most popular cheeses in the world. It is a semihard cheese with a unique flavor and smooth texture. Gouda is typically made from pasteurized cow's milk although some artisan may use raw milk, sheep's or goat's milk, to produce cheeses that will go for longer time, and Gouda cheeses of different age are commonly sold. To enhance the flavor of the cheese, herbs, seasonings, and nuts may be blended, and at the final stage, it may have a fat content of c.31 g/100 g of cheese.

Manchego

The manchego (Figure 6) is produced in La Mancha region of Spain, home to Don Quixote. It may be made from unpasteurized sheep's milk under the PDO guidelines or in the industrial version from pasteurized milk.

The rind is inedible with a distinctive, traditional herringbone basket weave pattern, pressed on it. It may be sold as semicurado (young manchego aged around 3 months), curado (manchego cheese aged for 6 months), or viejo (manchego cheese aged for a year becomes crumbly in texture while the interior of the cheese acquires a butterscotch color, having a fat content of c.57%).

São Jorge

São Jorge (Figures 7 and 8) is a PDO Portuguese traditional cheese made from cow's raw milk on the island of the same name. For its processing, raw milk from grass-fed cows is heated to 31 °C followed by the addition of a small amount of whey natural starter culture from a previous processing

Figure 3 (Left) Curds of mozzarella being stretched and (right) blocks of mozzarella cheeses ready for consumption.

Figure 4 A slice of Roquefort cheese showing the typical paste with spots or veins of the mold *Penicillium* sp.

Figure 5 Wheels of stacked Gouda cheeses ripening on wood shelves.

batch. After coagulation, the curds are cut, washed, salted, molded (10–15 kg size), and ripened under controlled temperature and humidity for a minimum of 3–7 months. After this period, members of the Brotherhood of St. George Cheese perform the required tasting tests, before the cheese is allowed to formally enter the market bearing the PDO seal.

Patterns of Cheese Consumption

The consumption of cheese has in general improved significantly over the years across the world, making the cheese industry a lucrative business. Cheese production and markets have thus emerged as important elements of the dairy industry over the past three decades. Industrially or traditionally (deli)

Figure 6 Manchego cheeses ripening on wood shelves. Notice the patterns of herringbone basket weave pattern on the rind.

produced, and mostly prepared from milk of cow, sheep, or goat, cheese continues to be a popular addition to everyday diet especially in the Western world.

Factors Affecting the Growth of Cheese Consumption

In general, the increasing of population and income, together with the growing popularity of dairy products, particularly among developing country consumers is a key factor behind strong demand in the medium term. Demand continues to be encouraged by the growing influence of retail chains and multinational companies in these countries, which is facilitating improved consumer access to dairy products. The demand for dairy products is expected to remain particularly strong not only in important developing dairy markets such as North Africa, the Middle East, and East Asia but also in more mature markets such as those in the European Union, the United States, and Russia.

Dairy product consumption in developed countries may increase only modestly, with the exception of cheese, for which growth may be 16% by 2020 as compared to the 2008–10 base period. New packaging technology, more convenience, and possible substitutability with meats help boost cheese consumption. In developing regions, the consumption of all products increases vigorously at around 30% from the base period, driven by increasing population and income levels.

The rate of growth and per capita consumption of milk and milk products remain significantly different among regions (Figure 9). Cheese from cow's milk represents 95–96% of the total cheese production, and the European countries registered the main production increase, with a similar tendency observed in the United States in the last decades.

LDC countries consume less than 50 kg per person per year on average, compared with 100 kg per person for developing countries, while the developed regions of North America and Europe consume well in excess of 200 kg per person (in milk equivalent). Such a per capita consumption disparity represents an investment potential and future opportunities for both the domestic and global dairy sectors.

Figure 7 São Jorge cheeses at an early ripening phase (left) and a wheel showing a casein seal, which is affixed in all cheese wheels.

Figure 8 A wheel of São Jorge cheeses at market (Toronto, Canada) and 4- and 3-month, respectively, cheeses at the final phase before going to market.

LDC, least developed countries.

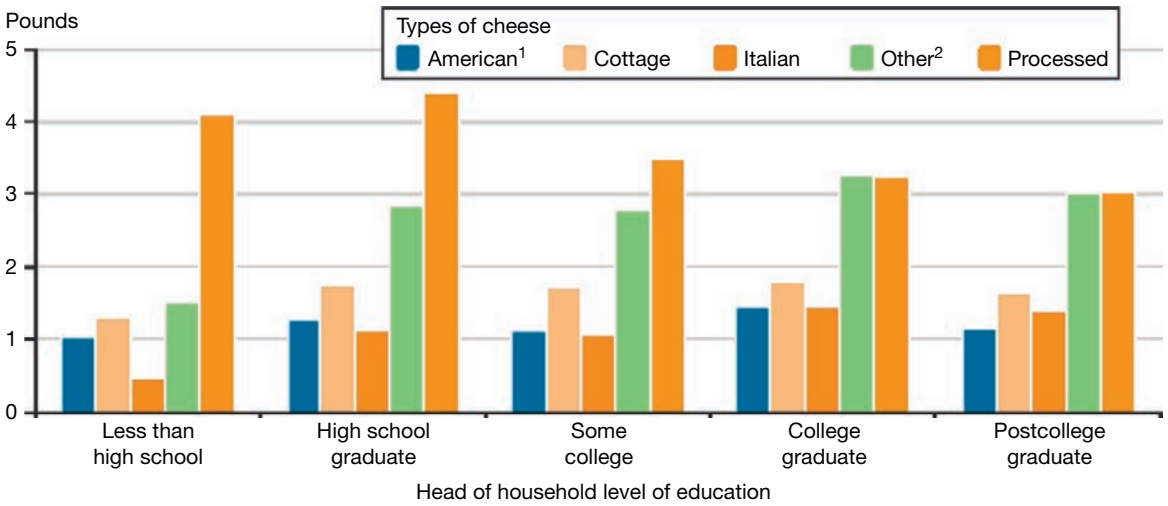
All cheese types = American, Italian, processed, cottage, and other as defined by Nielsen. Other cheeses, as defined by Nielsen Homescan, are cheeses that do not fall into the American, Italian, cottage, or processed categories.

Figure 10 Per capita cheese purchases of all cheese types, by household income in the United States in 2005. Reproduced from Davis, C. G., Blayney, D. P., Dong, D., Stefanova, S. and Johnson, A. (2010). Long-term growth in U.S. Cheese Consumption may slow. A report from the economic research service, www.ers.usda.gov, accessed on 15/05/2014.



[1]American cheeses are Cheddar, Colby, Monterey, and Jack.

[2]Other cheeses, as defined by Nielsen Homescan, are cheeses that do not fall into the American, Italian, cottage, or processed categories.

Figure 11 Per capita cheese purchases by female heads of households. Reproduced from Davis, C. G., Blayney, D. P., Dong, D., Stefanova, S. and Johnson, A. (2010). Long-term growth in U.S. Cheese Consumption may slow. A report from the economic research service. www.ers.usda.gov, accessed on 15/05/2014.

In fact, cheese consumption in developed economies will be fraught by challenges, such as a matured market profile, limited growth in population, and most importantly the fast aging population, which account for lesser per capita consumption than the younger generation. Therefore, increase in cheese consumption within these markets is likely to be marginal and mainly associated with changes in form and type of dairy products consumed.

In the United States, reports on consumption using selected demographic and economic factors indicate that income, age, racial/ethnic factors, location, gender, and education influence cheese consumption in different, but significant, ways (see Figures 10 and 11).

Food preferences and consumer attitudes are progressively gaining importance as a significant determinant of the demand for milk and dairy products, particularly in high-

income countries as consumers become more affluent and more educated.

Health and nutritional issues have become important factors in determining the overall demand and the compositional demand for milk and dairy products. Demand is progressively becoming orientated toward more natural products with a reduction in the demand for products that are perceived to be 'unhealthy' (e.g., fats). Research shows that in the United Kingdom, for example, health consciousness increases with income and age and women tend to be more health conscious than men.

Food safety has emerged as an important global issue with international trade and public health implications. In recent years, food safety incidents have seriously affected consumer attitudes toward food, which in turn has led to significant changes in food consumption and purchasing patterns. For example, following the EU BSE outbreak in 2000, the consumption of cheese as a protein substitute to beef and veal increased in many member states.

Quality (including factors such as taste, freshness, branding, and packaging) is an important factor driving purchasing decisions for milk and dairy products. The drive toward quality products has tended to result in a shift in demand from commodity-type products to value-added products.

Production ethics are receiving more attention from consumers when making their purchasing decisions, particularly in higher-income countries. Concern about the environment and animal welfare has grown considerably, resulting in an increasing demand for milk and dairy products that are perceived by consumers to be more 'environmentally' and 'animal-friendly.' These include organic, welfare-friendly, and locally produced milk and dairy products. Research has found that gender, age, educational level, and socioeconomic status are important factors, and young, educated women of a higher socioeconomic status tend to be more concerned about production ethics.

Strategies and the Future of the Cheese Industry

In the present context where purchasing decisions are being increasingly guided by price (Figure 12), cheaper yet healthy and wholesome foods are surfacing back into the spotlight, and with *small is beautiful* attitude, consumers are shifting their preferences from imported cheese brands to locally produced cheeses.

In general, consumption levels and cheese markets in developed countries will tend to show nearing saturation; thus, the focus of the global cheese industry now shifts toward emerging markets. Such markets (Asia, Latin America, Middle East, and Africa) are projected to display superior growth rates in the near future. Large population and rising incomes in these nations will prove to be the major driving factors for exceptional growth in dairy, namely, cheese consumption. Growth in this market will primarily be driven by improving income levels, strengthening consumer sentiment/confidence, waxing propensity to spend, and increase in the adoption of Western-styled food.

The EU cheese market is in general changing, forcing cheese suppliers to rethink their business models and explore new opportunities for growth. The main drivers behind these changes are falling growth rates in the EU, more pressure on margins because of higher revenues in powder and butter products, and volatility in commodity cheese markets.

The actual economic recession has certainly slowed cheese consumption pattern especially in the developed countries; however, the future outlook for global cheese market may still be bright. In the postrecession period, innovation and product diversification will be prominent market strategies for manufacturers and suppliers, satisfying new consumer demand with a diversity of cheese such as organic cheeses.

Looking at the new markets, new cheeses that suit the demand in developing dairy markets like China and India may be important.

Also, the growing demand for dairy products that meet consumers' changing diet and nutritional needs may result into strong growth for innovative and healthier cheese products, such as lactose-free goat cheese products and half-fat, reduced fat, and low-salt cheeses. The maturation process in the making of hard and semihard cheeses adds further complexity and risk in the market. Because the maturation process takes from a few weeks to over a year for cheeses like Gouda,

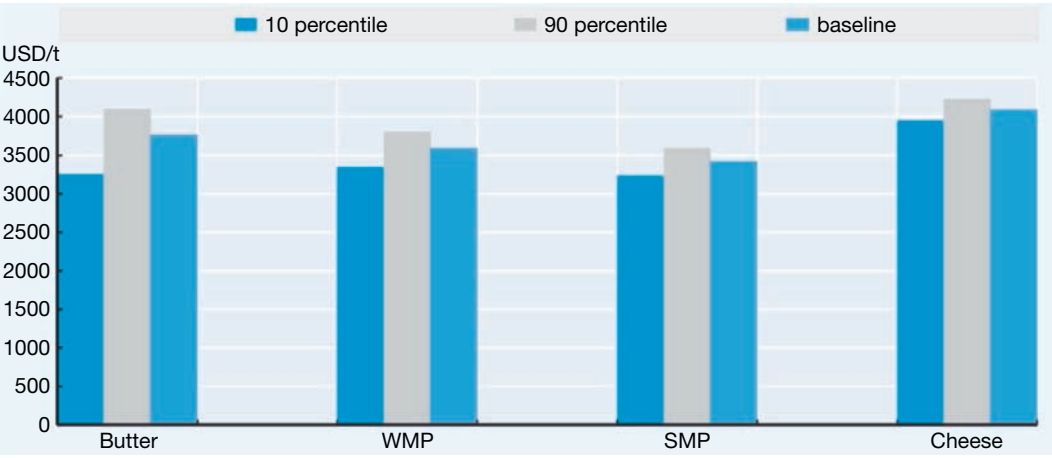


Figure 12 Projections of world dairy product prices in 2020. OECD-FAO Agricultural Outlook 2011–20.

Edam, and Emmental, it creates a time lag that makes a market-driven approach very difficult for these cheese types. Another area to possibly look at may be the production linked to the regions where they are produced such as products with protected geographical indication (PGI) or protected designations of origin (PDOs) for artisanal, organic, or other specialty cheeses.

Consumers are willing to pay more for regionally produced specialty cheeses when they combine good quality and taste with a strong marketing story (see Figure 13). Consumers have a growing interest in cheeses with a sense of history and tradition – and that is turning them away from processed cheeses and toward products unique to a single region or even a single farmstead. Natural, organic, artisan, and local cheeses, as well as cheeses made from blends of milk, are all part of this trend, and specialty cheese stores use these cheeses to distinguish their range from the large retailers.

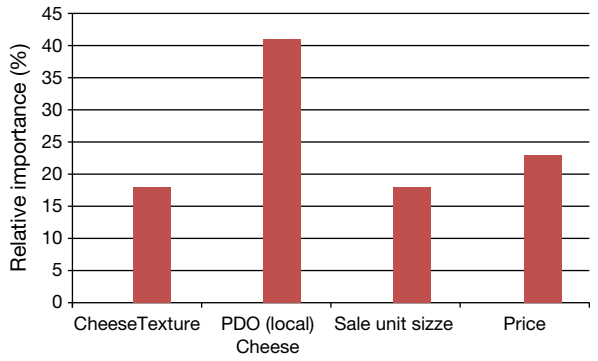

Figure 13 Finding consumer segments based on their preferences for four cheese attributes.

Ethnic Cheeses

In the US market, Italian cheeses are the most popular of ethnic cheeses – so popular that US production of Italian cheeses surpassed that of American natural cheeses for the first time in 2006. Italian cheeses accounted for almost 4 billion of the 9.5 billion lbs. of cheese produced in 2006. A large share of that volume was consumed in restaurants and other food service establishments. In fact, Latin American and Spanish cheeses are no longer a niche market, as an increasing number of non-Hispanic consumers incorporate them into their cooking. Half of the top 10 fastest-growing specialty cheeses in the United States at retail are Hispanic varieties (see Figure 14).

In Europe, specialty cheeses – PDO and PGI cheeses – represent a considerable market (Figure 15). As previously explained, PDO covers agricultural products and foodstuffs that are produced, processed, and prepared in a given geographic area using recognized know-how, while protected geographical indication covers agricultural products and foodstuffs closely linked to the geographic area. At least one of the stages of production, processing or preparation, takes place in the area.

Nutritional and Health Effects

Similar to soft cheeses, medium cheeses are nutritious foods rich in protein, fat, fat-soluble vitamins, and calcium. Many of the cheeses in this group are the so-called Gourmet cheeses making them highly priced cheeses in the market. As in the case of hard cheeses, medium cheeses may as well be suited for lactose-intolerant consumers as in many varieties, lactose is mostly depleted due to its use by the microflora present throughout processing and ripening, also having in general

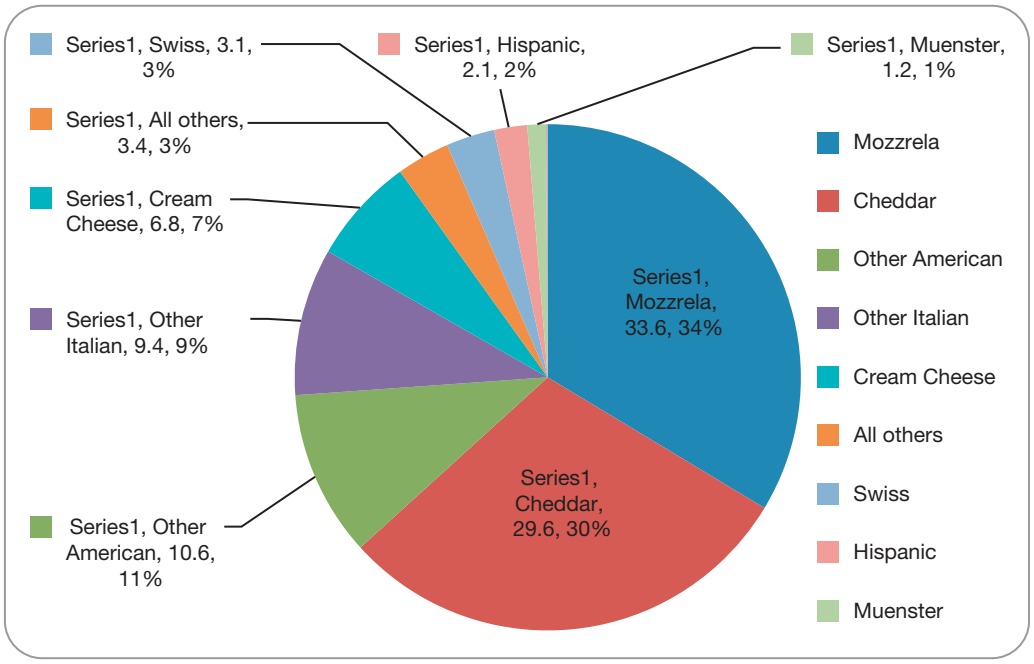

Figure 14 US cheese production by variety. USDA Dairy Products Annual Summary 2011.

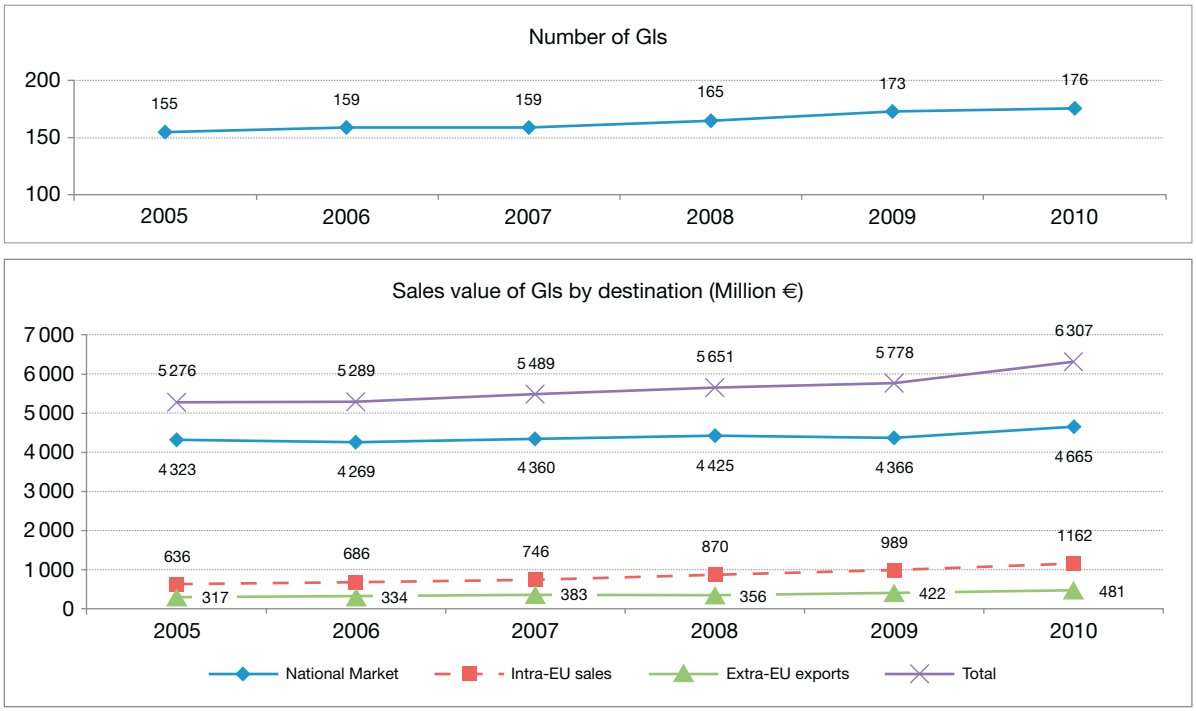

Figure 15 PDO and PGI cheese products and foodstuff sales in Europe. European Commission; Agriculture and Rural Development: public statistics, survey and estimates, 2008.

higher contents of short chain fatty acids as compared with nonripened soft cheeses.

Cheese: Types of Cheeses – Hard

JM Kongo, INOVA, Instituto de Inovação Tecnológica dos Açores, Ponta Delgada, Açores, Portugal
FX Malcata, University of Porto, Porto, Portugal

Introduction

Hard cheeses have lower moisture contents than other types of cheeses, and their processing in general requires cooking the curds to increase the release of whey. Due to their extensive ripening period, hard cheeses develop very distinct strong taste and aroma, and the starter culture, which must withstand the harsh conditions in the cheese to exert their proteolytic, lipolytic, and acidification activity, plays a key role in the processing of said cheeses. Nutritionally, hard cheeses are high in protein and fat, and there are some research evidences showing that they may have higher contents of CLA (conjugated linoleic acid) than their softer counterparts. Finally, lactose is in general absent or at very low levels in hard cheeses, which is an advantage for lactose-intolerant consumers.

Varieties

Cheddar

Cheddar cheese is probably the most widely purchased and eaten cheese in the world, especially in Anglo-Saxon countries. It is a hard cheese that matures over a period of time between 9 and 36 months. Its name is associated with the processing technique known as 'cheddaring,' which is a step used during cheesemaking to give cheese a dense, layered texture. It consists in cutting up the curds into smaller pieces to expel whey, and the more they are, the more liquid will drain from them and the harder the resulting cheese will be. While this step is common in most medium and hard cheeses, it is taken one step further for Cheddar cheese, as the curds are cut up and then pressed together into slabs and then the slabs of curds are stacked on top of each other. The weight of stacking the slabs of curds on top of one another presses out even more moisture. Then, the slabs of curds are cut up again, pressed into slabs again, and stacked again. The process continues until so much whey is expelled that after aging, the cheese will have a crumbly, layered, dense texture.

Idiazabal

Idiazabal (Figure 1) is a traditional, farmhouse, hard cheese made from raw milk of sheep in the Basque and Navarra regions of northern Spain. Named after the village of Idiazabal, the cheese received a protected designation of origin (PDO) distinction in 1987. Traditionally, the cheeses are made at early summer in higher zones of pastures and left in the rafters to mature. By the end of summer, the cheeses are ready for sale. Idiazabal is produced in the shape of a cylinder, with a smooth and hard natural rind that is pale yellow to amber in color.

Emmental

Emmental is a PDO cheese produced in the central cantons of Switzerland. Traditionally, it is made from unpasteurized cow's milk. The aroma is sweet, the flavor is fruity and acidic, and it is sold with a rind covered by paper with the producer's name on it. Inside, Emmental has the typical image of a Swiss cheese showing walnut-sized holes, which result from entrapped air produced by the starter culture *P. freudenreichii* that at later phase of the cheese production consumes the lactic acid and releases carbon dioxide gas, which slowly forms the bubbles that make holes.

Gruyere

Gruyere cheese is named after a Swiss village, and it is traditionally made form unpasteurized cows' milk, with a rusty brown, hard, and dry rind pitted with tiny holes. The cheese is darker yellow than Emmental but the texture is more dense and compact. After coagulation, cutting the curds and molding and pressing, the cheese is salted in brine for 8 days and curing from 3 to 10 months.

Parmesan

The Parmesan cheese is among the top cheeses chosen by cheese connoisseurs. The PDO designation states that for a cheese to be called as Parmesan, it has to be produced from cows grazing on fresh grass and hay. Parmesan cheese has a hard, gritty texture and is fruity and nutty in taste, and it is mostly consumed grated over pastas or used in soups and risottos although it can also be eaten on its own as a snack. Total processing time may last up to 2–4 years.

São Miguel

São Miguel cheese (Figure 2) is made from pasteurized milk from cows essentially grass-fed all year round on the island of the same name in Azores. At earlier ripening phase, the cheeses may be sold under the brand Famoso, while São Miguel requires 7–9 month of ripening. The cheese has a unique and distinctive rind colored black.

Source and Production

Cheese is a bacterial ecosystem that changes during ripening due to a series of biochemical transformations. When these changes are balanced, they result in a large variety of flavor compounds and thus the highly desirable aromas and flavors of different cheeses. To obtain their typical more intense taste and aroma, hard cheeses in general require extensive ripening periods.

Figure 1 A wheel of ripen Idiazabal cheese.

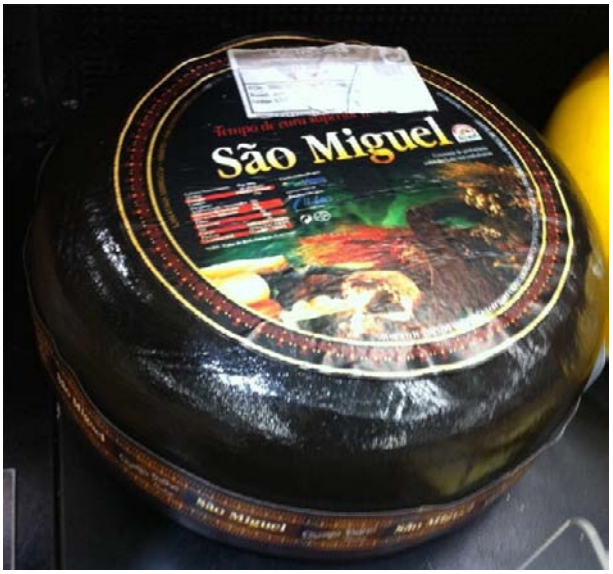

Figure 2 São Miguel cheese wheels showing typical rind color and paste texture.

While the general four processing steps are common for most varieties (see Figure 3), some specific details will differ and contribute to the peculiarities of each cheese. Such differences may be associated to the characteristics of the milk, starter culture type, time and temperature of coagulation, cooking and procedures for whey drainage, salting type, and ripening conditions.

Chemical Quality of Milk

Factors such as the type of the animal, its feed, and season may influence the quantity of calcium, casein, and whey proteins present in milk and consequently influence the quality and rate of milk coagulation during cheese processing. Recall that curd formation in the cheese vat is important for controlling the structure, moisture content, and rheological properties of the cheese. Industrially, corrections to the milk composition can be made by adding calcium chloride or powder (protein) milk, thus increasing the quality and consistency of the curds.

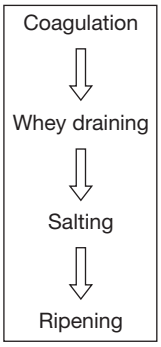

Figure 3 General cheeses processing steps.

Microbiological Quality of Milk

Hard and semihard cheeses manufacture requires that the fresh curd may be matured for several months or even years, which enables even slow-growing microorganisms to manifest themselves. In general, the microbial diversity underlying the benefits of raw milk cheese depends on both the milk microbiota and traditional practices, including inoculation practices. Thus, traditional or local know-how from farming to cheese processing may help in maintaining both the richness of the microbiota in individual cheeses and the diversity between cheeses throughout processing.

The microbiota in raw milk may be highly complex, and especially in raw milk cheeses, this will be reflected in the cheese taste and aroma. In fact, it has been shown that flavor is more intense and rich in raw milk cheeses than in processed ones and that many strains isolated from raw milk cheeses were associated with the formation of more complex volatile profiles and higher scores for some sensorial attributes. This abundant native microbiota can express in raw milk cheeses, which is not the case in cheeses made from pasteurized or microfiltered milk. The wide variation in the dynamics of the species in association with the prevalent physic chemical peculiarities of each cheese creates the diversity of aroma and taste among cheeses. Throughout ripening, the microflora biodiversity will usually decrease in cheese cores and only a small number of LAB species resist to the harsh conditions of hard cheeses. The living bacteria, as well as the enzymes from the bacteria dying off throughout the ripening process, play a key role in the final taste and aroma development of hard cheeses.

Starter Culture and Rennet

Cheese ripening is characterized by a number of microbiological changes and many biochemical changes that are caused by enzymes from the rennet, the milk, and the microorganisms associated with the cheese. The starter culture added to milk during cheese processing is expected to lower the pH of milk thus increasing the rate of syneresis and contribute to the development of the organoleptic characteristics of the cheese (less

important in fresh cheeses). Thus, using the right type and amount of starter culture is crucial to bring about more or less consistently the biochemical activities (proteolysis, lipolysis, and glycolysis) that are important for the development of aroma in cheeses.

The hydrolysis of the casein by rennet in cow's milk transforms the caseins from a stable colloidal system to an unstable one forming a gel that eventually can expel liquid by syneresis. The rate of the enzymatic hydrolysis of casein in milk is proportional to the amount of rennet added, and in this way, the rennet concentration indirectly affects aggregation.

While the starter bacteria generally die off after manufacture, they continue to contribute to ripening since their cells burst open after death releasing their enzymes into the cheese. In most long ripened cheeses, wild nonstarter lactic acid bacteria (NSLAB) grow slowly during ripening and may eventually reach high numbers.

In certain varieties, very obvious microbiological changes occur. The distinctive eyes (holes) in Swiss cheese are caused by the growth of a secondary bacterial flora, which converts the lactic acid produced by the starter bacteria to other products, including carbon dioxide gas, some of which is trapped in the cheese to form bubbles.

pH

Changing the pH of the milk strongly affects the structure of the micelles and the renneting reaction, as the rate of enzymatic breakdown of casein is very dependent on pH. Rennet (i.e., chymosin) is an acidic enzyme, with an optimum activity in milk around pH 6.0, thus, decreasing the milk natural pH increases the rate of proteolysis considerably. Lowering the pH of the milk leads to a decrease in coagulation time, the main effect probably being the increase in enzyme activity; aggregation is also affected. All together, these changes have an effect in whey expulsion and consequently in the inner conditions that will prevail throughout the long ripening process of hard cheeses. Different cheese varieties usually have different pH profiles throughout all the processing and ripening phases.

Temperature

In general, milk will not clot when the temperature is below 15 °C. This is an effect of the inefficiency of the aggregation reaction since the enzymatic hydrolysis of casein still proceeds at low temperature; heating will then lead to almost immediate coagulation, a phenomenon termed cold renneting. Coagulation and syneresis are optimized at a typical temperature for each hard cheese.

Manufacturing of Some Hard Cheeses

Cheddaring is a unique step in the making of Cheddar cheese. It is a multistep process that reduces whey content, adjusts acidity, adds characteristic flavor, and results in a denser and sometimes crumbly texture. Cheddaring implies that cooked curds are cut and then left to set forming loaves. The loaves are then cut, turned over, and stacked repeatedly. This process is complete when the acidity of the whey is between 5.1 and 5.3. The loaves now are milled, salted and put into molds, pressed, and put to ripening for a year or more, depending on the variety of Cheddar being processed.

In the case of Parmesan cheese, its traditional processing begins with the evening milk being kept overnight in metal trays, to allow the cream to rise to the top, skimmed, and combined with the whole milk from the morning milking. The milk is warmed in large cauldrons and naturally fermented whey from the previous day's production is added as a starter. Natural calf's rennet is then added to coagulate the milk and curds form after about 20 min.

Using a balloon whisk called a spino, the cheesemaker whisks the curds obtaining curds the size of a grain of wheat separated from the whey. All the mixture is cooked at a specific temperature and left to stand and allow the curds to sink to the bottom of the cauldron where they knit together forming a spongy mass. Using specific equipment and procedures, the cheesemaker lifts the curd mass and, dividing it in half, wraps each in a muslin. The cheeses are hung on poles to shed excess liquid, while the whey drains out, some of which will be used as starter culture in the next day cheese processing.

The curds are inserted in molds and, after pressing, become salty where they stay for about 24 days. The cheese wheels are then transferred to the curing rooms, where they remain usually for 1 year, being turned regularly, wiped, and brushed. Finally, through a series of tests, independent inspectors determine whether the cheese meets the standards of the Consorzio del Formaggio Parmigiano Reggiano.

An important and the longest part of the production of the Le Gruyere is the 'affinage,' that is, maturation. After the curds are put into molds, they must be ripened in caves with humidity near 94%. If the humidity is lower, the cheese dries out. If the humidity is too high, the cheese does not mature and becomes smeary and gluey. The temperature of the caves should be between 13 and 14 °C. Different combinations of temperature and humidity will result in cheeses of different characteristics such as harder or more crumbly.

The uniqueness of Emmental cheeses resides in the combination of a thermophilic starter culture with a culture of propionic bacteria that typically releases carbon dioxide gas, which slowly forms the bubbles that make eyes or holes typically present in Emmental cheeses. Emmental is somewhat a difficult cheese to produce because of the complicated eye-forming fermentation that requires specific conditions for the propionic bacteria to produce the gas in the required and not excessive amount.

Cheese Problems

The microbiological and biochemical changes that occur during ripening, and hence the flavor and aroma of the finished product, are largely predetermined by the manufacturing process. While the extensive ripening period of hard cheeses contributes to the development of their taste and aroma, it may also increase the chances of occurrence of a number of potential defects in the product.

A defect so-called 'early blowing' may appear some time after the cheese has been manufactured. This is usually a consequence of an unbalanced presence and activity of bacteria of

the group Enterbacteriaceae, which may be present in raw milk or introduced into pasteurized milk or curds by improper hygienic practices. High hygienic standards and pasteurization in general decrease substantially these type of problems.

Another problem common in hard cheeses is the so-called late blowing (**Figure 4**), associated with the presence of resistant spores from such bacteria as *Clostridium tyrobutyricum*, which when in vegetative form produces gases causing unwanted discontinuity of the cheese paste after 2–3 months after the cheeses have been manufactured. *C. tyrobutyricum* are commonly present in milk from cows fed with hay contaminated with the spores. Milk centrifugation (bactofugation), to eliminate spores, high-quality hay or addition to milk of preservatives such as nitrite, or lysosima are the common ways to lower the chances of appearance of the late blowing problem.

While an optimum activity of the starter culture is desirable, the excessive activity of the starter culture and of the rennet may lead to formation of undesirable substances and to defects such as bitterness, a consequence attributed to excessive proteolysis and formation of short hydrophobic peptides. The inhibition of citrate-fermenting starter cultures by bacteriophages (or for that matter, antibiotics present in milk) may also permit residual levels of citric acid to remain in the curd. In fact, inhibition of starter cultures is said to be a cause of explosion of entire wheels weighing more than 24 kg. Heterofermentative NSLAB are capable of fermenting citrate with the production of carbon dioxide. As a result, gassing may occur, with splits and fissures developing in Parmesan production.

The involvement of yeasts in the maturation and spoilage of many cheese types is complex and in many cases difficult to differentiate; however, they may also contribute to flavor development within and on the surface of Gorgonzola and Camembert.

Finally, concerns about safety of raw milk cheeses are the basis for legislation requiring that raw milk cheeses must have a minimum maturation time of 60 days, forming an integral part of the HACCP (hazard analysis critical control point) plan so that pathogens such as *Salmonella* spp., at levels that might

Figure 4 Intense gas production in cheeses contaminate by *Clostridium tyrobutyricum*.

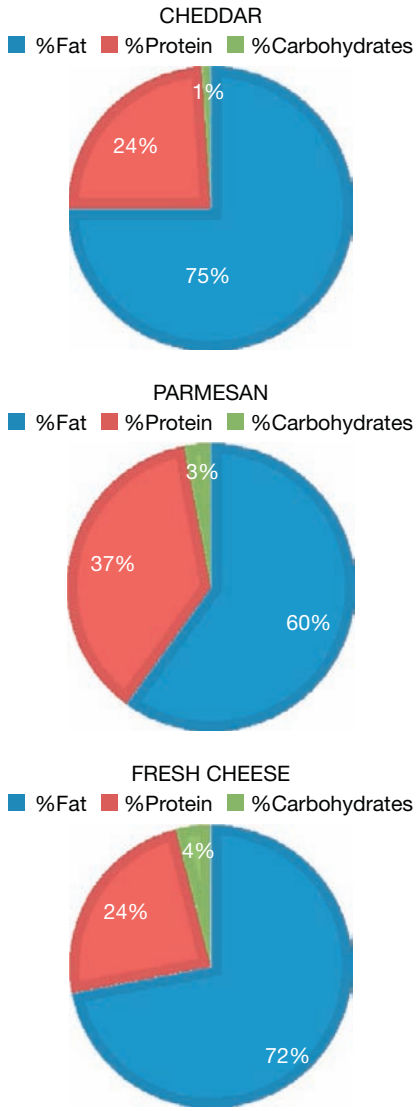

Figure 5 Caloric ratio for the three varieties of cheeses.

be encountered naturally, will be presumed to have died before the cheese is consumed.

Microbiological problems associated with cheese manufacture can be summarized in three categories: (a) failure to make the product as intended, (b) defects resulting in spoilage or loss of quality of the finished product, and (c) contamination that may result in an unsafe product. It has also been emphasized that these problems are likely to be highly variable, depending on the type of cheese, source of milk, processing, season of the year, geographic location and storage, distribution, and consumption.

Nutritional Considerations

Hard cheeses can be considered as highly concentrated sources of protein and fat, having low carbohydrate (lactose) contents (see **Table 1** and **Figure 5**). The protein content in cheese, especially hard cheeses, is of high biological availability, in the form of peptides and amino acids resulting from degradation of casein. The fat contents in hard cheeses (may be above 52%, mainly in the form of saturated fatty acids) make them to be high-caloric food products. Hard cheeses are also good sources of calcium and fat-soluble vitamins such as vitamins A and D as well as of CLA.

Introduction

Cheese can be defined as a consolidated curd of milk solids in which milk fat is entrapped by coagulated protein (casein).

It is believed that accidentally, man found that milk coagulate and sour, separating into curds and whey if exposed to natural heat in specific containers, and this was found to be a good way of preserving the valuable nutrients present in milk, making cheese an important component of human diet since then. Athletes in the Roman Empire had cheese as a preferred food choice, which was described then as 'a luxurious specialty for the palate of the kings.'

Today, cheesemaking is a major industry worldwide, as advances in food science and technology have led to large-scale industrialization, allowing for mass production with a focus on guaranteeing products with microbial safety and textural consistency. However, much is still practiced on a relatively small-scale accounting for a rich diversity of cheeses still available. At a small scale, cheesemaking may still be seen as an art, namely, in what concerns the processing of the so-called traditional cheeses, where the cheesemaker experience and empirical knowledge are key factors in obtaining cheeses of unique taste and flavor.

The removal of water during cheese processing increases the concentration of most nutrients (proteins, fat, mineral salts, and vitamins with the exception of lactose) present in milk, making cheese a nutrient rich food. Cheeses can be classified based on a number of criteria; however, classifications based on the source of milk, method of coagulation, or texture (which is largely determined by moisture and fat contents) are the most common. The latter allows the classification of cheeses as: 'soft,' 'semisoft' (medium), or 'hard.' Texture is an important quality parameter that determines the identity of a cheese and greatly affects its consumer preference and acceptance, and although it may mean different things to different people, cheese texture and general appearance such as mouthfeel are the primary quality attribute of any dairy food. Many instrumental methods do exist today to evaluate the rheology and structure of a product (texture); however, humans have been the cornerstone of food texture characterization.

Source and Production

There are more than 200 types of cheeses and their making involves a complex number of sequence procedures associated with specific biochemical transformation, which, as a whole, influences the development of cheese flavor, as well as the yield and composition, and thus the overall quality of the final cheese.

However, for convenience, all processes can be broken down into a number of relatively simple unit operations (Figure 1), and slight variations of these and the use of different milks (Table 1) combine to generate the huge range of cheeses available today.

At high output industry, due to the high volumes of milk being processed (Figure 2), cheesemaking is highly automatized and thus expected to be less prone to variations among batches. Although not compulsory (as for typical raw milk cheeses), a heat treatment equivalent to pasteurization is usually applied at the start of processing. The milk is then cooled to the fermentation temperature, which will differ from cheese to cheese but usually in the range of 30–37 °C, followed by the addition of the starter culture. This helps to ensure a safe product, and for cheeses undergoing the ripening phase, it leads also to a reliable fermentation, keeping variations in the course of industrial manufacture of cheese to a minimum. The salting of the curd is common to all cheeses giving it more taste and increasing the microbial safety of the curd due to the preservation properties of salt.

However, cheeses can be processed via more basic technology as happens in artisanal cheesemaking (Figures 3 and 4). These cheeses, also called traditional or specialty cheeses, are essentially handmade and when made from raw milk are usually considered to be of more interest in terms of taste and aroma (see Figure 5) than their industrial counterparts. Thus, artisanal cheesemaking is still an important part of the cheese market in the world. In fact, artisanal cheeses are often seen as alternative products that may actively contribute for consumer's health, although some concerns exist related to their safety. In particular, raw milk for processing raw milk cheeses should be of a standard microbial quality ($<10^4$ cfu ml^{-1}), which is a key factor in obtaining products of highest quality.

Whatever the process (industrial or artisanal), the resulting cheeses may be classified based on their moisture and fat contents as 'soft' (fresh), 'semisoft' (medium), or 'hard' cheeses; see Table 2.

Thus, there are hundreds of different types of cheese, but each is made using similar principles of coagulating the proteins in milk to form curds and then separating the curds from the liquid whey. Depending on the type of cheese, milk proteins may be coagulated in different ways, of which the most common include: (i) adding rennet (or 'chymosin') – an enzyme extracted from calves' stomachs or produced by micro-organisms, or from plant rennet extracts, (ii) via fermentation that releases lactic acid, and (iii) via addition of such acids as lemon juice, lime juice, or vinegar or by combination of above methods. The different cheese flavors and textures arise from a combination of such factors as the type of milk, the amount of fat in the milk, the bacteria culture used to ferment the milk, and specially from the processing conditions applied during cheese-making and ripening. Cheeses classified as soft-unripe, usually have a very short shelf-life as such.

Soft cheeses have water content in the range of 50–80% and, depending on the variety, may not undergo the ripening

 http://dx.doi.org/10.1016/B978-0-12-384947-2.00132-X

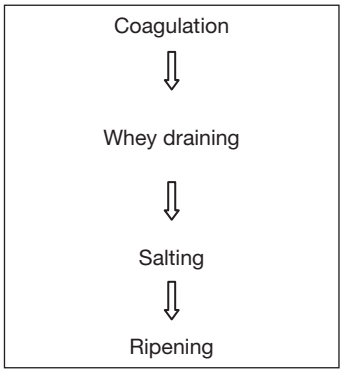

Figure 1 General cheesemaking steps.

phase, namely, in the case of the so-called fresh cheeses; thus, their processing may not require the addition of a starter culture. Soft cheeses are easier to make than hard cheeses and are traditional foods that are popular in many countries. In some varieties, the whey is drained to leave the cheese, which is pressed into blocks and stored in brine until it is sold. Coagulation may be achieved using rennet, or organic acids such as lactic acid, lemon juice or vinegar. These cheeses are soft, moist, and creamy and include curd cheese, paneer, queijo fresco, cottage cheese, Brie, Serra da Estrela cheeses, and others.

Table 1 Average chemical composition of milk of different species (for 100 g of fresh milk)

Species	*Water (%)*	*Proteins (%)*	*Fat (%)*	*Lactose (%)*	*Mineral salts (%)*
Buffalo	82.2	4.8	7.5	4.7	0.8
Goat	86.5	3.9	4.3	5.8	0.8
Ewe	80.9	6	7.5	5.4	1.1
Cow	87.5	3.2	3.7	4.6	1

Note: In cheese, these nutrients will appear on average ten times more concentrated.

Soft Unripened Cheeses

Queijo Fresco

The most simple known fresh cheese is queijo fresco (fresh cheese, queso blanco). Queijo fresco (see Figure 6) is a common type of cheeses in Southern Europe and Central and South America. Its processing simple requires the heating of milk followed by the addition of rennet or a food-grade organic acid (acetic, citric, or lactic acid or even lemon juice). After coagulation and whey drainage, the curds are salted, hooped, and packaged. The texture and mouthfeel of queijo fresco depend on the severity of heat treatment given to milk, the acid type used, and mode of clotting. If the curds are pressed, the cheese will have a more rubbery texture especially if it is made from low-fat milk. After packaging, queijo fresco is ready to eat and has on average 5–7 days of shelf life if kept in refrigeration.

Cottage

Cottage cheese (see Figure 7) is a common type of cheeses in Anglo-Saxon countries. It may be available in low-fat and non-fat forms; while regular cottage cheese only has 4% of fat by weight, low-fat cottage cheese has only 2%. Cottage cheese has long been considered an ideal source of protein for those on weight loss diets because it can be made in a variety of low-fat forms, it is inexpensive, and it can be used in a multitude of recipes. Billions of pounds of cottage cheese are consumed each year in the United States, probably as a result of a public's perception of cottage cheese as a health food.

Cottage cheese manufacturing typically begins with pasteurized skim milk, which is then inoculated with active lactic starter to raise the acid content and rennet to speed coagulation. Rennet is added for a rapid coagulation of milk in the cheesemaking process. Depending on the type of cottage cheese being made and the amount of active lactic starter used, the inoculated milk is held for 5–16 h at a temperature of 32° C (89.6 F). This allows the lactic starter to reproduce and acidify the milk, and the mixture to coagulate properly. The resulting coagulated milk is then cut into cubes that will form the curds that are seen in cottage cheese. Then, the mixture is cut, increasing whey draining, and rinsed with worm and cold water. Most other forms of cheese are then pressed, but cottage cheese is not, thus retaining significantly more moisture and does not form a solid block. The addition of cream, depending

Table 2 Most representative groups of cheeses and their texture classification

Type	*Moisture content*	*Fat content*	*Name*	
			Unripened	*Ripened*
Soft	50–80%	<40%	Cottage, quark, cream, queijo fresco (queso blanco)	Camembert, Brie, Neuchâtel, queijo Serra da Estrela
Semisoft	40–50%	<35%	Mozzarella, Roquefort, Stilton, Gorgonzola, São Jorge, Provolone, Gouda, Edam	
Hard	30–40%	<30%	Cheddar, Idiazabal, Gruyère, Parmesan, Emmental, São Miguel	

Table 2 GLUT transporters: location and importance

Transporter	*Location*	*Importance*
GLUT1	Erythrocytes Brain endothelial cells Blood–placenta barrier	High-affinity transporter in cells that rely almost exclusively on glucose for energy Critical for fetal development
GLUT2	Intestine Liver Kidney Pancreas (β-cells)	Low-affinity transporter that becomes more active when glucose levels are high. Important for the absorption of monosaccharides and for ensuring uptake of excess glucose in the liver. May also be used by the pancreas as a trigger for insulin release. Critical for glucose reabsorption by the kidney
GLUT3	Brain neurons	High-affinity transporter in a tissue that relies almost exclusively on glucose for energy
GLUT4	Skeletal muscle Cardiac muscle Adipose tissue	High-affinity transporters induced by insulin to increase glucose uptake into cells Failure of these transporters to respond to insulin leads to insulin resistance
GLUT5	Primarily intestine Testes Liver Skeletal muscle Adipose tissue	The predominant fructose transporter in tissues Critical in testes as fructose is an important energy source for sperm

body. Most of the GLUT proteins that transport glucose can also transport galactose and sometimes fructose; however, fructose is most frequently transported across tissues by GLUT5. Fructose and galactose levels in the blood are magnitudes lower than glucose due to the proportion of these monosaccharides in the diet compared to glucose and because galactose and fructose are rapidly taken up and metabolized by the liver.

The role of the tissue in carbohydrate metabolism is reflected by the type of GLUT transporter present in the cells. Tissues and cells that absolutely depend on glucose for fuel, such as erythrocytes (red blood cells) and brain endothelial cells, have higher concentrations of GLUT1 transporters. The GLUT1 transporter has a high affinity (low K_m) for glucose, thus ensuring that even at low blood glucose concentrations, the cells will be able to obtain glucose for energy. GLUT1 transporters are most concentrated in the erythrocyte (as much as 10% of the membrane protein), to not only ensure these glucose-dependent cells receive glucose but, possibly, also provide greater capacity for the bloodstream to carry glucose. GLUT1 also mediates glucose transport to the placenta and is critical throughout fetal development. Mice *in utero* that do not express GLUT1 do not survive gestation, and humans that have the genetic disease of GLUT1 deficiency syndrome experience developmental delays, seizures, and neurobehavioral issues from infancy.

Tissues that are involved in the absorption and regulation of blood glucose, such as the liver, kidney, pancreas, and intestine, express more of the GLUT2 transporter, which has a lower affinity (high K_m) for glucose. Thus, when glucose concentrations are high, these transporters become more active. In the liver, GLUT2 transporters begin to remove glucose from the bloodstream as glucose levels rise, thereby helping to regulate blood glucose levels. The liver is capable of converting and storing excess glucose for release at a later time when glucose levels are lower. In the pancreas, GLUT2 likely plays a role in glucose sensing that triggers the release of insulin as blood glucose levels rise. The expression of GLUT2 in the renal tubules of the kidney is critical for the reabsorption of glucose into the bloodstream and prevention of glucosuria.

Skeletal and cardiac muscle and adipose tissue predominantly express the insulin-dependent glucose transporter GLUT4. This transporter is fairly specific for glucose with little to no uptake of galactose or fructose. As insulin levels rise in response to an elevation in blood glucose, GLUT4 transporters are recruited from the intracellular compartment to the cell membrane. Most of the glucose in the bloodstream is taken up by skeletal muscle cells through this mechanism, making GLUT4 an important transporter for regulating blood glucose levels. In fact, disruption of the translocation of GLUT4 to the cell membrane is commonly known as insulin resistance and contributes to the development of type 2 diabetes. To learn more about the role of carbohydrates in health conditions, such as type 2 diabetes, see elsewhere in this Encyclopedia.

Glycemic Response

The change in the levels of glucose in the bloodstream after absorption of carbohydrate is considered the 'glycemic response.' Many physiological and food-related mechanisms influence the glycemic response to food, such as the type of carbohydrate consumed, the clearance of glucose from the bloodstream, and other components within the food (e.g., fat and protein). These factors are further discussed in the section in the succeeding text. For more information on the regulation of glucose in the bloodstream, see elsewhere in this Encyclopedia.

Factors Impacting Digestion and Absorption of Carbohydrates

Physiological and Genetic Factors

There are several congenital disorders that can lead to impaired digestion and absorption of carbohydrates. Disorders impacting digestion are typically defects in brush border enzymes, such as sucrase–isomaltase and lactase. Malabsorption disorders that are not a result of inadequate digestion are usually a result of genetic disorders in transporters or secondary to other digestive disorders, such as celiac disease.

Congenital deficiencies in digestive enzymes, such as sucrase–isomaltase, lactase–phlorizin hydrolase, and glucoamylase, are rare conditions but have been identified and characterized in various populations. The symptoms of these conditions are often similar: diarrhea, bloating, abdominal discomfort, vomiting, and dehydration; therefore, diagnosing these conditions often requires identifying the specific dietary carbohydrate trigger (e.g., sucrose or lactose) and sometimes intestinal biopsies. Treatment generally involves

on the type of cottage cheese being made, and of salt may follow.

Soft Ripened Cheeses

There are a number of soft cheeses that undergo a ripening period that usually may go up to 1 month. Examples of these are Brie, Feta, Camembert, Serra da Estrela cheese, and others.

Feta

Feta (Figure 8) is a protected designation of origin (PDO) cheese and may be the most famous Greek cheese occupying more or less 70% of the Greek cheese market.

Traditionally, the cheese is made by mixing 30% goat's milk with sheep's milk, although nowadays, goat's and cow's milk are also made. The coagulation requires the use a starter culture (a mixed culture that may contain *Lactococcus lactis*, *Lactobacillus bulgaricus*, *L. helveticus*, and *Streptococcus thermophilus*) and afterward the addition of rennet, draining the way followed by brine salting. Feta texture is creamy or crumbly dry, varying according to age, local environment, animal breeds, and starter cultures. Feta aged for 4–6 weeks is sold in blocks, and because it is a high-salt cheese sometimes, it is washed underwater to remove the extra saltiness.

Brie

Brie (Figure 9) and Camembert are the types of so-called mold ripened cheeses and are produced from whole or semi-skimmed cow's milk to which rennet is added. After coagulation and after curds are firm, they are injected with a mold infusion of *Penicillium candidum* or *P. camemberti*. The cheese is then cast as several layers of cheese into molds and then kept for around 18 h. After this, the cheese is salted and aged for minimum of 4 weeks. *P. candidum* or *P. camemberti* have a high proteolytic and lipolytic activity; thus, they are important contributors to development of the typical taste of Brie. There are several varieties of Brie cheese including plain, herb, and others with combinations of milk products. The microbial dynamics during Brie as well as Camembert ripening may be complex, implying succession of different types of microorganisms such as yeasts, molds, and lactic acid bacteria, each one prevailing at pH values and different ripening phases.

Camembert

Camembert (Figure 10) is a soft high fat cheese, also made from cow's milk. Camembert is ripened as a small round cheese and sold as such, so it is fully covered by the rind. Good Camembert cheese is bland, hard, and crumbly in texture when fresh. As the cheese matures, it forms a smooth, runny interior and a white bloomy rind that is typical to Camembert cheese. It has a rich, buttery flavor. The rind is bloomy white caused by a white fungus of the *Penicillium* group.

Figure 8 Blocks of Feta cheeses.

Figure 9 Brie cheese with its characteristic white rind.

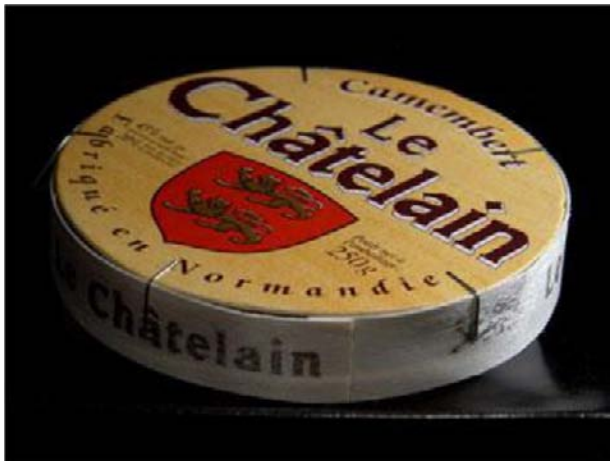

Figure 10 An elegant package of Camembert cheeses.

Figure 11 (Left) Serra da Estrela cheese with typical texture and rind covered by a cloth; (right) the thistle flower of cardo plant (*Cynara cardunculus*).

Serra da Estrela

Serra da Estrela is a PDO (Protected Designation of Origin) (Figure 11) Portuguese cheese and has been made for centuries by shepherds in the mountains of Serra da Estrela in the Beira region from sheep's milk. The cheese is entirely handmade, with the curds being broken up by hand. Serra da Estrela is so soft that it is almost spreadable. The affinage takes 30–40 days. Interestingly, Serra da Estrela among other Portuguese traditional cheeses is coagulated with a thistle rennet from a plant named cardo. The high proteolytic activity of the vegetal coagulant associated with the high fat content of ewe's milk gives the soft spreadable texture typical of Serra da Estrela cheese.

Nutritional and Health Effects

In general, cheeses are highly nutritious foods reach in protein, fat, fat soluble vitamins, and calcium. Due to their content in fat, cheese is a high caloric food; thus, efforts have been undertaken toward making low-fat cheeses. As reduction in fat results in an unpleasant rubbery texture, low-fat cheeses are usually of fresh (soft) type. Fresh unripened cheeses may still have considerable amount of lactose, and this, associated with a high moisture content, makes them more prone to spoilage by bacteria, thus having a short shelf life.

EDITORS-IN-CHIEF

Benjamin Caballero is professor of International Health and of Maternal and Child Health (Bloomberg School of Public Health), and professor of pediatrics (School of Medicine) at Johns Hopkins University.

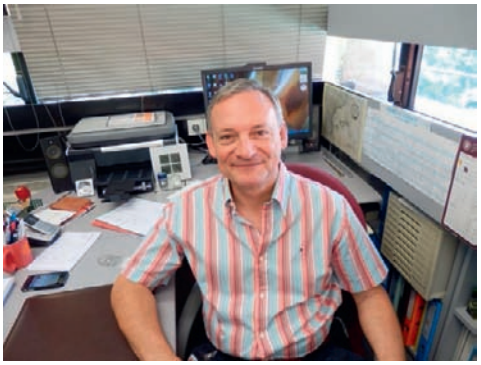
He obtained his MD from the University of Buenos Aires, his MSc in biochemistry from the University of San Carlos, and his PhD in neuroendocrine regulation from MIT, in Cambridge, MA. He started his academic career as assistant professor of pediatrics at Harvard Medical School and director of the Nutrition Unit of Boston Children's Hospital, and subsequently became the founding director of the Center for Human Nutrition at Johns Hopkins University, in Baltimore.

Prof. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries. He was a member of the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, USA, and of a number of expert panels created by the Institute, including the Dietary Reference Intakes (DRI) Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration (FDA), and of a number of advisory committees of the National Institutes of Health (USA).

He is the editor-in-chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption and biological effects. He is also editor-in-chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. His book *The Nutrition Transition: Diet and Disease in the Developing World* explored the impact of demographic and economic development on diet- and lifestyle-related diseases in developing countries. His book *Obesity in China* summarizes research conducted in rural and urban China to track the impact of socioeconomic development on health outcomes. He is also coeditor of a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

He is a member of the Spanish Academy of Nutritional Sciences, and a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK). Recent awards include the Donald Medearis Lectureship from the Massachusetts General Hospital/Harvard Medical School, the Mataix Prize for lifetime achievements in nutrition science from the Spanish Academy of Nutritional Sciences, the Ancel Keys Prize for achievements in international public health, and the Thompson–Beaudette Lectureship from Rutgers University.

Paul Finglas joined the Institute of Food Research in 1981 and is currently head of the Food Databanks National Platform and Research Leader in Food and Health at the Institute (http://www.ifr.ac.uk/science/platform/FD/default.html). He has, for most of his science career, been involved in a wide range of research in food composition and analysis, and the nutritional effects of micronutrients in food and health research. Paul has considerable experience of co-coordinating both national and international projects (e.g., EuroFIR, TDS-EXPOSURE, Bacchus and QualiFY (all EU FP7), and is currently of the spin-out EuroFIR AISBL, a non-profit international association based in Belgium, from one of these projects. Paul has a broad range of experience in science publishing and is currently editor of the journals *Food Chemistry* and *Trends in Food Science and Technology*, and was one of the coeditors for the *Encyclopedia of Food Science and Nutrition* (2nd Ed.). Paul has a degree in chemistry from Aston University in Birmingham and has published over 150 publications on a wide range of topics in food science and nutrition.



Fidel Toldrá holds a BSc in chemistry (1980), high degree on food technology (1981) and PhD in chemistry from the University of Valencia (1984). Professor Toldrá was a Fulbright postdoctoral scholar at Purdue University in West Lafayette (US, 1985–86) and visiting scientist at the University of Wisconsin-Madison (1991 and 1995), and the Institute of Food Research-Bristol (UK, 1987). Currently, he is research professor at the Instituto de Agroquímica y Tecnología de Alimentos (CSIC), in Paterna, Valencia (Spain). He is also associate professor of food technology at the Polytechnical University of Valencia.

Prof. Toldrá has focused his research on food biochemistry and its relationship with nutrition, quality and safety. He has filed 12 patents, directed 22 PhD thesis and published over 245 manuscripts in recognized scientific journals and more than 115 chapters of books. His h-index is 41. Prof. Toldrá has authored two books and edited/co-edited more than 30 books for major publishers like CRC Press, Wiley-Blackwell, Elsevier and Springer.

Prof. Toldrá is the European editor of *Trends in Food Science and Technology* (2005–) and associate editor of *Meat Science* (2014–); he was the editor-in-chief of *Current Nutrition & Food Science* (2005–2012), section editor of the *Journal of Muscle Foods* (2009–2010) and guest editor of 12 special journals issues. He is a member of the editorial boards of *Food Chemistry*, *Food Analytical Methods*, *Journal of Food Engineering*, *Journal of Food and Nutrition Research*, *The Open Nutrition Journal*, *The Open Enzyme Inhibition Journal*, *Recent Patents in Agriculture*, *Food and Nutrition*, *Food Science & Nutrition* and *Current Opinion in Food Science*.

He has been a member of the Scientific Panel on food additives, flavorings, processing aids and materials in contact with foods (periods 2003–2008) and the Scientific Panel on flavorings, enzymes, processing aids and materials in contact with foods (2008–2015) of the European Food Safety Authority (EFSA) acting as Chairman of the Working groups on Irradiation (2009–2010), Processing Aids (2011–2014) and Enzymes (2010–2015). He was a member of FAO/WHO group of experts to evaluate chlorine-based disinfectants in the processing of foods (2008–2009). He was a member of the Executive Committee of the European Federation of Food Science and Technology (EFFOST, 2002–2009). He is a Fellow of the International Academy of Food Science and Technology (IAFOST, 2008) and of the Institute of Food Technologists (IFT, 2009–). He received the Iber Award on Food and Cardiovascular Diseases (1992), the Institute Danone award in Food, Nutrition and Health (2001), the International Prize for Meat Science and Technology from the International Meat Secretariat (2002), GEA award on R+D activity from the Valencian Community (2002), and the Distinguished Research Award (2010) and Meat Processing Award (2014), both from the American Meat Science Association.

EDITORIAL ADVISORY BOARD

Siân Astley has worked extensively with individuals and organizations throughout Europe from a variety of disciplines including research, food and biotech industries, and the media. She is the author of more than 300 popular science articles for magazines and trade publications as well as 25 peer-reviewed papers, and she was awarded her Diploma in Science Communication in 2009 (Birkbeck University of London). After 14 years as a bench-scientist, Siân became communications manager for NuGO, one of the first FP6 networks of excellence, and was the European communications manager for the Institute of Food Research in Norwich (UK) until April 2012. Currently, she is the training and communications manager for the European Food Information Resource (EuroFIR AISBL) supporting training within EU-funded research projects and networks, and communication of research activities.

David J. Baer is a supervisory research physiologist with the US Department of Agriculture's Beltsville Human Nutrition Research Center located in Beltsville, Maryland. He serves as the research leader for the Center's Food Components and Health Laboratory and also serves as the director of the Center's Human Studies Facility.

Dr. Baer conducts controlled dietary intervention studies to investigate the relationship between diet and the risk for chronic degenerative diseases, especially cardiovascular disease, cancer, and diabetes in people. His research also includes studies on the health impacts of weight gain and determining the calorie content of foods. Some of the dietary interventions he has investigated include the effects of different types of protein, fats and fatty acids, fiber, margarine, butter, plant sterols, salad dressings, nuts, whole grains, berries, alcohol, and tea on overall nutrition and health. In addition to dietary intervention studies, Dr. Baer is involved in research studies to validate food survey methodologies and in developing new methods for dietary assessment.

Dr. Baer earned his bachelor's degree from the University of Illinois and his master's and doctorate in nutrition from Michigan State University.

Marina Carcea was awarded a master degree in agricultural sciences at the University of Pisa, Italy "cum laude" in 1980, and a PhD in food science also "cum laude."

She is currently a senior researcher in the Research Center on Food and Nutrition of the Council for research in agriculture and analysis of agricultural economy (CRA-NUT formerly INRAN National Research Institute on Food and Nutrition) and she was the director of the Cereals Research Programme in INRAN. CRA-NUT is a primary research institute in Italy under the egis of the Ministry of Agriculture. Dr. Carcea joined INRAN in 1989 after having worked in Italian and English universities (Queen Elizabeth College, King's College, and University of London) and after a two-year contract with the Food and Agriculture Organization (FAO) of the United Nations (UN), Rome.

She has a vast experience in the field of research on foods, cereals in particular. In recent years, her main research interests have been: chemical characterization and study of the functional properties of cereal components; study of the interactions between components and of the interrelationships between the biochemical properties of components and the technological properties of the raw material and derived products; development of new, cereal-based products; development of methods to assess technological parameters of the raw material; nutritional value of cereals; and developments of protocols for quality assurance of cereals, food authenticity.

She has taken part and/or co-ordinated several research projects within national or international programs (European Commission, FAO) involving several institutions. She is the author of more than 160 scientific publications, mostly in international journals, eight book chapters, and two scientific books. She delivered lectures on her research activity at about 150 national and international congresses and she seats in several national and international committees (Italian Ministry of Agriculture, Codex Alimentarius, and European Commission) regarding food and nutrition topics. She is also a member of the editorial board of scientific journals.

From 1994 to 2006, she has also been a lecturer of food science and technology at the University of Tor Vergata, Rome, Italy.

She is a founding member of AISTEC, the Italian Association of Cereal Science and Technology. Since 1996, she is an elected member in the Executive Committee of the same association and since 2009, president of the association.

Since 2000, she is the Italian National Delegate of the International Association for Cereal Science and Technology (ICC) and she was also the president of the same association for 2011–2012.

In 2004, she was the first woman to be awarded the International Harald Perten Prize for her excellent research achievements in the field of cereal science and technology.

She is also a member of the Georgofili Academy in Florence, Italy.

Lawrence J. Cheskin graduated from Dartmouth Medical School and completed a fellowship in gastroenterology at Yale–New Haven Hospital. He is an associate professor of health, behavior, and society at the Johns Hopkins Bloomberg School of Public Health, with a joint appointment in International Health–Human Nutrition, and in medicine (GI) at the Johns Hopkins University School of Medicine. Dr. Cheskin is also a founder and director of the Johns Hopkins Weight Management Center, a comprehensive treatment program for obesity.

In his research, Dr. Cheskin has studied the effects of medications on body weight, the gastrointestinal effects of olestra, how cigarette smoking relates to dieting and body weight, and the effectiveness of lifestyle and dietary changes in weight loss and weight maintenance.

He is also the author of four books: *Losing Weight for Good*, *New Hope for People with Weight Problems*, *Better Homes and Gardens' 3 Steps to Weight Loss*, and *Healing Heartburn*. Dr. Cheskin has appeared on television news programs and lectured to both professional and lay audiences on the topics of obesity and weight control.

Nigel Cook is a graduate of the University of Dundee. After postdoctoral research in the Universities of Aberdeen and Leicester, he moved to the Central Science Laboratory (now the Food and Environment Research Agency (FERA)) at the Food Science Laboratory, Torry, Aberdeen in September 1994, before relocating to new facilities in York. At FERA, he studies the transmission of pathogens, particularly enteric viruses, through foods and the environment. He has a visiting professorship at the Katholieke Universiteit Leuven in Belgium. He is a councilor of the International Association for Food and Environmental Virology. He is a project leader within the standardization working group ISO TC34 SC9 WG6, currently developing a standard for detection of *Cryptosporidium* and *Giardia* on berry fruits and leafy green vegetables. He was a coordinator of the European Framework 7 project "Integrated monitoring and control of foodborne viruses in European food supply chains (VITAL)," and a chair of COST Action 929 "A European Network for Environmental and Food Virology" from 2006 to 2010. Between 2009 and 2014, he was a member of various European Food Safety Authority's Working Groups preparing opinions on the risk of foodborne viruses, and represented the European Communities on the Codex Committee on Food Hygiene Working Group developing *Guidelines on the Application of General Principles of Food Hygiene to the Control of Viruses in Food*. He was a member of the UK Advisory Committee on the Microbiological Safety of Food's Viral Infections Subgroup. He was the founding editor of the journal *Food and Environmental Virology*, published by Springer.

Luca Simone Cocolin graduated in 1994 in food science with a grade of 110/110 and remark followed by food biotechnology PhD studies from 1995 to 1998. In February 1999, he defended his thesis acquiring the title of PhD in food biotechnology. From 1998 to 2001, he received a scholarship from the Friuli Venezia Giulia region (Italy). From November 1, 2001, he was an assistant professor at the University of Udine, Faculty of Agriculture, Food Science Department, Italy, and in October 1, 2006, he became an associate professor at the University of Torino, Italy. In January 2014, he had the habilitation for full professor and from June 2015, he is the full professor in food microbiology at the University of Torino.

From September 2008, he is an executive board member of the International Committee on Food Microbiology and Hygiene (ICFM) part of the International Union of Microbiological Societies (IUMS) (http://www.icfmh.org/). From January 2008, he is the editor-in-chief of the *International Journal of Food Microbiology* and he is a member of the editorial board of *Applied and Environmental Microbiology*, *Food Analytical Methods*, *Frontiers in Food Microbiology*, and *Frontiers in Nutrition and Food Science Technology*. He regularly reviews paper for *Food Microbiology*, *Meat Science*, *Journal of Applied Microbiology*, and *Letters in Applied Microbiology*. He is a co-author of more than 180 papers on national and international journals and he attended national and international congresses with oral and poster presentations. On Scopus (www.scopus.com, consulted on March 2015) he has 172 documents reviewed, which were cited 3520 times, resulting in an h index of 33.

His scientific interests comprise:

development, optimization, and application of molecular methods for the detection, quantification, and characterization of foodborne pathogens;
study of the microbial ecology of fermented foods (mainly sausage, cheese, and wine) by using culture independent and dependent methods;
bioprotection: molecular characterization of bacteriocin production and its study *in vitro* and *in situ*;
selection of new putative probiotics from artisanal fermented foods; and
study of the human microbiome and its influence on human health.

Christopher Duggan, for the past 25 years, has been performing clinical trials in the fields of pediatric nutrition, gastroenterology, and global health. His early work centered on the management of diarrheal diseases in children, including trials that demonstrated the feasibility and efficacy of oral rehydration solutions (ORS) for diarrhea management in the United States and globally. In collaboration with colleagues at Harvard TS Chan School of Public Health and Muhimbili University of Health and Allied Sciences in Dar es Salaam, Tanzania, Dr. Duggan and colleagues are evaluating the efficacy of micronutrient supplementation in infants and young children born to women with or at risk of HIV infection. Recent studies include the development of new biomarkers of environmental enteric dysfunction as well as the evaluation of nutritional status on neurodevelopment. With colleagues at St John's Research Institute in Bangalore, India, he is evaluating the efficacy of maternal vitamin B12 supplementation on biochemical and clinical parameters during pregnancy and infancy. He is a course co-director of the Bangalore, Boston Nutrition Collaborative (http://bbnc.globalhealth.harvard.edu). Past and present research support has come from the National Institutes of Health, the Gates Foundation, and the World Health Organization.

In addition to his global health research interests, he is a pediatric gastroenterologist and a nutrition physician at Boston Children's Hospital where he directs the Center for Nutrition (http://www.childrenshospital.org/nutrition). He is a medical director of the Center for Advanced Intestinal Rehabilitation, one of the largest centers in the United States for the care of children with intestinal failure/chronic diarrhea syndromes (http://www.childrenshospital.org/cair). He is also the course co-director of an inaugural Harvard College course "Nutrition and Global Health" and mentors undergraduate, graduate, and postdoctoral students at HMS and HSPH (http://www.hsph.harvard.edu/nutrition-and-global-health/).

He is a professor of pediatrics at Harvard Medical School and a professor in the Department of Nutrition at the Harvard TS Chan School of Public Health (http://www.hsph.harvard.edu/faculty/christopher-duggan/).

Jed William Fahey's current research concerns elucidating the mechanisms of how plants protect themselves against unfavorable and stressful conditions, and how this understanding can be translated to chemoprotection of eukaryotic mammalian systems. This work draws on elements of natural product chemistry, enzymology, nutritional epidemiology, and clinical research in order with isothiocyanates (e.g., sulforaphane) and glucosinolates. His work led to the discovery that broccoli sprouts are an exceptionally rich and consistent source of phytochemicals that induce the detoxification of carcinogens, and to the development of methods for their detection and for assessing their metabolism in humans. He discovered that one of the inducers, sulforaphane, has potent antibiotic activity against *Helicobacter pylori*, a causative agent of peptic ulcer and stomach cancer, and followed up with trials in animals and in *H. pylori*-infected humans. Ongoing collaborations examine the effects of broccoli, Moringa, and the other plants and their phytochemicals against a range of chronic diseases. Dr. Fahey has for years taught courses in chronic disease prevention and nutrition at both medical and public health schools.

Manuel Franco is an associate professor at University of Alcalá in Madrid (Spain) where he leads the social and cardiovascular epidemiology research group (http://www3.uah.es/cardiosocialepi/). He is also an adjunct professor at Johns Hopkins University (Baltimore).

Prof. Franco's work focuses on the social determinants of cardiovascular diseases and its major risk factors as diet. His methodological interests include the measurement of the urban environment and large social and economic changes in relation to cardiovascular health. He is the lead investigator of the Heart Healthy Hoods, study funded by the European Research Council, that will study the urban environment in relation to cardiovascular health in Madrid (http://hhhproject.eu/). This longitudinal study will be collecting neighborhood level data (via audits, Google Street view, photovoice, and qualitative methods) and linking them to clinical outcomes collected from patients enrolled at the City of Madrid primary healthcare clinics. Prof. Franco trained in Spain and Germany to obtain his MD and obtained his PhD from Johns Hopkins Bloomberg School of Public Health working with Dr. Ana Diez-Roux in the MESA study on food environment and dietary patterns. He has published over 30 international high impact articles and collaborates with universities in the United States, Europe, and Latin America.

Maria Glibetic is a research director of Centre of Research Excellence in nutrition research, Institute for Medical Research in Belgrade, University of Belgrade, Serbia, and member of executive board of directors for food data association EuroFIR AISBL. She is an experienced basic and nutritional scientist with over 250 scientific publications and presentations. Maria has considerable experience in leading national and international projects and since 2006, she participated in nine EU funded projects including EuroFIR, EURRECA, BaseFOOD, CHANCE, BACCHUS, and ODIN. Maria and her team are responsible for the creation of the first online national food database, for designing food data management system, and for the development of different nutritional tools for intake analysis. She was a principal leader of many nutrition intervention studies evaluating the plant bioactive component effects on human cardiovascular health. She leads postgraduate department for integrated nutritional sciences at University of Belgrade, where she teaches two courses.

Linda Harvey obtained her PhD from the University of East Anglia, UK. She is currently the head of the Human Nutrition Unit at the Institute of Food Research, Norwich, UK. Her research interests include micronutrient requirements, bioavailability, and metabolism.

Ronald Jackson received his bachelor's and master's degrees from Queen's University and doctorate from the University of Toronto. His time in Vineland, Ontario, and subsequent sabbatical at Cornell University, redirected his interest in *Botrytis* toward viticulture and enology. As part of his teaching duties at Brandon University, he developed the first wine technology course in Canada. For many years he was a technical advisor to the Manitoba Liquor Control Commission, developing sensory tests to assess candidates of its sensory panel, and was a member of its external tasting panel. He is the author of *Wine Science: Principles and Applications, 4th edition* (2014), *Wine Tasting: A Professional Handbook, 2nd edition* (2009), *Conserve Water, Drink Wine*, and chapters and technical reviews in other multiple books and encyclopedia. He is retired in Bronte, Ontario, but remains active writing, cycling, doing yoga, and traveling, as well as being a fellow in the Cool Climate Viticulture and Oenology Institute, Brock University, St. Catharines, Ontario, Canada.

Joe P. Kerry is a senior college lecturer and the head of the food packaging research group in the School of Food and Nutritional Sciences at University College Cork (UCC). He received his doctorate in microbiology at University College Galway in 1995. Prof. Kerry is also a qualified member of the Institute of Packaging. He is very involved in national and international research projects both at fundamental and applied levels. Primary research interests address various aspects of food packaging, shelf-life stability, food composition, and numerous aspects of food quality, particularly in relation to muscle foods. He also has very strong links with industry and his research team assists companies in relation to many aspects of new food product development. He has over 220 publications in peer-reviewed international journals, over 300 presentations at major international conferences, along with several other significant publications. His expertise includes use and manipulation of modified atmosphere packaging systems for use with foods, use of extrusion technology for the manufacture of food products/packaging materials, and applications and sensor/new technology developments within the area of food packaging, especially in the area of smart packaging.

Frédéric Leroy, after studying bio-engineering at Ghent University, obtained a PhD in applied biological sciences at the Vrije Universiteit Brussel in 2002, where he continued his academic career at the research group of Industrial Microbiology and Food Biotechnology (faculty of sciences and bio-engineering sciences). As associate professor, his lecturing activities include courses in food science and technology (i.e., "Nutrition," "Technology of animal products," "Food microbiology and ecology," and "Quantitative and predictive microbiology"). Dr. Leroy's research primarily deals with the ecology and functional roles of bacterial communities in (fermented) foods, in particular with respect to the generation of quality, safety, and/or nutritional and health advantages. Focus is mostly on meat products, but other food systems are also being studied, including fermented milks and sourdough breads. In addition, his research interests relate to elements of tradition and innovation in foods, both from a technological and societal point of view.

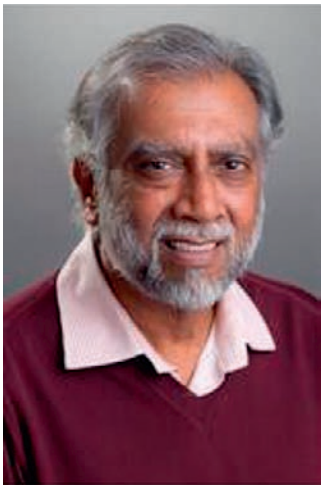
Catherine M. Logue completed her undergraduate and postgraduate degrees in Ireland and earned a PhD in meat microbiology from the University of Ulster, UK in 1996. Dr. Logue was a faculty member at North Dakota State University from 1999 to 2011 rising through the ranks of assistant to associate and full professor. In 2011, she re-located to Iowa State University's College of Veterinary Medicine and is a professor of veterinary microbiology and preventive medicine. Dr. Logue is also the director of faculty and staff advancement and equity for the college. Her research interests focus on foodborne pathogens of food animals and the contamination of meat and meat products destined for human consumption. Her research studies the detection, isolation, and characterization of a range of foodborne pathogens such as *Salmonella*, *Campylobacter*, *Listeria*, *Escherichia coli*, and methicillin-resistant *Staphylococcus aureus* (MRSA) in poultry, bovine, and swine. She also focuses her research on antimicrobial resistance in commensals and pathogens of production animals. She has been an author and a co-author on more than 90 peer-reviewed papers and book chapters as well as more than 150 abstracts and presentations at national and international meetings.

F. Xavier Malcata graduated in chemical engineering in 1986 from the University of Porto (Portugal), received a PhD in chemical engineering/food science from University of Wisconsin, Madison (USA) in 1991, and his habilitation in food science and engineering by Portuguese Catholic University in 2002. He was the dean of College of Biotechnology of Portuguese Catholic University, the chairman of Portuguese Society of Biotechnology, Portuguese representative at VI and VII European Union Framework Programs of research and development, expert for European Food Safety Agency, and a co-ordinator of Portuguese Engineering Accreditation Board in chemical engineering for Northern Region. He is currently a full professor at University of Porto.

His major research interests have focused on technological improvement of traditional Portuguese foods and upgrade of byproducts thereof, development of nutraceutical ingredients and functional foods, design and optimization of enzymatic reactors for edible oil processing, characterization of plant proteases toward cheese and whey cheese manufacture, production of starter and nonstarter cultures from adventitious microflora, and optimized application of unit operations to food processing.

With an academic career of independent research and teaching for more than two decades, Prof. Malcata published more than 450 papers in refereed journals worldwide, wrote 11 books, and prepared more than 45 chapters for edited books. Among many international distinctions, he was

recipient of Ralph H. Potts Memorial Award in 1991 by American Oil Chemists' Society (AOCS, USA), Foundation Scholar Award – Dairy Foods in 1998 by American Dairy Science Association (ADSA, USA), Young Scientist Research Award in 2001 by AOCS, Canadian/International Constituency Investigator Award in physical sciences and engineering in 2002 and 2004 by Sigma Xi (USA), Danisco International Dairy Science Award in 2007 by ADSA, Scientist of the Year Award in 2007 by European Federation of Food Science and Technology (the Netherlands), Samuel C. Prescott Award in 2008 by Institute of Food Technologists (IFT, USA), International Leadership Award in 2008 by International Association for Food Protection (IAFP, USA), Elmer Marth Educator Award in 2011 by IAFP, Distinguished Service Award in 2012 by ADSA, and William V. Cruess Award in 2014 by IFT. He has been elected for the honor societies of food science (Phi Tau Sigma, USA), scientific research (Sigma Xi, USA), and engineering (Tau Beta Pi, USA). He was also elected for fellow of IFT, ADSA, AOCS, and International Academy of Food Science and Technology.



Gopinadhan Paliyath is a professor at the Department of Plant Agriculture, University of Guelph, and the research program director for "Food for Health," under the UG/OMAFRA partnership. Dr. Paliyath is a biochemist and has an interest in various aspects of fruits and vegetables, specifically the nutraceutical components and their mechanism of action. He obtained his BSc Ed degree (botany and chemistry) from the University of Mysore, MSc degree (botany) from the University of Calicut, and PhD degree (biochemistry) from the Indian Institute of Science, Bangalore. Subsequently, he did postdoctoral work at Washington State University, University of Waterloo, and University of Guelph. Dr. Paliyath's research is focused on the biochemistry of plant senescence, specifically pertaining to postharvest biology and technology of fruits and vegetables. Investigations on the role of phospholipase D (PLD) in membrane homeostasis and signal transduction have led to advances in the understanding of the mechanism of membrane deterioration that occur during stress and senescence. Another aspect of his research is focused on understanding the mechanism of action of food components in disease prevention. The efficacy, bio-accessibility, bioavailability, and molecular mechanisms of action of nutraceuticals in fruits and processed products in relation to their cancer-preventive and anti-inflammatory actions are being investigated using mammalian cell lines, and animal model systems.

Dr. Paliyath has developed technologies and products for enhancing the shelf life and quality of fruits and vegetables based on PLD inhibition. R&D activities relevant to the industry sector include: (1) optimization of an enhanced freshness formulation for application to various fruits, vegetables, and flowers; (2) developing methods for nutraceutical carriers that would enhance the functional food quality and delivery (e.g., stabilizing lycopene in tomato juice, sauce, etc., for health beneficial effects); and (3) developing novel technologies to enhance the cancer-preventive ingredients in fruit products, etc. Patents awarded include: (1) # 6,514,914 (US) and 2,298,249 (Canada); (2) #7,198,811 (USA), 4141387-1 (Japan), 260738 (Mexico), 1469736 (Turkey), 028 284763 (China), and 223077 (India). The patents describe the use of nanoformulations based on hexanal and other generally regarded as safe (GRAS) ingredients for enhancing the shelf life and quality of fruits, vegetables, and flowers by pre or postharvest treatments. These technologies are currently being evaluated for extending shelf life and quality of mango in India and Sri Lanka with the assistance of the Canadian International Food Security Research fund. The collaboration involves researchers from Canada, India (Tamil Nadu Agricultural University), and Sri Lanka (Industrial Technology Institute).

Dr. Paliyath is also the research program director for the food and health theme-related activities under the OMAF/MRA/University of Guelph research partnership. He serves on the editorial board of several journals. He is a member of American Chemical Society and Canadian Society of Plant Biologists.

(Total-refereed publications in journals – 92; patents and intellectual properties – 2; disclosures – 4; chapters in books – 27; nonrefereed contributions – 10; research reports – 28; conference proceedings – 88; edited books – 9; book reviews – 6 (Google Scholar: h index – 31, i10 index – 68, citations – 4332; RG score – 35.63)).

Yolanda Picó is a full professor of nutrition and food science at the University of Valencia since 1998. She is currently the head of the research group on food and environmental safety of the University of Valencia. Her research interests are the development of new analytical methods to determine organic contaminants in food and the environment, identification of unknown compounds by liquid chromatography–mass spectrometry, micro-extraction separations, and environmental and food safety. To the date, she is the author of nearly 200 peer-reviewed papers, 170 scientific papers in journals of SCI, 25 book chapters, and editor of four books on food and environmental safety.

Vieno Piironen is a professor of food chemistry at the Department of Food and Environmental Sciences, University of Helsinki, Finland. She received her PhD in food chemistry at the University of Helsinki in 1987 and has approximately 35 years of experience in food research and education on bachelor, master, and PhD levels. She has participated actively in international research and education projects and networks. Her research has focused especially on chemical and nutritional properties, reactions and analysis of lipids, vitamins, and other bioactive compounds. Research on vitamins has been active from the beginning of 1980s. She has studied both lipid- and water-soluble vitamins; their chemical and nutritional properties and importance in foods and diets as well as factors influencing vitamin levels. In addition, development of analytical methods for different vitamers as well as validation and harmonization of the methods through international collaboration have been among the priorities. Recent collaboration projects have focused on enhancing vitamin contents in cereal-based foods by plant breeding, utilization of vitamin-rich grain fractions, and bioprocessing. Currently, the research focus lies on investigating microbial *in situ* synthesis of folate, vitamin B12, and other B vitamins in cereal and legume matrices as a means to improve nutritional quality of foods and to develop new food applications. In lipid research, different lipid classes and their chemical and enzymatic reactions in food matrices are studied. Diverse methods are used to study proceeding of oxidation from primary products to monomeric oxides, volatiles, and polymerization products and to study possibilities to control oxidation. Controlling enzymatic reactions leading to off-flavors in cereal and legume matrices is also among the interests. Phytosterols and their conjugates have been studied as natural food components belonging to the dietary fiber complex. On the other hand, questions related to sterol enrichment such as oxidation susceptibility and mechanisms as well as factors affecting oxidation reactions have been of interest. She has also studied nutrients and anti-nutrients in legumes and more recently started research on utilization of high value components in microalgae. She has approximately 160 papers in international journals and a number of other publications.

David Rodríguez-Lázaro is a doctor in veterinary medicine (DVM), specialized in food science (BSc and MSc) and molecular microbiology (PhD). He is a senior scientist at ITACyL and an assistant professor of microbiology at the University of Burgos. He has performed research stays in the Danish Institute for Food and Veterinary Research (Denmark), the University of Prague (Czech Republic), the Food and Environmental Research Agency (UK), and the University of Bristol (UK). He was a Leverhulme visiting professor in the Institute of Advanced Sciences in the University of Bristol during the years 2004 and 2005 and Marie Curie research fellow in the faculty of medical and veterinary sciences in the University of Bristol (UK) until 2007.

His research interest is focused on the establishment of reliable, quantitative molecular strategies for detection of important food-borne pathogens from environmental sources and various types of foodstuffs, the characterization of the prevalence of the main foodborne pathogens in food and food-related environments, and the development of emergent food preservation processes and their effects in the microbial virulence. He has participated in a number of coordinated EU-funded projects such as PROMISE, BASELINE, VITAL, FOOD-PCR, SACROHN, and MONI-QA, having established active links with the leading European research groups working in food safety.

He has published more than 100 international scientific papers and book or book chapters regarding food safety. He is currently a member of the editorial board of *Applied and Environmental Microbiology*, *International Journal of Food Microbiology*, *Food and Environmental Virology*, and *International Journal of Food Contamination* and the editor-in-chief of the journal *Food Analytical Methods*. He was awarded with the XV Jaime Ferrán Award in 2013 by the Spanish Society for Microbiology for his promising scientific career in microbiology.

Turid Rustad is a professor and the head of the food science group at the Department of Biotechnology, Norwegian University of Science and Technology. The main research focuses on the biochemistry of marine raw materials, the relationship between biochemistry and quality, and changes in raw material properties during processing. Studies of enzymatic activities in different raw materials have been linked to studies of changes in the biochemistry of these raw materials. She has worked with characterization of composition and enzymatic processes in a wide range of different raw materials, such as fish, fish by-products, and zooplankton in relation to different storage and processing methods such as chilling, heating, superchilling, and frozen storage.

Noel W. Solomons has lived and worked in Guatemala for 40 years. He was born and educated in Massachusetts in the United States. As a young child, he became an amateur naturalist and was a nature counselor at various summer camps; this would guide him to a career in science. In his young adulthood, he would participate in the civil rights and anti-war movements, only to become disillusioned by the intractable nature of the injustice elements in the fabric of American society. As a physician by graduate training, he performed his university studies at Harvard College and Harvard Medical School; it was during overseas electives in his medical training that he visited Peru and Colombia and committed to an expatriate life trajectory outside of his homeland. Clinical training included a residency in internal medicine and infectious diseases at the Hospital of the University of Pennsylvania and specialization in gastroenterology and clinical nutrition at the University of Chicago. He became a resident of Guatemala in 1974 as an affiliated investigator at the Institute of Nutrition of Central America and Panama. He would later commute for eight years to a faculty position in the Department of Nutrition and Food Science of the Massachusetts Institute of Technology. Assuming a full-time Guatemala commitment in 1985, he co-founded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) where he remains its scientific director. Over 40 local university theses have been completed by Central American students in that institution as well as an equal number of master's degree research projects from international students from Europe, and North and South America. He has supervised doctoral dissertations for 12 PhD candidates from the United States, Canada, Germany, Spain, and the Netherlands through CeSSIAM.

Dr. Solomons has 332 publications indexed on Medline. In addition, he has edited two books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection.

Among the honors bestowed upon Dr. Solomons are the International Nutrition Prize of the International Union of Nutritional Sciences and the Kellogg Prize of the Society for International Nutrition Research. He is a fellow of the American Society of Nutrition. He is an academic member of the Guatemalan Academy of Medical, Physical and Natural Sciences and the Spanish Academy of Nutrition and Food Science. He was the awardee of the 2010 National Medal for Science and Technology for Guatemala.

He has been a visiting professor in university courses in Mexico, Peru, Brazil, Indonesia, and Spain. He currently holds adjunct professorial appointments at the Boston University School of Public Health, and the Friedman School of Nutrition Science and Policy and the Department of Community Medicine and Public Health, both at Tufts University. He is a founding board of directors, member of the Hildegard Grunow Foundation in Munich and the Essential Nutrient Foundation of Singapore. Finally, Dr. Solomons is a coordinator for Central America of the Nevin Scrimshaw International Nutrition Foundation in Boston, and an associate editor for the Foundation's *Food and Nutrition Bulletin*. He serves on editorial boards for ten scientific journals.

Maria Tsimidou is a professor of food chemistry and the head of the Laboratory of Chemistry and Technology in the School of Chemistry at the Aristotle University of Thessaloniki (AUTh), Greece. Her teaching is food chemistry, analysis, quality control, and food legislation. Research interests are related to virgin olive oil chemistry, quality and authenticity, saffron chemistry, authenticity and quality, antioxidant activity of plant extracts and constituents, new sources of targeted bioactive compounds (squalene, carotenoids, and phenols), and analytical procedures for their determination. She has published many research papers, review articles, and contributions to scientific books and encyclopedias on the above-mentioned topics. Currently, she is an associate editor in the *European Journal of Lipid Science and Technology* and chairs the COST ACTION FA1101 "Saffronomics."

Jorge Welti-Chanes earned his degree in biochemical engineering (1976) and master of science in food engineering (1978) at Tecnológico de Monterrey (ITESM, Mexico), later he moved to Spain to perform his doctoral studies in chemistry, in the area of food technology, obtaining his degree at the University of Valencia. He is currently the national director of graduate studies at School of Engineering and Sciences at Tecnológico de Monterrey also is professor and researcher in the areas of biotechnology and food at the same institution. He started his academic activity in 1976 as a university professor of ITESM, has additionally been a full professor at the National Polytechnic Institute (IPN, Mexico) and the University of the Americas, Puebla, Mexico (UDLA). He has an experience of 37 years as a teacher and university researcher, 20 of which were spent in combination with the development of administration work in education, science and technology. In the UDLA, he was teaching in the Departments of Chemistry and Biology and Chemical Engineering and Food, in the latter was responsible for the leadership for a period of a year and subsequently became dean of the School of Engineering (1986–1988). From January 1989 to June 2002, he was an academic vice chancellor at UDLA. He has published 14 books and has over 200 scientific publications in refereed journals and books, has given more than 250 presentations at international conferences. He is an associate editor of the journals *Food Engineering Reviews* and *Journal of Food Science* and participates as a member of the editorial boards of *Journal of Food Engineering* and *Current Opinion in Food Science*. In May 2011, he received the Life Achievement Award by the International Association for Engineering and Food (IAEF), for his career as a researcher and academic worldwide, and in January 2014, the Romulo Garza Award from the Tecnológico de Monterrey for the impact of their research work and as recognition for being one of the most productive researchers in the life of Tecnológico de Monterrey. He has been the president of ISOPOW and IAEF and is the currently president of the International Society of Food Engineering (ISFE).

Peter J. Wilde graduated in biophysics at the University of East Anglia in 1985 and has been researching the colloidal and interfacial properties of food systems at the Institute of Food Research (IFR) for over 25 years. IFR is the only publicly funded UK research institute that focuses on the underlying science of food and health to address the global challenges of food security, diet, and health, healthy aging, and food waste. IFR is the one of eight institutes that receives strategic funding from the Biotechnology and Biological Sciences Research Council (BBSRC). It also receives funding from government agencies and departments, the EU, charities, and industry, from the UK and overseas.

Pete's research expertise is the interfacial behavior of proteins and other surface active components in food relevant systems. The aim is to determine how the molecular and interfacial processes control the functionality of foams and emulsions. Currently, the functional aspects of his research have focused on improving the dietary impact of emulsified foods. These include fundamental studies on how interfacial layers control emulsion rheology to develop novel fat reduction strategies; the design of interfacial structures to control lipid digestion to promote satiety or the delivery of fat-soluble nutrients and drugs; and to determine the physico-chemical role played by the salivary film in perceiving fat content in emulsions. The impact of this research will be to aid the rational design of foods with enhanced nutritional benefits to address the global challenges of obesity, type 2 diabetes, and other major diet-related conditions.

HOW TO USE THE ENCYCLOPEDIA

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Contents

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

The majority of articles within the encyclopedia have an extensive list of cross-references that appear at the end of each article, for example:

See also: Anemia: Causes and Prevalence; Anemia: Prevention and Dietary Strategies; Iron: Biosynthesis and Significance of Heme; Iron: Physiology of Iron.

3. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

4. Contributors

A full list of contributors appears at the end of volume 5.

INTRODUCTION

Until a few decades ago, virtually all known health effects of foods were related to their content of essential nutrients. The clinical description of most diet-related illnesses mirrored the signs of essential nutrient deficiencies, such as pellagra, beriberi, and others. Consequently, the key public health concern regarding diet was ensuring that everyone consumed enough food. It was only in the past 50 years that large-scale epidemiological observations began to associate chronic diseases like diabetes and cardiovascular disease with nonessential diet constituents such as saturated fat, fiber, and cholesterol. Taking advantage of the emergence of digital informatics, these studies were able to manipulate increasingly large sets of data and provide, for the first time, a picture of the secular changes in the health of large populations and its association with what they ate regularly. These findings progressively shifted the concern from eating enough to avoiding excessive consumption of certain foods. Eating enough was replaced by eating well.

But it turned out that defining how to eat well is far more complex than defining minimum needs of essential nutrients. First, there is no single paradigm to study those relationships, given the wide variety of biological mechanisms and the long exposures involved. Second, many of the experimental models used to define essential nutrient needs are not applicable to the study of long-term effects of diets in free-living populations. And it is now clear that experiments with isolated dietary compounds do not reflect the actual effects of the complex food matrix we consume daily. Finally, while the discovery of essential nutrients and their role in health was the domain of a few specialties speaking a common language (primarily biochemists and physiologists), the study of the long-term effects of whole diets in humans must of necessity involve epidemiologists, social and behavioral scientists, food scientists, clinicians, policy experts, etc., making far more difficult the development of consensus and foundational concepts.

It is thus not surprising that today we have still not achieved a stable consensus on how to eat 'well.' Furthermore, while few nonscientists would care about the minimum requirement of a vitamin to sustain life, there are plenty of opinions among nonscientists on how to eat 'well.'

Our goal in preparing this encyclopedia has been to contribute to the understanding of that complex diet–health relationship by providing a multidisciplinary, integrative and accurate source of information. We aim to serve the needs not only of established and in-training scientists, but also of the increasingly important group of professionals who are key to disseminate and sustain the practice of science: journalists, science writers, science administrators, fund raisers, donors, and policymakers. In preparing this work, we had the enormous advantage of working with one of the publishers with the most extensive expertise in major reference works, Elsevier. This first edition builds on the impressive breadth of knowledge of over 922 authors and on the tireless work of our editorial advisory board. We are very grateful to all of them.

Introduction

Chemometrics can be defined as the chemical discipline, which makes use of mathematical, statistical, and logical methods to extract meaningful information from experimental data and to optimize processes and/or products. It is evident from this definition that it accompanies all stages of the chemical measurement process, from sampling to interpretation passing through the definition of the optimal experimental conditions and data collection and processing. Even if it finds its roots in analytical chemistry, chemometrics is highly interdisciplinary and its domain of application is becoming wider and wider. However, since the very beginning, food-related issues have constituted an important field of application of chemometric techniques. Indeed, foodstuffs are rather complex matrices and their authentication often relies on a holistic characterization through the measurement of different chemical indexes or through the recording of whole instrumental fingerprints. The construction of traceability models for the verification of labeling compliance of products with a designated origin, the monitoring and control of food production processes, the correlation of volatile compound profiles with the sensory evaluation of a trained panel, and the indirect quantification of one or multiple analytes based on cheap and rapid spectroscopic techniques are only a few emblematic examples of application where the use of chemometrics is not only advisable but also necessary.

Chemical Data: Types and Representation

As anticipated, the main goal of chemometrics is to extract useful and meaningful information from chemical data. Therefore, prior to illustrating the chemometric toolbox with all its plethora of methods, it is essential to understand the data, which constitute the basis for modeling. A chemical system is usually characterized and described by a set of measured or calculated variables, which can be either quantitative or qualitative in nature. In the former case, variables are defined on a numerical (interval or ratio) scale, can undergo any kind of algebraic operation, and can assume an infinite (continuous) set of values; examples of these types of indices are pH, concentration, and temperature. On the other hand, qualitative variables may assume only a discrete set of values, which are often categorical or expressed in the form of attributes: the presence or absence of a constituent, genuine/adulterated, and sensory panel evaluation on a 1–5 scale are all examples of such kind. Usually, one variable only is not enough to characterize a chemical system, so that multiple descriptors are recorded on the same sample: these may come from different instruments or analytic procedures (e.g., total acidity, peroxide number, and concentration of iron or calcium) or be acquired with the same platform (e.g., absorbances at different wavelengths or detector intensities at different retention times, in the case of spectroscopic or chromatographic profiles, respectively). The resulting data are then *multivariate* and each sample may be described by a numerical row vector $\mathbf{x}_i$, collecting the results of all the measurements performed:

$$\mathbf{x}_i = \left[x_{i1}x_{i2}x_{i3}\ldots x_{ip}\right] \qquad [1]$$

p being the total number of variables. Accordingly, when more than a single sample is analyzed, the data can be arranged into a matrix $\mathbf{X}$, having as many rows as the number of samples (n) and, as already stated in eqn [1], as many columns as the number of variables (p):

$$\mathbf{X} = \begin{pmatrix} x_{11} & \ldots & x_{1p} \\ \vdots & \ddots & \vdots \\ x_{n1} & \ldots & x_{np} \end{pmatrix} \qquad [2]$$

Each row of the matrix $\mathbf{X}$, then, contains the results of the experimental measurement performed on a particular sample, while each column is made of the values of a single variable along all the samples.

One of the advantages of the matrix representation in eqn [2] is that it has a geometric counterpart: Each variable can be thought as an axis in a (hyper-)space having p dimensions so that the value of the matrix element x_{ij} represents the coordinate of the ith object along the jth direction. Accordingly, each sample can be described as a point in the p-dimensional space (see Figure 1).

Experimental Design

Although this aspect is often still neglected by many chemists, chemometrics enters the analytical process long before the data processing and interpretation stage, on one hand as it is necessary to sketch the most appropriate sampling strategies in order to have representativeness and to meet specific requirements (e.g., a target accuracy or precision) and, on the other, as the quality of the data obtained and the possibility of retrieving the information sought strongly rely on a careful experimental planning. Indeed, as already pointed out by Fisher, "Statistical procedure and experimental design are only two different aspects of the same whole, and that whole comprises all the logical requirements of the complete process of adding to natural knowledge by experimentation."

By the term experimental design, one indicates the family of techniques whose aim is to identify a parsimonious set of experimental conditions. The aim of experimental design techniques is (a) to understand the effect of controlled variables (factors) on one or more responses (often with the final intent of optimization) and (b) to define an empirical model (response surface) for the relation between the responses (dependent variables) and the factors (independent variables), which may be used either to support the optimization process

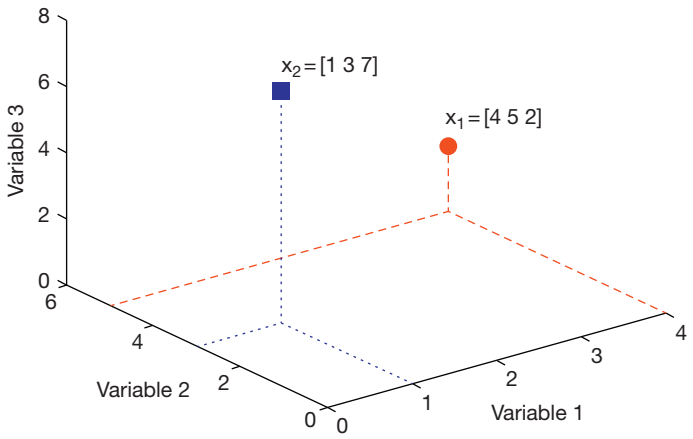

Figure 1 Geometric representation of data vectors as points in the multidimensional space of the variables.

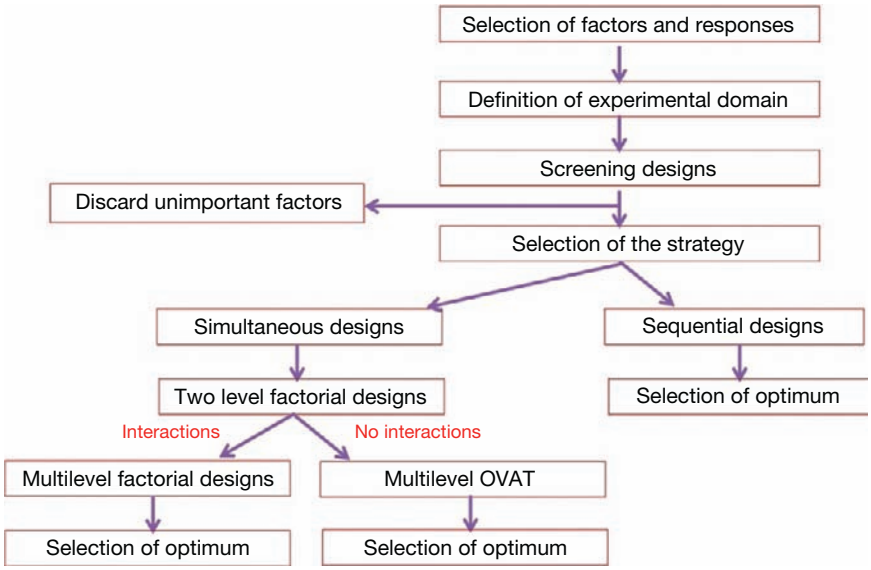

Figure 2 Flowchart of experimental design.

defined in point (a) or for prediction purposes. In both cases, a systematic and efficient mapping of the experimental domain, at the same time looking for the minimum number of experiments to be performed, is sought.

Given the scopes summarized earlier, the family of experimental designs encompasses a wide range of techniques of increasing complexity, as evidenced by the pipeline shown in Figure 2.

Screening designs are the most parsimonious ones, as they include only the experiments needed to estimate in a semiquantitative fashion the main effect of the investigated factors, not taking into account the possible interactions among variables. A linear relation is assumed between the response(s) y and each of the f controlled factors:

$$y = b_0 + b_1x_1 + b_2x_2 + \ldots + b_fx_f \qquad [3]$$

where b_0 is an offset term, corresponding to the predicted response in the center of the experimental domain, while $b_1 \ldots b_f$ are estimates of the effect of the factors $1 \ldots f$ on y. A direct consequence of the assumption of linearity is that only two levels are investigated for each factor and the resulting strategies are on one hand the so-called saturated or supersaturated factorial and on the other the Plackett–Burman designs. Screening designs are normally used to have information on which of possible factors may be discarded as very likely unaffecting the response. After screening, it is necessary to choose the strategy that may be more appropriate for the specific problem: Indeed, there are two options available, the factorial approach and the sequential approach. The sequential strategy is most suited when there are only a few factors, the goal is optimization of (possibly) a single response, and there is no interest in calculating the response surface. It operates by selecting a small number of initial experiments and then iteratively choosing the coordinates for the successive experiment based on the coordinates and the responses of the previous ones, up to when a stopping/optimality criterion is met. On the other hand, in the factorial approach, the whole set of

experiments to be conducted is defined a priori, before any of those is actually carried out: This approach is in general to be preferred, but it is for sure the one to be adopted when the effect of controlled factors on multiple responses has to be investigated and also when modeling is the purpose. In this context, two level factorial designs, that is, factorial designs in which each factor is controlled only at two values, allow to assess the main effect of the factors and at the same time to verify the presence of interactions. Indeed, they assume a linear model with mixed terms, which, in the case of two factors, takes the form

$$y = b_0 + b_1x_1 + b_2x_2 + b_{12}x_1x_2 \quad [4]$$

where b_{12} is the term that accounts for the interaction between factor 1 and factor 2, while all other terms have the same meaning as in eqn [3]. Although such mathematical assumption is often too approximate to lead to reliable estimation of the main effects and interaction terms or to accurate predictions of the response values, still, two level factorial designs allow to have a semiquantitative understanding of the relation between dependent and independent variables and to assess the presence or absence of interactions.

When the linearity assumption is released, so that nonlinear (almost always second- or third-order polynomial) relationships are modeled, factors cannot be controlled at two levels only anymore, so that multilevel designs are needed. The use of multilevel designs, the most famous of which are the central composite, the Box-Behnken, and the Doehlert ones, together with the family of optimal designs (D-optimal, A-optimal, and so on), allows to better approximate the response surface, which, in the case of three factors, usually takes the form

$$y = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_{12}x_1x_2 + b_{23}x_2x_3 + b_{13}x_1x_3 + b_{11}x_1^2 + b_{22}x_2^2 + b_{33}x_3^2 \quad [5]$$

where b_{11}, b_{22}, and b_{33} account for the effect of the squared factors and all the other terms have the same meaning as in eqns [2] and [3]. Specific designs may also be used when the factors to be investigated are the constituents of a mixture or when they are qualitative variables.

Exploratory Analysis

Exploratory analysis is a strategy/philosophy that makes use of a variety of techniques to summarize the main characteristics of a data matrix in an easy-to-understand form, often with visual graphs, without using a statistical model or having formulated a hypothesis. Its main purposes are to maximize insight into a data set, to uncover underlying structure, to extract important variables, to detect outliers and anomalies, to test underlying assumptions, and to develop parsimonious models. All these characteristics suggest that exploration is and should always be the first step in data analysis, even when the final goal is some kind of predictive modeling.

According to the definitions reported earlier, exploratory data analysis is normally carried out by means of two families of techniques: projection methods and clustering algorithms. The need for the projection method is evident when thinking that, in the situations when many variables are measured on the samples, which is what normally occurs with chemical systems, graphical inspection of the data in the original p-dimensional space described in the section '**Chemical Data: Types and Representation**' may result difficult or even unfeasible. Indeed, as the name suggests, projection methods operate by projecting the data on a relevant subspace, which can be used to summarize the data conveniently and explore the data set using plots and figures, in order, for instance, to find patterns, relation, differences, and similarities between objects and variables. The most famous and used multivariate projection method is for sure principal component analysis (PCA), whose aim is to find the best low-rank approximation of the original data in a least squares sense. This is equivalent to state that PCA identifies those directions in the multivariate space, which in turn account for the maximum explained variance and which are mutually orthogonal, and projects the original data onto this reduced subspace. Mathematically, the PCA model can be expressed by the following equation:

$$\underset{n\times F}{\mathbf{T}} = \underset{n\times p}{\mathbf{X}}\ \underset{p\times F}{\mathbf{P}} \quad [6]$$

where $\mathbf{T}$ is the matrix collecting the coordinates (*scores*) of the sample onto the new reduced (F usually $\ll p$) set of variables (called principal components), while the matrix $\mathbf{P}$ contains the coefficients of the projection (*loadings*). The same relation can be rearranged as in eqn [7], to show the so-called *bilinear* nature of the PCA decomposition:

$$\mathbf{X} = \hat{\mathbf{X}} + \mathbf{E} = \mathbf{TP}^{\mathrm{T}} + \mathbf{E} \quad [7]$$

where the matrix $\mathbf{E}$ (*residuals*) accounts for the portion of the variability originally present in the data, which is not explained by the PCA model and the hat ($\hat{}$) indicates that $\mathbf{X}$ is approximated by the model. Indeed, bilinear modeling, that is, the approach that assumes that a data matrix $\mathbf{X}$ may be approximated by the product of two low-rank matrices, one representing the coordinates of the samples onto a reduced subspace and the other expressing the variable contribution to the definition of the subspace, is one of the core elements of chemometrics. Due to its characteristics, PCA represents the optimal tool to perform exploratory data analysis, as it can provide information about the relationship among samples and among variables, together with the possibility of noise filtering and outlier detection. Graphical representation of the samples in the principal component space (*scores plot*) allows to identify the presence of clusters or groups in the data or to evidence some trends; on the other hand, correlation between the experimental variables or irrelevant descriptors may be assessed by visually inspecting the elements of the loadings matrix (*loadings plot*). An example of the application of PCA in the context of food analysis may be observed in **Figure 3**, where the scores and the loadings plots for a problem involving the authentication of honey samples are shown. In particular, the data set was made on the results of 15 chemical analyses on 73 honey samples coming from different botanical origin (sulla, heather, eucalyptus, chestnut, honeydew, and wildflower).

Inspection of the scores plot in **Figure 3(a)** evidences the presence of different clusters in the data: If no information about the origin of samples were available, one would have stated that there were seven different groups of honey; however, integrating the scores plot with the information available,

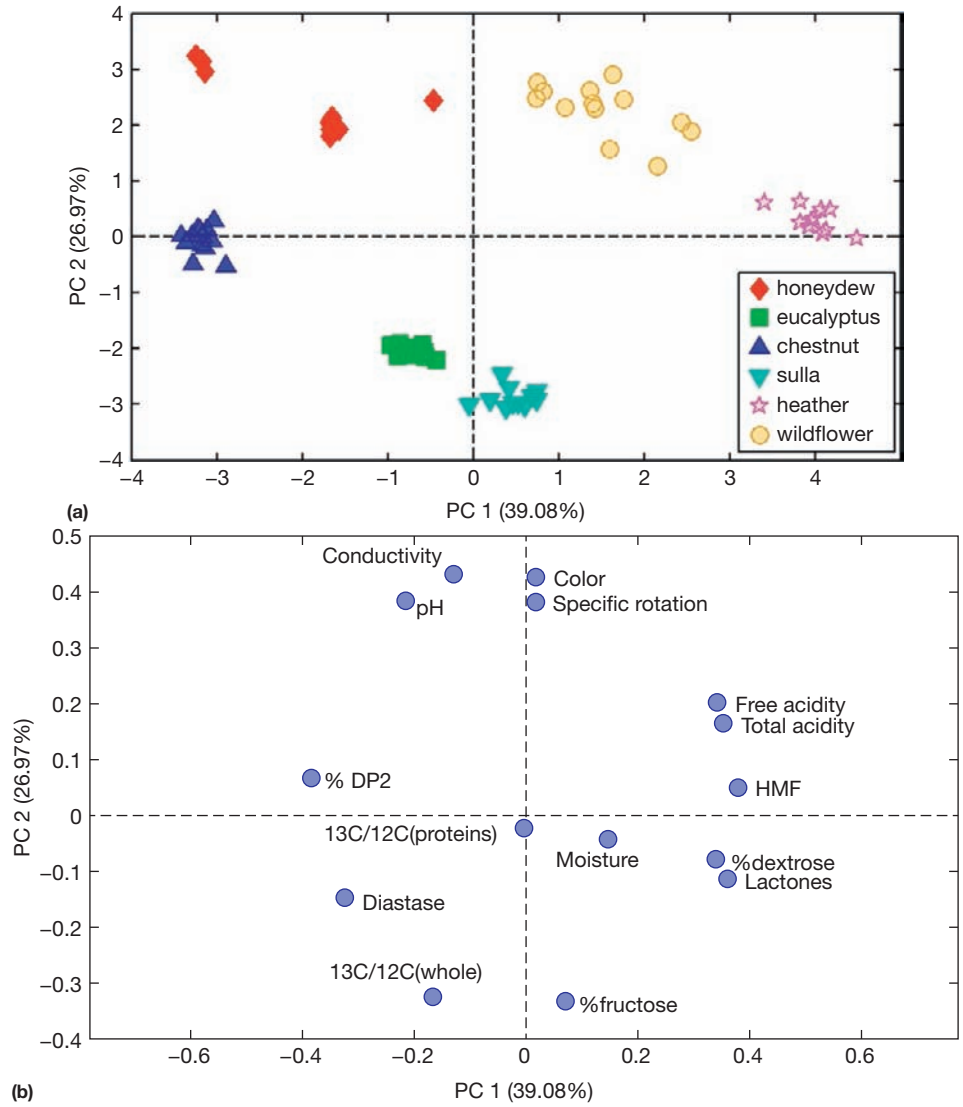

Figure 3 Principal component analysis of honey data set. (a) Scores and (b) loadings plots.

it is possible to affirm that there are six clusters, one for each of the different floral origin of the samples and that the group corresponding to honeydew is further split in two subclusters. Moreover, in general, it is also possible to see how the clusters corresponding to multifloral origin (honeydew and wildflower), which are separated from the unifloral ones along PC2, are less homogeneous, as it could be expected. Information about the variables can, instead, be obtained by looking at the loadings plot reported in Figure 3(b): At first, one can observe that dextrose and lactones are correlated, as well as color and specific rotation or free and total acidity, as they fall very close to one another in the PC space; on the other hand, the carbon isotope ratio in the proteic fraction does not seem to contribute much to the model as its loadings are almost zero. Lastly, comparison of the scores and the loadings plot allows to interpret the differences observed among samples in terms of the original variables. As stated, unifloral honeys are separated from multifloral ones along the second principal component: looking at the loadings plot, this means that the former are characterized by a higher fructose content and carbon isotope ratio, at the same time showing a lower pH, conductivity, color, and specific rotation. On the other hand, wildflower is separated from honeydew along PC1, and the same component differentiates also among the various unifloral honeys: this means that in going from honeydew to wildflower or from chestnut to heather, there are a systematic increase of dextrose, lactones, free and total acidity, and hydroxymethylfurfural (HMF) and a corresponding decrease of diastase and DP2.

The second family of techniques normally used for exploratory data analysis are clustering algorithms. As the name suggests, the aim of clustering techniques is to look for the presence of groups (usually of samples, but it is possible to apply the same concepts to variables or to both) in the data, based on the calculation of some kind of similarity or dissimilarity index. Indeed, the underlying idea is that object belonging to the same group will be similar to one another and dissimilar to the object belonging to other clusters, so that

the definition of a proper measure to quantify (dis-)similarity plays a key role for this family of methods. In many applications, dissimilarity is expressed in terms of a distance measure in the multivariate space, but other indexes may also be used. Once the proper way of quantifying (dis-)similarity is chosen, clustering may be carried out according to two different approaches: hierarchical and partitional. In hierarchical clustering, as the name suggests, objects are ranked from the most similar to the most dissimilar in a hierarchical fashion, and the main result is a graphical representation called a *dendrogram*. In particular, at the beginning of the hierarchical clustering procedure, each sample is considered a cluster per se; at each step, the two most similar clusters are merged together and the procedure is continued until all objects are joined into a single group. This approach is called agglomerative (bottom up) and it is the most widely used: hierarchical clustering may also be carried out in a divisive way (top down), by starting from a single cluster and iteratively arriving to as many groups as the number of objects, but this approach is more computationally intensive and, therefore, it is rarely adopted. Here, it must be stressed that, whatever the approach, hierarchical clustering does not provide a unique grouping: partitioning of object into clusters may be achieved only by cutting the dendrogram at a specific level, which usually corresponds to a large distance among the merged groups. As an example, the dendrogram corresponding to agglomerative hierarchical clustering for the honey data set already presented in the case of PCA is reported in Figure 4.

The dendrogram in Figure 4 shows very clearly the presence of clusters among the data, and also, as already evidenced by PCA, the groups of honeydew and wildflower samples are less homogenous than the other ones (their final merging distance is higher). Moreover, it can be also seen how the identified number of clusters would vary, depending on the level at which the dendrogram be cut: If one chooses a threshold distance of 8 (dashed line), then honeydew samples would be seen as two different groups and a total number of seven clusters would be identified; instead, if a threshold distance of 10 (continuous line) be adopted, then the number of detected groups would be six. On the other hand, partitional clustering attempts to directly decompose the data into a predefined number of groups by minimizing some criterion, which should reflect the local structure. The most famous member of this family of algorithm is k-means where the criterion function is the sum of the squared distances of each sample to its nearest cluster centroid:

$$E = \sum_{i=1}^{N} ||\mathbf{x}_i - \mathbf{m}_{C(\mathbf{x}_i)}||^2 \quad [8]$$

where $\mathbf{m}_{C(\mathbf{x}_i)}$ is the vector collecting the coordinates of the centroid of the cluster closer to $\mathbf{x}_i$.

Calibration

When dealing with food analysis or characterization, exploratory data analysis, although necessary, may not be sufficient, as many problems may require the prediction of one or more quantitative or qualitative properties of the samples. Calibration is the use of empirical data and prior knowledge for determining how to predict quantitative information $\mathbf{Y}$ from available measurement $\mathbf{X}$ via some mathematical transfer function f:

$$\mathbf{Y} = \hat{\mathbf{Y}} + \mathbf{E}_Y = f(\mathbf{X}) + \mathbf{E}_Y \quad [9]$$

where the matrix of residuals $\mathbf{E}_Y$ collects the variance in $\mathbf{Y}$ not accounted for by the regression model, that is, the difference between the actual values of $\mathbf{Y}$ and those predicted by the

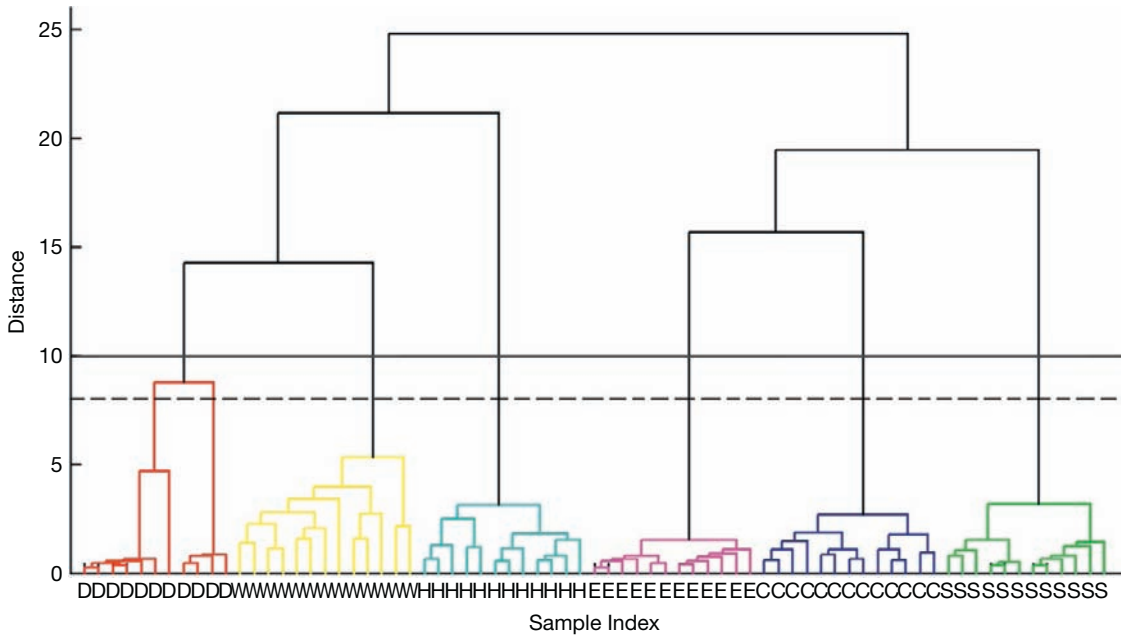

Figure 4 Dendrogram resulting from hierarchical clustering of honey data. Dashed and dotted lines (corresponding to distance values of 8 and 10, respectively) indicate two possible threshold values, which may be used to cut the dendrogram in order to define sample grouping.

model ($\hat{\mathbf{Y}}$). In food analysis, calibration plays a key role as quite often, the direct measurements of the properties of interest may not be feasible or it may be too expensive, time-consuming, or inaccurate, so that quantification is usually based on secondary measures (e.g., chromatographic peak area, absorption or emission intensity, current, and voltage). In this context, the simplest relation between the experimental measurements collected in **X** and the properties to be predicted is a linear one:

$$\hat{\mathbf{Y}} = \mathbf{XB} \qquad [10]$$

where **B** is a matrix of the so-called regression coefficients, which constitute the model parameters and uniquely define the mathematical relation. In particular, each column of the regression coefficient matrix collects the weights associated with the independent variables for the prediction of the corresponding column of the **Y** matrix, and this information can be used also for the sake of interpretation. Indeed, in principle, the larger the absolute value of the coefficient b_{ij} (the ith row and jth column element of **B**), the higher the contribution of the ith X-variable to the prediction of the jth response. However, particular care should be taken when inspecting the values of **B**, as their magnitude directly reflects the scales of both **X** and **Y**. Moreover, when dealing with instrumental fingerprints, interpretation can be further hindered by the presence of overlapping signals: As an example, one may consider the case when a spectroscopic measurement is used to predict the concentration of an analyte in a solution. If no interferent is present, the regression coefficients would resemble the spectrum of the pure analyte; however, if the solution contains also an interferent, whose spectrum partially overlaps with that of the analyte, the regression vector no longer looks like the pure spectrum because negative parts and shifts in position of peak maximum are introduced. Accordingly, there may be cases when a negative regression coefficient is correctly obtained for a variable that is positively correlated with the response. Operationally, the most straightforward way of estimating the regression coefficients in eqn [10] is provided by multiple linear regression (MLR). MLR is the multivariate generalization of the univariate least squares method; the values of the coefficient are calculated as the ones, which minimize the sum of squared residuals:

$$\min_{\mathbf{B}} \left(||\mathbf{E}_Y||^2\right) = \min_{\mathbf{B}} \left(||\mathbf{Y} - \hat{\mathbf{Y}}||^2\right) \qquad [11]$$

Accordingly, the matrix **B** is estimated as

$$\mathbf{B}_{MLR} = \left(\mathbf{X}^T\mathbf{X}\right)^{-1}\mathbf{X}^T\mathbf{Y} \qquad [12]$$

Unfortunately, even if MLR is the simplest method for linear regression, it is quite often inapplicable to the matrices resulting from food analysis and characterization. Indeed, in order for the term $(\mathbf{X}^T\mathbf{X})^{-1}$ in eqn [12] to be estimated accurately, the matrix **X** should meet some mathematical requirements, which are rarely fulfilled in problems involving instrumental fingerprinting of real-world samples: the number of samples should be lower than the number of predictors and the variables should be as uncorrelated as possible from one another. In this context, the bilinear approach introduced in the section '**Exploratory Analysis**' for PCA, by involving the projection of the samples onto a low-dimensional space of orthogonal variables, represents a way of overcoming the previously mentioned limitations. In particular, principal component regression (PCR) is a calibration method that originated by directly combining a preliminary dimensionality reduction step by means of PCA with the calculation of a MLR model on the resulting scores. In mathematical terms, at first, the matrix **X** is decomposed into the product of scores and loadings according to eqn [7], and successively, the scores are used as predictors to build the MLR model:

$$\hat{\mathbf{Y}} = \mathbf{TV} \Rightarrow \mathbf{V} = \left(\mathbf{T}^T\mathbf{T}\right)^{-1}\mathbf{T}^T\mathbf{Y} \qquad [13]$$

V being the matrix of regression coefficients relating **Y** to **T**. By combining eqns [13] and [7], it is possible to obtain the model coefficients directly in terms of the original independent matrix **X**:

$$\hat{\mathbf{Y}} = \mathbf{TV} = \mathbf{XPV} = \mathbf{XB}_{PCR} \Rightarrow \mathbf{B}_{PCR} = \mathbf{PV} \qquad [14]$$

Due to the nature of PCA decomposition, PCR provides a reliable answer to the drawback discussed earlier for MLR, even if it may not provide the best low-rank representation of the data to be used for calibration purposes. Indeed, principal components are calculated as those directions in space that account for the maximum variance in the data set; however, when multiple sources of spurious (irrelevant) variation are present in the data set, the directions of maximum variance may not account for the correlation with the responses to be predicted. On the other hand, partial least squares regression (PLS) makes active use of the information in **Y** to define the low-rank subspace onto which the data should be projected. In PLS, both the **X**- and the **Y**-blocks are decomposed in a bilinear fashion, and the axes of the low-dimensional subspace (called latent vectors) are chosen so that the scores of **Y** (**U**) have maximum covariance with those of **X** (**T**) and are linearly dependent, through what is called the *inner relation* (last one of the following equations):

$$\begin{aligned} \mathbf{T} &= \mathbf{XR} \\ \mathbf{Y} &= \mathbf{UQ}^T + \mathbf{E}_Y \\ \mathbf{U} &= \mathbf{TC} \end{aligned} \qquad [15]$$

where **R** is a matrix of weights, governing the projection of the **X**-block, **Q** are the loadings for the **Y**-block, and **C** is a diagonal matrix of coefficients. Also, in the case of PLS, it is possible to combine the equations in eqn [15] to obtain a matrix of regression coefficients directly relating **Y** to **X**:

$$\begin{aligned} &\mathbf{Y} = \mathbf{UQ}^T + \mathbf{E}_Y = \mathbf{TCQ}^T + \mathbf{E}_Y = \mathbf{XRCQ}^T + \mathbf{E}_Y = \mathbf{XB}_{PLS} + \mathbf{E}_Y \\ &\mathbf{B}_{PLS} = \mathbf{RCQ}^T \end{aligned} \qquad [16]$$

However, inspection of regression coefficients is not the only tool for interpretation, when dealing with PLS: the bilinear nature of the relations reported in eqn [15] suggests that scores and loadings plots also constitute a valid support to model understanding and diagnostics.

Although, for all the methods described so far, a linear relationship between the property (or properties) to be predicted and the secondary measurements is assumed, this need not always be the case: the important is to have a defined calibration equation in order to be able to make predictions on future samples, so that several nonlinear algorithms have

been proposed in the literature to tackle with more complex functional dependencies. In this framework, since a detailed discussion would be far beyond the scope of the present article, it is just worth mentioning, among the various possibilities, kernel- or dissimilarity-based approaches, neural networks, or locally weighted regression.

Classification

Food-related issues may not always call for a quantitative prediction, and rather, problems such as the authentication of a good, its quality control, and traceability (just to cite a few) involve the assessment of one or more qualitative properties. For instance, one may be interested in assessing whether a product is organically grown or not, or if a wine was produced in Italy, Spain, South Africa, or Chile, or, again, if a food will be good, acceptable, or bad according to consumer preferences. From a chemometric standpoint, all those methods, which deal with the possibility of predicting one or more qualitative responses on a set of samples, belong to the family of classification tools. Indeed, classification techniques aim at building models, which, based on the values of the measured variables, assign a sample to a *category* or *class*, the latter being a group of objects sharing similar characteristics. Accordingly, in the language of classification techniques, the wine authentication problem, cited earlier as an example, would involve four categories ('Spain,' 'Italy,' 'South Africa,' and 'Chile'), while the three classes 'good,' 'bad,' and 'acceptable' would be considered for the food preference one. Since samples can be represented as points in the multivariate space of the variables, classification may be seen under a geometric perspective as the search for surfaces identifying regions of space where it is more likely to find objects belonging to a particular category. In this context, it is particularly useful to operate a distinction between two possible approaches: discrimination and class modeling. Discriminant techniques partition the space in as many regions as the number of categories in the data set, so that if an object falls in the region corresponding to a particular class, it is univocally assigned to it; as a consequence, each sample is predicted to belong to one and only one of the categories postulated by the problem. On the other hand, modeling techniques, as the name suggest, try to model each category independently on the others and operate by identifying a region of the multivariate space where it is likely to find samples from that particular class (the model space): If a sample falls within that region, it is accepted by the class model; otherwise, it is rejected. Accordingly, when more than one category is modeled, a sample can be accepted by only one class (and then be univocally assigned to it), by more than one (i.e., confused), or by none (and be considered an outlier). In the remainder of the section, discriminant and modeling approaches will be further discussed through the illustration of two widely used methods, respectively, partial least squares discriminant analysis (PLS-DA) and soft independent modeling of class analogies (SIMCA).

PLS-DA is a discriminant classification technique based on the PLS algorithm already described in the section 'Calibration,' and it was introduced to overcome the limitations suffered by traditional methods such as linear (LDA) and quadratic (QDA) discriminant analysis, in the presence of ill-conditioned $\mathbf{X}$ matrices. Indeed, the same kind of problems (high number of highly correlated variables), which make MLR unsuitable to build regression models, hinders the applicability of LDA and QDA for classification. Accordingly, after finding a suitable coding that allows to transform a classification problem into a regression one, the use of the PLS algorithm represents a solution to these drawbacks. In particular, PLS-DA is based on coding the information about class belonging into a binary dummy matrix $\mathbf{Y}$ having as many rows as the number of samples and as many columns as the number of classes: the matrix element y_{ij} will be equal to 1 if the ith sample belongs to class j or to zero if it does not. A PLS model is then built between the experimental matrix $\mathbf{X}$ and the dummy matrix $\mathbf{Y}$, and classification is achieved on the basis of the predicted values $\hat{\mathbf{Y}}$, usually via the introduction of a suitable threshold. An example of application is reported in Figure 5, where the use of PLS-DA on chromatographic data to discriminate olive oils from the PDO Sabina from other extra virgin oils is shown. In this case, since there are only two categories, due to the symmetry of the problem, the dummy matrix $\mathbf{Y}$ boils down to a vector $\mathbf{y}$ in which 1 indicates 'Sabina' and 0 'other oils.' Classification is then achieved by setting a threshold of 0.5 to the predictions: all the samples for which the predicted response is higher than the threshold are classified as Sabina oils, while all the others are recognized as from other origins.

Differently than what happens for discriminant methods, modeling techniques focus on capturing the similarity among samples belonging to the same category, rather than the differences between individuals from competing classes. Under many respects, they can be considered as outlier detection techniques, as their aim is to verify whether a sample fits the model of a particular category or not. In particular, SIMCA operates by describing the class-related variability in the experimental fingerprint using a PCA model of appropriate dimensionality:

$$\mathbf{X}_G = \mathbf{T}_G\mathbf{P}_G^T + \mathbf{E}_G \quad [17]$$

where the subscript G indicates that only the samples from category G are used to define the projection. Then, for each sample, an overall distance to the class model, measuring the extent of outlyingness, is defined as the combination of the distance to the model space (which is a function of the residuals) and the distance within the model space (which accounts for the distance of the sample scores to the origin of the PC space). Accordingly, if the distance to the model is below a prespecified threshold, the sample is accepted by the category; otherwise, it is rejected. When more than a single category is modeled, a straightforward way of representing the results of SIMCA is the so-called Coomans plot, which is shown in Figure 6 for the same data set used to exemplify PLS-DA.

The axes of the Coomans plot represent the sample distances to the two investigated categories, and the thresholds used to define acceptance/rejection by the class models divide the plot in four different regions: Objects falling in the uppermost left region of the plot are univocally accepted by the class 'Sabina,' while those mapped onto the rightmost lower part are uniquely accepted by 'other oils'; the samples falling in the lowermost left part of the plot are confused between the two categories, while those in the uppermost right regions are considered as outliers by both classes.

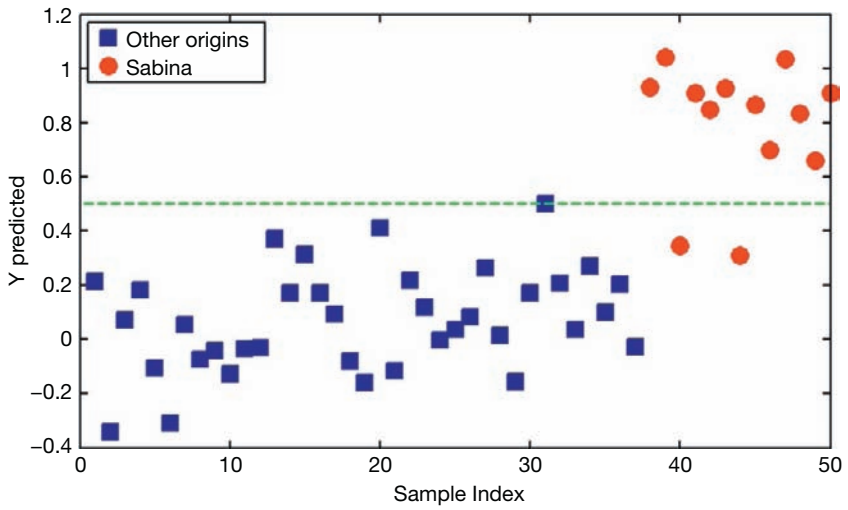

Figure 5 Illustration of how classification is accomplished in PLS-DA: samples are assigned to one or the other class based on the predicted *y* values and the green dashed line indicates the classification threshold. Accordingly, all samples except the two Sabina oils that fall below the threshold are correctly classified.

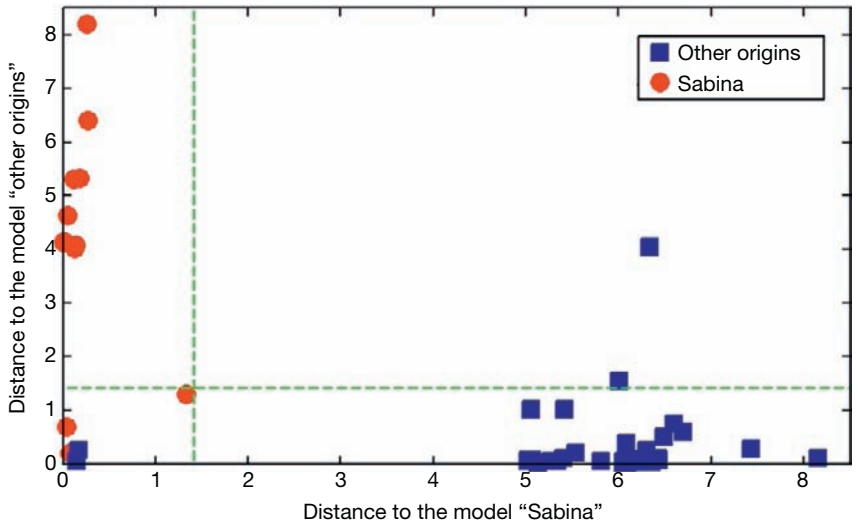

Figure 6 SIMCA modeling of the olive oil data set: Coomans plot. The dashed lines indicate the acceptance thresholds used by the two class models.

A Continually Increasing Toolbox

Although the topics presented in the previous sections cover most of the fields of application of chemometrics to food analysis and characterization, the chemometric toolbox is continuously evolving to match the increase in the complexity of the problems to be tackled and, at the same time, in the availability of high-throughput instrumentation. For instance, multiway and multiset resolution techniques may be used to extract chemically relevant profiles from data collected by means of hyphenated techniques or, in general, resulting from experiments where signals are recorded as a function of different sources of variability. On the other hand, hyperspectral image analysis techniques allow to extract both spatial information (e.g., texture and homogeneity) and spectral information from the samples, while data fusion approaches combine information from multiple sources into a holistic characterization of the sample for both exploratory and predictive purposes.

In general, one may affirm that chemometric techniques constitute an essential and valid tool for all of those who are involved at different levels in the characterization and analysis of foodstuff.

Cherries (*Prunus* spp.): The Fruit and Its Importance

W Loescher, Michigan State University, East Lansing, MI, USA

Introduction: Cherry Taxonomy and Types

Commercially, the two most important cherry species are sweet cherry (*Prunus avium*, L.) and tart cherry (*Prunus cerasus* L.), both tree fruits native to Southeastern Europe and Western Asia. They are closely related and graft-compatible and will hybridize to form interspecific (Duke) cultivars. Sweet cherry (diploid, with a base chromosome number of 8 and a somatic number of 16) probably originated between the Black Sea and the Caspian Sea, but it spread into Europe in ancient times. Tart cherry (tetraploid, with a base chromosome number of 16 and somatic chromosome number of 32) is native to the same areas as sweet cherry, and there is good evidence that crosses between *Prunus avium* and the ground cherry (*Prunus fruticosa* Pall) gave rise to tart cherry. There are other cherry species, but most, for example, Nanking cherry (*Prunus tomentosa*), have limited commercial value as fruits.

Sweet cherries can be divided into two major types based on fruit characteristics. Heart-type cherries are ovoid or heart-shaped with relatively soft flesh, often ripening early. Most of the commercially important cultivars, however, are of the Bigarreau type with firmer, crisp-fleshed fruit, ripening mid to late season. Fruit flesh may be red or yellow, and the skin may be dark (red to nearly black) or light (yellow-red to yellow-white).

Many sweet cherry cultivars grown throughout the world originated in Europe, but a number of important ones were selected or bred in local cherry districts. European cultivars grown in the United States are Napoleon (Royal Ann), Black Tartarian, Eagle, Early Purple, Early Rivers, Elkhorn, Hedelfingen, Knight's Early Black, Lyon, and Schmidt. The cultivars Windsor, Van, Sam, Vista, Victor, Sue, Vega, Summit, and Stella were developed in Canada. Chinook and Rainier were developed in Washington. Bing, Lambert, Black Republican, Corum, and Hoskins were selected and developed in Oregon. Chapman, Burbank, Bush Tartarian, and the new cultivars Mona, Larian, Jubilee, Berryessa, and Bada originated in California. Recent introductions include Ulster and Hudson from New York and Angela from Utah.

The most important sweet cherry cultivars in the Western United States, where over 80% of the US crop is produced, have been dark-fruited, crisp-fleshed cultivars: Bing (the leading cultivar in North America), Van, and Lambert. But others may be available because of their use as pollenizers or as the result of recent fresh market demand for large, light-colored, and crisp-fleshed fruits from cultivars like Rainier. Firmness, size, color, and soluble solids are all important market considerations, and growers in regions where summer rains are prevalent, for example, the eastern United States and Eastern Europe, are at a disadvantage because the main cultivars are often the softer-fleshed, rain cracking-resistant types, for example, Emperor Francis, Hedelfingen, and Schmidt. In these regions, light-fleshed cultivars, Rainier, Napoleon (Royal Ann), Corum, and Emperor Francis, are best for making into maraschino cherries (because pigment is undesirable), but a few are nonetheless grown for the fresh market. Napoleon is also used for canning. Bing is mainly a fresh market cultivar, and Lambert is used both for canning and fresh market. Black Republican and other very firm, dark cherries are good for freezing.

Tart cherry fruit are generally soft, juicy, and depressed-globose in shape, but colors may range from the Morello types with red to dark red flesh and juice to the Amarelle types with nearly colorless juice and flesh.

Although new cultivars are being tested, there are only a few tart cherry cultivars commonly grown in North America, ranging from the light red Early Richmond, to the medium red-skinned Montmorency, to the late dark red English Morello, but Montmorency is still the standard. In Western Europe, Schattenmorelle and Sternsbaer are common, but many others are grown in Russia, Slovenia, Romania, and Hungary. Most, unlike sweet cherry, are more or less self-fertile and generally do not require pollenizers. Almost all of those grown in the United States and Western Europe are harvested mechanically and sold for processing, primarily as a frozen or canned ingredient for use in manufactured food products such as pies, but more recently as a dried fruit product, and in Europe and other areas, there have been uses developing for juice, liqueur, and marmalade production and combinations with yogurt.

Production Areas

Turkey, the United States, Iran, and Russia are large producers of both sweet and tart cherries (FAO Statistics, Table 1). In some areas of northern Europe, tart cherries are, after apples, the second most important fruit grown. Otherwise, within Europe, tart cherry production is concentrated in Eastern Europe, Slovenia, Hungary, and Romania, while sweet cherry production is more common in Western Europe, Italy, Switzerland, France, and Spain. Sweet cherry production is increasing in the Southern Hemisphere, New Zealand, Australia, and Chile, for fresh shipments to northern markets in their winter season. In the United States, sweet cherry cultivation has also been increasing, with production mostly in the west, not only in Washington but also in Oregon and California. Most US tart cherry production occurs near the Great Lakes, primarily in Michigan with 70–75% of the US crop, which with New York, Wisconsin, and Pennsylvania totals 90–95% of the US crop.

Average world production values for sweet and tart cherries are now approximately 1 200 000 and 2 200 000 metric tons, respectively. Wide annual supply fluctuations, especially regionally, in both sweet and tart cherries characterize production and create high risks in product availability and price change for producers, processors, and marketers.
